The development of a prostate cancer involves a multistep process. Hypermethylation of the GSTP1 gene promoter, leading to a loss of function of a gene that detoxifies carcinogens, is one early change. Epidemiologic studies show that the risk of being diagnosed with prostate cancer increases by a factor of 2 if one first-degree relative is affected and by 4 if two or more are affected. Current estimates are that 40% of early-onset and 5 to 10% of all cancers are hereditary and follow a Mendelian inheritance pattern. Prostate cancer affects ethnic groups differently. Matched for age, the prostates of African-American males have both a greater number of precursor prostatic intraepithelial neoplasia (PIN) lesions and larger tumors than white males, possibly related to the higher levels of testosterone seen in African-American males. These lesions are highly unstable, and typically multifocal. Polymorphic variants of the androgen receptor gene, the cytochrome P450 C17 gene, and the steroid 5α-reductase type II (*SRD5A2*) gene have also been implicated in the variations in incidence. The incidence of autopsy-detected cancers is similar around the world, while the incidence of the clinical disease varies. Thus, environmental factors may play a role. High consumption of dietary fats, such as α-linoleic acid, or polycyclic aromatic hydrocarbons that form when red meats are cooked is believed to increase risk. Similar to breast cancer in Asian women, the risk of prostate cancer in Asian males increases when they move to western environments. Protective factors include the isoflavinoid genistein (which inhibits 5α-reductase), cruciferous vegetables that contain isothiocyanate sulfuraphane, retinoids such as lycopene (in pizza and tomatoes), and inhibitors of cholesterol biosynthesis. The antioxidant α-tocopherol (vitamin E) and selenium may also reduce risk.

DIAGNOSIS AND TREATMENT BY CLINICAL STATE

The clinical states framework considers the risk of morbidity from an enlarging but nonmalignant gland; the probability that a clinically significant cancer is present in an individual with or without urinary symptoms; or, for those with a prostate cancer diagnosis; the probability of developing symptoms or dying from disease. At any point in time, a patient resides in one state and remains there until the disease has progressed to the next state. Applying this paradigm, a patient with localized prostate cancer who has had all cancer removed surgically remains in the state of localized disease as long as the PSA remains undetectable. The time within a state becomes a measure of the impact of an intervention on the natural history of disease, be it benign or malignant in etiology, recognizing that the impact may not be assessable for years. It also allows a distinction between *cure*—the elimination of all cancer cells, the primary therapeutic objective when treating most cancers—and *cancer control*, in which the tempo of the illness is modulated and symptoms controlled until the patient dies of other causes. It is the concept of cancer control that makes the man-

agement of prostate cancer unique. Even when a recurrence is documented, immediate therapy is not always necessary. Rather, as at the time of diagnosis, the need for intervention is based on the tempo of the illness as it unfolds in the individual, relative to the risk:reward ratio of the therapy being considered.

NO CANCER DIAGNOSIS ■ Symptoms The need to pursue a diagnosis of prostate cancer is based on symptoms, an abnormal DRE, or an elevated serum PSA. The urologic history should focus on symptoms of outlet obstruction, continence, potency, or a change in ejaculatory pattern. Benign proliferative disease may produce hesitancy, intermittent voiding, a diminished stream, incomplete emptying, and postvoid leakage. The severity of these symptoms can be quantitated with the self-administered American Urological Association (AUA) *Symptom Index* (Table 81-1) recognizing that the degree of symptoms does not always relate to gland size. Resistance to urine flow reduces bladder compliance, leading to nocturia, urgency, and, ultimately, to retention. Infection, tranquilizing drugs, antihistamines, or alcohol can precipitate urinary retention. Prostatitis often produces pain or induration. Symptoms of metastatic disease include pain secondary to osseous metastases, although many are asymptomatic despite extensive spread. Less common are symptoms related to marrow compromise (myelophthisis), a coagulopathy, or spinal cord compression.

Physical Examination The DRE focuses on the size, consistency, and abnormalities within or beyond the gland. Many cancers occur in the peripheral zone and can be palpated on DRE. Carcinomas are characteristically hard, nodular, and irregular, while induration may be due to benign prostatic hypertrophy (BPH) or to calculi or tumor. Overall, 20 to 25% of men with an abnormal DRE have cancer.

PROSTATE-SPECIFIC ANTIGEN

PSA is a kallikrein-like serine protease that causes liquefaction of seminal coagulum. It is produced by both nonmalignant and malignant epithelial cells. PSA is prostate specific, not prostate cancer specific, and increases may occur from prostatitis, nonmalignant enlargement of the gland (BPH), prostate cancer, and prostate biopsies. The level is not affected by the performance of a DRE. It circulates in the blood as an inactive complex with the protease inhibitors α-$_1$-antichymotrypsin and β_2-macroglobulin and has an estimated half-life in the serum of 2 to 3 days. Levels should be undetectable if the prostate has been removed. PSA immunostaining is used to establish a prostate cancer diagnosis.

PSA testing was approved for early detection in 1994. It is recommend on an annual basis along with a DRE for men over age 50 (with an anticipated survival of >10 years; this includes men up to age 76 years). For African Americans and men with a family history, testing is advised to begin at age 40. The normal range of PSA is 0 to 4 ng/mL. For values >4, the sensitivity for prostate cancer detection is 57 to 79%, the specificity is 59 to 68%, and the positive predictive value is 40 to 49%.

The PSA-based criteria used to recommend a diagnostic prostate biopsy have evolved over time. PSA values may fluctuate for no apparent reason; thus, an isolated abnormal value should be confirmed before proceeding with further testing. These evolving criteria aim to increase the sensitivity of the test for younger men more likely to die of the disease and to reduce the frequency of detecting cancers of low malignant potential in elderly men more likely to die of other causes. Age-specific reference ranges apply a lower "upper" limit of normal for younger males and higher "upper" limit for older individuals. Different thresholds alter sensitivity and specificity of detection. The threshold for performance of a biopsy is now 2.6 ng/mL for men under age 60. Prostate-specific antigen density (PSAD) measurements were developed to correct for the contribution of BPH to the total PSA level. PSAD is calculated by dividing the serum PSA by the estimated prostate weight calculated by transrectal ultrasound (TRUS). Values <0.10 are consistent with BPH, while those >0.15 suggest cancer. *PSA velocity* is the rate of change in PSA levels over time. It is particularly useful for men with values that are rising in the seemingly "normal" range. Rates of rise >0.75 ng/mL per year suggest cancer. As an example, an increase from 2.5 to 3.9 in a 1-year period would warrant further testing. Free and complexed PSA measurements are used when levels are between 4 and 10 ng/mL to decide who needs a biopsy. In cancer, the level of free PSA is lower. The ratios of free to total, complexed to total, and free to complexed PSA have also been used. In one series, specificity improved by 20% using a normal range of free/total >0.15; complexed/total <0.70; and free/complexed >0.25. A diagnostic algorithm based on the DRE and PSA findings is illustrated in Fig. 81-2. In general, a biopsy is recommended if the DRE or PSA are abnormal.

Prostate Biopsy A diagnosis of cancer is established by a TRUS-guided needle biopsy. Direct visualization assures that all areas of gland are sampled. A minimum of six separate cores, three from the right and three from the left, are advised, as is a separate biopsy of the transition zone, if clinically indicated. Performance of a biopsy is not advised in a patient with prostatitis until a course of antibiotics has been administered. The positive predictive value of an abnormal DRE is 21%, while 25% of men with a PSA > 4 ng/mL and an abnormal DRE, and 17% of men with a PSA of 2.5 to 4.0 ng/mL and normal DRE, have cancer. Those with an abnormal PSA and negative biopsy are advised to undergo a repeat biopsy.

TABLE 81-1 AUA System Index

Questions to Be Answered	AUA Symptom Score (Circle 1 Number on Each Line)					
	Not at All	Less than 1 Time in 5	Less than Half the Time	About Half the Time	More than Half the time	Almost Always
Over the past month, how often you have had a sensation of not emptying your bladder completely after you finished urinating?	0	1	2	3	4	5
Over the past month, how often have you had to urinate again less than 2 h after you finished urinating?	0	1	2	3	4	5
Over the past month, how often have you found you stopped and started again several times when you urinated?	0	1	2	3	4	5
Over the past month, how often have you found it difficult to postpone urination?	0	1	2	3	4	5
Over the past month, how often have you had a weak urinary stream?	0	1	2	3	4	5
Over the past month, how often have you had to push or strain to begin urination?	0	1	2	3	4	5
Over the past month, how many times did you most typically get up to urinate from the time you went to bed at night until the time you got up in the morning?	(None)	(1 time)	(2 times)	(3 times)	(4 times)	(5 times)
Sum of 7 circled numbers (AUA Symptom Score): ———

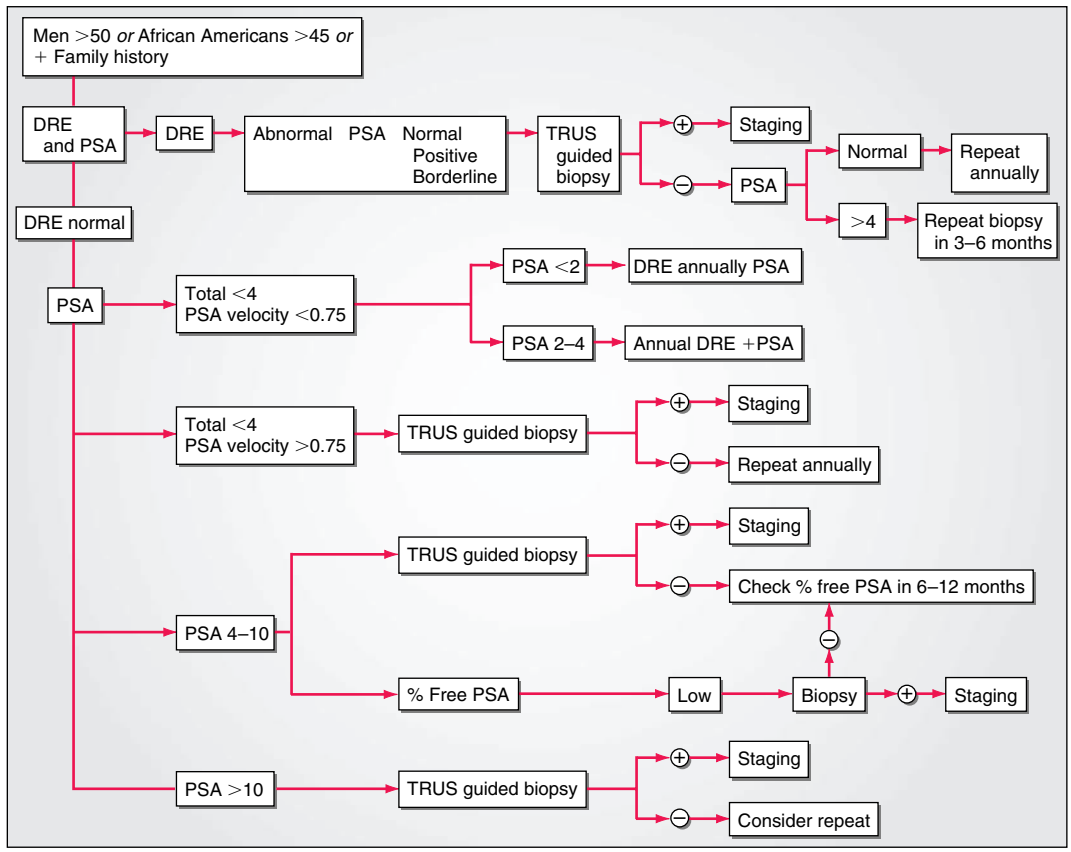

FIGURE 81-2 Algorithm for diagnostic evaluation of men based on digital rectal examination and prostate-specific antigen levels.

Pathology The noninvasive proliferation of epithelial cells within ducts is termed *prostatic intraepithelial neoplasia*. PIN is a precursor of cancer, but not all PIN lesions develop into invasive cancers. Of the cancers identified, >95% are adenocarcinomas; the remaining are squamous, transitional cell tumors, and rarely, carcinosarcomas. Metastases to the prostate are rare, but in some cases, transitional cell tumors of the bladder or colon cancers invade the gland by direct extension. Each core of the biopsy is examined for the presence of cancer, and the amount of cancer present is quantified. A measure of histologic aggressiveness is also assigned using the *Gleason grading system*, in which the dominant and secondary glandular histologic patterns are scored from 1 (well differentiated) to 5 (undifferentiated) and summed to give a total score of 2 to 10 for each tumor. The most poorly differentiated area of tumor (i.e., the area with the highest histologic grade) often determines biologic behavior. The presence or absence of perineural invasion and extracapsular spread are also recorded.

PSA-based detection strategies have changed the clinical spectrum of the disease. Now, 95 to 99% of newly diagnosed cancers are clinically localized, 40% are not palpable, and, of these, 70% are pathologically organ-confined. The downside of widespread use is the detection and treatment of cancers with such a low malignant potential that they would not have shortened survival or produced symptoms during the patient's lifetime. The side effects of treatment, including impotence, incontinence, and bowel dysfunction, are unacceptable for these cases. Formal clinical trials to assess the value of screening on prostate cancer morbidity and mortality are ongoing. Until the results of these studies are available, men are advised to make an informed decision about whether to undergo testing.

Prevention It is difficult to identify individuals who are at risk for developing a cancer that is clinically significant. The Prostate Cancer Prevention Trial is a double-blinded, randomized multicenter trial designed to investigate the ability of finasteride, a 5α-reductase inhibitor, to prevent the development of prostate cancer in men age ≥55 years. The prostate cancer detection rate was 18.4% (803 of 4364) for finasteride and 24.4% (1147 of 4692) for placebo-treated men. However, more of the cancers detected in the finasteride group were high-grade [37% (280 of 757) vs. 22% (237 of 1068 cancers) for the placebo]. No effect on survival was detected. Vitamin E and selenium (the SELECT study) are also being tested as preventive agents.

Treatment of Benign Disease Asymptomatic patients do not require treatment regardless of the size of the gland, while those with an inability to urinate, gross hematuria, recurrent infection, or bladder stones may require surgery. Typically, obstruction does not occur and the symptoms remain stable over time. In these cases, uroflowmetry can identify patients with normal flow rates who are unlikely to benefit from treatment and those with high postvoid residuals who may need other interventions. Pressure-flow studies detect primary bladder dysfunction. Cystoscopy is recommended if hematuria is documented and to assess the urinary outflow tract before surgery. Imaging of the upper tracts is advised for patients with hematuria, a history of calculi, or prior urinary tract problems. Therapies such as finasteride, which blocks the conversion of testosterone to dihydrotestosterone, have been shown to decrease prostate size, increase urine flow rates, and improve symptoms. They will also lower baseline PSA levels by 50%, an important consideration when using PSA to guide biopsy recommendations. α-Adrenergic blockers such as terazosin act by relaxing the smooth muscle of the bladder neck and increasing peak urinary flow rates. No data show that these agents influence the progression of the disease. Surgical approaches include a transurethral resection of the prostate (TURP), transurethral incision, or removal of the gland via a retropubic, suprapubic or perineal approach. TULIP (transurethral ultrasound-guided laser-induced prostatectomy), coils, stents, and hyperthermia are also utilized.

PROSTATE CANCER STAGING The TNM staging system includes categories for cancers that are palpable on DRE, those identified solely on the basis of an abnormal PSA (T1c), those that are palpable but clin-

ically confined to the gland (T2), and those that have extended outside of the gland (T3 and T4) (Table 81-2). The assessment of disease extent based on DRE alone is inaccurate with respect to the extent of the disease within the gland, the presence or absence of capsular invasion, involvement of seminal vesicles, and extension of disease to lymph nodes. This led to a modification of the staging system to include the results of imaging studies on the assignment of T stage. Unfortunately, no single test has proven to predict the pathologic stage accurately, be it the presence of organ-confined disease, seminal vesical involvement, or lymph node spread.

TRUS is most frequently used to assess the primary tumor, but no consistent finding predicts cancer with certainty. TRUS is used primarily to direct prostate biopsies. Computed tomography (CT) scans lack sensitivity and specificity to detect extraprostatic extension and are inferior to magnetic resonance imaging (MRI) in visualization of lymph nodes. MRI specificity is improved with an endorectal coil and aids in planning radiation therapy. T1-weighted images demonstrate the periprostatic fat, periprostatic venous plexus, perivesicular tissues, lymph nodes, and bone marrow. T2-weighted images demonstrate the internal architecture of the prostate and seminal vesicles. Most cancers have a low signal, while the normal peripheral zone has a high signal, although the technique lacks sensitivity and specificity.

Radionuclide bone scans are used to evaluate spread to osseous sites. This test is sensitive but relatively nonspecific because areas of increased uptake are not always related to metastatic disease. Healing fractures, arthritis, Paget's disease, and other conditions will also show abnormal uptake. True-positive bone scan results are rare if the PSA <8 ng/mL and uncommon when the PSA $<$ 10 ng/mL unless the tumor is high grade. When the PSA <10 ng/mL, a positive bone scan is usually falsely positive, which in turn, leads to additional low-yield testing.

CLINICALLY LOCALIZED DISEASE Localized prostate cancers are clinically confined to the prostate. Patients with localized disease are managed by radical surgery, radiation therapy, or watchful waiting. Data from the literature do not provide clear evidence for the superiority of any one treatment. Choice of therapy needs consideration of several factors: the presence of symptoms, the probability that the untreated tumor will adversely affect the patient during his lifetime and thus require treatment, and whether the tumor can be cured by single-modality therapy directed at the prostate or requires both local and systemic therapy to achieve cure. As most of the tumors detected are deemed clinically significant, most men undergo treatment.

Comparing the outcomes of various forms of therapy is limited by the lack of prospective trials, referral bias, and differences in the outcomes used. The primary outcomes are cancer control and treatment-related morbidities. These benchmarks of success or failure vary by modality. Often, PSA relapse–free survival is used because an effect on metastatic progression or survival may not be apparent for years. Based on a half-life in the blood of 3 days, PSA should be undetectable in the blood 4 weeks after all prostate tissue has been removed by radical surgery. If PSA remains detectable, the patient is considered to have persistent disease. In contrast, the PSA does not become undetectable after radiation therapy because the remaining nonmalignant elements of the gland continue to produce PSA even if all cancer cells have been eliminated. Similarly, there is no adequate cancer control definition for a patient treated with watchful waiting because PSA levels will continue to rise in the absence of therapy. Other outcomes are the time to objective progression (local or systemic) and cancer-specific and overall survival; however, these outcomes may take years to define.

The more advanced the disease, the lower the probability of local control and the higher the probability of systemic relapse. More important is that within the categories of T1, T2, and T3 disease are tumors with a range of prognoses. Some T3 tumors are curable with therapy directed solely at the prostate, and some T1 lesions have a high probability of systemic relapse that requires the integration of local and systemic therapy to achieve cure. T1c tumors particularly require the use of other factors to predict outcomes and select treatment. Many groups have developed prognostic models based on a combination of the initial T stage, Gleason score, and baseline PSA. Some are based on discrete cut points (PSA <10 or $\geq$ 10; Gleason score of $\leq$6, 7, or $\geq$8). Others are nomograms that use PSA and Gleason score as continuous variables. These algorithms are used to predict disease extent: organ confined vs. nonorgan confined, node negative or positive, and the probability of success using a PSA-based definition of failure specific to the local therapy under consideration. Exactly what cut-off value would lead a patient to accept one form of therapy vs. another is an area of active debate. Specific nomograms have been developed for radical prostatectomy, external-beam radiation therapy, and brachytherapy (seed implantation). These are being refined continually to incorporate other clinical parameters and biologic determinants. Surgical technique, radiation therapy delivery, and criteria for watchful waiting continue to be refined and improved; the year treatment was given affects outcomes independent of other factors. The improvements make treatment decisions a dynamic process.

The frequency of adverse events for the different modalities is highly variable. Of greatest concern to patients are the effects on continence, sexual potency, and bowel function. Part of the variability relates to the definition used for a specific complication and whether the patient or physician is reporting the event. Incontinence figures range from 2% to 47% and impotence rates range from 25% to 89% following radical prostatectomy. The time of the assessment is also important. After surgery, impotence is immediate but may reverse over time, while with radiation therapy, impotence is not immediate but may develop over time.

Radical Retropubic Prostatectomy (RRP) The goal of radical prostatectomy is to excise the cancer completely with a clear margin, to maintain continence by preserving the external sphincter, and to preserve potency by sparing the autonomic nerves in the neurovascular bundle. RRP is advised for patients with a life expectancy of $>$10 years and is performed using a retropubic, perineal, or laparoscopic approach.

TABLE 81-2 *Comparison of Clinical Stage by the TNM Classification System and the Whitmore-Jewett Staging System*

TNM Stage	*Description*	*Whitmore-Jewett Stage*	*Description*
T1a	Nonpalpable, with 5% or less of resected tissue with cancer	A1	Well differentiated tumor on few chips from 1 lobe
T1b	Nonpalpable, with >5% of resected tissue with cancer	A2	Involvement more diffuse
T1c	Nonpalpable, detected due to elevated serum PSA		
T2a	Palpable, half of one lobe or less	BIN	Palpable, < one lobe, surrounded by normal tissue
T2b	Palpable, > half of one lobe but not both lobes	B1	Palpable, < one lobe
T2c	Palpable, involves both lobes	B2	Palpable, one entire lobe or both lobes
T3a	Palpable, unilateral extracapsular extension	C1	Palpable, outside capsule, not into seminal vesicles
T3b	Palpable, bilateral extracapsular extension		
T3c	Tumor invades seminal vesicle(s)	C2	Palpable, seminal vesicle involved
MI	Distant metastases	D	Metastatic disease

Source: Adapted from FF Schroder et al: TNM classification of prostate cancer. Prostate (Suppl) 4:129, 1992; and American Joint Committee on Cancer, 1992.

Outcomes can be predicted using postoperative nomograms that consider pretreatment factors and the pathologic findings at surgery. PSA failure is defined as a detectable value of 0.2 or 0.4 ng/mL, although the exact definition varies among series. The techniques continue to improve as the ability to localize the tumor within or beyond the prostate are refined with different biopsy algorithms and with imaging. The result is better case selection and surgical planning, which in turn have led to more rapid recovery and higher rates of continence and potency. Factors associated with incontinence include older age, shorter urethra length, surgical technique, preservation of neurovascular bundles, and development of an anastomotic stricture. Surgical experience is also a factor. In one series, 6% of patients had mild stress urinary incontinence (SUI) (requiring 1 pad/day), 2% moderate SUI (>1 pad/day), and 0.3% severe SUI (requiring an artificial urinary sphincter). At 1 year, 92% were completely continent. In contrast, the results in a Medicare population treated at multiple centers showed that at 3, 12, and 24 months following surgery, 58, 35, and 42% wore pads in their underwear, and 24, 11, and 15% reported "a lot" of urine leakage. Factors associated with recovery of erectile function include younger age, quality erections before surgery, and the absence of damage to the neurovascular bundles. Erectile function returns in a median of 4 to 6 months if both bundles are preserved. Potency is reduced by half if at least one nerve bundle is sacrificed. In cases where cancer control requires the removal of both bundles, sural nerve grafts are being explored. Overall, with the availability of drugs such as sildenafil, intraurethral inserts of alprostadil, and intracavernosal injections of vasodilators, many patients recover satisfactory sexual function.

High-risk patients are those with a predicted high probability of failure with surgery alone based on pretreatment factors. In these situations, nomograms and predictive models can only go so far. Exactly what probability of success or failure would lead a physician to recommend and a patient to seek alternative approaches is controversial. For example, it may be appropriate to recommend radical surgery for a younger patient with a low probability of cure. To improve the outcomes of surgery for high-risk patients, neoadjuvant hormonal therapy has been explored. The results of several large trials testing 3 or 8 months of androgen ablation before surgery showed that serum PSA levels decreased by 96%, prostate volumes reduced by 34%, and margin positivity rates declined from 41 to 17%. Unfortunately, hormones did not produce an improvement in PSA relapse–free survival. Thus, neoadjuvant hormonal therapy is not recommended.

Radiation Therapy Radiation therapy is given by external beam, the implantation of radioactive sources into the gland, or a combination of both. Contemporary external beam radiation techniques now use three-dimensional conformal treatment plans to maximize the administered dose to the tumor and to minimize the exposure of the surrounding normal structures. The addition of intensity modulation (IMRT) has allowed further shaping of the isodose curves and the delivery of higher doses to the tumor and a further reduction in normal tissue exposure. These advances have allowed the safe administration of doses >80 Gy, higher local control rates, and fewer side effects. Overall, radiation therapy is associated with a higher frequency of bowel complications (mainly diarrhea) than surgery. Measures of cancer control include the proportion of patients who show a decline in PSA to <0.5 or 1 ng/mL, the proportion with "nonrising" PSA values, or the proportion with a negative biopsy of the prostate 2 years after completion of treatment. PSA relapse is defined as three consecutive rising PSA values from the nadir value, with the time to failure as the midpoint between the nadir and first rising value.

Radiation dose is important. A PSA nadir of <1.0 ng/mL was observed in 90% of patients receiving 75.6 or 81.0 Gy vs. 76 and 56% for those receiving 70.2 Gy and 64.8 Gy, respectively. The positive biopsy rates at 2.5 years were 4% for those treated with 81 Gy, vs. 36 and 27% for those receiving 70.2 or 75.6 Gy. The frequency of rectal complications relates directly to the volume of the anterior rectal wall receiving full-dose treatment. Grade 3 rectal or urinary toxicities were seen in 2.1% of cases at a median dose of 75.6 Gy. Grade 3 urethral strictures requiring dilatation developed in 1% of cases, all of whom had undergone a TURP. Pooled data show that the frequency of grade 3 to 4 toxicities is 6.9 and 3.5%, respectively, for patients who received >70 Gy. The frequency of erectile dysfunction is related to the quality of erections pretreatment, the dose administered, and the time of assessment. The etiology is related to a disruption of the vascular supply and not the nerve fibers.

Neoadjuvant hormone therapy has also been studied in combination with radiation therapy to increase local control rates, decrease the size of the prostate so that the exposure of normal tissues to full-dose radiation is reduced, and decrease the rate of systemic failure. Short-term hormone exposures can reduce toxicities and improve local control rates, but long-term (2 to 3 years) treatment is needed to prolong the time to PSA failure and the development of metastatic disease. The impact on survival has been less clear.

Brachytherapy involves the direct implantation of the prostate with radioactive sources. It is based on the principle that the deposition of radiation energy in tissues decreases exponentially as a function of the square of the distance from the source. The goal is to deliver intensive irradiation to the prostate, minimizing the exposure of the surrounding tissues. Techniques have evolved from intraoperative manual insertion methods to the current standard, in which customized templates based on CT and ultrasonographic assessment of the tumor are used for seed placement based on computer-optimized dosimetry to achieve more homogeneous dose distributions. The implants themselves are now performed transperineally, without an open procedure, with real-time imaging. The result is a marked reduction in local failure rates with fewer complications. In a series of 197 patients followed for a median of 3 years, 5-year actuarial PSA relapse–free survival for patients with pretherapy PSA levels of 0 to 4, 4 to 10, and >10 μg/mL were 98, 90 and 89%, respectively. In a separate report of 201 patients who underwent posttreatment biopsies, 80% were negative, 17% indeterminate, and 3% were positive. The results did not change with longer follow-up. Nevertheless, many physicians feel that implantation is best reserved for patients with good or intermediate prognostic features. The procedure is well tolerated, although most patients experience urinary frequency and urgency that can persist for several months. Incontinence has been seen in 2 to 4% of cases. Higher complication rates are observed in patients who have undergone a prior TURP or who have obstructive symptoms at baseline. Proctitis has been reported in <2% of patients.

Watchful waiting, or deferred therapy, is a policy of no therapeutic intervention(s) until the tumor progresses. Progression can be based on PSA changes, local tumor growth, the development of symptoms, or metastatic disease. The practice evolved from studies of predominantly elderly men with well-differentiated tumors in whom clinically significant progression could not be demonstrated for protracted periods, during which a significant proportion died of intercurrent disease. In a structured literature review of patients treated by radical surgery, a deferred approach, or external beam radiation, the 10-year mean survivals were 93% for radical prostatectomy, 84% for deferred treatment, and 74% for external beam radiation. Risk of progression was related to grade. Men with grade 1 or 2 tumors had a 13% risk of death and 19% risk of metastases at 10 years; those with grade 3 tumors had 63 and 74% risks, respectively.

Case selection is critical, and the criteria to select those to whom watchful waiting can be applied safely are under intense study. In a recent prostatectomy series, it was estimated that 10 to 15% of patients had "insignificant" cancers. Given the multifocality of the disease, a concern is the limited ability to predict pathologic findings on the basis of a needle biopsy, even when multiple cores are obtained. Arguing against this approach is the result of a randomized trial of radical prostatectomy vs. watchful waiting from Sweden. With a median follow-up of 6.2 years, men treated by radical surgery had a lower risk of prostate cancer death relative to watchful waiting patients (4.6 vs. 8.9%) and a lower risk of metastatic progression, hazard ratio .63.

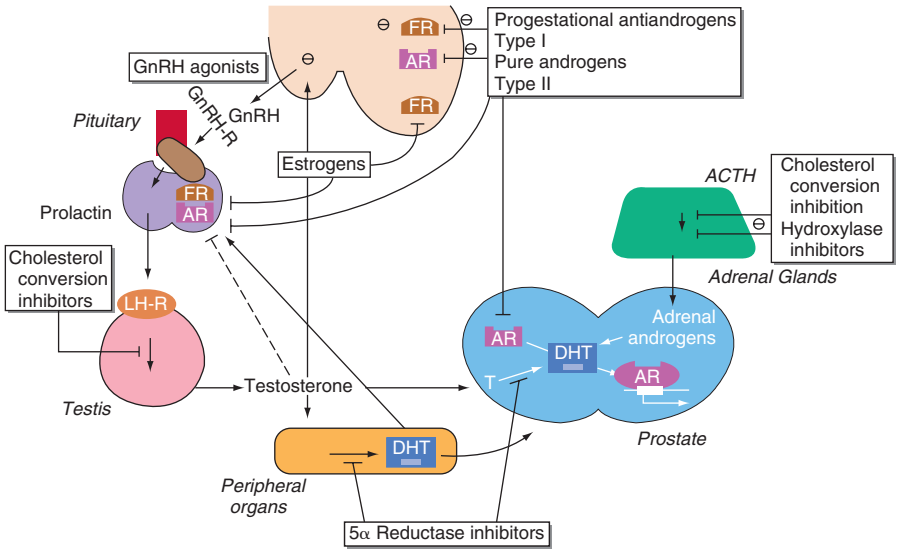

FIGURE 81-3 Sites of action of different hormone therapies.

Nevertheless, it can be anticipated that more patients may be candidates for a deferred approach as PSA testing is applied more widely and earlier.

RISING PSA This state includes patients in whom the sole manifestation of disease is a rising PSA after surgery and/or radiation therapy. By definition, no evidence of disease is found on scan. For these patients the central issue is whether the rise in PSA is the result of persistent disease in the primary site, a systemic recurrence, or both. In theory, disease that persists or has recurred in the primary site may be curable by additional local treatment. For patients who had undergone surgery, the question is whether external beam radiation therapy to the prostate bed can eliminate the disease and lead to an undetectable PSA. For radiation therapy–treated patients, the question is whether a prostatectomy would achieve cure.

The decision to recommend radiation therapy is often made on clinical grounds, as imaging studies such as CT and bone scan are typically uninformative. Some recommend a Prostascint scan: imaging with a radiolabeled antibody to prostate-specific membrane antigen (PSMA), which is highly expressed on prostate epithelial cells. Antibody localization to the prostatic fossa suggests local recurrence; localization to extrapelvic sites predicts failure of radiation therapy. Others recommend that a biopsy of the urethrovesical anastamosis be obtained before considering radiation. Factors that predict for response to salvage radiation are a positive surgical margin, a lower Gleason grade, a long interval from surgery to PSA failure, a slow PSA doubling time, and a low (<0.5 to 1.0 ng/mL) PSA value at the time of treatment. Radiation is generally not recommended if the PSA was persistently elevated after surgery (indicating that disease-free status was not achieved).

For patients with a rising PSA after radiation therapy, a salvage prostatectomy can be considered if the disease was "curable" at the onset, persistent disease has been documented by a biopsy of the prostate, and no metastatic disease is seen on imaging studies. Unfortunately, case selection is poorly defined in most series, and morbidities are significant. As currently performed, virtually all patients are impotent, and ~45% have either total urinary incontinence or stress incontinence. Major bleeding, bladder neck contractures, and rectal injury are not uncommon.

In the majority of cases, the rise in PSA indicates systemic disease. In these cases, the need for treatment should consider the probability of developing clinically detectable disease on scan and in what time frame. That immediate therapy is not required was shown in a series where patients did not receive systemic therapy until metastatic disease was documented. Overall, the median time to metastatic progression was 8 years and 63% of the patients with rising PSA values remained free of metastases at 5 years. Factors associated with progression include Gleason grade, time to recurrence, and PSA doubling times. For those with Gleason grade ≥8 tumors, the probability of metastatic progression was 37, 51, and 71% at 3, 5, and 7 years, respectively. If the time to recurrence was <2 years and PSA doubling time was long (> 10 months), the proportion with metastatic disease was 23, 32, and 53% vs. 47, 69, and 79% if the doubling time was short (< 10 months) during the same time intervals. These models continue to be refined. A difficulty making these predictions is that most patients with a rising PSA receive some form of therapy before the development of metastases.

METASTATIC DISEASE: NONCASTRATE *Metastatic disease noncastrate* refers to patients with tumors visible on an imaging study and noncastrate levels of testosterone. The patient may be newly diagnosed or have recurrent disease after treatment for localized disease. Standard treatment is to block androgen action or decrease androgen production by medical or surgical means. Over 90% of male hormones originate in the testes; <10% are synthesized in the adrenal gland. Surgical orchiectomy is the "gold standard" approach but is least acceptable by patients. Medical therapies can be divided into those that lower testosterone levels, e.g., gonadotropin-releasing hormone (GnRH) agonists and antagonists, estrogens and progestational agents, and the antiandrogens that bind to the androgen receptor but do not signal (Fig. 81-3). Ketoconazole inhibits adrenal androgen synthesis and is used after first-line castration is no longer effective. In this setting, the adrenal glands may contribute up to 40% of the active androgens in the prostate.

GnRH analogues (leuprolide acetate and goserelin acetate) initially produce a rise in luteinizing hormone and follicle-stimulating hormone (FSH), followed by a downregulation of receptors in the pituitary gland, which effects a chemical castration. They were approved on the basis of randomized comparisons showing an improved safety profile (specifically, reduced cardiovascular toxicities) relative to diethylstilbestrol (DES), with equivalent potency. The initial rise in testosterone may result in a clinical flare of the disease. As such, these agents are contraindicated in men with significant obstructive symptoms, cancer-related pain, or spinal cord compromise. Estrogens such as DES also lower testosterone levels but have fallen out of favor due to the risk of vascular complications such as fluid retention, phlebitis, emboli, and stroke.

In contrast, nonsteroidal antiandrogens such as flutamide, bicalutamide, or nilutamide block the binding of androgens to the receptor. Given alone, testosterone levels remain the same or increase. These agents were approved initially to block the flare associated with the initial rise in testosterone that results following GnRH administration. They have also been studied as part of a combined androgen blockade (CAB) or maximal androgen blockade (MAB) and as monotherapy. The concept of CAB was developed to inhibit testicular and adrenal androgens at the outset, and it preoccupied the field for many years. It is achieved clinically by combining an antiandrogen with a GnRH agonist or surgical orchiectomy. Cumulative results of randomized comparisons involving thousands of patients showed no advantage for combining an antiandrogen with surgical orchiectomy, while separate analyses of trials combining an antiandrogen with a GnRH analogue have shown a modest (<10%) survival advantage. Meta-analysis of all combined androgen blockade trials concluded that there was no benefit to the approach. In practice, most patients treated with GnRH analogue therapy receive an antiandrogen for the first 2 to 4 weeks of treatment.

The anti–prostate cancer effects of agents that lower serum testos-

terone levels are similar, and the clinical course is predictable: an initial response, a period of stability in which the cells are dormant and not proliferating, followed by regrowth after a variable period of time as a hormone-independent tumor. Androgen ablation is not curative. Cells that survive castration are present when the disease is first diagnosed. Considered by disease manifestation, PSA levels return to normal in 60 to 70% of cases and measurable disease regression occurs in 50%; while improvements in bone scan occur in 25% of cases, the majority remain stable. Survival is inversely proportional to disease extent. Agents that lower testosterone are associated with an androgen-deprivation syndrome that includes hot flushes, weakness, fatigue, impotence, loss of muscle mass, changes in personality, anemia, depression, and a reduction in bone density. The bone changes can be prevented by treatment with bisphosphonates along with vitamin D and calcium supplementation.

A question often asked is whether antiandrogens, which are associated with fewer hot flashes, less of an effect on libido, less muscle wasting, fewer personality changes, and less bone loss, can be used alone without compromising outcomes. Gynecomastia remains a significant problem but can be alleviated in part with the addition of tamoxifen. Most reported randomized trials suggest that the cancer-specific outcomes are inferior. Even a comparison of bicalutamide, 150 mg (three times the recommended dose of 50 mg), versus surgical castration showed a shorter time to progression and inferior survival for patients with established metastatic disease. Nevertheless, some men may accept the trade-off of a potentially inferior cancer outcome for an improved quality of life.

Another question is whether hormones should be given early, in the adjuvant setting or at the time recurrence is first documented, or late, when metastatic disease or symptoms are manifest. Trials in support of early therapy have often been underpowered relative to the "net benefit" reported or have been criticized on methodologic grounds. In one, although a survival benefit was shown for patients treated with radiation therapy and 3 years of androgen ablation relative to radiation alone, the trial was criticized for the poor outcomes for the control group. Another showing a survival benefit for patients with positive nodes randomized to medical or surgical castration compared to observation ($p = .02$) was criticized because the confidence intervals around the 5- and 8-year survival distributions overlapped between the two groups. A large randomized study comparing early to late hormone treatment (orchiectomy or GnRH analogue) in patients with locally advanced or asymptomatic metastatic disease showed that patients treated early were less likely to progress from M0 to M1 disease, develop pain, and die of prostate cancer. This trial was criticized because therapy was delayed "too long" in the late-treatment group. When patients treated by radical surgery, radiation therapy, or watchful waiting were randomly assigned to receive bicalutamide, 150 mg, or placebo, hormone treatment produced a significant reduction in the proportion of patients who developed osseous metastases at 2 years (9% for bicalutamide; 13.8% for placebo). This result has not gained acceptance in part because too many "good-risk" patients were treated and because no effect on survival was demonstrated. These criticisms are valid; however, the net influence on survival from early hormone intervention is similar to that observed in patients with breast cancer where adjuvant hormonal therapy is routinely given.

Another way to reduce the side effects of androgen ablation is to administer hormones on an intermittent basis. This was proposed as a way to prevent the emergence of castration-resistant cells by "forcing" the cells that survive androgen ablation into a normal differentiation pathway by repleting testosterone. Theoretically, surviving cells that are allowed to proliferate in the presence of androgen will retain sensitivity to androgen ablation. The duration of treatment varies from 2 to 6 months beyond the point of maximal response. Once therapy is stopped, endogenous testosterone levels increase, and the symptoms associated with androgen ablation abate. PSA levels also begin to rise, and, at some level, androgen ablation is restarted. Using this approach, multiple cycles of regression and proliferation have been documented in individual patients. It is unknown whether the intermittent approach increases, decreases, or does not change the overall duration of sensitivity to androgen ablation. A trial to address this question is ongoing.

METASTATIC DISEASE: CASTRATE Castration-resistant disease can be manifest in many ways. For some it is a rise in PSA with no change in radiographs and no new symptoms. In others, it is a rising PSA and progression in bone, with or without symptoms of disease. Still others will show soft tissue disease with or without osseous metastases, and others have a pattern of visceral spread. The prognosis, highly variable, can also be predicted using nomograms designed for this cohort. The important distinction is that despite the failure of first-line hormone treatment, the majority of these tumors remain sensitive to second- and third-line hormonal treatments. Castration resistance does not indicate hormonal resistance. The rising PSA is an indication of continued signaling through the androgen receptor axis.

The manifestations of disease in this patient group hinder the development of drugs and treatment standards because the traditional measures of outcome such as tumor regression do not apply. No PSA-based outcomes are true surrogates for a survival benefit, and assessing changes in osseous disease using bone scans is notoriously inaccurate. It is essential to define therapeutic objectives before initiating treatment, as standards of care have changed on the basis of randomized comparisons that provide clinical benefits without prolonging life. These endpoints include the relief of symptoms and delaying metastases or the time to the development of new symptoms of disease.

The management of these patients requires first that the castrate status be documented. Patients receiving an antiandrogen alone who have elevated levels of serum testosterone should be treated first with a GnRH analogue or orchiectomy and observed for response. Patients on an anti-androgen in combination with a GnRH analogue should have the antiandrogen discontinued, as ~30% will respond to the withdrawal of the antiandrogen. Any response occurs within weeks of stopping flutamide, but may take 8 to 12 weeks with nilutamide and bicalutamide (they have a long terminal half-life). At the time of progression, a different antiandrogen can be given as these agents are not cross-resistant. Other hormones that may be active include estrogens, progestins, ketoconazole, and glucocorticoids. Those who respond to estrogens or progestins should also be evaluated for a withdrawal response at the time of progression. Cytotoxic agents are considered when hormone responses stop.

No chemotherapy regimen has been proven to prolong life in these patients. However, responses to chemotherapy that improve symptom control are not uncommon. Drugs directed at the tumor cell cytoskeleton such estramustine (Emcyt) and a taxane such as paclitaxel or docetaxel can induce responses in ≥50% using measurable disease regression as the endpoint. Seventy percent will show a >50% decline in PSA from baseline. Studies evaluating survival effects are nearly done.

Management of pain is a critical part of therapy. Optimal palliation requires assessing whether the symptoms and metastases are focal or diffuse and whether disease threatens the spinal cord, the cauda equina, or the base of the skull. Neurologic symptoms require emergent evaluation because loss of function may be permanent if not addressed in a timely manner. Single sites of pain or areas of neurologic involvement are best treated with external beam radiation. As the disease is often diffuse, palliation at one site often leads to the emergence of symptoms at another. An important principle of management was established in two randomized trials of mitoxantrone and prednisone vs. prednisone alone. In both studies, mitoxantrone-treated patients had a greater reduction in pain, used fewer narcotics, were more mobile, and had less fatigue. No survival benefit was shown.

Given the bone-dominant nature of prostate cancer spread, bone-directed therapies may be usesful in patients with diffuse disease. Two bone-seeking radioisotopes, ^{89}Sr (metastron) and ^{153}Sm-EDTMP (quadramet), are approved for palliation of pain although they have no effect on PSA or on survival. Fewer patients treated with an isotope

developed new areas of pain or required additional radiation therapy compared to patients receiving external beam radiation therapy alone. Addition of zoledronate to "standard therapy" in patients with castration-resistant disease resulted in fewer skeletal events relative to placebo-treated patients. The bone events included development of new pain, need for radiation therapy, and microfractures. Finally, patients randomly assigned to a combination of ^{89}Sr and doxorubicin after induction chemotherapy had fewer skeletal events and longer survival than patients treated with doxorubicin alone. Confirmatory studies are ongoing.

82 TESTICULAR CANCER

Robert J. Motzer, George J. Bosl

Primary germ cell tumors (GCTs) of the testis, arising by the malignant transformation of primordial germ cells, constitute 95% of all testicular neoplasms. Infrequently, GCTs arise from an extragonadal site, including the mediastinum, retroperitoneum, and, very rarely, the pineal gland. This disease is notable for the young age of the afflicted patients, the totipotent capacity for differentiation of the tumor cells, and its curability; about 95% of all newly diagnosed patients will be cured. Experience in the management of GCTs leads to improved outcome.

INCIDENCE AND EPIDEMIOLOGY Nearly 9000 new cases of testicular GCT were diagnosed in the United States in 2004; the incidence of this malignancy has increased slowly over the past 40 years. The tumor occurs most frequently in men between the ages of 20 and 40. A testicular mass in a man ≥50 years should be regarded as a lymphoma until proved otherwise. GCT is at least four to five times more common in white than in African-American males, and a higher incidence has been observed in Scandinavia and New Zealand than in the United States.

ETIOLOGY AND GENETICS Cryptorchidism is associated with a severalfold higher risk of GCT. Abdominal cryptorchid testes are at a higher risk than inguinal cryptorchid testes. Orchiopexy should be performed before puberty, if possible. Early orchiopexy reduces the risk of GCT and improves the ability to save the testis. An abdominal cryptorchid testis that cannot be brought into the scrotum should be removed. About 2% of men with GCTs of one testis will develop a primary tumor in the other testis. Testicular feminization syndromes increase the risk of testicular GCT, and Klinefelter's syndrome is associated with mediastinal GCT.

An isochromosome of the short arm of chromosome 12 [i(12p)] is pathognomonic for GCT of all histologic types. Excess 12p copy number either in the form of i(12p) or as increased 12p on aberrantly banded marker chromosomes occurs in nearly all GCTs, but the gene(s) on 12p involved in the pathogenesis are not yet defined.

CLINICAL PRESENTATION A painless testicular mass is pathognomonic for a testicular malignancy. More commonly, patients present with testicular discomfort or swelling suggestive of epididymitis and/or orchitis. In this circumstance, a trial of antibiotics is reasonable. However, if symptoms persist or a residual abnormality remains, then testicular ultrasound examination is indicated.

Ultrasound of the testis is indicated whenever a testicular malignancy is considered and for persistent or painful testicular swelling. If a testicular mass is detected, a radical inguinal orchiectomy should be performed. Because the testis develops from the gonadal ridge, its blood supply and lymphatic drainage originate in the abdomen and descend with the testis into the scrotum. An inguinal approach is taken to avoid breaching anatomic barriers and permitting additional pathways of spread.

Back pain from retroperitoneal metastases is common and must be distinguished from musculoskeletal pain. Dyspnea from pulmonary metastases occurs infrequently. Patients with increased serum levels of human chorionic gonadotropin (hCG) may present with gynecomastia. A delay in diagnosis is associated with a more advanced stage and possibly worse survival.

The staging evaluation for GCT includes a determination of serum levels of α fetoprotein (AFP), hCG, and lactate dehydrogenase (LDH). After orchiectomy, a chest radiograph and a computed tomography (CT) scan of the abdomen and pelvis should be performed. A chest CT scan is required if pulmonary nodules or mediastinal or hilar disease is suspected. Stage I disease is limited to the testis, epididymis, or spermatic cord. Stage II disease is limited to retroperitoneal (regional) lymph nodes. Stage III disease is disease outside the retroperitoneum, involving supradiaphragmatic nodal sites or viscera. The staging may be "clinical"—defined solely by physical examination, blood marker evaluation, and radiographs—or "pathologic"—defined by an operative procedure.

The regional draining lymph nodes for the testis are in the retroperitoneum, and the vascular supply originates from the great vessels (for the right testis) or the renal vessels (for the left testis). As a result, the lymph nodes that are involved first by a right testicular tumor are the interaortocaval lymph nodes just below the renal vessels. For a left testicular tumor, the first involved lymph nodes are lateral to the aorta (para-aortic) and below the left renal vessels. In both cases, further nodal spread is inferior and contralateral and, less commonly, above the renal hilum. Lymphatic involvement can extend cephalad to the retrocrural, posterior mediastinal, and supraclavicular lymph nodes. Treatment is determined by tumor histology (seminoma versus nonseminoma) and clinical stage (Table 82-1).

PATHOLOGY GCTs are divided into nonseminoma and seminoma subtypes. Nonseminomatous GCTs are most frequent in the third decade of life and can display the full spectrum of embryonic and adult cellular differentiation. This entity comprises four histologies: embryonal carcinoma, teratoma, choriocarcinoma, and endodermal sinus (yolk sac) tumor. Choriocarcinoma, consisting of both cytotrophoblasts and syncytiophoblasts, represents malignant trophoblastic differentiation and is invariably associated with secretion of hCG. Endodermal sinus tumor is the malignant counterpart of the fetal yolk sac and is associated with secretion of AFP. Pure embryonal carcinoma may secrete AFP or hCG, or both; this pattern is biochemical evidence of differentiation. Teratoma is composed of somatic cell types derived from two or more germ layers (ectoderm, mesoderm, or endoderm). Each of these histologies may be present alone or in combination with others. Nonseminomatous GCTs tend to metastasize early to sites such as the retroperitoneal lymph nodes and lung parenchyma. One-third of patients present with disease limited to the testis (stage I), one-third with retroperitoneal metastases (stage II), and one-third with more extensive supradiaphragmatic nodal or visceral metastases (stage III).

Seminoma represents about 50% of all GCTs, has a median age in the fourth decade, and generally follows a more indolent clinical course. Most patients (70%) present with stage I disease, about 20% with stage II disease, and 10% with stage III disease; lung or other visceral metastases are rare. Radiation therapy is the treatment of

choice in patients with stage I disease and stage II disease where the nodes are <5 cm in maximum diameter. When a tumor contains both seminoma and nonseminoma components, patient management is directed by the more aggressive nonseminoma component.

TUMOR MARKERS Careful monitoring of the serum tumor markers AFP and hCG is essential in the management of patients with GCT, as these markers are important for diagnosis, as prognostic indicators, in monitoring treatment response, and in the detection of early relapse. Approximately 70% of patients presenting with disseminated nonseminomatous GCT have increased serum concentrations of AFP and/or hCG. While hCG concentrations may be increased in patients with either nonseminoma or seminoma histology, the AFP concentration is increased only in patients with nonseminoma. The presence of an increased AFP level in a patient whose tumor showed only seminoma indicates that an occult nonseminomatous component exists and the patient should be treated for nonseminomatous GCT. LDH levels are not as specific as AFP or hCG, but are increased in 50 to 60% patients with metastatic nonseminoma and in up to 80% of patients with advanced seminoma.

AFP, hCG, and LDH levels should be determined before and after orchiectomy. Increased serum AFP and hCG concentrations decay according to first-order kinetics; the half-life is 24 to 36 h for hCG and 5 to 7 days for AFP. AFP and hCG should be assayed serially during and after treatment. The reappearance of hCG and/or AFP or the failure of these markers to decline according to the predicted half-life is an indicator of persistent or recurrent tumor.

TABLE 82-1 *Germ Cell Tumor Staging and Treatment*

		Treatment	
Stage	*Extent of Disease*	*Seminoma*	*Nonseminoma*
IA	Testis only, no vascular/lymphatic invasion (T1)	Radiation therapy	RPLND or observation
IB	Testis only, with vascular/lymphatic invasion (T2), or extension through tunica albuginea (T2), or involvement of spermatic cord (T3) or scrotum (T4)	Radiation therapy	RPLND
IIA	Nodes < 2 cm	Radiation therapy	RPLND or chemotherapy often followed by RPLND
IIB	Nodes 2–5 cm	Radiation therapy	RPLND +/− adjuvant chemotherapy or chemotherapy followed by RPLND
IIC	Nodes > 5 cm	Chemotherapy	Chemotherapy, often followed by RPLND
III	Distant metastases	Chemotherapy	Chemotherapy, often followed by surgery (biopsy or resection)

Note: RPLND, retroperitoneal lymph node dissection.

TREATMENT

Stage I Nonseminoma If, after an orchiectomy (for clinical stage I disease), radiographs and physical examination show no evidence of disease, and serum AFP and hCG concentrations are either normal or declining to normal according to the known half-life, patients may be managed by either a nerve-sparing retroperitoneal lymph node dissection (RPLND) or surveillance. The retroperitoneal lymph nodes are involved by GCT (pathologic stage II) in 20 to 50% of these patients. The choice of surveillance or RPLND is based on the pathology of the primary tumor. If the primary tumor shows no evidence for lymphatic or vascular invasion and is limited to the testis (T1), then either option is reasonable. If lymphatic or vascular invasion is present or the tumor extends into the tunica, spermatic cord, or scrotum (T2 through T4), then surveillance should not be offered. Either approach should cure >95% of patients.

A RPLND is the standard operation for removal of the regional lymph nodes of the testis (retroperitoneal nodes). The operation removes the lymph nodes ipsilateral to the primary site and the nodal groups adjacent to the primary landing zone. The standard (modified bilateral) RPLND removes all node-bearing tissue down to the bifurcation of the great vessels, including the ipsilateral iliac nodes. The major long-term effect of this operation is retrograde ejaculation and infertility. A nerve-sparing RPLND, usually accomplished by identification and dissection of individual nerve fibers, may avoid injury to the sympathetic nerves responsible for ejaculation. Normal ejaculation is preserved in ~90% of patients. Patients with pathologic stage I disease are observed, and only the <10% who relapse require additional therapy. If retroperitoneal nodes are found to be involved at RPLND, then a decision regarding adjuvant chemotherapy is made on the basis of the extent of retroperitoneal disease (see below).

Surveillance is an option in the management of clinical stage I disease when no vascular/lymphatic invasion is found (T1). Only 20 to 30% of patients have pathologic stage II disease, implying that most RPLNDs in this situation are not therapeutic. Although surveillance has not been compared to RPLND in a randomized trial, all large studies show that surveillance and RPLND lead to equivalent long-term survival rates. Patient compliance is essential if surveillance is to be successful. Patients must be carefully followed with periodic chest radiography, physical examination, CT scan of the abdomen, and serum tumor marker determinations. The median time to relapse is about 7 months, and late relapses (>2 years) are rare. The 70 to 80% of patients who do not relapse require no intervention after orchiectomy; treatment is reserved for those who do relapse. When the primary tumor is classified as T2 through T4 (extension beyond testis and epididymis or lymphatic/vascular invasion is identified), nerve-sparing RPLND is preferred. About 50% of these patients have pathologic stage II disease and are destined to relapse without the RPLND.

Stage II Nonseminoma Patients with limited, ipsilateral retroperitoneal adenopathy (nodes usually ≤3 cm in largest diameter) and normal levels of AFP and hCG generally undergo a modified bilateral RPLND as primary management. Increased levels of either AFP or hCG or both imply metastatic disease outside the retroperitoneum; chemotherapy is used in this setting. The local recurrence rate after a properly performed RPLND is very low. Depending on the extent of disease, the postoperative management options include either surveillance or two cycles of adjuvant chemotherapy. Surveillance is the preferred approach for patients with resected "low-volume" metastases (tumor nodes ≤2 cm in diameter *and* <6 nodes involved) because the probability of relapse is one-third or less. For those who relapse, risk-directed chemotherapy is indicated (see below). Because relapse occurs in ≥50% of patients with "high-volume" metastases (>6 nodes involved, *or* any involved node >2 cm in largest diameter, *or* extranodal tumor extension), two cycles of adjuvant chemotherapy should be considered, as it results in cure in ≥98% of patients. Regimens consisting of etoposide (100 mg/m^2 daily on days 1 through 5) plus cisplatin (20 mg/m^2 daily on days 1 through 5) with or without bleomycin (30 units per day on days 2, 9, and 16) given at 3-week intervals are effective and well tolerated.

Stages I and II Seminoma Inguinal orchiectomy followed by retroperitoneal radiation therapy cures ~98% of patients with stage I seminoma. The dose of radiation therapy (2500 to 3000 cGy) is low and well tolerated, and the in-field recurrence rate is negligible. About 2% of patients relapse with supradiaphragmatic or systemic disease. Surveillance has been proposed as an option, and studies have shown that about 15% of patients relapse. The median time to relapse is 12 to 15 months, and late relapses (>5 years) may be more frequent than with

nonseminoma. The relapse is usually treated with chemotherapy. Surveillance for clinical stage I seminoma is generally not recommended.

Nonbulky retroperitoneal disease (stage IIA and IIB) is also treated with radiation therapy. Prophylactic supradiaphragmatic fields are not used. Relapses in the anterior mediastinum are unusual. Approximately 90% of patients achieve relapse-free survival with retroperitoneal masses <5 cm in diameter. Because at least one-third of patients with bulkier disease relapse, initial chemotherapy is preferred for stage IIC disease.

Chemotherapy for Advanced GCT Regardless of histology, patients with stage IIC and stage III GCT are treated with chemotherapy. Combination chemotherapy programs based on cisplatin at doses of 100 mg/m^2 plus etoposide at doses of 500 mg/m^2 per cycle cure 70 to 80% of such patients, with or without bleomycin, depending on risk stratification (see below). A complete response (the complete disappearance of all clinical evidence of tumor on physical examination and radiography plus normal serum levels of AFP and hCG for ≥1 month) occurs after chemotherapy alone in ~60% of patients, and another 10 to 20% become disease-free with surgical resection of residual masses containing viable GCT. Lower doses of cisplatin result in inferior survival rates.

The toxicity of four cycles of the cisplatin/bleomycin/etoposide (BEP) regimen is substantial. Nausea, vomiting, and hair loss occur in most patients, although nausea and vomiting have been markedly ameliorated by modern antiemetic regimens. Myelosuppression is frequent, and symptomatic bleomycin pulmonary toxicity occurs in ~5% of patients. Treatment-induced mortality due to neutropenia with septicemia or bleomycin-induced pulmonary failure occurs in 1 to 3% of patients. Dose reductions for myelosuppression are rarely indicated. Long-term permanent toxicities include nephrotoxicity (reduced glomerular filtration and persistent magnesium wasting), ototoxicity, and peripheral neuropathy. When bleomycin is administered by weekly bolus injection, Raynaud's phenomenon appears in 5 to 10% of patients. Other evidence of small blood vessel damage is seen less often, including transient ischemic attacks and myocardial infarction.

Risk-Directed Chemotherapy Because not all patients are cured and treatment may cause significant toxicities, patients are stratified into "good-risk" and "poor-risk" groups according to pretreatment clinical features. For good-risk patients, the goal is to achieve maximum efficacy with minimal toxicity. For poor-risk patients, the goal is to identify more effective therapy with tolerable toxicity.

The International Germ Cell Cancer Consensus Group (IGCCCG) developed criteria to assign patients to three risk groups (good, intermediate, poor) (Table 82-2). The marker cut-offs have been incorporated into the revised TNM staging of GCT. Hence, TNM stage groupings are now based on both anatomy (site and extent of disease) and biology (marker status and histology). Seminoma is either good or intermediate risk based on the absence or presence of nonpulmonary visceral metastases. No poor-risk category exists for seminoma. Marker levels play no role in defining risk for seminoma. Nonseminomas have good-, intermediate-, and poor-risk categories based on the site of the primary tumor, the presence or absence of nonpulmonary visceral metastases, and marker levels.

For ~90% of patients with good-risk GCTs, four cycles of etoposide plus cisplatin (EP) or three cycles of BEP produce durable complete responses, with minimal acute and chronic toxicity. Pulmonary toxicity is absent when bleomycin is not used and is rare when therapy is limited to 9 weeks; myelosuppression with neutropenic fever is less frequent; and the treatment mortality rate is negligible. About 75% of intermediate-risk patients and 45% of poor-risk patients achieve durable complete remission with four cycles of BEP, and no regimen has proved superior. More effective therapy is needed.

Postchemotherapy Surgery Resection of residual metastases after the completion of chemotherapy is an integral part of therapy. If the initial histology is nonseminoma and the marker values have normalized, all sites of residual disease should be resected. In general, residual retroperitoneal disease requires a modified bilateral RPLND. Thoracotomy (unilateral or bilateral) and neck dissection are less frequently required to remove residual mediastinal, pulmonary parenchymal, or cervical nodal disease. Viable tumor (seminoma, embryonal carcinoma, yolk sac tumor, or choriocarcinoma) will be present in 15%, mature teratoma in 40%, and necrotic debris and fibrosis in 45% of resected specimens. The frequency of teratoma or viable disease is highest in residual mediastinal tumors. If necrotic debris or mature teratoma is present, no further chemotherapy is necessary. If viable tumor is present but is completely excised, two additional cycles of chemotherapy are given.

If the initial histology is pure seminoma, mature teratoma is rarely present, and the most frequent finding is necrotic debris. For residual retroperitoneal disease, a complete RPLND is technically difficult owing to extensive postchemotherapy fibrosis. Observation is recommended when no radiographic abnormality exists or a residual mass <3 cm is present. Controversy exists over what to do when the residual mass exceeds 3 cm in diameter. About 25% of such masses contain viable GCT. Some investigators prefer excision or biopsy, but radiation therapy and surveillance are alternatives.

Salvage Chemotherapy Of patients with advanced GCT, 20 to 30% fail to achieve a durable complete response to first-line chemotherapy. A combination of cisplatin, ifosfamide and vinblastine (VeIP) will cure about 25% of patients as a second-line therapy. Substitution of paclitaxel for vinblastine may be more effective in this setting. Patients are more likely to achieve a durable complete response if they had a testicular primary tumor and relapsed from a prior complete remission to first-line cisplatin-containing chemotherapy. In contrast, if the patient failed to achieve a complete response or has a primary mediastinal nonseminoma, then standard-dose salvage therapy is rarely beneficial. Treatment options for such patients include dose-intensive treatment, experimental therapies, and surgical resection.

Chemotherapy consisting of dose-intensive, high-dose carboplatin (≥1500 mg/m^2) plus etoposide (≥1200 mg/m^2), with or without cyclophosphamide or ifosfamide, with peripheral blood stem cell support induces a complete response in 25 to 40% of patients who have progressed after ifosfamide-containing salvage chemotherapy. About one-half of the complete responses will be durable. High-dose therapy is the treatment of choice and standard of care for this patient population. Paclitaxel is also active in previously treated patients and shows prom-

TABLE 82-2 IGCCCG Risk Classification for Advanced Germ Cell Tumors

Risk	Nonseminoma	Seminoma
Good	Gonadal or retroperitoneal primary site	Any primary site
	Absent nonpulmonary visceral metastases	Absent nonpulmonary visceral metastases
	AFP < 1000 ng/mL	Any LDH, hCG
	Beta-hCG < 5000 mIU/mL	
	LDH < 1.5 × upper limit or normal (ULN)	
Intermediate	Gonadal or retroperitoneal primary site	Any primary site
	Absent nonpulmonary visceral metastases	Presence of nonpulmonary visceral metastases
	AFP 1000–10,000 ng/mL	Any LDH, hCG
	Beta-hCG 5000–50,000 mIU/mL	
	LDH 1.5–10 × ULN	
Poor	Mediastinal primary site	No patients classified as poor prognosis
	Presence of nonpulmonary visceral metastases	
	AFP ≥ 10,000 ng/ML	
	Beta-hCG > 50,000 mIU/mL	
	LDH > 10 × ULN	

Note: AFP, α fetoprotein; hCG, human chorionic gonadotropin; LDH, lactate dehydrogenase.

ise in high-dose combination programs. Cure is still possible in some relapsed patients.

EXTRAGONADAL GCT AND MIDLINE CARCINOMA OF UNCERTAIN HISTOGENESIS

The prognosis and management of patients with extragonadal GCTs depends on the tumor histology and site of origin. All patients with a diagnosis of extragonadal GCT should have a testicular ultrasound examination. Nearly all patients with retroperitoneal or mediastinal seminoma achieve a durable complete response to BEP or EP. The clinical features of patients with primary retroperitoneal nonseminoma GCT are similar to those of patients with a primary of testis origin, and careful evaluation will find evidence of a primary testicular GCT in about two-thirds of cases. In contrast, a primary mediastinal nonseminomatous GCT is associated with a poor prognosis; one-third of patients are cured with standard therapy (four cycles of BEP). Patients with newly diagnosed mediastinal nonseminoma are considered to have poor-risk disease and should be considered for clinical trials testing regimens of possibly greater efficacy. In addition, mediastinal nonseminoma is associated with hematologic disorders, including acute myelogenous leukemia, myelodysplastic syndrome, and essential thrombocytosis unrelated to previous chemotherapy. These hematologic disorders are very refractory to treatment. Nonseminoma of any primary site may change into other malignant histologies such as embryonal rhabdomyosarcoma or adenocarcinoma. This is called malignant transformation. i(12p) has been identified in the transformed cell type, indicating GCT clonal origin.

A group of patients with poorly differentiated tumors of unknown histogenesis, midline in distribution, and not associated with secretion of AFP or hCG has been described; a few (10 to 20%) are cured by standard cisplatin-containing chemotherapy. i(12p) is present in ~25% of such tumors (the fraction that are cisplatin-responsive), confirming their origin from primitive germ cells. This finding is also predictive of the response to cisplatin-based chemotherapy and resulting long-term survival. These tumors are heterogeneous; neuroepithelial tumors and lymphoma may also present in this fashion.

FERTILITY Infertility is an important consequence of the treatment of GCTs. Preexisting infertility or impaired fertility is often present. Azoospermia and/or oligospermia are present at diagnosis in at least 50% of patients with testicular GCTs. Ejaculatory dysfunction is associated with RPLND, and germ cell damage may result from cisplatin-containing chemotherapy. Nerve-sparing techniques to preserve the retroperitoneal sympathetic nerves have made retrograde ejaculation less likely in the subgroups of patients who are candidates for this operation. Spermatogenesis does recur in some patients after chemotherapy. However, because of the significant risk of impaired reproductive capacity, semen analysis and cryopreservation of sperm in a sperm bank should be recommended to all patients before treatment.

83 GYNECOLOGIC MALIGNANCIES

Robert C. Young

OVARIAN CANCER

Incidence and Epidemiology Epithelial ovarian cancer is the leading cause of death from gynecologic cancer in the United States. In 2004, 25,580 new cases were diagnosed and 16,090 women died from ovarian cancer. The disease accounts for 5% of all cancer deaths in women in the United States; more women die of this disease than from cervical and endometrial cancer combined.

The age-specific incidence of the common epithelial type of ovarian cancer increases progressively and peaks in the eighth decade. Epithelial tumors, unlike germ cell and stromal tumors, are uncommon before the age of 40. Epidemiologic studies suggest higher incidences in industrialized nations and an association with disordered ovarian function, including infertility, nulliparity, frequent miscarriages, and use of ovulation-inducing drugs such as clomiphene. Each pregnancy reduces the ovarian cancer risk by about 10%, and breast-feeding and ubal ligation also appear to reduce the risk. Oral contraceptives reduce the risk of ovarian cancer in patients with a familial history of cancer and in the general population. Many of these risk-reduction factors support the "incessant ovulation" hypothesis for ovarian cancer etiology, which implies that an aberrant repair process of the surface epithelium is central to ovarian cancer development. Estrogen replacement after menopause does not appear to increase the risk of ovarian cancer, although one study showed a modest increase in risk with >11 years of use.

Familial cases account for about 5% of all ovarian cancer, and a family history of ovarian cancer is a major risk factor. Compared to a lifetime risk of 1.6% in the general population, women with one affected first-degree relative have a 5% risk. In families with two or more affected first-degree relatives, the risk may exceed 50%. Three types of autosomal dominant familial cancer are recognized: (1) site-specific, in which only ovarian cancer is seen; (2) families with cancer of the ovary and breast; and (3) the Lynch type II cancer family syndrome with nonpolyposis colorectal cancer, endometrial cancer, and ovarian cancer.

Etiology and Genetics In women with hereditary breast/ovarian cancer, two susceptibility loci have been identified: *BRCA1*, located on chromosome 17q12-21, and *BRCA2*, on 13q12-13. Both are tumor-suppressor genes, and their protein products act as inhibitors of tumor growth. Both genes are large, and numerous mutations have been described; most are frameshift or nonsense mutations, and 86% produce truncated protein products. The implications of the many other mutations including many missense mutations are not known. The cumulative risk of ovarian cancer with critical mutations of *BRCA1* or -2 is 25%, compared to the lifetime risk of 50% for breast cancer for similar mutations. Men in such families have an increased risk of prostate cancer.

Cytogenetic analysis of sporadic epithelial ovarian cancers generally reveals complex karyotypic rearrangements. Structural abnormalities frequently appear on chromosomes 1 and 11, and loss of heterozygosity is common on 3q, 6q, 11q, 13q, and 17. Abnormalities of oncogenes are frequently found in ovarian cancer and include c-*myc*, H-*ras*, K-*ras*, and *neu*.

Ovarian tumors (usually not epithelial) are sometimes components of complex genetic syndromes. Peutz-Jeghers syndrome (mucocutaneous pigmentation and intestinal polyps) is associated with ovarian sex cord stromal tumors and Sertoli cell tumors in men. Patients with gonadal dysgenesis (46XY genotype or mosaic for Y-containing cell lines) develop gonadoblastomas, and women with nevoid basal cell carcinomas have an increased risk of ovarian fibromas.

Clinical Presentation and Differential Diagnosis Most patients with ovarian cancer are first diagnosed when the disease has already spread beyond the true pelvis. The occurrence of abdominal pain, bloating, and urinary symptoms usually indicates advanced disease. Localized ovarian cancer is generally asymptomatic. However, progressive enlargement of a localized ovarian tumor can produce urinary frequency or constipation, and rarely torsion of an ovarian mass causes acute abdominal pain or a surgical abdomen. In contrast to cervical or endometrial cancer, vaginal bleeding or discharge is rarely seen with early ovarian cancer. The diagnosis of early disease usually occurs with palpation of an asymptomatic adnexal mass during routine pelvic examination. However, most ovarian enlargements discovered this way, especially in premenopausal women, are benign functional cysts that characteristically resolve over one to three menstrual cycles. Adnexal masses in premenarchal or postmenopausal women are more likely to be pathologic. A solid, irregular, fixed pelvic mass is usually ovarian cancer. Other causes of adnexal masses include pedunculated uterine fibroids, endometriosis, benign ovarian neoplasms, and inflammatory lesions of the bowel.

Evaluation of patients with suspected ovarian cancer should include measurement of serum levels of the tumor marker CA-125. CA-125 determinants are glycoproteins with molecular masses from 220 to 1000 kDa, and a radioimmunoassay is used to determine circulating CA-125 antigen levels. Between 80 and 85% of patients with epithelial ovarian cancer have levels of CA-125 $\geq$ 35 U/mL. Other malignant tumors can also elevate CA-125 levels, including cancers of the endometrium, cervix, fallopian tubes, pancreas, breast, lung, and colon. Certain nonmalignant conditions that can produce moderate elevations of CA-125 levels include pregnancy, endometriosis, pelvic inflammatory disease, and uterine fibroids. About 1% of normal females have serum CA-125 levels >35 U/mL. However, in postmenopausal women with an asymptomatic pelvic mass and CA-125 levels $\geq$65 U/mL, the test has a sensitivity of 97% and a specificity of 78%.

Screening In contrast to patients who present with advanced disease, patients with early ovarian cancers (stages I and II) are commonly curable with conventional therapy. Thus, effective screening procedures would improve the cure rate in this disease. Although pelvic examination can occasionally detect early disease, it is a relatively insensitive screening procedure. Transvaginal sonography is often useful, but significant false-positive results are noted, particularly in premenopausal women. In one study, 67 laparotomies were required to diagnose 1 primary ovarian cancer. Doppler flow imaging coupled with transvaginal ultrasound may improve accuracy and reduce the high rate of false positives.

CA-125 has been studied as a screening tool. Unfortunately, half of women with stages I and II ovarian cancer have CA-125 levels <65 U/mL. Attempts have been made to improve the sensitivity and specificity by combinations of procedures, commonly transvaginal ultrasound and CA-125 levels. In a screening study of 22,000 women, 42 had a positive screen and 11 had ovarian cancer (7 with advanced disease). In addition, eight women with a negative screen developed ovarian cancer. Thus, the false-positive rate would lead to a large number of unnecessary (i.e., negative) laparotomies if each positive screen resulted in a surgical exploration. The National Institutes of Health Consensus Conference recommended against screening for ovarian cancer among the general population without known risk factors for the disease. Although no evidence shows that screening saves lives, many physicians use annual pelvic examinations, transvaginal ultrasound, and CA-125 levels to screen women with a family history of ovarian cancer or breast/ovarian cancer syndromes.

In one study, proteomic spectra in the serum analyzed by an iterative searching algorithm were used to identify women with ovarian cancer. Preliminary studies have identified all 50 stage I patients with a sensitivity of 100%, a specificity of 95%, and a positive predictive value of 94%. The procedure can be automated, requires a pinprick of blood, and has many characteristics of an ideal screening test. However, difficulty in consistency of replicate samples, variation in spectroscopy equipment, and the tendency of the artificial intelligence algorithms to overfit the data makes conformation studies necessary before widespread application to screening is warranted.

Pathology Common epithelial tumors comprise most (85%) of the ovarian neoplasms. These may be benign (50%), frankly malignant (33%), or tumors of low malignant potential (16%) (tumors of borderline malignancy). Epithelial tumors of low malignant potential have the cytologic features of malignancy but do not invade the ovarian stroma. More than 75% of borderline malignancies present in early stage and generally occur in younger women. They have a much better natural history than their malignant counterpart.

There are five major subtypes of common epithelial tumors: serous (50%), mucinous (25%), endometroid (15%), clear cell (5%), and Brenner tumors (1%), the latter derived from the urothelium. Benign common epithelial tumors are almost always serous or mucinous and develop in women ages 20 to 60. They are frequently large (20 to 30 cm), bilateral, and cystic.

Malignant epithelial tumors are usually seen in women over 40. They present as solid masses, with areas of necrosis and hemorrhage. Masses >10 to 15 cm have usually already spread into the intraabdominal space. Spread eventually results in intraabdominal carcinomatosis, which leads to bowel and renal obstruction and cachexia.

Although most ovarian tumors are epithelial, two other important ovarian tumor types exist—stromal and germ cell tumors. These tumors are distinct in their cell of origin but also have different clinical presentations and natural histories and are often managed differently (see below).

Metastasis to the ovary can occur from breast, colon, gastric, and pancreatic cancers, and the Krukenberg tumor was classically described as bilateral ovarian masses from metastatic mucin-secreting gastrointestinal cancers.

Staging and Prognostic Factors Laparotomy is often the primary procedure used to establish the diagnosis. Less invasive studies useful in defining the extent of spread include chest x-rays, abdominal computed tomography scans, and abdominal and pelvic sonography. If the woman has specific gastrointestinal symptoms, a barium enema or gastrointestinal series can be performed. Symptoms of bladder or renal dysfunction can be evaluated by cystoscopy or intravenous pyelography.

A careful staging laparotomy will establish the stage and extent of disease and allow for the cytoreduction of tumor masses in patients with advanced disease. Proper laparotomy requires a vertical incision of sufficient length to ensure adequate examination of the abdominal contents. The presence, amount, and cytology of any ascites fluid should be noted. The primary tumor should be evaluated for rupture, excrescences, or dense adherence. Careful visual and manual inspection of the diaphragm and peritoneal surfaces is required. In addition to total abdominal hysterectomy and bilateral salpingo-oophorectomy, a partial omentectomy should be performed and the paracolic gutters inspected. Pelvic lymph nodes as well as para-aortic nodes in the region of the renal hilus should be biopsied. Since this surgical procedure defines stage, establishes prognosis, and determines the necessity for subsequent therapy, it should be performed by a surgeon with special expertise in ovarian cancer staging. Studies have shown that patients operated upon by gynecologic oncologists were properly staged 97% of the time, compared to 52% and 35% of cases staged by obstetricians/gynecologists and general surgeons, respectively. At the end of staging, 23% of women have stage I disease (cancer confined to the ovary or ovaries); 13% have stage II (disease confined to the true pelvis); 47% have stage III (disease spread into but confined to the abdomen); and 16% have stage IV disease (spread outside the pelvis and abdomen). The 5-year survival correlates with stage of disease: stage I—90%, stage II—70%, stage III—15 to 20%, and stage IV—1 to 5% (Table 83-1).

Prognosis in ovarian cancer is dependent not only upon stage but

on the extent of residual disease and histologic grade. Patients presenting with advanced disease but left without significant residual disease after surgery have a median survival of 39 months, compared to 17 months for those with suboptimal tumor resection.

Prognosis of epithelial tumors is also highly influenced by histologic grade but less so by histologic type. Although grading systems differ among pathologists, all grading systems show a better prognosis for well- or moderately differentiated tumors and a poorer prognosis for poorly differentiated histologies. Typical 5-year survivals for patients with all stages of disease are: well-differentiated—88%, moderately differentiated—58%, poorly differentiated—27%.

The prognostic significance of pre- and postoperative CA-125 levels is uncertain. Serum levels generally reflect volume of disease, and high levels usually indicate unresectability and a poorer survival. Postoperative levels, if elevated, usually indicate residual disease. The rate of decline of CA-125 levels during initial therapy or the absolute level after one to three cycles of chemotherapy correlates with prognosis but is not sufficiently accurate to guide individual treatment decisions. Even when the CA-125 level falls to normal after surgery or chemotherapy, "second-look" laparotomy identifies residual disease in 60% of women.

Genetic and biologic factors may influence prognosis. Increased tumor levels of p53 are associated with a worse prognosis in advanced disease. Epidermal growth factor receptors in ovarian cancer are associated with a high risk of progression, but the increased expression of HER-2/neu has given conflicting prognostic results, and expression of Mdr-1 has not been of prognostic value. HER-2/neu is highly expressed in 20% of ovarian cancers, and responses have been seen to trastuzumab in this subset of patients.

TABLE 83-1 *Staging and Survival in Gynecologic Malignancies*

Stage	Ovarian	5-Year Survival, %	Endometrial	5-Year Survival, %	Cervix	5-Year Survival, %
0	—		—		Carcinoma in situ	100
I	Confined to ovary	90	Confined to corpus	89	Confined to uterus	85
II	Confined to pelvis	70	Involves corpus and cervix	80	Invades beyond uterus but not to pelvic wall	60
III	Intraabdominal spread	15–20	Extends outside the uterus but not outside the true pelvis	30	Extends to pelvic wall and/or lower third of vagina, or hydronephrosis	33
IV	Spread outside abdomen	1–5	Extends outside the true pelvis or involves the bladder or rectum	9	Invades mucosa of bladder or rectum or extends beyond the true pelvis	7

TREATMENT

The selection of therapy for patients with epithelial ovarian cancer depends upon the stage, extent of residual tumor, and histologic grade. In general, patients are considered in three separate treatment groups: (1) those with early (stages I and II) ovarian cancer and microscopic or no residual disease; (2) patients with advanced (stage III) disease but minimal residual tumor (<1 cm) after initial surgery; and (3) patients with bulky residual tumor and advanced (stage III or IV) disease.

Patients with stage I disease, no residual tumor, and well or moderately differentiated tumors need no adjuvant therapy after definitive surgery, and 5-year survival exceeds 95%. For all other patients with early disease and those stage I patients with poor prognosis histologic grade, adjuvant therapy is probably warranted, and single-agent cisplatin or platinum-containing drug combinations improve survival by 8% (82% vs 76%, $p = .08$).

For the patients with advanced (stage III) disease but with limited or no residual disease after definitive cytoreductive surgery (about half of all stage III patients), the primary therapy is platinum-based combination chemotherapy. Approximately 70% of women respond to initial combination chemotherapy, and 40 to 50% have a complete regression of disease. Only about half of these patients are free of disease if surgically restaged. Although a variety of combinations are active, a randomized prospective trial of paclitaxel and cisplatin compared to paclitaxel and carboplatin in patients with optimally resected advanced disease demonstrated equivalent results (median time to progression 20.7 months vs 19.4 months, median survival 57.4 months vs 48.7 months) but with significantly reduced toxicity using carboplatin. This regimen of paclitaxel, 175 mg/m^2 by 3-h infusion, and carboplatin, dosed to an AUC (area under the curve) of 7.5 is the treatment of choice for patients with previously untreated advanced-stage disease.

Patients with advanced disease (stages III and IV) and bulky residual tumor are generally treated with a paclitaxel-platinum combination regimen as well and, while the overall prognosis is poorer, 5-year survival may reach 10 to 15%.

Historically, patients who had an excellent initial response to chemotherapy and no clinical evidence of disease have had a second-look laparotomy. For patients with stage I ovarian cancer or for germ cell tumors, the operation rarely detects residual tumor and has been largely abandoned. Even for those with stages II and III epithelial tumors, the second-look surgical procedure itself does not prolong overall survival. Its routine use cannot be recommended. Maintenance therapy (12 cycles of paclitaxel every 28 days) may extend progression-free survival among patients who achieve a complete response; an effect on overall survival has not yet been shown.

Patients with advanced disease whose disease recurs after initial treatment are usually not curable but may benefit significantly from limited surgery to relieve intestinal obstruction, localized radiation therapy to relieve pressure or pain from mass lesions or metastasis, or palliative chemotherapy. The selection of chemotherapy for palliation depends upon the initial regimen and evidence of drug resistance. Patients who have a complete regression of disease that lasts ≥6 months often respond to reinduction with the same agents. Patients relapsing within the first 6 months of initial therapy rarely do. Chemotherapeutic agents with >15% response rates in patients relapsing after initial combination chemotherapy include gemcitabine, topotecan, liposomal doxorubicin, and vinorelbine. Intraperitoneal chemotherapy (usually cisplatin) may be used if a small residual volume (<1 cm^3) of tumor exists. Progestational agents and antiestrogens produce responses in 5 to 15% of patients and have minimal side effects.

Patients with tumor of low malignant potential, even with advanced-stage disease, have longer survivals when managed with surgery alone. The added value of radiation and chemotherapy has not been shown.

OVARIAN GERM CELL TUMORS Fewer than 5% of all ovarian tumors are germ cell in origin. They include teratoma, dysgerminoma, endodermal sinus tumor, and embryonal carcinoma. Germ cell tumors of the ovary generally occur in younger women (75% of ovarian malignancies in women <30), display an unusually aggressive natural history, and are commonly cured with less extensive nonsterilizing surgery and chemotherapy. Women cured of these malignancies are able to conceive and have normal children.

These neoplasms can be divided into three major groups: (1) benign tumors (usually dermoid cysts); (2) malignant tumors that arise from dermoid cysts; and (3) primitive malignant germ cell tumors including dysgerminoma, yolk sac tumors, immature teratomas, embryonal carcinomas, and choriocarcinoma.

Dermoid cysts are teratomatous cysts usually lined by epidermis and skin appendages. They often contain hair, and calcified bone or

teeth can sometimes be seen on conventional pelvic x-ray. They are almost always curable by surgical resection. Approximately 1% of these tumors have malignant elements, usually squamous cell carcinoma.

Malignant germ cell tumors are usually large (median—16 cm). Bilateral disease is rare except in dysgerminoma (10 to 15% bilaterality). Abdominal or pelvic pain in young women is the usual presenting symptom. Serum human chorionic gonadotropin (β-hCG) and α fetoprotein levels are useful in the diagnosis and management of these patients. Before the advent of chemotherapy, extensive surgery was routine, but it has now been replaced by careful evaluation of extent of spread followed by resection of bulky disease and preservation of one ovary, uterus, and cervix, if feasible. This allows many affected women to preserve fertility. After surgical staging, 60 to 75% of women have stage I disease and 25 to 30% have stage III disease. Stages II and IV are infrequent.

Most of the malignant germ cell tumors are managed with chemotherapy after surgery. Regimens used in testicular cancer such as PVB (cisplatin, vinblastine, bleomycin) and BEP (bleomycin, 30 units IV weekly; etoposide, 100 mg/m^2 days 1 to 5; and cisplatin, 20 mg/m^2 days 1 to 5), with three or four courses given at 21-day intervals, have produced 95% long-term survival in patients with stages I to III disease. This regimen is the treatment of choice for all malignant germ cell tumors except grade I, stage I immature teratoma, where surgery alone is adequate, and perhaps early-stage dysgerminoma, where surgery and radiation therapy are used.

Dysgerminoma is the ovarian counterpart of testicular seminoma. The tumor is very sensitive to radiation therapy. The 5-year disease-free survival is 100% in early-stage patients and 61% in stage III disease. Unfortunately, the use of radiation therapy makes many patients infertile. BEP chemotherapy is equally or more effective and does not cause infertility. In incompletely resected patients with dysgerminoma, the 2-year disease-free survival is 95% and infertility is not observed. Combination chemotherapy (BEP) has replaced postoperative radiation therapy as the treatment of choice in women with ovarian dysgerminoma.

OVARIAN STROMAL TUMORS Stromal tumors make up <10% of ovarian tumors. They are named for the stromal tissue involved: granulosa, theca, Sertoli, Leydig, and collagen-producing stromal cells. The granulosa and theca cell stromal cell tumors occur most frequently in the first three decades of life. Granulosa cell tumors frequently produce estrogen and cause menstrual abnormalities, bleeding, and precocious puberty. Endometrial carcinoma can be seen in 5% of these women, perhaps related to the persistent hyperestrogenism. Sertoli and Leydig cell tumors, when functional, produce androgens with resultant virilization or hirsutism. Some 75% of these stromal cell tumors present in stage I and can be cured with total abdominal hysterectomy and bilateral salpingo-oophorectomy. Stromal tumors generally grow slowly, and recurrences can occur 5 to 10 years after initial surgery. Neither radiation therapy nor chemotherapy have been documented to be consistently effective, and surgical management remains the primary treatment.

CARCINOMA OF THE FALLOPIAN TUBE

The fallopian tube is the least common site of cancer in the female genital tract, although its epithelial surface far exceeds that of the ovary, where epithelial cancer is 20 times more common. Approximately 300 new cases occur yearly; 90% are papillary serous adenocarcinomas, with the remainder being mixed mesodermal, endometroid, and transitional cell tumors. *BRCA1* and *-2* mutations are found in 7% of cases. The gross and microscopic characteristics and the spread of the tumor are similar to those of ovarian cancer but can be distinguished if the tumor arises from the endosalpinx where the tubal epithelium shows a transition between benign and malignant, and the ovaries and endometrium are normal or minimally involved. The differential diagnosis includes primary or metastatic ovarian cancer, chronic salpingitis, tuberculous salpingitis, salpingitis isthmica nodosa, and cautery artifact.

Unlike patients with ovarian cancer, patients often present with early symptoms, usually postmenopausal vaginal bleeding, pain, and leukorrhea. Surgical staging is similar to that used for ovarian cancer, and prognosis is related to stage and extent of residual disease. Patients with stages I and II disease are generally treated with surgery alone or with surgery and pelvic radiation therapy, although radiation therapy does not clearly improve 5-year survival (5-year survival stage I: 74 versus 75%, stage II: 43 versus 48%). Patients with stages III and IV disease are treated with the same chemotherapy regimens used in advanced ovarian carcinoma, and 5-year survival is similar (stage III—20%, stage IV—5%).

UTERINE CANCER

Carcinoma of the endometrium is the most common female pelvic malignancy. Approximately 40,300 new cases are diagnosed yearly, although in most (75%), tumor is confined to the uterine corpus at diagnosis and therefore most can be cured. The 7,000 deaths yearly make uterine cancer only the eighth leading cause of cancer death in females. It is primarily a disease of postmenopausal women, although 25% of cases occur in women <age 50 and 5% <age 40. The disease is common in Eastern Europe and the United States and uncommon in Asia.

Phenotypic characteristics and risk factors common in patients with endometrial cancer include obesity, altered menstruation, low fertility index, late menopause, anovulation, and postmenopausal bleeding. Exposure to unopposed estrogen from either endogenous or exogenous sources may play a central etiologic role. Women taking tamoxifen for breast cancer treatment or prevention have a twofold increased risk.

Endometrial carcinoma occurs most often in the sixth and seventh decades of life. Symptoms often include abnormal vaginal discharge (90%); abnormal bleeding (80%), which is usually postmenopausal; and leukorrhea (10%). Evaluation of such patients should include a history and physical and pelvic examinations followed by an endometrial biopsy or a fractional dilation and curettage. Outpatient procedures such as endometrial biopsy or aspiration curettage can be used but are definitive only when positive.

Between 75 and 80% of all endometrial carcinomas are adenocarcinomas, and the prognosis depends upon stage, histologic grade, and extent of myometrial invasion. Grade I tumors are highly differentiated adenocarcinomas, grade II contain some solid areas, and grade III tumors are largely solid or undifferentiated. Adenocarcinoma with squamous differentiation is seen in 10% of patients; the most differentiated form is known as *adenoacanthoma*, and the poorly differentiated form is called *adenosquamous carcinoma*. Other less common pathologies include mucinous carcinoma (5%) and papillary serous carcinoma (<10%). This latter type has a natural history similar to ovarian carcinoma and should be managed as an ovarian cancer. Rarer histologies include secretory (2%), ciliated, clear cell, and undifferentiated carcinomas.

The staging of endometrial cancer requires surgery to establish the extent of disease and the depth of myometrial invasion. Peritoneal fluid should be sampled; the abdomen and pelvis explored; and pelvic and para-aortic lymphadenectomy performed depending upon the histology, grade, and depth of invasion in the uterine specimen on frozen section. After evaluation and staging, 74% of patients are stage I, 13% are stage II, 9% are stage III, and 3% are stage IV. Five-year survival by stage is as follows: stage I—89%, stage II—80%, stage III—30%, and stage IV—9% (Table 83-1).

Patients with uncomplicated endometrial carcinoma are effectively managed with total abdominal hysterectomy and bilateral salpingo-oophorectomy. Pre- or postoperative irradiation has been used, and although vaginal cuff recurrence is reduced, survival is not altered. In women with poor histologic grade, deep myometrial invasion, or extensive involvement of the lower uterine segment or cervix, intracavitary or external beam irradiation is warranted.

About 15% of women have endometrial carcinoma with extension to the cervix only (stage II), and management depends upon the extent of cervical invasion. Superficial cervical invasion can be managed like stage I disease, but extensive cervical invasion requires radical hysterectomy or preoperative radiotherapy followed by extrafascial hysterectomy. Once disease is outside the uterus but still confined to the true pelvis (stage III), management generally includes surgery and irradiation. Patients who have involvement only of the ovary or fallopian tubes generally do well with such therapy (5-year survivals of 80%). Other stage III patients with disease extending beyond the adnexa or those with serous carcinomas of the endometrium have a significantly poorer prognosis (5-year survival of 15%).

Patients with stage IV disease (outside the abdomen or invading the bladder or rectum) are treated palliatively with irradiation, surgery, and/or progestational agents. Progestational agents produce responses in about 25% of patients. Well-differentiated tumors respond most frequently, and response can be correlated with the level of progesterone receptor expression in the tumor. The commonly used progestational agents hydroxyprogesterone (Dilalutin), megastrol (Megace), and deoxyprogesterone (Provera) all produce similar response rates, and the antiestrogen tamoxifen (Nolvadex) produces responses in 10 to 25% of patients in a salvage setting.

Chemotherapy is not very successful in advanced endometrial carcinoma. The most active single agents with consistent response rates of ≥20% include cisplatin, carboplatin, doxorubicin, epirubicin, and paclitaxel. Combinations of drugs with or without progestational agents have generally produced response rates similar to single agents.

CERVIX CANCER Carcinoma of the cervix was once the most common cause of cancer death in women, but over the past 30 years, the mortality rate has decreased by 50% due to widespread screening with the Pap smear. In 2004, ~10,500 new cases of invasive cervix cancer occurred, and >50,000 cases of carcinoma in situ were detected. There were 3,900 deaths from the disease, and of those patients, ~85% had never had a Pap smear. It remains the major gynecologic cancer in underdeveloped countries. It is more common in lower socioeconomic groups, in women with early initial sexual activity and/or multiple sexual partners, and in smokers. Venereal transmission of human papilloma virus (HPV) has an important etiologic role. Over 66 types of HPVs have been isolated, and many are associated with genital warts. Those types associated with cervical carcinoma are 16, 18, 31, 45, and 51 to 53. These, along with many other types, are also associated with cervical intraepithelial neoplasia (CIN). The protein product of HPV-16, the E7 protein, binds and inactivates the tumor-suppressor gene Rb, and the E6 protein of HPV-18 has sequence homology to the SV40 large T antigen and has the capacity to bind and inactivate the tumor-suppressor gene p53. E6 and E7 are both necessary and sufficient to cause cell transformation in vitro. These binding and inactivation events may explain the carcinogenic effects of the viruses (Chap. 169).

Vaccination against pathologic HPV appears quite promising as a cervix cancer prevention strategy. The administration of HPV-16 vaccine in a double-blind study of 2392 women completely prevented infection with the virus, and no cases of HPV-16-related CIN were seen in vaccinated women. Although this vaccine is promising, polyvalent vaccines incorporating the known pathologic HPV virus types may ultimately be required.

Uncomplicated HPV lower genital tract infection and condylomatous atypia of the cervix can progress to CIN. This lesion precedes invasive cervical carcinoma and is classified as low-grade squamous intraepithelial lesion (SIL), high-grade SIL, and carcinoma in situ. Carcinoma in situ demonstrates cytologic evidence of neoplasia without invasion through the basement membrane, can persist unchanged for 10 to 20 years, but eventually progresses to invasive carcinoma.

The Pap smear is 90 to 95% accurate in detecting early lesions such as CIN but is less sensitive in detecting cancer when frankly invasive cancer or fungating masses are present. Inflammation, necrosis, and hemorrhage may produce false-positive smears, and colposcopic-directed biopsy is required when any lesion is visible on the cervix, regardless of Pap smear findings. The American Cancer Society recommends that women after onset of sexual activity, or >age 20, have two consecutive yearly smears. If negative, smears should be repeated every 3 years. The American College of Obstetrics and Gynecology recommends yearly Pap smears with routine annual pelvic and breast examinations. The Pap smear can be reported as normal (includes benign, reactive, or reparative changes); atypical squamous cells of undetermined significance (ASCUS) or cannot exclude high-grade SIL (ASC-H); low- or high-grade CIN; or frankly malignant. Women with ASCUS, ASC-H, or low-grade CIN should have repeat smears in 3 to 6 months and be tested for HPV. Women with high-grade CIN or frankly malignant Pap smears should have colposcopic-directed cervical biopsy. Colposcopy is a technique using a binocular microscope and 3% acetic acid applied to the cervix in which abnormal areas appear white and can be biopsied directly. Cone biopsy is still required when endocervical tumor is suspected, colposcopy is inadequate, the biopsy shows microinvasive carcinoma, or when a discrepancy is noted between the Pap smear and the colposcopic findings. Cone biopsy alone is therapeutic for CIN in many patients, although a less radical electrocautery excision may be sufficient.

Approximately 80% of invasive cervix cancers are squamous cell tumors, 10 to 15% are adenocarcinomas, 2 to 5% are adenosquamous with epithelial and glandular structures, and 1 to 2% are clear cell mesonephric tumors.

Patients with cervix cancer generally present with abnormal bleeding or postcoital spotting that may increase to intermenstrual or prominent menstrual bleeding. Yellowish vaginal discharge, lumbosacral back pain, and urinary symptoms can also be seen.

The staging of cervical carcinoma is clinical and generally completed with a pelvic examination under anesthesia with cystoscopy and proctoscopy. Chest x-rays, intravenous pyelograms, and computed tomography are generally required, and magnetic resonance imaging (MRI) may be used to assess extracervical extension. Stage 0 is carcinoma in situ, stage I is disease confined to the cervix, stage II disease invades beyond the cervix but not to the pelvic wall or lower third of the vagina, stage III disease extends to the pelvic wall or lower third of the vagina or causes hydronephrosis, stage IV is present when the tumor invades the mucosa of bladder or rectum or extends beyond the true pelvis. Five-year survivals are as follows: stage I—85%, stage II—60%, stage III—33%, and stage IV—7% (Table 83-1).

Carcinoma in situ (stage 0) can be managed successfully by cone biopsy or by abdominal hysterectomy. For stage I disease, results appear equivalent for either radical hysterectomy or radiation therapy. Patients with stages II to IV disease are primarily managed with radical radiation therapy or combined modality therapy. Retroperitoneal lymphadenectomy has no proven therapeutic role. Pelvic exenterations, although uncommon, are performed for centrally recurrent or persistent disease. Reconstruction of the vagina, bladder, and rectum can often be done following this operation.

In women with locally advanced disease (stages IIB to IVA), platinum-based chemotherapy given concomitantly with radiation therapy improves survival compared to radiation therapy alone. Cisplatin, 75 mg/m^2 over 4 h, followed by 5-fluorouracil (5-FU), 4 g given by 96-h infusion on days 1 to 5 of radiation therapy, is a common regimen. Two additional cycles of chemotherapy are given at 3-week intervals. Concurrent chemoradiotherapy reduced the risk of recurrence by 30 to 50% across a wide spectrum of stages and presentations and is the treatment of choice in stages IIB to IV cervix cancer.

Chemotherapy has been used in patients with unresectable advanced disease or recurrent disease. Active agents with ≥20% response rates include cisplatin, 5-FU, ifosfamide, and irinotecan. No combination of agents has proved better than single agents. Intraarterial chemotherapy has been studied, either pre- or postoperatively, but is associated with substantial local toxicity and response rates of 20%.

GESTATIONAL TROPHOBLASTIC NEOPLASIA

Gestational trophoblastic diseases are a group of interrelated diseases that form a spectrum from benign hydatidiform mole to trophoblastic malignancy (placental-site trophoblastic tumor and choriocarcinoma). Malignant forms account for <1% of female gynecologic malignancies and can be cured with appropriate chemotherapy. Deaths from this disease have become rare in the United States.

Epidemiology The incidence is about 1 per 1500 pregnancies in the United States and is nearly tenfold higher in Asia. Maternal age >45 years is a risk factor for hydatidiform mole. A prior history of molar pregnancy is also a risk factor. Choriocarcinoma occurs in ~1 in 25,000 pregnancies or 1 in 20,000 live births. Prior history of hydatidiform mole is a risk factor for choriocarcinoma. A woman with a molar pregnancy is 1000 times more likely to develop choriocarcinoma than a woman with a prior normal-term pregnancy.

Pathology and Etiology The trophoblastic neoplasms have been divided by morphology into complete or partial hydatidiform mole, invasive mole, placental-site trophoblastomas, and choriocarcinomas. Hydatidiform moles contain clusters of villi with hydropic changes, hyperplasia of the trophoblast, and the absence of fetal vessels. Invasive moles differ only by invasion into the uterine myometrium. Placental-site trophoblastic tumors are predominately made up of cytotrophoblast cells arising from the placental implantation site. Choriocarcinomas consist of anaplastic trophoblastic tissue with both cytotrophoblastic and syncytiotrophoblastic elements and no identifiable villi.

Complete moles result from uniparental disomy in which loss of the maternal genes (23 autosomes plus X) occurs by unknown mechanisms and is followed by duplication of the paternal haploid genome (23 autosomes plus X). Uncommonly (5%), moles result from dispermic fertilization of an empty egg, resulting in either 46XY or 46XX genotype. Partial moles result from dispermic fertilization of an egg with retention of the maternal haploid set of chromosomes, resulting in diandric triploidy (Chap. 56).

Clinical Presentation Molar pregnancies are generally associated with first-trimester bleeding, ectopic pregnancies, or threatened abortions. The uterus is inappropriately large for the length of gestation, and β-hCG levels are higher than expected. Fetal parts and heart sounds are not present. The diagnosis is generally made by the passage of grapelike clusters from the uterus, but ultrasound demonstration of the hydropic mole can be diagnostic. Patients suspected of a molar pregnancy require a chest film, careful pelvic examinations, and weekly serial monitoring of β-hCG levels.

Rx TREATMENT

Patients with hydatidiform moles require suction curettage coupled with postevacuation monitoring of β-hCG levels. In most women (80%), the β-hCG titer progressively declines within 8 to 10 days of evacuation (serum half-life is 24 to 36 h). Patients should be monitored on a monthly basis and should not become pregnant for at least a year. Patients found to have invasive mole at curettage are generally treated with hysterectomy and chemotherapy. Approximately half of patients with choriocarcinoma develop the malignancy after a molar pregnancy, and the other half develop the malignancy after abortion, ectopic pregnancy, or occasionally after a normal full-term pregnancy.

Chemotherapy is generally used for gestational trophoblastic neoplasia and is often used in hydatidiform mole if β-hCG levels rise or plateau or if metastases develop. Patients with invasive mole or choriocarcinoma require chemotherapy. Several regimens are effective, including methotrexate at 30 mg/m^2 intramuscularly on a weekly basis until β-hCG titers are normal. However, methotrexate (1 mg/kg) every other day for 4 days followed by leukovorin (0.1 mg/kg) intravenously 24 h after methotrexate is associated with a cure rate of ≥90% and low toxicity. Intermittent courses are continued until the β-hCG titer becomes undetectable for 3 consecutive weeks, and then patients are monitored monthly for a year.

Patients with high-risk tumors (high β-hCG levels, disease presenting ≥4 months after antecedent pregnancy, brain or liver metastasis, or failure of single-agent methotrexate) are initially treated with combination chemotherapy. EMA-CO (a cyclic non-cross-resistant combination of etoposide, methotrexate, and dactinomycin alternating with cyclophosphamide and vincristine); cisplatin, bleomycin, and vinblastine; and cisplatin, etoposide, and bleomycin are effective regimens. EMA-CO is now the regimen of choice for patients with high-risk disease because of excellent survival rates (>80%) and less toxicity. The use of etoposide carries a 1.5% lifetime risk of acute myeloid leukemia (16-fold relative risk). Because of this problem, etoposide-containing regimens should be reserved for patients with high-risk features. Patients with brain or liver metastases are usually treated with local irradiation to metastatic sites in conjunction with chemotherapy. Long-term studies of patients cured of trophoblastic disease have not demonstrated an increased risk of maternal complications or fetal abnormalities with subsequent pregnancies.

84 SOFT TISSUE AND BONE SARCOMAS AND BONE METASTASES

Shreyaskumar R. Patel, Robert S. Benjamin

Sarcomas are rare (<1% of all malignancies) mesenchymal neoplasms that arise in bone and soft tissues. These tumors are usually of mesodermal origin, although a few are derived from neuroectoderm, and they are biologically distinct from the more common epithelial malignancies. Sarcomas affect all age groups; 15% are found in children <15 years and 40% occur after age 55. Sarcomas are one of the most common solid tumors of childhood and are the fifth most common cause of cancer deaths in children. Sarcomas may be divided into two groups, those derived from bone and those derived from soft tissues.

SOFT TISSUE SARCOMAS

Soft tissues include muscles, tendons, fat, fibrous tissue, synovial tissue, vessels, and nerves. Approximately 60% of soft tissue sarcomas arise in the extremities, with the lower extremities involved three times as often as the upper extremities. Thirty percent arise in the trunk, the

retroperitoneum accounting for 40% of all trunk lesions. The remaining 10% arise in the head and neck.

INCIDENCE Approximately 8680 new cases of soft tissue sarcomas occurred in the United States in 2004. The annual age-adjusted incidence is ~2 per 100,000 population, but the incidence varies with age. Soft tissue sarcomas constitute 0.7% of all cancers in the general population and 6.5% of all cancers in children.

EPIDEMIOLOGY Malignant transformation of a benign soft tissue tumor is extremely rare, with the exception that malignant peripheral nerve sheath tumors (neurofibrosarcoma, malignant schwannoma) can arise from neurofibromas in patients with neurofibromatosis. Several etiologic factors have been implicated in soft tissue sarcomas.

Environmental Factors Trauma or previous injury is rarely involved, but sarcomas can arise in scar tissue resulting from a prior operation, burn, fracture, or foreign body implantation. Chemical carcinogens such as polycyclic hydrocarbons, asbestos, and dioxin may be involved in the pathogenesis.

Iatrogenic Factors Sarcomas in bone or soft tissues occur in patients who are treated with radiation therapy. The tumor nearly always arises in the irradiated field. The risk increases with time.

Viruses Kaposi's sarcoma (KS) in patients with HIV type 1, classic KS, and KS in HIV-negative homosexual men is caused by human herpes virus (HHV) 8 (Chap. 166). No other sarcomas are associated with viruses.

Immunologic Factors Congenital or acquired immunodeficiency, including therapeutic immunosuppression, increases the risk of sarcoma.

Genetic Factors Li-Fraumeni syndrome is a familial cancer syndrome in which affected individuals have germ-line abnormalities of the tumor-suppressor gene p53 and an increased incidence of soft tissue sarcomas and other malignancies, including breast cancer, osteosarcoma, brain tumor, leukemia, and adrenal carcinoma (Chap. 68). Neurofibromatosis 1 (NF-1, peripheral form, von Recklinghausen's disease) is characterized by multiple neurofibromas and café au lait spots. Neurofibromas occasionally undergo malignant degeneration to become malignant peripheral nerve sheath tumors. The gene for NF-1 is located in the pericentromeric region of chromosome 17 and encodes neurofibromin, a tumor-suppressor protein with GTPase-activating activity that inhibits Ras function (Chap. 358). Germ-line mutation of the *Rb-1* locus (chromosome 13q14) in patients with inherited retinoblastoma is associated with the development of osteosarcoma in those who survive the retinoblastoma and of soft tissue sarcomas unrelated to radiation therapy. Other soft tissue tumors, including desmoid tumors, lipomas, leiomyomas, neuroblastomas, and paragangliomas, occasionally show a familial predisposition.

Ninety percent of synovial sarcomas contain a characteristic chromosomal translocation t(X;18) (p11;q11) involving a nuclear transcription factor on chromosome 18 called *SYT* and two breakpoints on X. Patients with translocations to the second X breakpoint (*SSX2*) may have longer survival than those with translocations involving *SSX1*.

Insulin-like growth factor (IGF) type 2 is produced by some sarcomas and may act as an autocrine growth factor and as a motility factor that promotes metastatic spread. IGF-2 stimulates growth through IGF-1 receptors but its effects on motility are through different receptors. If secreted in large amounts, IGF-2 may produce hypoglycemia (Chaps. 86 and 324).

CLASSIFICATION Approximately 20 different groups of sarcomas are recognized on the basis of the pattern of differentiation toward normal tissue. For example, rhabdomyosarcoma shows evidence of skeletal muscle fibers with cross-striations; leiomyosarcomas contain interlacing fascicles of spindle cells resembling smooth muscle; and liposarcomas contain adipocytes. When precise characterization of the group is not possible, the tumors are called *unclassified sarcomas*. All of the primary bone sarcomas can also arise from soft tissues (e.g., extraskeletal osteosarcoma). The entity *malignant fibrous histiocytoma* includes many tumors previously classified as fibrosarcomas or as pleomorphic variants of other sarcomas and is characterized by a mixture of spindle (fibrous) cells and round (histiocytic) cells arranged in a storiform pattern with frequent giant cells and areas of pleomorphism.

For purposes of treatment, most soft tissue sarcomas can be considered together. However, some specific tumors have distinct features. For example, *liposarcoma* can have a spectrum of behaviors. Pleomorphic liposarcomas and dedifferentiated liposarcomas behave like other high-grade sarcomas; in contrast, well-differentiated liposarcomas (better termed *atypical lipomatous tumors*) lack metastatic potential, and myxoid liposarcomas metastasize infrequently but, when they do, have a predilection for unusual metastatic sites containing fat, such as the retroperitoneum, mediastinum, and subcutaneous tissue. Rhabdomyosarcomas, Ewing's sarcoma, and other small-cell sarcomas tend to be more aggressive and are more responsive to chemotherapy than other soft tissue sarcomas.

Gastrointestinal stromal cell tumors (GISTs), previously classified as gastrointestinal leiomyosarcomas, are now recognized as a distinct entity within soft tissue sarcomas. Its cell of origin resembles the interstitial cell of Cajal, which controls peristalsis. The majority of malignant GISTs have activating mutations of the c-*kit* gene that result in ligand-independent phosphorylation and activation of the KIT receptor tyrosine kinase, leading to tumorigenesis.

DIAGNOSIS The most common presentation is an asymptomatic mass. Mechanical symptoms referable to pressure, traction, or entrapment of nerves or muscles may be present. All new and persistent or growing masses should be biopsied, either by a cutting needle (core-needle biopsy) or by a small incision, placed so that it can be encompassed in the subsequent excision without compromising a definitive resection. Lymph node metastases occur in 5%, except in synovial and epithelioid sarcomas, clear-cell sarcoma (melanoma of the soft parts), angiosarcoma, and rhabdomyosarcoma, where nodal spread may be seen in 17%. The pulmonary parenchyma is the most common site of metastases. Exceptions are GISTs, which metastasize to the liver; myxoid liposarcomas, which seek fatty tissue: and clear-cell sarcomas, which may metastasize to bones. Central nervous system metastases are rare, except in alveolar soft part sarcoma.

Radiographic Evaluation Imaging of the primary tumor is best with plain radiographs and magnetic resonance imaging (MRI) for tumors of the extremities or head and neck and by computed tomography (CT) for tumors of the chest, abdomen, or retroperitoneal cavity. A radiograph and CT scan of the chest are important for the detection of lung metastases. Other imaging studies may be indicated, depending on the symptoms, signs, or histology.

STAGING AND PROGNOSIS The histologic grade, relationship to fascial planes, and size of the primary tumor are the most important prognostic factors. The current American Joint Commission on Cancer (AJCC) staging system is shown in Table 84-1. Prognosis is related to the stage. Cure is common in the absence of metastatic disease, but a small number of patients with metastases can also be cured. Most patients with stage IV disease die within 12 months, but some patients may live with slowly progressive disease for many years.

Rx TREATMENT

AJCC stage I patients are adequately treated with surgery alone. Stage II patients are considered for adjuvant radiation therapy. Stage III patients may benefit from adjuvant chemotherapy. Stage IV patients are managed primarily with chemotherapy with or without other modalities.

Surgery Soft tissue sarcomas tend to grow along fascial planes, with the surrounding soft tissues compressed to form a pseudocapsule that gives the sarcoma the appearance of a well-encapsulated lesion. This is invariably deceptive, because "shelling out" or marginal excision of

TABLE 84-1 *AJCC Staging System for Sarcomas*

B: any G; any T; any N; M1	

such lesions results in a 50 to 90% probability of local recurrence. Wide excision with a negative margin, incorporating the biopsy site, is the standard surgical procedure for local disease. The adjuvant use of radiation therapy and/or chemotherapy improves the local control rate and permits the use of limb-sparing surgery with a local control rate (85 to 90%) comparable to that achieved by radical excisions and amputations. Limb-sparing approaches are indicated except when negative margins are not obtainable, when the risks of radiation are prohibitive, or when neurovascular structures are involved so that resection will result in serious functional consequences to the limb.

Radiation Therapy External beam radiation therapy is an adjuvant to limb-sparing surgery for improved local control. Preoperative radiation therapy allows the use of smaller fields and smaller doses but results in a higher rate of wound complications. Postoperative radiation therapy must be given to larger fields, as the entire surgical bed must be encompassed, and in higher doses to compensate for hypoxia in the operated field. Brachytherapy or interstitial therapy, in which the radiation source is inserted into the tumor bed, is comparable in efficacy (except in low-grade lesions), less time consuming, and less expensive.

Adjuvant Chemotherapy Chemotherapy is the mainstay of treatment for Ewing's primitive neuroectodermal tumors (PNET) and rhabdomyosarcomas. Meta-analysis of 14 randomized trials revealed a highly significant improvement in local control and disease-free survival in favor of doxorubicin-based chemotherapy. Overall survival is improved only for extremity sarcomas, however. A chemotherapy regimen including an anthracycline and ifosfamide with growth factor support improved overall survival for high-risk (high-grade, ≥5 cm primary, or locally recurrent) extremity soft tissue sarcomas.

Advanced Disease Metastatic soft tissue sarcomas are largely incurable, but up to 20% of patients who achieve a complete response become long-term survivors. The therapeutic intent, therefore, is to produce a complete remission with chemotherapy and/or surgery. Surgical resection of metastases, whenever possible, is an integral part of the management. Some patients benefit from repeated surgical excision of metastases. The two most active chemotherapeutic agents are doxorubicin and ifosfamide. These drugs show a steep dose-response relationship in sarcomas. Gemcitabine and dacarbazine also have some activity. Taxanes have selective activity in angiosarcomas, and vincristine, etoposide, and irinotecan are effective in rhabdomyosarcomas and Ewing's sarcomas. Imatinib mesylate targets the KIT tyrosine kinase activity and is standard therapy for advanced/metastatic GISTs.

BONE SARCOMAS

INCIDENCE AND EPIDEMIOLOGY Bone sarcomas are rarer than soft tissue sarcomas; they accounted for only 0.2% of all new malignancies and ~2400 new cases in the United States in 2004. Several benign bone lesions have the potential for malignant transformation. Enchondromas and osteochondromas can transform into chondrosarcoma; fibrous dysplasia, bone infarcts, and Paget's disease of bone can transform into either malignant fibrous histiocytoma or osteosarcoma.

CLASSIFICATION ■ Benign Tumors The common benign bone tumors include enchondroma, osteochondroma, chondroblastoma, and chondromyxoid fibroma, of cartilage origin; osteoid osteoma and osteoblastoma, of bone origin; fibroma and desmoplastic fibroma, of fibrous tissue origin; hemangioma, of vascular origin; and giant cell tumor, of unknown origin.

Malignant Tumors The most common malignant tumors of bone are plasma cell tumors (Chap. 98). The four most common malignant nonhematopoietic bone tumors are osteosarcoma, chondrosarcoma, Ewing's sarcoma, and malignant fibrous histiocytoma. Rare malignant tumors include chordoma (of notochordal origin), malignant giant cell tumor and adamantinoma (of unknown origin), and hemangioendothelioma (of vascular origin).

Musculoskeletal Tumor Society Staging System Sarcomas of bone are staged according to the Musculoskeletal Tumor Society staging system based on grade and compartmental localization. A Roman numeral reflects the tumor grade: stage I is low-grade, stage II is high-grade, and stage III includes tumors of any grade that have lymph node or distant metastases. In addition, the tumor is given a letter reflecting its compartmental localization. Tumors designated A are intracompartmental (i.e., confined to the same soft tissue compartment as the initial tumor), and tumors designated B are extracompartmental (i.e., extending into the adjacent soft tissue compartment or into bone). The tumor node metastasis (TNM) staging system is shown in Table 84-2.

TABLE 84-2 *Staging System for Bone Sarcomas*

Primary tumor (T)	TX	Primary tumor cannot be assessed
	T0	No evidence of primary tumor
	T1	Tumor ≤8 cm in greatest dimension
	T2	Tumor >8 cm in greatest dimension
	T3	Discontinuous tumors in the primary bone site
Regional lymph nodes (N)	NX	Regional lymph nodes cannot be assessed
	N0	No regional lymph node metastasis
	N1	Regional lymph node metastasis
Distant metastasis (M)	MX	Distant metastasis cannot be assessed
	M0	No distant metastasis
	M1	Distant metastasis
	M1a	Lung
	M1b	Other distant sites
Histologic grade (G)	GX	Grade cannot be assessed
	G1	Well differentiated—low grade
	G2	Moderately differentiated—low grade
	G3	Poorly differentiated—high grade
	G4	Undifferentiated—high grade (Ewing's is always classed G4)

STAGE GROUPING

Stage IA	T1	N0	M0	G1,2 low grade
Stage IB	T2	N0	M0	G1,2 low grade
Stage IIA	T1	N0	M0	G3,4 high grade
Stage IIB	T2	N0	M0	G3,4 high grade
Stage III	T3	N0	M0	Any G
Stage IVA	Any T	N0	M1a	Any G
Stage IVB	Any T	N1	Any M	Any G
	Any T	Any N	M1b	Any G

OSTEOSARCOMA Osteosarcoma, accounting for almost 45% of all bone sarcomas, is a spindle cell neoplasm that produces osteoid (unmineralized bone) or bone. About 60% of all osteosarcomas occur in children and adolescents in the second decade of life, and about 10% occur in the third decade of life. Osteosarcomas in the fifth and sixth decades of life are frequently secondary to either radiation therapy or transformation in a preexisting benign condition, such as Paget's disease. Males are affected 1.5 to 2 times as often as females. Osteosarcoma has a predilection for metaphyses of long bones; the most common sites of involvement are the distal femur, proximal tibia, and proximal humerus. The classification of osteosarcoma is complex, but 75% of osteosarcomas fall in the "classic" category, which include osteoblastic, chondroblastic, and fibroblastic osteosarcomas. The remaining 25% are classified as "variants" on the basis of (1) clinical characteristics, as in the case of osteosarcoma of the jaw, postradiation osteosarcoma, or Paget's osteosarcoma; (2) morphologic characteristics, as in the case of telangiectatic osteosarcoma, small-cell osteosarcoma, or epithelioid osteosarcoma; or (3) location, as in parosteal or periosteal osteosarcoma. Diagnosis usually requires a synthesis of clinical, radiologic, and pathologic features. Patients typically present with pain and swelling of the affected area. A plain radiograph reveals a destructive lesion with a moth-eaten appearance, a spiculated periosteal reaction (sunburst appearance), and a cuff of periosteal new bone formation at the margin of the soft tissue mass (Codman's triangle). A CT scan of the primary tumor is best for defining bone destruction and the pattern of calcification, whereas MRI is better for defining intramedullary and soft tissue extension. A chest radiograph and CT scan are used to detect lung metastases. Metastases to the bony skeleton should be imaged by a bone scan. Almost all osteosarcomas are hypervascular. Angiography is not helpful for diagnosis, but it is the most sensitive test for assessing the response to preoperative chemotherapy. Pathologic diagnosis is established either with a core-needle biopsy, where feasible, or with an open biopsy with an appropriately placed incision that does not compromise future limb-sparing resection. Most osteosarcomas are high-grade. The most important prognostic factor for long-term survival is response to chemotherapy. Preoperative chemotherapy followed by limb-sparing surgery (which can be accomplished in >80% of patients) followed by postoperative chemotherapy is standard management. The effective drugs are doxorubicin, ifosfamide, cisplatin, and high-dose methotrexate with leucovorin rescue. The various combinations of these agents that have been used have all been about equally successful. Long-term survival rates in extremity osteosarcoma range from 60 to 80%. Osteosarcoma is radioresistant; radiation therapy has no role in the routine management. Malignant fibrous histiocytoma is considered a part of the spectrum of osteosarcoma and is managed similarly.

CHONDROSARCOMA Chondrosarcoma, which constitutes ~20 to 25% of all bone sarcomas, is a tumor of adulthood and old age with a peak incidence in the fourth to sixth decades of life. It has a predilection for the flat bones, especially the shoulder and pelvic girdles, but can also affect the diaphyseal portions of long bones. Chondrosarcomas can arise de novo or as a malignant transformation of an enchondroma or, rarely, of the cartilaginous cap of an osteochondroma. Chondrosarcomas have an indolent natural history and typically present as pain and swelling. Radiographically, the lesion may have a lobular appearance with mottled or punctate or annular calcification of the cartilaginous matrix. It is difficult to distinguish low-grade chondrosarcoma from benign lesions by x-ray or histologic examination. The diagnosis is therefore influenced by clinical history and physical examination. A new onset of pain, signs of inflammation, and progressive increase in the size of the mass suggest malignancy. The histologic classification is complex, but most tumors fall within the classic category. Like other bone sarcomas, high-grade chondrosarcomas spread to the lungs. Most chondrosarcomas are resistant to chemotherapy, and surgical resection of primary or recurrent tumors, including pulmonary metastases, is the mainstay of therapy. There are two histologic variants for which this rule does not hold, however. Dedifferentiated chondrosarcoma has a high-grade osteosarcoma or a malignant fibrous histiocytoma component that responds to chemotherapy. Mesenchymal chondrosarcoma, a rare variant composed of a small cell element, also is responsive to systemic chemotherapy and is treated like Ewing's sarcoma.

EWING'S SARCOMA Ewing's sarcoma, which constitutes ~10 to 15% of all bone sarcomas, is common in adolescence and has a peak incidence in the second decade of life. It typically involves the diaphyseal region of long bones and also has an affinity for flat bones. The plain radiograph may show a characteristic "onion peel" periosteal reaction with a generous soft tissue mass, which is better demonstrated by CT or MRI. This mass is composed of sheets of monotonous, small, round, blue cells and can be confused with lymphoma, embryonal rhabdomyosarcoma, and small-cell carcinoma. The presence of p30/32, the product of the *mic-2* gene (which maps to the pseudoautosomal region of the X and Y chromosomes) is a cell-surface marker for Ewing's sarcoma (and other members of a family of tumors called PNETs). Most PNETs arise in soft tissues; they include peripheral neuroepithelioma, Askin's tumor (chest wall), and esthesioneuroblastoma. Glycogen-filled cytoplasm detected by staining with periodic acid–Schiff is also characteristic of Ewing's sarcoma cells. The classic cytogenetic abnormality associated with this disease (and other PNETs) is a reciprocal translocation of the long arms of chromosomes 11 and 22, t(11; 22), which creates a chimeric gene product of unknown function with components from the *fli-1* gene on chromosome 11 and *ews* on 22. This disease is very aggressive, and it is therefore considered a systemic disease. Common sites of metastases are lung, bones, and bone marrow. Systemic chemotherapy is the mainstay of therapy, often being used before surgery. Doxorubicin, cyclophosphamide or ifosfamide, etoposide, vincristine, and dactinomycin are active drugs. Local treatment for the primary tumor includes surgical resection, usually with limb salvage or radiation therapy. Patients with lesions below the elbow and below the mid-calf have a 5-year survival rate of 80% with effective treatment. Ewing's sarcoma is a curable tumor, even in the presence of obvious metastatic disease, especially in children <11 years old.

TUMORS METASTATIC TO BONE

Bone is a common site of metastasis for carcinomas of the prostate, breast, lung, kidney, bladder, and thyroid and for lymphomas and sarcomas. Prostate, breast, and lung primaries account for 80% of all bone metastases. Metastatic tumors of bone are more common than primary bone tumors. Tumors usually spread to bone hematogenously, but local invasion from soft tissue masses also occurs. In descending order of frequency, the sites most often involved are the vertebrae, proximal femur, pelvis, ribs, sternum, proximal humerus, and skull. Bone metastases may be asymptomatic or may produce pain, swelling, nerve root or spinal cord compression, pathologic fracture, or myelophthisis (replacement of the marrow). Symptoms of hypercalcemia may be noted in cases of bony destruction.

Pain is the most frequent symptom. It usually develops gradually over weeks, is usually localized, and often is more severe at night. When patients with back pain develop neurologic signs or symptoms, emergency evaluation for spinal cord compression is indicated (Chap. 88). Bone metastases exert a major adverse effect on quality of life in cancer patients.

Cancer in the bone may produce osteolysis, osteogenesis, or both. Osteolytic lesions result when the tumor produces substances that can directly elicit bone resorption (vitamin D–like steroids, prostaglandins, or parathyroid hormone–related peptide) or cytokines that can induce the formation of osteoclasts (interleukin 1 and tumor necrosis factor). Osteoblastic lesions result when the tumor produces cytokines that activate osteoblasts. In general, purely osteolytic lesions are best detected by plain radiography, but they may not be apparent until they are >1 cm. These lesions are more commonly associated with hyper-

calcemia and with the excretion of hydroxyproline-containing peptides indicative of matrix destruction. When osteoblastic activity is prominent, the lesions may be readily detected using radionuclide bone scanning (which is sensitive to new bone formation), and the radiographic appearance may show increased bone density or sclerosis. Osteoblastic lesions are associated with higher serum levels of alkaline phosphatase, and, if extensive, may produce hypocalcemia. Although some tumors may produce mainly osteolytic lesions (e.g., kidney cancer) and others mainly osteoblastic lesions (e.g., prostate cancer), most metastatic lesions produce both types of lesion and may go through stages where one or the other predominates.

In older patients, particularly women, it may be necessary to distinguish metastatic disease of the spine from osteoporosis. In osteoporosis, the cortical bone may be preserved, whereas cortical bone destruction is usually noted with metastatic cancer.

TREATMENT

Treatment of metastatic bone disease depends on the underlying malignancy and the symptoms. Some metastatic bone tumors are curable (lymphoma, Hodgkin's disease), and others are treated with palliative intent. Pain may be relieved by local radiation therapy. Hormonally responsive tumors are responsive to hormone inhibition (antiandrogens for prostate cancer, antiestrogens for breast cancer). Strontium 89 and samarium 153 are bone-seeking radionuclides that can exert antitumor effects and relieve symptoms. Bisphosphonates such as pamidronate may relieve pain and inhibit bone resorption. Monthly administration prevents bone-related clinical events and may reduce the incidence of bone metastases in women with breast cancer. When the integrity of a weight-bearing bone is threatened by an expanding metastatic lesion that is refractory to radiation therapy, prophylactic internal fixation is indicated. Overall survival is related to the prognosis of the underlying tumor. Bone pain at the end of life is particularly common; an adequate pain relief regimen including sufficient amounts of narcotic analgesics is required. →***The management of hypercalcemia is discussed in Chap. 332.***

85 METASTATIC CANCER OF UNKNOWN PRIMARY SITE

Richard M. Stone

INCIDENCE AND EPIDEMIOLOGY

The presenting findings in a patient with a newly discovered malignancy may not reveal its site of origin. Patients with cancer of unknown primary site (CUPS) present difficult diagnostic and therapeutic dilemmas. First, as additional studies may be many, costly, and/or uncomfortable for the patient, the strategy used in searching for the primary must assess what, if any, result the identification of the site of origin would have on the patient's treatment and survival. Second, while individuals with CUPS fare poorly overall (median survival is 4 to 11 months), certain subgroups of patients are more likely to benefit from treatment and, in some cases, to enjoy long disease-free survival. Population-based analysis shows that two-thirds receive only supportive treatment and that only 15% are alive 1 year after diagnosis, suggesting the selection bias inherent in the more typically reported studies from tertiary care centers.

No universally accepted definition of the CUPS syndrome exists. An occult neoplasm should fulfill all of the following criteria: (1) biopsy-proven malignancy; (2) unrevealing history, physical examination, chest film, abdominal and pelvic computed tomography (CT) scans, complete blood counts, chemistry survey, mammography (women), β human chorionic gonadotropin (βhCG) levels (men), α fetoprotein (AFP) levels (men), and prostate-specific antigen (PSA) levels (men); (3) histologic evaluation not consistent with a primary tumor at the biopsy site; and (4) failure of additional diagnostic studies (based only on findings from the laboratory and pathologic review) to identify the primary site. Such additional diagnostic tests could include, for example, colonoscopy in a patient whose rectal examination discloses guaiac-positive stool or a meticulous otolaryngologic examination in a patient who presents with squamous cell carcinoma in a cervical node. Many cases that fulfill the definition of CUPS offer clues that a given organ is the probable site of origin. Epidemiologic data suggest that the incidence of cancers for which the primary site is unknown is decreasing. CUPS accounts for about 2% of all cancer diagnoses—about 24,400 cases in the year 2000. Most patients with CUPS are over age 60.

BIOLOGIC CONSIDERATIONS The biologic behavior of CUPS is unique. In ~25% of patients, the primary site becomes apparent during the course of the illness; in about 57% of patients, the primary site can be diagnosed at autopsy; but in almost 20%, the primary site remains obscure even at autopsy. Cancers presenting as CUPS often display unusual patterns of metastatic spread (e.g., pancreatic cancer presenting with bony metastases). The fact that more tumor bulk is present at distant sites than in the tissue of origin suggests that the genetic lesions underlying cases of CUPS produce a distinctly aggressive phenotype. Microsatellite DNA analysis has shown that the same pattern of genetic alterations that appears in a cervical lymph node metastasis can be found in seemingly morphologically normal aerodigestive tissue. Such data imply that clinically evident metastases may be able to arise from microscopic primary lesions. Tumors in 11% of CUPS patients, almost all with poorly differentiated adenocarcinoma, express the HER2/neu protein. Although physiologic and genetic data that might account for the distinctive natural history of CUPS neoplasms are scant, cell lines derived from such tumors may have abnormalities of chromosome 1, a finding generally associated with advanced malignancy. In some patients, the primary tumor spontaneously regresses (perhaps under immunologic attack) or necroses. In some, a primary lesion was resected years before presentation (e.g., melanoma).

CLINICAL PRESENTATION, DIAGNOSTIC EVALUATION, AND PATHOLOGY ■ History and Physical Examination Patients present with a variety of symptoms and signs, including fatigue, weight loss, other systemic symptoms, pain, abnormal bleeding, abdominal swelling, subcutaneous masses, and lymphadenopathy. Once CUPS is considered, the physician's approach must involve reasonable efforts to identify the primary site or to determine the histology or subcategory of the metastatic tumor to decide on the optimal therapy. Though usually unrevealing, a thorough history and physical examination should be carried out to elicit easily obtainable clues regarding the primary site. The patient should be questioned concerning epigastric pain, which, if present, would mandate careful exclusion of pancreatic carcinoma as well as other gastrointestinal malignancies. Symptoms referable to a given location (e.g.,

new cough, hematochezia, hemoptysis, change in bowel habits, unusual vaginal bleeding, nipple discharge) should prompt an aggressive specific diagnostic approach. Occupational exposure to asbestos, for example, would raise the suspicion of mesothelioma. The absence of prior smoking reduces the likelihood of lung cancer but does not exclude it. A history of fulguration of a skin lesion, colonic polypectomy, dilatation and curettage, or prostate biopsy should prompt a review of the original histology.

Pathology Review The most important aspect of the workup of a patient with CUPS is the thorough evaluation of the tissue obtained at biopsy by light microscopy, immunohistochemistry, ultrastructural studies, immunophenotyping, and karyotypic and molecular biologic analysis. First, if the original biopsy sample is inadequate for either confirmation of malignancy or the performance of additional specialized studies, rebiopsy is mandatory. The clinician must have a close working relationship with a pathologist skilled in the evaluation of tumor specimens, especially when the organ of origin is uncertain. Plans may be made to process the tissue for (1) routine light-microscopic, histochemical, and immunohistochemical analysis; (2) freezing for DNA and RNA isolation or for in situ genetic and immunologic evaluation; and (3) special fixation for ultrastructural analysis. Single-cell tumor suspensions in short-term culture permit cytogenetic analysis.

If routine histologic analysis fails to suggest the tissue of origin (e.g., gland formation in adenocarcinoma, psammoma bodies in ovarian or thyroid cancer, or spindle architecture in sarcomas), special histochemical studies may be helpful. For example, mucin positivity is helpful in recognizing a poorly differentiated adenocarcinoma. Light-microscopic analysis will show ~60% of CUPS tumors to be well or moderately differentiated adenocarcinomas, 30% poorly differentiated carcinomas/adenocarcinomas, and 5% poorly differentiated malignant neoplasms not further classifiable. In the poorly differentiated neoplasms, immunohistochemical, cytogenetic, and molecular biologic studies can be extremely useful in identifying sarcomas, germ cell carcinomas, lymphomas, neuroendocrine neoplasms (including melanoma), and other tumors whose diagnosis would suggest a more specific therapeutic approach.

Immunohistochemical Analysis Antibodies to specific cell components make it possible to characterize tumors that are not identified by standard techniques. Table 85-1 provides a list of antigens that may be assessed in undifferentiated or poorly differentiated specimens. A diagnosis of lymphoma should be excluded by employing antibodies reactive to the leukocyte common antigen (LCA, CD45). LCA-positive tumors are lymphomas and have the same chances of responding to therapy as if the diagnosis were unambiguous. About half of patients with aggressive-histology lymphoma can be cured with combination chemotherapy (Chap. 97). The immunohistochemical detection of specific types of filament proteins is helpful in the identification of carcinomas and sarcomas. The presence of keratin suggests carcinoma; all epithelial tumors contain this protein. Specific types of cytokeratins (CKs) may aid in diagnosis. For example, ovarian and lung cancers are CK20−/CK7+, colorectal cancers are CK20+/CK7−, and pancreaticobiliary tumors and transitional cell cancers are CK20+/CK7+. However, certain sarcomas, mesotheliomas, and germ cell tumors are also keratin-positive. Sarcomas may react with antibodies to desmin. Coexpression of p53 and CK5/6 is suggestive of a squamous cell primary. Sarcoma subgroups may be identified by expression of myoglobin (rhabdomyosarcoma) or factor VIII (angiosarcoma or Kaposi's sarcoma). Prostate, breast, and thyroid carcinomas express, respectively, PSA, gross cystic fluid protein, or thyroglobulin. The finding of AFP, βhCG, or placental alkaline phosphatase staining is very helpful in assigning a germ cell origin. The S-100 protein is present in virtually all primary and metastatic melanomas, including the amelanotic variety. However, S-100 positivity is also found in other tumors of neuroendocrine origin (e.g., small cell lung cancer, carcinoid, neuroepithelioma); a more specific marker for melanomas is the HMB45 (human melanoma black) antigen.

TABLE 85-1 *Possible Pathologic Evaluation of Biopsy Specimens from Patients with Metastatic Cancer of Unknown Primary Site*

Evaluation/Findings	Suggested Primary Site or Neoplasm
HISTOLOGY (HEMATOXYLIN AND EOSIN STAINING)	
Psammoma bodies, papillary configuration	Ovary, thyroid
Signet ring cells	Stomach
IMMUNOHISTOLOGY	
Leukocyte common antigen (LCA, CD45)	Lymphoid neoplasm
Leu-M1	Hodgkin's disease
Epithelial membrane antigen	Carcinoma
Cytokeratin	Carcinoma[a]
CEA	Carcinoma
HMB45	Melanoma
Desmin	Sarcoma
Thyroglobulin	Thyroid carcinoma
Calcitonin	Medullary carcinoma of the thyroid
Myoglobin	Rhabdomyosarcoma
PSA/prostatic acid phosphatase	Prostate
AFP	Liver, stomach, germ cell
Placental alkaline phosphatase	Germ cell
B, T cell markers	Lymphoid neoplasm
S-100 protein	Neuroendocrine tumor, melanoma
Gross cystic fluid protein	Breast, sweat gland
Factor VIII	Kaposi's sarcoma, angiosarcoma
Thyroid transcription factor-1 (TTF-1)	Lung adenocarcinoma, thyroid
FLOW CYTOMETRY	
B, T cell markers	Lymphoid neoplasm
ULTRASTRUCTURE	
Actin-myosin filaments	Rhabdomyosarcoma
Secretory granules	Neuroendocrine tumors
Desmosomes	Carcinoma
Premelanosomes	Melanoma
CYTOGENETICS	
Isochromosome 12p; 12q(−)	Germ cell
t(11;22)	Ewing's sarcoma, primitive neuroectodermal tumor
t(8;14)[b]	Lymphoid neoplasm
3p(−)	Small cell lung carcinoma; renal cell carcinoma, mesothelioma
t(X;18)	Synovial sarcoma
t(12;16)	Myxoid liposarcoma
t(12;22)	Clear cell sarcoma (melanoma of soft parts)
t(2;13)	Alveolar rhabdomyosarcoma
1p(−)	Neuroblastoma
RECEPTOR ANALYSIS	
Estrogen/progesterone receptor	Breast
MOLECULAR BIOLOGIC STUDIES	
Immunoglobulin, *bcl*-2, T-cell receptor gene rearrangement	Lymphoid neoplasm

[a] See text for discussion of cytokeratins.
[b] Or any other rearrangement involving an antigen-receptor gene.
Note: CEA, carcinoembryonic antigen; PSA, prostate-specific antigen; AFP, α fetoprotein.

Other Diagnostic Approaches Electron microscopy can identify cell junctions (i.e., desmosomes, typical of epithelial cancers), neuroendocrine granules, melanosomes, and muscle filaments. Cytogenetic analysis may identify tumors with specific chromosomal translocations or other genetic abnormalities (Table 85-1). Cytogenetic abnormalities can also be determined by fluorescence in situ hybridization with chromosome-specific probes, a technique that does not require cells to divide, as is the case with traditional karyotype analysis. Fresh tissue may be re-

quired for detection of estrogen or progesterone receptors (to assess breast cancer) or antigens that are sensitive to fixation. Lineage can be assigned by analysis of DNA for signature gene rearrangements, such as those of immunoglobulin (B cell) or T cell receptor (T cell). Technological advances promise to influence the diagnosis of cancer. Isolation of mRNA from tumor specimens may permit the molecular profiling of tumors by microarray analysis of gene expression. This could lead to novel classifications of tumors based on molecular characteristics that may predict clinical behavior and/or response to specific therapies.

Additional Studies If the pathologist does not identify the likely tissue of origin, it is unlikely that additional expensive diagnostic tests will benefit the patient. In females with metastatic adenocarcinoma or poorly differentiated carcinoma, mammography should be performed, although the diagnostic yield will be quite low except in patients with axillary metastases. Magnetic resonance imaging, positron-emission tomography (PET), or indium 111-pentreotide scanning can identify occult primary lesions but are expensive. The use of abdominal/pelvic CT scans leads to the identification of the primary site (often the pancreas) in up to 35% of patients but has little effect on natural history. While more sensitive than CT in detection of a primary site, the now frequently employed PET scan does not clearly lead to better outcomes. Whether to measure serum tumor markers such as AFP, βhCG, carcinoembryonic antigen (CEA), CA-125 (associated with ovarian cancer), and PSA is controversial; value has not been proved. Numerous studies have shown a lack of benefit of contrast studies (upper gastrointestinal series, barium enema, or intravenous pyelogram) in patients with CUPS who have no specific symptoms and no findings referable to the gastrointestinal or urinary tract. Moreover, autopsy series reveal that the most likely primary site of origin includes epithelial tissues such as lung, stomach, colon, and kidney, which give rise to tumors that respond poorly to chemotherapy, minimizing the therapeutic impact of such a diagnosis.

Additional invasive diagnostic studies are indicated if the presentation strongly suggests a particular primary site. For example, radiographic evidence of lung or mediastinal involvement would mandate fiberoptic bronchoscopy to exclude lung cancer. In the relatively unusual case of metastatic squamous cell cancer presenting in an inguinal lymph node, anoscopy and colposcopy should be performed to detect carcinoma of the vulva, cervix, vagina, penis, or anus, all of which may be cured even with lymph node spread. A reasonable diagnostic approach is provided in Table 85-2.

TREATMENT

Prognostic Subgroups The exclusion of treatable and potentially curable neoplasms is important. Patients with squamous cell carcinoma have a somewhat longer median survival (9 months) than do those with adenocarcinoma or unclassifiable neoplasms (4 to 6 months). If laboratory studies indicate a significant likelihood that the neoplasm is a lymphoma, germ cell tumor, sarcoma, neuroendocrine tumor, or breast or prostate cancer, then disease-appropriate therapy should be administered. Patients with lymphoma or a germ cell neoplasm may be cured with combination chemotherapy. In other malignancies, effective palliative chemotherapy (for sarcoma or a breast or neuroendocrine tumor) or hormonal therapy (for breast or prostate cancer) should be strongly considered. Although often requiring electron microscopy for diagnosis, neuroendocrine tumors (especially if anaplastic) often respond to cisplatin-based chemotherapy.

Patients in whom the primary site can be identified fare somewhat better than those in whom it remains undefined. A validated prognostic model based on a multivariate analysis of clinical parameters suggested those with a good performance status without liver metastases had a median survival of 10.8 months compared with 2.4 months for patients who were more symptomatic and who had spread to the liver. Elevated serum lactate dehydrogenase alone predicted a median survival of 3.9 months (Table 85-3). Forty percent of CUPS patients may be found to have one of several clinical syndromes for which a specific therapeutic approach may be useful:

TABLE 85-2 Suggested Clinical Evaluation of Patients with Metastatic Cancer of Unknown Primary Site

History: smoking history, asbestos exposure, abdominal pain
Physical examination: lymph nodes, thyroid, skin;
Men: prostate
Women: breasts, pelvic examination
Laboratory evaluation: stool evaluation for occult blood; urinalysis; complete blood count; liver function tests; calcium, electrolytes, creatine; measurement of serum levels of βhCG, AFP, CEA, and CA-125 (women); chest x-ray; abdominal and pelvic CT; mammography
Pathologic evaluation: see Table 85-1

Note: PSA, prostate-specific antigen; βhCG, β-human chorionic gonadotropin; AFP, α fetoprotein; CEA, carcinoembryonic antigen; CT, computed tomography.

SYNDROME OF UNRECOGNIZED EXTRAGONADAL GERM CELL CANCER Some patients with poorly differentiated CUPS are responsive to chemotherapy. These patients display one or more of the following features: age <50; tumor involving midline structures, lung parenchyma, or lymph nodes; an elevated serum AFP or βhCG level; evidence of rapid tumor growth; or tumor responsiveness to previously administered radiotherapy or chemotherapy. Platinum-based chemotherapy has led to long-term survival in a fraction of patients with these features, especially those who have a favorable performance status at diagnosis, suggesting that their tumors behaved like germ cell neoplasms. If all patients with poorly differentiated carcinoma (including poorly differentiated adenocarcinoma) are treated with a chemotherapy regimen designed for germ cell cancer (e.g., cisplatin plus etoposide or vinblastine, often also with bleomycin) (Chap. 82), about 25% will respond completely and 33% will have a partial response. Patients whose disease does not respond to two cycles of therapy should not continue

TABLE 85-3 Presentations That Dictate Specific Therapies in Patients with CUPS

Clinicopathologic Features	Suspected Primary Site	Suggested Therapy
Squamous cell carcinoma, cervical node	Head and neck cancer	Radical neck dissection; radiotherapy ± chemotherapy
Carcinoma, axillary nodes (female)	Breast cancer	Breast radiotherapy or mastectomy, systemic adjuvant therapy
Peritoneal carcinomatosis (female)	Ovarian cancer	Debulking surgery, cisplatin-based chemotherapy
Pleural effusion, adenocarcinoma cells estrogen and/or progesterone receptor positive	Breast cancer	Systemic therapy for metastatic breast cancer
Poorly differentiated cancer, age <50, lung or retroperitoneal or mediastinal mass or lymph nodes, elevated serum βhCG or AFP levels	Germ cell tumor (extragonadal)	Cisplatin/VP-16-based chemotherapy
Bony metastases (male)	Prostate cancer	Androgen blockade (leuprolide plus flutamide)
Adenocarcinoma, liver metastases, elevated CEA level	Gastrointestinal malignancy	Surgical resection of liver lesion feasible; colonoscopy with resection (if appropriate) of tumors; 5-fluorouracil/leucovorin

Note: βhCG, β-human chorionic gonadotropin; AFP, α fetoprotein; CEA, carcinoembryonic antigen.

therapy. One in six patients survives >5 years without evidence of disease. Patients with poorly differentiated carcinoma or adenocarcinoma whose tumors have abnormalities of chromosome 12 similar to those described in patients with proven germ cell cancer are more likely to respond to platinum-based chemotherapy than are patients with a similar presentation whose tumors lack this cytogenetic abnormality.

PERITONEAL CARCINOMATOSIS IN WOMEN Women who present with increased abdominal girth and a pelvic mass or pain and who are found to have adenocarcinoma throughout the peritoneal cavity without a clear site of origin may also benefit from platinum-based chemotherapy. This syndrome has been termed *primary peritoneal papillary serous carcinoma* or *multifocal extraovarian serous carcinoma*. While breast cancer or a gastrointestinal malignancy can produce these findings, peritoneal carcinomatosis is most commonly ascribed to ovarian cancer, even in patients with apparently normal ovaries at the time of laparotomy. Especially if psammoma bodies or a papillary configuration is noted in the pathology examination or if the CA-125 level is elevated, women with adenocarcinoma of the peritoneal cavity without a defined primary should receive maximum surgical cytoreduction followed by cisplatin (or carboplatin) plus paclitaxel. The stage-specific response to such therapy appears to be comparable to that for patients with proven ovarian cancer. About 10% of patients who present in this fashion may remain free of disease 2 years after diagnosis.

CARCINOMA IN AN AXILLARY LYMPH NODE IN A FEMALE Women with adenocarcinoma or poorly differentiated carcinoma in an axillary mass should receive treatment for stage II breast cancer whether or not a careful breast examination or mammography suggests the diagnosis of primary breast cancer and whether or not estrogen or progesterone receptors are detectable in the node. Even if no lesion is found in the breast, a breast recurrence will develop in one-half of these patients if no mastectomy is performed. Modified radical mastectomy or breast irradiation may be equivalent in reducing the risk of local recurrence. In addition, adjuvant systemic therapy (chemotherapy and/or tamoxifen, depending on menopausal and estrogen receptor status) should be given to reduce the risk of developing evident metastatic breast cancer (Chap. 76). Adjuvant systemic therapy may be administered before definitive local radiation treatment. Women with axillary metastases without an obvious breast primary appear to have the same likelihood of prolonged disease-free survival as patients with typical stage II breast cancer.

BONE METASTASES IN MALES Particularly if the lesions are osteoblastic, the serum PSA level should be measured, as the probability of prostate carcinoma is high. Empirical hormonal therapy (e.g., leuprolide and flutamide) should be strongly considered.

CERVICAL LYMPH NODE METASTASES Patients who present with a neck mass should be considered to have a primary tumor of the upper aerodigestive tract (head and neck cancer) until a different source is proven. Especially if the pathologist diagnoses squamous histology and the node is located in a high or midcervical area, a careful ear, nose, and throat examination including direct laryngoscopy, nasopharyngoscopy, and random blind biopsies should be undertaken. A thyroid examination and scan should be performed to rule out a primary thyroid tumor, especially if the histology is not definitely squamous. Definitive local therapy (external beam radiation or radical neck dissection) combined with platinum-based chemotherapy may lead to prolonged survival in those with head and neck primaries (Chap. 74).

ADENOCARCINOMA AND LIVER METASTASES Liver metastases from an adenocarcinoma are not as well characterized as a syndrome as the unrecognized germ cell cancer syndrome (nor as responsive to therapy). However, such patients may have a primary stomach, biliary, or colorectal tumor. Tumors with limited hepatic involvement may be amenable to resection. A flexible sigmoidoscopy or colonoscopy may detect a potentially obstructive colon lesion. If a tumor is found, resection may be beneficial, depending on the tumor's size; even if none is found, treatment with a combination of 5-fluorouracil plus leucovorin, with or without irinotecan, is palliative for some patients with presumed metastatic gastrointestinal malignancy. Given the severe diarrhea that may be a consequence of this regimen and the relative resistance of gastrointestinal tumors to chemotherapy, patients should be informed of the risks before treatment.

Other Patients Patients not falling into one of the preceding categories should be treated palliatively. In some patients, observation is appropriate. For example, individuals without evidence of additional metastatic disease who have undergone resection of a solitary pulmonary nodule containing malignant cells may actually have undergone definitive therapy for a small primary lung tumor. Patients presenting with a solitary brain metastasis from an unknown primary source who undergo resection of the lesion followed by whole-brain radiation therapy have a median survival of 13 months, suggesting benefit for aggressive local therapy. Radiation therapy may relieve symptoms in patients with bony pain or neurologic compromise. The largest and most poorly responsive subgroup are those with moderate to well-differentiated adenocarcinomas. Combination chemotherapy is frequently employed in such patients; however, response rates to "all-purpose" regimens [e.g., FACP (5-fluorouracil, doxorubicin, cyclophosphamide, cisplatin)] or to ICE (ifosfamide, carboplatin, etoposide) are generally well under 50%, especially if patients with poorly differentiated adenocarcinoma, who have a higher response rate, are excluded; complete responses are rare. The addition of a taxane (taxotere or paclitaxel) to such regimens has been associated with a higher response rate, albeit in selected patients. High-dose chemotherapy is not beneficial. In some series, patients with a good performance status whose disease is limited to soft tissue sites or extends only above the diaphragm have shown a better rate of response to therapy. While patients whose disease responds to treatment seem to have better survival than those whose disease does not respond, the difference may be related to inherent characteristics of the tumor rather than to a beneficial effect of chemotherapy.

Before combination chemotherapy is attempted in a patient with CUPS, the potential benefits must be weighed carefully against the certainty of toxicity. While some randomized studies have reported a benefit of one form of therapy over another, these reports are generally plagued by small numbers of patients and inadequate control of potential prognostic variables. Depending on motivation, eligibility, and availability, patients with CUPS may be candidates for evaluation of new (phase I) therapies.

86 PARANEOPLASTIC SYNDROMES: ENDOCRINOLOGIC/HEMATOLOGIC

J. Larry Jameson, Bruce E. Johnson

In addition to local tissue invasion and metastasis, neoplastic cells can produce a variety of peptides that exert biologic actions at local and distant sites and can elicit responses that cause a variety of hormonal, hematologic, dermatologic, and neurologic symptoms. *Paraneoplastic syndromes* refer to the disorders that accompany benign or malignant tumors but are not directly related to mass effects or invasion by the primary tumor or its metastases. Tumors of neuroendocrine origin, such as small cell lung carcinoma (SCLC) and carcinoids, produce a wide array of peptide hormones and are common causes of paraneoplastic syndromes. However, almost every type of malignancy has the potential to produce hormones or cytokines or to induce immunologic responses. Careful studies of the prevalence of paraneoplastic syndromes indicate that they are more common than is generally appreciated. The signs, symptoms, and metabolic alterations associated with paraneoplastic disorders may be overlooked in the context of a malignancy and its treatment. Consequently, atypical clinical manifestations in a patient with cancer should prompt consideration of a paraneoplastic syndrome. In this chapter, we review the most common endocrinologic, hematologic, and dermatologic syndromes associated with underlying neoplasia.

ENDOCRINE PARANEOPLASTIC SYNDROMES

ETIOLOGY Hormones can be produced from eutopic or ectopic sources. *Eutopic* refers to the expression of a hormone from its normal tissue of origin, whereas *ectopic* refers to hormone production from an atypical tissue source. For example, adrenocorticotropic hormone (ACTH) is expressed eutopically by the corticotrope cells of the anterior pituitary but it can be expressed ectopically in SCLC. As assay methodologies have become more sensitive, it is now apparent that many hormones are produced at low levels from a wide array of tissues, in addition to the classic endocrine source. Thus, ectopic expression is often a quantitative change rather than an absolute change in tissue expression. Nevertheless, the term *ectopic expression* is firmly entrenched and conveys the abnormal physiology associated with neoplastic hormone production. In addition to high levels of hormones, ectopic expression is typically characterized by abnormal regulation of hormone production (e.g., defective feedback control) and peptide processing (resulting in large, unprocessed precursors).

A diverse array of molecular mechanisms has been suggested to cause ectopic hormone production, but this process remains incompletely understood. In rare instances, genetic rearrangements explain aberrant hormone expression. For example, translocation of the *parathyroid hormone (PTH)* gene resulted in high levels of PTH expression in an ovarian carcinoma, presumably because the genetic rearrangement brings the *PTH* gene under the control of ovary-specific regulatory elements. A related phenomenon is well documented in many forms of leukemia and lymphoma, in which somatic genetic rearrangements confer a growth advantage and frequently alter cellular differentiation and function (see Chap. 97). Although genetic rearrangements may cause selected cases of ectopic hormone production, this mechanism is probably unusual, as many tumors are associated with excessive production of a wide variety of peptides. It is likely that cellular dedifferentiation underlies most cases of ectopic hormone production. In support of this idea, many cancers are poorly differentiated histologically, and certain tumor products, such as human chorionic gonadotropin (hCG), parathyroid hormone–related protein (PTHrP), and α fetoprotein, are characteristic of gene expression at earlier developmental stages. On the other hand, the propensity of certain cancers to produce particular hormones (e.g., squamous cell carcinomas produce PTHrP) suggests that dedifferentiation is partial or that selective pathways are derepressed. These expression profiles are likely to be driven by alterations in transcriptional repression, changes in DNA methylation, or other factors that govern cell differentiation. In SCLC, the pathway of differentiation has been relatively well defined. The neuroendocrine phenotype is dictated in part by the basic-helix-loop-helix (bHLH) transcription factor human achaete-scute homologue-1 (hASH1), which is expressed at abnormally high levels in SCLC associated with ectopic ACTH. The activity of hASH-1 is inhibited by hairy enhancer of split-1 (HES-1) and by Notch proteins, which are also capable of inducing growth arrest. Thus, abnormal expression of these developmental transcription factors appears to provide a link between cell proliferation and differentiation.

Ectopic hormone production would only be an epiphenomenon associated with cancer if it did not sometimes result in clinical manifestations. Excessive and unregulated production of hormones such as ACTH, PTHrP, or vasopressin can lead to substantial morbidity and can complicate the cancer treatment plan. Moreover, the paraneoplastic endocrinopathies are sometimes the presenting feature of underlying malignancy and may prompt the search for an unrecognized tumor.

A large number of paraneoplastic endocrine syndromes have been described, linking overproduction of particular hormones with specific types of tumors. However, certain recurring syndromes emerge from this large group (Table 86-1). The most common paraneoplastic endocrine syndromes include hypercalcemia from overproduction of PTHrP and other factors, hyponatremia from excess vasopressin, and Cushing's syndrome from ectopic ACTH.

SELECTED PARANEOPLASTIC ENDOCRINE SYNDROMES

HYPERCALCEMIA CAUSED BY ECTOPIC PRODUCTION OF PTHrP (See also Chap. 332) ■ **Etiology** Humoral hypercalcemia of malignancy (HHM) occurs in up to 5% of patients with cancer. HHM is most common in cancers of the lung, breast, head and neck, genitourinary tract, esophagus, and skin, and in multiple myeloma and lymphomas. There are several humoral causes of HHM but it is most often associated with overproduction of PTHrP. In addition to acting as a circulating humoral factor, many bone metastases (e.g., breast, multiple myeloma) produce PTHrP, leading to local osteolysis and hypercalcemia.

PTHrP is structurally related to PTH and it binds to the PTH receptor, explaining the similar biochemical features of HHM and hyperparathyroidism. PTHrP plays a key role in skeletal development and regulates cellular proliferation and differentiation in other tissues including skin, bone marrow, breast, and hair follicles. The mechanism of PTHrP induction in malignancy is incompletely understood but it is notable that tumor-bearing tissues commonly associated with HHM normally produce PTHrP during development or cellular renewal. Mutations in certain oncogenes, such as *Ras*, can activate PTHrP expression. In adult T cell lymphoma, the transactivating Tax protein produced by human T-cell lymphotropic virus-1 (HTLV-1) stimulates PTHrP promoter activity. Metastatic lesions to bone are more likely to produce PTHrP than are metastases in other tissues, suggesting that bone produces factors that enhance PTHrP production, or that PTHrP-producing metastases have a selective growth advantage in bone. Thus, PTHrP production can be stimulated by mutations in oncogenes, by altered expression of viral or cellular transcription factors, and by local growth factors.

Another relatively common cause of HHM is excess production of 1,25-dihydroxyvitamin D. Like granulomatous disorders associated with hypercalcemia, lymphomas can produce an enzyme that converts 25-hydroxyvitamin D to the more active 1,25-dihydroxyvitamin D, leading to enhanced gastrointestinal calcium absorption. Other causes of HHM include tumor-mediated production of osteolytic cytokines and inflammatory mediators.

Clinical Manifestations The typical presentation of HHM is a patient with a known malignancy who is found to be hypercalcemic on routine laboratory tests. Less often, hypercalcemia is the initial presenting feature of malignancy. Particularly when calcium levels are markedly

increased (>14 mg/dL), patients may experience fatigue, mental status changes, dehydration, or symptoms of nephrolithiasis.

Diagnosis Features that favor HHM as opposed to primary hyperparathyroidism include known malignancy, recent onset of hypercalcemia, and very high serum calcium levels. Like hyperparathyroidism, hypercalcemia caused by PTHrP is accompanied by hypercalciuria and hypophosphatemia. Measurement of PTH is useful to exclude primary hyperparathyroidism; the PTH level should be suppressed in HHM. An elevated PTHrP level confirms the diagnosis, and it is increased in about 80% of hypercalcemic patients with cancer. 1,25-Dihydroxyvitamin D levels may be increased in patients with lymphoma.

TREATMENT

The management of HHM begins with saline rehydration to dilute serum calcium and promote calciuresis. Forced diuresis with furosemide or other loop diuretics can enhance calcium excretion but provides relatively little value except in life-threatening hypercalcemia. When used, loop diuretics should be administered only after complete rehydration and with careful monitoring of fluid balance. Bisphosphonates such as pamidronate (30 to 90 mg IV) or zoledronate (4 to 8 mg IV) can reduce serum calcium within 1 to 2 days and suppress calcium release for several weeks. Oral bisphosphonates can also be used for chronic treatment. Previously used agents, such as calcitonin and mithramycin, have little utility now that bisphosphonates are available. Calcitonin (2 to 8 U/kg SC every 6 to 12 h) should be considered when rapid correction of severe hypercalcemia is needed. Hypercalcemia associated with lymphomas, multiple myeloma, or leukemia may respond to glucocorticoid treatment (e.g., prednisone 40 to 100 mg PO in four divided doses).

TABLE 86-1 *Paraneoplastic Syndromes Caused by Ectopic Hormone Production*

Paraneoplastic Syndrome	Ectopic Hormone	Typical Tumor Types[a]
COMMON		
Hypercalcemia of malignancy	Parathyroid hormone-related protein (PTHrP)	Squamous cell (head and neck, lung, skin), breast, genitourinary, gastrointestinal
	1,25 dihydroxyvitamin D	Lymphomas
	Parathyroid hormone (PTH) (rare)	Lung, ovary
	Prostaglandin E2 (PGE2) (rare)	Renal, lung
Syndrome of inappropriate antidiuretic hormone secretion (SIADH)	Vasopressin	Lung (squamous, small cell), gastrointestinal, genitourinary, ovary
Cushing's syndrome	Adrenocorticotropic hormone (ACTH)	Lung (small cell, bronchial carcinoid, adenocarcinoma, squamous), thymus, pancreatic islet, medullary thyroid carcinoma
	Corticotropin-releasing hormone (CRH) (rare)	Pancreatic islet, carcinoid, lung, prostate
	Ectopic expression of gastric inhibitory peptide (GIP), luteinizing hormone (LH)/human chorionic gonadotropin (hCG), other G protein–coupled receptors (rare)	Macronodular adrenal hyperplasia
LESS COMMON		
Non-islet cell hypoglycemia	Insulin-like growth factor (IGF-II)	Mesenchymal tumors, sarcomas, adrenal, hepatic, gastrointestinal, kidney, prostate
	Insulin (rare)	Cervix (small cell carcinoma)
Male feminization	hCG[b]	Testis (embryonal, seminomas), germinomas, choriocarcinoma, lung, hepatic, pancreatic islet
Diarrhea or intestinal hypermotility	Calcitonin[c]	Lung, colon, breast, medullary thyroid carcinoma
	Vasoactive intestinal peptide (VIP)	Pancreas, pheochromocytoma, esophagus
RARE		
Oncogenic osteomalacia	Phosphatonin [Fibroblast growth factor 23 (FGF23)]	Hemangiopericytomas, osteoblastomas, fibromas, sarcomas, giant cell tumors, prostate, lung
Acromegaly	Growth hormone–releasing hormone (GHRH)	Pancreatic islet, bronchial and other carcinoids
	Growth hormone (GH)	Lung, pancreatic islet
Hyperthyroidism	Thyroid-stimulating hormone (TSH)	Hydatidiform mole, embryonal tumors, struma ovarii
Hypertension	Renin	Juxtaglomerula tumors, kidney, lung, pancreas, ovary

[a] Only the most common tumor types are listed. For most ectopic hormone syndromes, an extensive list of tumors has been reported to produce one or more hormones.
[b] hCG is produced eutopically by trophoblastic tumors. Certain tumors produce disproportionate amounts of the hCG α or hCG β subunits. High levels of hCG rarely cause hyperthyroidism because of weak binding to the TSH receptor.
[c] Calcitonin is produced eutopically by medullary thyroid carcinoma and is used as a tumor marker.

ECTOPIC VASOPRESSIN: TUMOR-ASSOCIATED SIADH (See also Chap. 41) ■

Etiology Vasopressin is an antidiuretic hormone normally produced by the posterior pituitary gland. Ectopic vasopressin production by tumors is a common cause of the syndrome of inappropriate antidiuretic hormone (SIADH), occurring in at least half of patients with SCLC. Compensatory mechanisms, such as decreased thirst, suppression of aldosterone, and production of atrial natriuretic peptide (ANP), may mitigate the development of hyponatremia in patients who produce excessive vasopressin. Tumors with neuroendocrine features, such as SCLC and carcinoids, are the most common sources of ectopic vasopressin production, but it also occurs in other forms of lung cancer and with CNS lesions, head and neck cancer, and genitourinary, gastrointestinal, and ovarian cancers. The mechanism of activation of the vasopressin gene in these tumors is unknown but often involves concomitant expression of the adjacent oxytocin gene, suggesting derepression of this locus.

Clinical Manifestations Most patients with ectopic vasopressin secretion are asymptomatic and are identified because of the presence of hyponatremia on routine chemistry testing. Symptoms may include weakness, lethargy, nausea, confusion, depressed mental status, and seizures. The severity of symptoms reflects the rapidity of onset as well as the extent of hyponatremia. In most cases, hyponatremia develops slowly but may be exacerbated by the administration of intravenous fluids or the institution of new medications. Thirst is typically suppressed.

Diagnosis The diagnostic features of ectopic vasopressin production are the same as those of other causes of SIADH (see Chaps. 41 and 318). Hyponatremia and reduced serum osmolality occur in the setting of an inappropriately normal or increased urine osmolality. Unless there is concomitant volume depletion, urine sodium excretion is normal or increased. Other causes of hyponatremia should be excluded, including renal, adrenal, or thyroid insufficiency. Physiologic sources

of vasopressin stimulation (CNS lesions, pulmonary disease, nausea) and adaptive circulatory mechanisms (hypotension, heart failure, hepatic cirrhosis), as well as medications, including many chemotherapeutic agents, should also be considered as possible causes of hyponatremia. Measurement of vasopressin is not usually necessary to make the diagnosis.

TREATMENT

Most patients with ectopic vasopressin production develop hyponatremia over several weeks or months and it is reasonable to correct the disorder gradually unless mental status is altered or there is risk of seizures. Treatment of the underlying malignancy may reduce ectopic vasopressin production but this response is slow, if it occurs at all. Fluid restriction to less than urine output, plus insensible losses, is often sufficient to partially correct hyponatremia. However, strict monitoring of the amount and types of liquids consumed or administered intravenously is required for fluid restriction to be effective. Salt tablets or saline are not helpful unless there is concomitant volume depletion. Demeclocycline (150 to 300 mg orally three to four times daily) can be used to inhibit vasopressin action on the renal distal tubule but its onset of action is relatively slow (1 to 2 weeks). Other vasopressin antagonists are under investigation. Severe hyponatremia ($Na < 115$ mEq/L) or mental status changes may require treatment with hypertonic (3%) or normal saline infusion together with furosemide, to enhance free water clearance. The rate of sodium correction should be slow (0.5 to 1 mEq/L per h) to prevent rapid fluid shifts and the possible development of central pontine myelinolysis.

CUSHING'S SYNDROME CAUSED BY ECTOPIC ACTH PRODUCTION (See also Chap. 321) ■ **Etiology** Ectopic production of ACTH accounts for 10 to 20% of Cushing's syndrome. The syndrome is particularly common in neuroendocrine tumors. SCLC (>50%) is by far the most common cause of ectopic ACTH, followed by thymic carcinoid (15%), islet cell tumors (10%), bronchial carcinoid (10%), other carcinoids (5%), and pheochromocytomas (2%). As noted above, the mechanism of ectopic ACTH production in neuroendocrine tumors appears to be linked to the expression of transcription factors that dictate pathways of cell differentiation. Ectopic ACTH production is caused by increased expression of the proopiomelanocortin (POMC) gene, which encodes ACTH, along with melanocyte-stimulating hormone (MSH), β lipotropin, and several other peptides. In many tumors, there is abundant but aberrant expression of the POMC gene from an internal promoter, proximal to the third exon, which encodes ACTH. However, because this product lacks the signal sequence necessary for protein processing, it is not secreted. Increased production of ACTH arises instead from less abundant, but unregulated, POMC expression from the same promoter site used in the pituitary. However, because the tumors lack many of the enzymes needed to process the POMC polypeptide, it is typically released as multiple large, biologically inactive fragments along with relatively small amounts of fully processed, active ACTH.

Rarely, corticotropin-releasing hormone (CRH) is produced by pancreatic islet tumors, SCLC, medullary thyroid cancer, carcinoids, or prostate cancer. When levels are high enough, CRH can cause pituitary corticotrope hyperplasia and Cushing's syndrome. Tumors that produce CRH sometimes also produce ACTH, raising the possibility of a paracrine mechanism for ACTH production.

A distinct mechanism for ACTH-independent Cushing's syndrome involves ectopic expression of various G protein–coupled receptors in the adrenal nodules. Ectopic expression of the gastric inhibitory peptide (GIP) receptor is the best-characterized example of this mechanism. In this case, meals induce GIP secretion, which inappropriately stimulates adrenal growth and glucocorticoid production.

Clinical Manifestations The clinical features of hypercortisolemia are detected in only a small fraction of patients with documented ectopic ACTH production. However, the ectopic ACTH syndrome is associated with several clinical features that distinguish it from other causes of Cushing's syndrome (e.g., pituitary adenomas, adrenal adenomas, iatrogenic glucocorticoid excess). The metabolic manifestations of ectopic ACTH syndrome are dominated by fluid retention and hypertension, hypokalemia, metabolic alkalosis, glucose intolerance, and, often, steroid psychosis. Patients with ectopic ACTH syndrome generally exhibit less marked weight gain and centripetal fat redistribution, probably because the exposure to excess steroids is relatively short and because cachexia reduces the propensity for weight gain and fat deposition. The very high levels of ACTH often cause increased pigmentation, and melanotrope-stimulating hormone (MSH) activity derived from the POMC precursor peptide is also increased. The extraordinarily high glucocorticoid levels in patients with ectopic sources of ACTH can lead to marked skin fragility and easy bruising. In addition, the high cortisol levels often overwhelm the renal 11β-hydroxysteroid dehydrogenase type II enzyme, which normally inactivates cortisol and prevents it from binding to renal mineralocorticoid receptors. Consequently, in addition to the excess mineralocorticoids produced by ACTH stimulation of the adrenal gland, high levels of cortisol exert activity through the mineralocorticoid receptor, leading to severe hypokalemia.

Diagnosis The diagnosis of ectopic ACTH syndrome is usually not difficult in the setting of a known malignancy. Urine free cortisol levels fluctuate but are typically greater than 2 to 4 times normal and the plasma ACTH level is usually >100 pg/mL. A suppressed ACTH level excludes this diagnosis and indicates an ACTH-independent cause of Cushing's syndrome (e.g., adrenal or exogenous glucocorticoid). In contrast to pituitary sources of ACTH, most ectopic sources of ACTH do not respond to glucocorticoid suppression. Therefore, high-dose dexamethasone (8 mg PO) suppresses 8:00 A.M. serum cortisol (50% decrease from baseline) in about 80% of pituitary ACTH-producing adenomas but fails to suppress ectopic ACTH in about 90% of cases. Bronchial and other carcinoids are well-documented exceptions to these general guidelines, as these ectopic sources of ACTH may exhibit feedback regulation indistinguishable from pituitary adenomas, including suppression by high-dose dexamethasone, and ACTH responsiveness to adrenal blockade with metyrapone. If necessary, petrosal sinus catheterization can be used to evaluate a patient with ACTH-dependent Cushing's syndrome when the source of ACTH is unclear. After CRH stimulation, a 3:1 petrosal sinus:peripheral ACTH ratio strongly suggests a pituitary ACTH source. Imaging studies are also useful in the evaluation of suspected carcinoid lesions, allowing biopsy and characterization of hormone production using special stains.

TREATMENT

The morbidity associated with the ectopic ACTH syndrome can be substantial. Patients may experience depression or personality changes because of extreme cortisol excess. Metabolic derangements including diabetes mellitus and hypokalemia can worsen fatigue. Poor wound healing and predisposition to infections can complicate the surgical management of tumors, and opportunistic infections, caused by organisms such as *Pneumocystis carinii* and mycoses, are often the cause of death in patients with ectopic ACTH production. Depending on prognosis and treatment plans for the underlying malignancy, measures to reduce cortisol levels are often indicated. Treatment of the underlying malignancy may reduce ACTH levels but is rarely sufficient to reduce cortisol levels to normal. Adrenalectomy is not practical for most of these patients but should be considered if the underlying tumor is not resectable and the prognosis is otherwise favorable (e.g., carcinoid). Medical therapy with ketoconazole (200 to 400 mg PO twice daily), metyrapone (250 to 500 mg PO every 6 h), mitotane (3 to 6 g PO in four divided doses, tapered to maintain low cortisol production), or other agents that block steroid synthesis or action is often the most practical strategy for managing the hypercortisolism associated with ectopic ACTH production (see Chap. 318). Glucocorticoid replacement should be provided to avoid adrenal insufficiency. Unfortunately, many patients will eventually escape from medical blockade.

TUMOR-INDUCED HYPOGLYCEMIA CAUSED BY EXCESS PRODUCTION OF IGF-II (See also Chap. 324) Mesenchymal tumors, hemangiopericytomas, hepatocellular tumors, adrenal carcinomas, and a variety of other large tumors have been reported to produce excessive amounts of insulin-like growth factor type II (IGF-II) precursor, which binds weakly to insulin receptors and strongly to IGF-I receptors, leading to insulin-like actions. The IGF-II gene resides on a locus on chromosome 11p15 that is normally imprinted (that is, expression is exclusively from a single parental allele). There is mounting evidence for biallelic expression of the IGF-II gene in a subset of tumors, suggesting loss of methylation and loss of imprinting as a mechanism for gene induction. In addition to increased IGF-II production, IGF-II bioavailability is increased due to complex alterations in circulating binding proteins. Increased IGF-II suppresses growth hormone (GH) and insulin, resulting in reduced IGF binding protein-3 (IGFBP-3), IGF-I, and acid-labile subunit (ALS). The reduction in ALS and IGFBP-3, which normally sequester IGF-II, causes it to be displaced to a small circulating complex that has greater access to insulin target tissues. For this reason, circulating IGF-II levels may not be markedly increased, despite causing hypoglycemia. In addition to IGF-II–mediated hypoglycemia, tumors may occupy enough of the liver to impair gluconeogenesis.

In most cases, the tumor causing hypoglycemia is clinically apparent and hypoglycemia develops in association with fasting. The diagnosis is made by documenting low serum glucose and suppressed insulin levels in association with symptoms of hypoglycemia. Serum IGF-II levels may not be increased (IGF-II assays may not detect IGF-II precursors). Increased IGF-II mRNA expression is found in most tumors. Any medications associated with hypoglycemia should be eliminated. Treatment of the underlying malignancy, if possible, may reduce the predisposition to hypoglycemia. Frequent meals and intravenous glucose, especially during sleep or fasting, are often necessary to prevent hypoglycemia. Glucagon, GH, and glucocorticoids have also been used to enhance glucose production.

HUMAN CHORIONIC GONADOTROPIN hCG is composed of α and β subunits and can be produced as intact hormone, which is biologically active, or as uncombined biologically inert subunits. Ectopic production of intact hCG occurs most often in association with testicular embryonal tumors, germ cell tumors, extragonadal germinomas, lung cancer, hepatoma, and pancreatic islet tumors. Eutopic production of hCG occurs with trophoblastic malignancies. Low levels of hCG or its uncombined α or β subunits have been reported in a wide range of tumors. hCG α subunit production is particularly common in lung cancer and pancreatic islet cancer. In men, high hCG levels stimulate steroidogenesis and aromatase activity in testicular Leydig cells, resulting in increased estrogen production and the development of gynecomastia. Precocious puberty in boys or gynecomastia in men should prompt measurement of hCG and consideration of a testicular tumor or another source of ectopic hCG production. Most women are asymptomatic. hCG is easily measured using sensitive immunoradiometric assays. Treatment should be directed at the underlying malignancy.

ONCOGENIC OSTEOMALACIA Hypophosphatemic oncogenic osteomalacia is characterized by markedly reduced serum phosphorus and renal phosphate wasting, leading to muscle weakness and osteomalacia. Serum calcium and PTH levels are normal and 1,25 dihydroxyvitamin D is low. Oncogenic osteomalacia is usually caused by benign mesenchymal tumors, such as hemangiopericytomas, fibromas, or giant cell tumors, often of the skeletal extremities or head. It has also been described in sarcomas and in patients with prostate and lung cancer. Resection of the tumor reverses the disorder, confirming its humoral basis. The circulating phosphaturic factor is called *phosphatonin*—a factor that inhibits renal tubular reabsorption of phosphate and renal conversion of 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D. Phosphatonin has been identified as fibroblast growth factor 23 (FGF23). The disorder exhibits biochemical features similar to those seen with inactivating mutations in the *PHEX* gene, the cause of hereditary X-linked hypophosphatemia. The *PHEX* gene encodes a protease that activates FGF23. Treatment involves removal of the tumor, if possible, and supplementation with phosphate and vitamin D. Octreotide treatment reduces phosphate wasting in some patients with tumors that express somatostatin receptor subtype 2. Octreotide scans may also be useful to detect these tumors.

HEMATOLOGIC SYNDROMES

The elevation of granulocyte, platelet, and eosinophil counts in most patients with myeloproliferative disorders is caused by the proliferation of the myeloid elements due to the underlying disease rather than a paraneoplastic syndrome. The paraneoplastic hematologic syndromes in patients with solid tumors are less well characterized than the endocrine syndromes because the ectopic hormone(s) or cytokines responsible have not been identified in most of these tumors (Table 86-2). The severity of the paraneoplastic syndromes parallels the course of the cancer.

ERYTHROCYTOSIS Ectopic production of erythropoietin by cancer cells causes most paraneoplastic erythrocytosis. The ectopically produced erythropoietin stimulates the production of red blood cells in the bone marrow and raises the hematocrit. Other lymphokines and hormones produced by cancer cells may stimulate erythropoietin release but have not been proven to cause erythrocytosis.

Most patients with erythrocytosis have an elevated hematocrit (>52% in men; >48% in women) that is detected on a routine blood count. Approximately 3% of patients with renal cell cancer, 10% of patients with hepatoma, and 15% of patients with cerebellar hemangioblastomas have erythrocytosis. In most cases the erythrocytosis is asymptomatic.

Patients with erythrocytosis due to a renal cell cancer, hepatoma, or CNS cancer should have measurement of red cell mass. If the red cell mass is elevated, the serum erythropoietin level should then be measured. Patients with an appropriate cancer, elevated erythropoietin levels, and no other explanation for erythrocytosis (e.g., hemoglobinopathy that causes increased O_2 affinity; see Chap. 91) have the paraneoplastic syndrome.

TREATMENT

Successful resection of the cancer usually resolves the erythrocytosis. If the tumor cannot be resected or treated effectively with radiation

TABLE 86-2 Paraneoplastic Hematologic Syndromes

Syndrome	Proteins	Cancers Typically Associated with Syndrome
Erythrocytosis	Erythropoietin	Renal cancers Hepatocarcinoma Cerebellar hemangioblastomas
Granulocytosis	G-CSF GM-CSF IL-6	Lung cancer Gastrointestinal cancer Ovarian cancer Genitourinary cancer Hodgkin's disease
Thrombocytosis	IL-6	Lung cancer Gastrointestinal cancer Breast cancer Ovarian cancer Lymphoma
Eosinophilia	IL-5	Lymphoma Leukemia Lung cancer
Thrombophlebitis	Unknown	Lung cancer Pancreatic cancer Gastrointestinal cancer Breast cancer Genitourinary cancer Ovarian cancer Prostate cancer Lymphoma

therapy or chemotherapy, phlebotomy may control any symptoms related to erythrocytosis.

GRANULOCYTOSIS Approximately 30% of patients with solid tumors have granulocytosis (granulocyte count >8000/μL). In about half of patients with granulocytosis and cancer, the granulocytosis has an identifiable nonparaneoplastic etiology (infection, tumor necrosis, glucocorticoid administration, etc.). The other patients have proteins in urine and serum that stimulate the growth of bone marrow cells. Tumors and tumor cell lines from patients with lung, ovarian, and bladder cancers have been documented to produce granulocyte colony-stimulating factor (G-CSF), granulocyte-macrophage colony-stimulating factor (GM-CSF), and/or interleukin 6 (IL-6). However, the etiology of granulocytosis has not been characterized in most patients.

Patients with granulocytosis are nearly all asymptomatic, and the differential white blood cell count does not have a shift to immature forms of neutrophils. Granulocytosis occurs in 40% of patients with lung and gastrointestinal cancers, 20% of patients with breast cancer, 30% of patients with brain tumors and ovarian cancers, and 10% of patients with renal cell carcinoma. Patients with advanced-stage disease are more likely to have granulocytosis than those with early-stage disease.

Paraneoplastic granulocytosis does not require treatment. The granulocytosis resolves when the underlying cancer is successfully treated.

THROMBOCYTOSIS Some 35% of patients with thrombocytosis (platelet count >400,000/μL) have an underlying diagnosis of cancer. IL-6, a candidate molecule for the etiology of paraneoplastic thrombocytosis, stimulates the production of platelets in vitro and in vivo. Some patients with cancer and thrombocytosis have elevated levels of IL-6 in plasma. Another candidate molecule is thrombopoietin, a peptide hormone that stimulates megakaryocyte proliferation and platelet production. The etiology of thrombocytosis has not been established in most cases.

Patients with thrombocytosis are nearly all asymptomatic. Thrombocytosis is not clearly linked to thrombosis in patients with cancer. Thrombocytosis is present in 40% of patients with lung and gastrointestinal cancers, 20% of patients with breast, endometrial, and ovarian cancers, and 10% of patients with lymphoma. Patients with thrombocytosis are more likely to have advanced-stage disease and have a poorer prognosis than patients without thrombocytosis. Paraneoplastic thrombocytosis does not require treatment.

EOSINOPHILIA Eosinophilia is present in ~1% of patients with cancer. Tumors and tumor cell lines from patients with lymphomas or leukemia may produce IL-5, which stimulates eosinophil growth. Activation of IL-5 transcription in lymphomas and leukemias may involve translocation of the long arm of chromosome 5, to which the genes for IL-5 and other cytokines map.

Patients with eosinophilia are typically asymptomatic. Eosinophilia is present in 10% of patients with lymphoma, 3% of patients with lung cancer, and occasional patients with cervical, gastrointestinal, renal, and breast cancer. Patients with markedly elevated eosinophil counts (>5000/μL) can develop shortness of breath and wheezing. A chest radiograph may reveal diffuse pulmonary infiltrates from eosinophil infiltration and activation in the lungs.

TREATMENT

Definitive treatment is directed at the underlying malignancy: tumors should be resected or treated with radiation or chemotherapy. In most patients who develop shortness of breath related to eosinophilia, symptoms resolve with the use of oral or inhaled glucocorticoids.

THROMBOPHLEBITIS Deep venous thrombosis and pulmonary embolism are the most common thrombotic conditions in patients with cancer. Migratory or recurrent thrombophlebitis may be the initial manifestation of cancer. Nearly 15% of patients who develop deep venous thrombosis or pulmonary embolism have a diagnosis of cancer (Chap. 102). The coexistence of peripheral venous thrombosis with visceral carcinoma, particularly pancreatic cancer, is called *Trousseau's syndrome*.

Pathogenesis Patients with cancer are predisposed to thromboembolism because they are often at bedrest or immobilized, and tumors may obstruct or slow blood flow. Chronic intravenous catheters also predispose to clotting. In addition, clotting may be promoted by release of procoagulants or cytokines from tumor cells or associated inflammatory cells, or by platelet adhesion or aggregation. The specific molecules that mediate the increased risk of thromboembolism have not been identified.

Clinical Manifestations Patients with cancer who develop deep venous thrombosis usually develop swelling or pain in the leg, and physical examination reveals tenderness, warmth, and redness. Patients who present with pulmonary embolism develop dyspnea, chest pain, and syncope, and physical examination shows tachycardia, cyanosis, and hypotension. Some 5% of patients with no history of cancer who have a diagnosis of deep venous thrombosis or pulmonary embolism will have a diagnosis of cancer within 1 year. The most common cancers associated with thromboembolic episodes include lung, pancreatic, gastrointestinal, breast, ovarian, and genitourinary cancers, lymphomas, and brain tumors. Patients with cancer who undergo surgical procedures requiring general anesthesia have a 20 to 30% risk of deep venous thrombosis.

Diagnosis The diagnosis of deep venous thrombosis in patients with cancer is made by impedance plethysmography or bilateral compression ultrasonography of the leg veins. Patients with a noncompressible venous segment have deep venous thrombosis. If compression ultrasonography is normal and a high clinical suspicion exists for deep venous thrombosis, venography should be done to look for a luminal filling defect. Elevation of D-dimer is not as predictive of deep venous thrombosis in patients with cancer as it is in patients without cancer.

Patients with symptoms and signs suggesting a pulmonary embolism should be evaluated with a chest radiograph, electrocardiogram, arterial blood gas analysis, and ventilation–perfusion scan. Patients with mismatched segmental perfusion defects have a pulmonary embolus. Patients with equivocal ventilation–perfusion findings should be evaluated as described above for deep venous thrombosis in their legs. If deep venous thrombosis is detected, they should be anticoagulated. If deep venous thrombosis is not detected, they should be considered for a pulmonary angiogram.

Patients without a diagnosis of cancer who present with an initial episode of thrombophlebitis or pulmonary embolus need no additional tests for cancer other than a careful history and physical exam. In light of the many possible primary sites, diagnostic testing in asymptomatic patients is wasteful. However, if the clot is refractory to standard treatment or is in an unusual site, or if the thrombophlebitis is migratory or recurrent, efforts to find an underlying cancer are indicated.

TREATMENT

Patients with cancer and a diagnosis of deep venous thrombosis or pulmonary embolism should be treated initially with intravenous unfractionated heparin or low-molecular-weight heparin for at least 5 days and warfarin started within 1 or 2 days. The warfarin dose should be adjusted so the international normalized ratio (INR) is 2 to 3. Patients with proximal deep venous thrombosis and a relative contraindication to heparin anticoagulation (hemorrhagic brain metastases or pericardial effusion) should be considered for placement of a filter in the inferior vena cava (Greenfield filter) to prevent pulmonary embolism. Warfarin should be administered for 3 to 6 months. An alternative approach is to use low-molecular-weight heparin for 6 months. Patients with cancer who undergo a major surgical procedure should be considered for heparin prophylaxis or pneumatic boots. Breast cancer patients undergoing chemotherapy and patients with implanted

catheters should be considered for prophylaxis (1 mg warfarin per day).

→Cutaneous paraneoplastic syndromes are discussed in Chap. 48. Neurologic paraneoplastic syndromes are discussed in Chap. 87. More extensive discussion of functional endocrine tumors is given in Chap. 329.

87 PARANEOPLASTIC NEUROLOGIC SYNDROMES

Josep Dalmau, Myrna R. Rosenfeld

Paraneoplastic neurologic disorders (PNDs) are cancer-related syndromes that can affect any part of the nervous system (Table 87-1). They are remote effects of cancer, caused by mechanisms other than metastasis or by any of the complications of cancer such as coagulopathy, stroke, metabolic and nutritional conditions, infections, and side effects of cancer therapy. In 60% of patients the neurologic symptoms precede the cancer diagnosis. Overall, clinically disabling PNDs occur in 0.5 to 1% of all cancer patients, but they occur in 2 to 3% of patients with neuroblastoma or small-cell lung cancer (SCLC), and in 30 to 50% of patients with thymoma or sclerotic myeloma.

PATHOGENESIS Most PNDs are mediated by immune responses triggered by the tumor expression of neuronal proteins (onconeuronal antigens). In PNDs of the central nervous system (CNS), many antibody-associated immune responses have been identified (Table 87-2). These antibodies usually react with the patient's tumor, and their detection in serum or cerebrospinal fluid (CSF) strongly predicts the presence of cancer. The target antigens are usually intracellular proteins with roles in neuronal development and function. Some of the antibodies react with epitopes located in critical protein domains, disrupting protein function leading to neuronal apoptosis. In addition to onconeuronal antibodies, most PNDs of the CNS are associated with infiltrates of CD4+ and CD8+ T cells, microglial activation, gliosis, and variable neuronal loss. The infiltrating T cells are often in close contact with neurons undergoing degeneration, suggesting a primary pathogenic role. T cell–mediated cytotoxicity may contribute directly to cell death in these PNDs. Thus both humoral and cellular immune mechanisms participate in the pathogenesis of many PNDs. This complex immunopathogenesis may underlie the resistance of many of these conditions to therapy.

Only three of the antibodies listed in Table 87-2 have been shown to play a direct pathogenic role in PNDs; all produce distinctive disorders of the peripheral nervous system. These are: antibodies to P/Q-type voltage-gated calcium channels (VGCC) in patients with the Lambert-Eaton myasthenic syndrome (LEMS); antibodies to acetylcholine receptors in patients with myasthenia gravis; and antibodies to voltage-gated potassium channels (VGKC) in some patients with peripheral nerve hyperexcitability (neuromyotonia). Common features of these three antibodies are that they target cell-surface molecules and that their passive transfer to animals reproduces the disorders. Plasma exchange or immunomodulation with intravenous immunoglobulin (IVIg) usually produces neurologic improvement. Each of these disorders can occur without cancer, and therefore detection of these antibodies does not predict the presence of cancer.

Other PNDs are likely immune-mediated although their antigens are unknown. These include several syndromes of inflammatory neuropathies and myopathies. In addition, many patients with typical PND syndromes are antibody-negative.

For still other PNDs, the cause remains quite obscure. These include, among others, several neuropathies that occur in the terminal stages of cancer and a number of neuropathies associated with plasma cell dyscrasias or lymphoma without evidence of inflammatory infiltrates or deposits of immunoglobulin, cryoglobulin, or amyloid.

TABLE 87-1 Paraneoplastic Syndromes of the Nervous System

Syndromes of the brain, brainstem, and cerebellum
Focal encephalitis
Cortical encephalitis
Limbic encephalitis
Brainstem encephalitis
Cerebellar dysfunction
Autonomic dysfunction
Paraneoplastic cerebellar degeneration
Opsoclonus-myoclonus
Syndromes of the spinal cord
Subacute necrotizing myelopathy
Motor neuron dysfunction
Myelitis
Stiff-person syndrome
Syndromes of dorsal root ganglia
Sensory neuronopathy
Multiple levels of involvement
Encephalomyelitis[a], sensory neuronopathy, autonomic dysfunction
Syndromes of peripheral nerve
Chronic and subacute sensorimotor peripheral neuropathy
Vasculitis of nerve and muscle
Neuropathy associated with malignant monoclonal gammopathies
Peripheral nerve hyperexcitability
Autonomic neuropathy
Syndromes of the neuromuscular junction
Lambert-Eaton myasthenic syndrome
Myasthenia gravis
Syndromes of the muscle
Polymyositis/dermatomyositis
Acute necrotizing myopathy
Syndromes affecting the visual system
Cancer-associated retinopathy (CAR)
Melanoma-associated retinopathy (MAR)
Uveitis (usually in association with encephalomyelitis)

[a] Includes cortical, limbic, or brainstem encephalitis, cerebellar dysfunction, myelitis.

APPROACH TO THE PATIENT

The diagnosis and management of PNDs may be difficult for several reasons. First, it is common for symptoms to appear before the presence of a tumor is known. Second, the neurologic syndrome can evolve in a rapidly progressive fashion, producing a severe and usually irreversible neurologic deficit in a short period of time. There is evidence that prompt tumor control improves the course of PNDs. Therefore, the major concern of the physician is to recognize a disorder promptly as paraneoplastic in order to identify and treat the tumor.

PND of the Central Nervous System and Dorsal Root Ganglia When symptoms involve brain, spinal cord, or dorsal root ganglia, the

TABLE 87-2 *Paraneoplastic Antineuronal Antibodies, Associated Syndromes and Cancers*

Antibody	Syndrome	Associated Cancers
Anti-Hu (ANNA-1)	PEM (including cortical, limbic, brainstem encephalitis, cerebellar dysfunction, myelitis), PSN, autonomic dysfunction	SCLC, other neuroendocrine tumors
Anti-Yo (PCA-1)	PCD	Ovary and other gynecologic cancers, breast
Anti-Ri (ANNA-2)	PCD, brainstem encephalitis, opsoclonus-myoclonus	Breast, gynecological, SCLC
Anti-Tr	PCD	Hodgkin's lymphoma
Anti-Zic	PCD, encephalomyelitis	SCLC and other neuroendocrine tumors
Anti-CV_2/CRMP5	PEM, PCD, chorea, peripheral neuropathy, uveitis	SCLC, thymoma, other
Anti-Ma proteins[a]	Limbic, hypothalamic, brainstem encephalitis (infrequently PCD)	Germ-cell tumors of testis, lung cancer, other solid tumors
Anti-amphiphysin	Stiff-person syndrome, PEM	Breast, SCLC
Anti-VGCC[b]	LEMS, PCD	SCLC, lymphoma
Anti-AChR[b]	MG	Thymoma
Anti-VGKC[b]	Peripheral nerve hyperexcitability (neuromyotonia)	Thymoma, SCLC, others
Anti-recoverin	Cancer-associated retinopathy (CAR)	SCLC and other
Anti-bipolar cells of the retina	Melanoma-associated retinopathy (MAR)	Melanoma

[a] Patients with antibodies to Ma2 are usually men with testicular cancer. Patients with additional antibodies to other Ma proteins are men or women with a variety of solid tumors.
[b] These antibodies can occur with or without a cancer association.
Note: PEM: paraneoplastic encephalomyelitis; PCD, paraneoplastic cerebellar degeneration; PSN, paraneoplastic sensory neuronopathy; LEMS, Lambert-Eaton myasthenic syndrome; MG, myasthenia gravis; VGCC, voltage-gated calcium channel; AChR, acetylcholine receptor; VGKC, voltage-gated potassium channel; SCLC, small-cell lung cancer.

suspicion of PND is usually based on a combination of clinical, radiologic, and CSF findings. In these cases, a biopsy of the affected tissue is often difficult to obtain, and although useful to rule out other disorders (e.g., metastasis, infection), neuropathologic findings are not specific for PND. Furthermore, there are no specific radiologic or electrophysiologic tests that are diagnostic of PND. The presence of antineuronal antibodies (Table 87-2) may help in the diagnosis with the following caveats: (1) antibodies are detected in only 40 to 50% of PNDs of the CNS; (2) antibodies may be present in both the serum and CSF, but in some patients only the CSF is positive (especially with antibodies to Tr and Ma proteins); (3) antibodies (usually at low titer) are present in a variable proportion of cancer patients without PND; (4) there is an imperfect correlation between antibody titers and the course of the neurologic disorder; (5) several antibodies may associate with a similar syndrome, with the antibody specificity often correlating with the tumor type (e.g., cerebellar degeneration is associated with anti-Tr antibodies if the tumor is Hodgkin's disease but with anti-Yo antibodies if the tumor is ovarian or breast cancer); and (6) several antibodies may be present in the serum or CSF of the same patient (e.g., anti-Hu and anti-CV_2/CRMP5, or less frequently anti-Ri).

Magnetic resonance imaging (MRI) and CSF studies are important to rule out neurologic complications due to the direct spread of cancer, particularly metastatic and leptomeningeal disease. In most PNDs the MRI findings are nonspecific. Paraneoplastic limbic encephalitis is usually associated with characteristic MRI abnormalities in the mesial temporal lobes (see below), but similar findings can occur with other disorders [e.g., systemic lupus erythematosus, human herpesvirus (HHV) 6 encephalitis]. The CSF profile of patients with PND of the CNS or dorsal root ganglia typically consists of mild to moderate pleocytosis (<200 mononuclear cells, predominantly lymphocytes), an increase in the protein concentration, intrathecal synthesis of IgG, and a variable presence of oligoclonal bands.

PND of Nerve and Muscle If symptoms involve peripheral nerve, neuromuscular junction, or muscle, the diagnosis of a specific PND is usually established on clinical, electrophysiologic, and pathologic grounds. The clinical history, accompanying symptoms (e.g., anorexia, weight loss), and type of syndrome dictate the studies and degree of effort needed to demonstrate a neoplasm. For example, the frequent association of LEMS with SCLC should lead to a chest and abdomen computed tomography or body positron emission tomography (PET) scan and, if negative, periodic tumor screening for at least 3 years after the neurologic diagnosis. In contrast, the weak association of polymyositis with cancer calls into question the need for repeated cancer screenings in this situation. Serum and urine immunofixation studies should be considered in patients with peripheral neuropathy of unknown cause; detection of a monoclonal gammopathy suggests the need for additional studies to uncover a B cell or plasma cell malignancy. In paraneoplastic neuropathies, diagnostically useful antineuronal antibodies are limited to anti-CV_2/CRMP5 and anti-Hu.

For any type of PND, if antineuronal antibodies are negative, the diagnosis relies on the demonstration of cancer and the exclusion of other cancer-related or independent neurologic disorders. Body PET scans often uncover tumors undetected by other tests.

SPECIFIC PARANEOPLASTIC NEUROLOGIC SYNDROMES (Table 87-3)

PARANEOPLASTIC ENCEPHALOMYELITIS AND FOCAL ENCEPHALITIS The term *encephalomyelitis* describes an inflammatory process with multifocal involvement of the nervous system, including brain, brainstem, cerebellum, and spinal cord. It is often associated with dorsal root ganglia and autonomic dysfunction. For any given patient, the clinical manifestations are determined by the area or areas predominantly involved, but pathology almost always reveals abnormalities (inflammatory infiltrates, neuronal loss, gliosis) beyond the symptomatic regions. Several clinicopathologic syndromes may occur alone or in combination: (1) *cortical encephalitis*, which may present as "epilepsia partialis continua"; (2) *limbic encephalitis*, characterized by confusion, depression, agitation, anxiety, severe short-term memory deficits, partial complex seizures, and dementia; the MRI usually shows unilateral or bilateral medial temporal lobe abnormalities, best seen with T2 and fluid-attenuated inversion recovery sequences, and occasionally enhancing with gadolinium; (3) *brainstem encephalitis,* resulting in eye movement disorders (nystagmus, opsoclonus, supranuclear or nuclear paresis), cranial nerve paresis, dysarthria, dysphagia, and central autonomic dysfunction; (4) *cerebellar gait and limb ataxia*; (5) *myelitis*, which may cause lower or upper motor neuron symptoms, myoclonus, muscle rigidity, and spasms; and (6) *autonomic dysfunction* as a result of involvement of the neuraxis at multiple levels, including hypothalamus, brainstem, and autonomic nerves (see autonomic neuropathy). Cardiac arrhythmias, postural hypotension, or central hypoventilation are frequent causes of death in patients with encephalomyelitis.

Paraneoplastic encephalomyelitis and focal encephalitis are usually associated with SCLC, but many other cancers have also been reported. Patients with SCLC and these syndromes usually have anti-Hu antibodies in serum and CSF. Anti-CV_2/CRMP5 antibodies occur less frequently; some of these patients may develop chorea or uveitis. Antibodies to Ma proteins are associated with limbic and brainstem encephalitis and occasionally with cerebellar symptoms; prominent hypothalamic dysfunction, hypersomnia, and cataplexy can also occur. MRI abnormalities are frequent, including those described with limbic

TABLE 87-3 *A Guide to Antibody-Associated Paraneoplastic and Non-Paraneoplastic Syndromes*[a]

	Antibodies		
	Paraneoplastic		
Syndrome	*Frequent*	*Infrequent*	*Non-Paraneoplastic*
Limbic encephalitis	Ma2, Hu, CV_2/CRMP5	Tr, VGKC	VGKC
Cerebellar degeneration	Yo, Tr, P/Q VGCC, Hu, *Zic*, Ri, CV_2/CRMP5, Ma1-2	*mGluR1*; *MAZ*	Gliadin GAD
Hypothalamic, brainstem encephalitis	Ma2, Hu	CV_2/CRMP5	
Encephalomyelitis	Hu, *Zic*	CV_2/CRMP5, Ri, amphiphysin	
Chorea	CV_2/CRMP5		
Opsoclonus-myoclonus	Ri	Hu, Ma2, Yo,	*APC*
Stiff-person syndrome	Amphiphysin	*Gephyrin*, Ri	GAD
PNH (neuromyotonia)	VGKC		VGKC
Myasthenia gravis	AChR		AChR, MuSK
LEMS	P/Q-type VGCC	*MysB*	P/Q-type VGCC
Sensory neuronopathy	Hu		
Axonal sensorimotor neuropathy	Hu, CV_2/CRMP5		Monoclonal gammopathy (M protein)[b]
Autonomic neuropathy	Hu	CV_2/CRMP5, ganglionic AChR	Ganglionic AChR
Predominant sensory demyelinating neuropathy		MAG, ganglioside antibodies: often present with Waldenström's macroglobulinemia	MAG, ganglioside antibodies, often present with MGUS
Paraneoplastic retinopathy	Recoverin (CAR), anti-bipolar cell antibodies (*MAR*)	*Tubby-like protein 1*, *PNR*	

[a] Antibodies have been validated by more than one laboratory and/or the protein sequence of the target antigen is known.
[b] The M protein usually does not have specific antibody activity.
Note: *Italics* indicate that commercial testing for these antibodies is not available. PNH, peripheral nerve hyperexcitability; CAR, cancer-associated retinopathy; MAR, melanoma-associated retinopathy; PNR, photoreceptor-specific nuclear receptor; MGUS, monoclonal gammopathy of uncertain significance; VGKC, voltage-gated potassium channel; GAD, glutamic acid decarboxylase; AChR, acetylcholine receptor; LEMS, Lambert-Eaton myasthenic syndrome; VGCC, voltage-gated calcium channel; MAG, myelin-associated glycoprotein.

encephalitis and variable involvement of the hypothalamus, basal ganglia, or brainstem. The oncologic associations of these antibodies are shown in Table 87-2.

All types of paraneoplastic encephalitis and encephalomyelitis, except limbic encephalitis, respond poorly to treatment. Stabilization of symptoms or partial neurologic improvement may occasionally occur, particularly if there is a satisfactory response of the tumor to treatment. The roles of plasma exchange, IVIg, and immunosuppression have not been established. Rare patients with limbic encephalitis have shown dramatic improvement after treatment, but it is not known whether remission of the cancer, glucocorticoids, or IVIg was responsible.

PARANEOPLASTIC CEREBELLAR DEGENERATION This disorder is often preceded by a prodrome that may include dizziness, oscillopsia, blurry or double vision, nausea, and vomiting. A few days or weeks later, dysarthria, gait and limb ataxia, and variable dysphagia can appear. The examination usually shows downbeating nystagmus and, rarely, opsoclonus. Brainstem dysfunction, upgoing toes, or a mild neuropathy may occur, but more often the symptoms and signs are restricted to the cerebellum. Early in the course, MRI studies are usually normal; in some patients a transient enhancement of the cerebellar cortex has been noted. Later, the MRI typically reveals cerebellar atrophy. The disorder results from extensive degeneration of Purkinje cells, with variable involvement of other cerebellar cortical neurons, deep cerebellar nuclei, and spinocerebellar tracts. An immune-mediated pathogenesis is supported by CSF findings and biopsy studies obtained during the early stage of the disorder. The tumors more frequently involved are SCLC, cancer of the breast and ovary, and Hodgkin's lymphoma.

Anti-Yo antibodies in patients with breast and gynecologic cancers and anti-Tr antibodies in patients with Hodgkin's lymphoma are the two paraneoplastic antibodies typically associated with prominent or pure cerebellar degeneration. Antibodies to P/Q-type VGCC occur in some patients with SCLC and cerebellar dysfunction; only some of these patients develop LEMS. A subacute cerebellar ataxia can also be the presenting symptom of paraneoplastic encephalomyelitis; in this syndrome, symptoms of widespread CNS involvement eventually occur. Of note, a variable degree of cerebellar dysfunction can be associated with virtually any type of antibody-related PND of the CNS (Table 87-2). A number of single case reports have described neurologic improvement after tumor removal, plasma exchange, IVIg, cyclophosphamide, or glucocorticoids. However, large series of patients with well-defined antibody-positive paraneoplastic cerebellar degeneration show that these disorders rarely improve with any treatment.

PARANEOPLASTIC OPSOCLONUS-MYOCLONUS SYNDROME *Opsoclonus* is a disorder of eye movement characterized by involuntary, chaotic saccades that occur in all directions of gaze; it is frequently associated with myoclonus and ataxia. Opsoclonus-myoclonus may be cancer-related or idiopathic. When the cause is paraneoplastic, the tumors involved are usually cancer of the lung and breast in adults and neuroblastoma in children. The pathologic substrate of opsoclonus-myoclonus is unclear. The majority of SCLC patients do not harbor antineuronal antibodies. A small subset of patients with ataxia, opsoclonus, and other eye movement disorders develop anti-Ri antibodies; in rare instances muscle rigidity, autonomic dysfunction, and dementia also occur. The tumor most frequently involved in anti-Ri-associated syndromes is breast cancer; however, only 50% of patients with anti-Ri antibodies develop opsoclonus.

If the tumor is not successfully treated, the paraneoplastic opsoclonus-myoclonus syndrome in adults often progresses to encephalopathy, coma, and death. In addition to treating the tumor, symptoms may respond to immunotherapy (glucocorticoids and/or IVIg).

At least 50% of children with opsoclonus-myoclonus have an underlying neuroblastoma. Hypotonia, ataxia, behavioral changes, and irritability are frequent accompanying symptoms. Although some patients harbor anti-Hu antibodies, most are antibody-negative. Neurologic symptoms often improve with treatment of the tumor (including chemotherapy) and with glucocorticoids, adrenocorticotropic hormone (ACTH), plasma exchange, and IVIg. The response to treatment varies; patients who do not improve with glucocorticoids may respond to ACTH. Neurologic relapses are frequent, and many patients are left with psychomotor retardation and behavioral and sleep problems.

PARANEOPLASTIC SYNDROMES OF THE SPINAL CORD The number of reports of paraneoplastic spinal cord syndromes, such as *subacute motor neuronopathy* and *acute necrotizing myelopathy*, has decreased in recent years. This may represent a true decrease in incidence, due to improved

and prompt oncologic interventions, or may be because of the identification of nonparaneoplastic etiologies; e.g., subacute necrotizing myelopathy may occur with HSV infection, usually HSV-2.

Some patients with cancer develop *upper* or *lower motor neuron dysfunction* or both, resembling amyotrophic lateral sclerosis. Because paraneoplastic antibody markers are lacking, it is unclear whether these disorders have a paraneoplastic etiology or simply coincide with the presence of cancer. There are isolated case reports of cancer patients with motor neuron dysfunction who had neurologic improvement after tumor treatment. A more than coincidental association occurs between lymphoma and motor neuron dysfunction. A search for lymphoma should be undertaken in patients with a motor neuron syndrome who are found to have a monoclonal protein in serum or CSF or an increased protein concentration in the CSF.

Paraneoplastic myelitis may present with upper or lower motor neuron symptoms, segmental myoclonus, and rigidity. This syndrome can appear as the presenting manifestation of encephalomyelitis and may be associated with SCLC and serum anti-Hu, anti-CV_2/CRMP5, or anti-amphiphysin antibodies.

Paraneoplastic myelopathy can also produce several syndromes characterized by prominent muscle stiffness and rigidity. The spectrum ranges from focal symptoms in one or several extremities (*stiff-limb syndrome* or *stiff-person syndrome*) to a disorder that also affects the brainstem (known as *encephalomyelitis with rigidity*) and likely has a different pathogenesis.

PARANEOPLASTIC STIFF-PERSON SYNDROME This disorder is characterized by progressive muscle rigidity, stiffness, and painful spasms triggered by auditory, sensory, or emotional stimuli. Rigidity mainly involves the lower trunk and legs, but it can affect the upper extremities and neck. Symptoms improve with sleep and general anesthetics. Electrophysiologic studies demonstrate continuous motor unit activity. Antibodies associated with the stiff-person syndrome target proteins [glutamic acid decarboxylase (GAD), amphiphysin] involved in the function of inhibitory synapses utilizing γ-aminobutyric acid (GABA) or glycine as neurotransmitters. Paraneoplastic stiff-person syndrome and amphiphysin antibodies are often related to breast cancer. By contrast, antibodies to GAD may occur in some cancer patients but are much more frequently present in the non-paraneoplastic disorder. Optimal treatment of stiff-person syndrome requires therapy of the underlying tumor, glucocorticoids, and symptomatic use of drugs that enhance GABA-ergic transmission (diazepam, baclofen, sodium valproate, vigabatrin). A benefit of IVIg has been demonstrated for the non-paraneoplastic disorder but remains to be established for the paraneoplastic syndrome.

PARANEOPLASTIC SENSORY NEURONOPATHY OR DORSAL ROOT GANGLIONOPATHY This syndrome is characterized by sensory deficits that may be symmetric or asymmetric, painful dysesthesias, radicular pain, and decreased or absent reflexes. All modalities of sensation and any part of the body including face and trunk can be involved. Specialized sensations such as taste and hearing can also be affected. Electrophysiologic studies show decreased or absent sensory nerve potentials with normal or near-normal motor conduction velocities. Symptoms result from an inflammatory, likely immune-mediated, process that targets the dorsal root ganglia, causing neuronal loss, proliferation of satellite cells, and secondary degeneration of the posterior columns of the spinal cord. The dorsal nerve roots, and less frequently the anterior nerve roots and peripheral nerves, may also be involved.

This disorder often precedes or is associated with encephalomyelitis and autonomic dysfunction and has the same immunologic and oncologic associations, i.e., anti-Hu antibodies and SCLC. As with anti-Hu-associated encephalomyelitis, the therapeutic approach focuses on prompt treatment of the tumor. Glucocorticoids occasionally produce clinical stabilization or improvement. The benefit of IVIg and plasma exchange is not proved.

PARANEOPLASTIC PERIPHERAL NEUROPATHIES These disorders may develop any time during the course of the neoplastic disease. Neuropathies occurring at late stages of cancer or lymphoma usually cause mild to moderate sensorimotor deficits due to axonal degeneration of unclear etiology. These neuropathies are often masked by concurrent neurotoxicity from chemotherapy and other cancer therapies. In contrast, the neuropathies that develop in the early stages of cancer often show a rapid progression, sometimes with a relapsing and remitting course, and evidence of inflammatory infiltrates and axonal loss or demyelination in biopsy studies. If demyelinating features predominate (Chap. 363), IVIg or glucocorticoids may improve symptoms. These neuropathies are not usually associated with antineuronal antibodies. Occasionally anti-CV_2/CRMP5 antibodies are present; detection of anti-Hu suggests concurrent dorsal root ganglionitis.

Guillain-Barré syndrome and *brachial plexitis* have occasionally been reported in patients with lymphoma, but there is no clear evidence of a paraneoplastic association.

Malignant monoclonal gammopathies include: (1) multiple myeloma and sclerotic myeloma associated with IgG or IgA monoclonal proteins; and (2) Waldenström's macroglobulinemia, B cell lymphoma, and chronic B cell lymphocytic leukemia associated with IgM monoclonal proteins. These disorders may cause neuropathy by a variety of mechanisms, including compression of roots and plexuses by metastasis to vertebral bodies and pelvis, deposits of amyloid in peripheral nerves, and paraneoplastic mechanisms. The paraneoplastic variety has several distinctive features. Approximately half of patients with sclerotic myeloma develop a sensorimotor neuropathy with predominantly motor deficits, resembling a chronic inflammatory demyelinating neuropathy (Chap. 365); some patients develop elements of the POEMS syndrome (*p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy, *M* protein, *s*kin changes). Treatment of the plasmacytoma or sclerotic lesions usually improves the neuropathy. In contrast, the sensorimotor or sensory neuropathy associated with multiple myeloma rarely responds to treatment. Between 5 and 10% of patients with Waldenström's macroglobulinemia develop a distal symmetric sensorimotor neuropathy with predominant involvement of large sensory fibers. These patients may have IgM antibodies in their serum against myelin-associated glycoprotein (Chap. 365). In addition to treating the Waldenström's macroglobulinemia, other therapies may improve the neuropathy, including plasma exchange, IVIg, chlorambucil, cyclophosphamide, fludarabine, or rituximab.

Vasculitis of the nerve and muscle causes a painful symmetric or asymmetric distal sensorimotor neuropathy with variable proximal weakness. It predominantly affects elderly men and is associated with an elevated erythrocyte sedimentation rate and increased CSF protein concentration. SCLC and lymphoma are the primary tumors involved. Pathology demonstrates axonal degeneration and T cell infiltrates involving the small vessels of the nerve and muscle. Immunosuppressants (glucocorticoids and cyclophosphamide) often result in neurologic improvement.

Peripheral nerve hyperexcitability (*neuromyotonia* or *Isaacs' syndrome*) is characterized by spontaneous and continuous muscle fiber activity of peripheral nerve origin. Clinical features include cramps, muscle twitching (fasciculations or myokymia), stiffness, delayed muscle relaxation (pseudomyotonia), and spontaneous or evoked carpal or pedal spasms. The involved muscles may be hypertrophic, and some patients develop paresthesias and hyperhydrosis. CNS dysfunction, including mood changes, sleep disorder, or hallucinations, may occur. The electromyogram (EMG) shows fibrillations; fasciculations; and doublet, triplet, or multiplet single unit (myokymic) discharges that have a high intraburst frequency. An immune pathogenesis is suggested by the frequent presence of serum antibodies to VGKC. The disorder often occurs without cancer; if paraneoplastic, benign and malignant thymomas and SCLC are the usual tumors. Some patients with thymoma develop acetylcholine receptor antibodies with or without myasthenia gravis. Diphenylhydantoin, carbamazepine, and plasma exchange improve symptoms.

The *cramps-fasciculation syndrome* resembes neuromyotonia, but

the EMG does not show myokymic discharges. It may also occur with thymoma, lung cancer, and antibodies to VGKC.

Paraneoplastic autonomic neuropathy usually develops as a component of other disorders, such as LEMS and encephalomyelitis. It may rarely occur as a pure or predominantly autonomic neuropathy with adrenergic or cholinergic dysfunction at the pre- or postganglionic levels. Patients can develop several life-threatening complications, such as gastrointestinal paresis with pseudoobstruction, cardiac dysrhythmias, and postural hypotension. Other symptoms include dry mouth, erectile dysfunction, anhidrosis, and sphincter dysfunction. The disorder has been reported to occur in association with several tumors, including SCLC, cancer of the pancreas or testis, carcinoid tumors, and lymphoma. Because autonomic symptoms can also be the presenting feature of encephalomyelitis, serum anti-Hu and anti-CV_2/CRMP5 antibodies should also be sought. Serum antibodies to ganglionic acetylcholine receptors have been reported in this syndrome, but they also occur without a cancer association. (See also Table 354-6).

LAMBERT-EATON MYASTHENIC SYNDROME →*LEMS is discussed in Chap. 366.*

MYASTHENIA GRAVIS →*For discussion of myasthenia gravis, see Chap. 366.*

POLYMYOSITIS-DERMATOMYOSITIS →*Polymyositis and dermatomyositis are discussed in detail in Chap. 369.*

ACUTE NECROTIZING MYOPATHY Patients with this syndrome develop myalgias and rapid progression of weakness involving the extremities and the pharyngeal and respiratory muscles, often resulting in death. Serum muscle enzymes are elevated, and muscle biopsy shows extensive necrosis with minimal or absent inflammation and sometimes deposits of complement. The disorder occurs as a paraneoplastic manifestation of a variety of cancers including SCLC and cancer of the gastrointestinal tract, breast, kidney, and prostate, among others. Glucocorticoids or treatment of the underlying tumor rarely control the disorder.

PARANEOPLASTIC VISUAL SYNDROMES This group of disorders involves the retina and, less frequently, the uvea and optic nerves. The term *cancer-associated retinopathy* is used to describe paraneoplastic cone and rod dysfunction characterized by photosensitivity, progressive loss of vision and color perception, central or ring scotomas, night blindness, and attenuation of photopic and scotopic responses in the electroretinogram (ERG). The most commonly associated tumor is SCLC. Melanoma-associated retinopathy affects patients with metastatic cutaneous melanoma. Patients develop the acute onset of night blindness and shimmering, flickering, or pulsating photopsias that often progress to visual loss. The ERG demonstrates reduction in the b-wave amplitude. Paraneoplastic optic neuritis and uveitis are very uncommon and can develop in association with encephalomyelitis. Some patients with paraneoplastic uveitis harbor anti-CV_2/CRMP5 antibodies.

Some paraneoplastic retinopathies are associated with serum antibodies that specifically react with the subset of retinal cells undergoing degeneration, supporting an immune-mediated pathogenesis (Tables 87-2 and 87-3). Paraneoplastic retinopathies usually fail to improve with treatment, although rare responses to glucocorticoids, plasma exchange, and IVIg have been reported.

88 ONCOLOGIC EMERGENCIES

Rasim Gucalp, Janice Dutcher

Emergencies in patients with cancer may be classified into three groups: pressure or obstruction caused by a space-occupying lesion, metabolic or hormonal problems (paraneoplastic syndromes, Chap. 86), and complications arising from the effects of treatment.

STRUCTURAL-OBSTRUCTIVE ONCOLOGIC EMERGENCIES

SUPERIOR VENA CAVA SYNDROME Superior vena cava syndrome (SVCS) is the clinical manifestation of superior vena cava (SVC) obstruction, with severe reduction in venous return from the head, neck, and upper extremities. Malignant tumors, such as lung cancer, lymphoma, and metastatic tumors, are responsible for more than 90% of all SVCS cases. Lung cancer, particularly of small-cell and squamous-cell histologies, accounts for approximately 85% of all cases of malignant origin. In young adults, malignant lymphoma is a leading cause of SVCS. Hodgkin's lymphoma involves the mediastinum more commonly than other lymphomas but rarely causes SVCS. When SVCS is noted in a young man with a mediastinal mass, the differential diagnosis is lymphoma vs primary mediastinal germ cell tumor. Metastatic cancers to the mediastinum, such as testicular and breast carcinomas, account for a small proportion of cases. Other causes include benign tumors, aortic aneurysm, thyroid enlargement, thrombosis, and fibrosing mediastinitis caused by prior irradiation or histoplasmosis.

Patients with SVCS usually present with neck and facial swelling (especially around the eyes), dyspnea, and cough. Other symptoms include hoarseness, tongue swelling, headaches, nasal congestion, epistaxis, hemoptysis, dysphagia, pain, dizziness, syncope, and lethargy. Bending forward or lying down may aggravate the symptoms. The characteristic physical findings are dilated neck veins, an increased number of collateral veins covering the anterior chest wall, cyanosis, and edema of the face, arms, and chest. More severe cases include proptosis, glossal and laryngeal edema, and obtundation. The clinical picture is milder if the obstruction is located above the azygos vein.

Signs and symptoms of cerebral and/or laryngeal edema, though rare, are associated with a poorer prognosis and require urgent evaluation. Seizures may be related to brain metastases rather than cerebral edema from venous occlusion. Patients with small cell lung cancer and SVCS have a higher incidence of brain metastases than those without SVCS.

Cardiorespiratory symptoms at rest, particularly with positional changes, suggest significant airway and vascular obstruction and limited physiologic reserve. Cardiac arrest or respiratory failure can occur, particularly in patients receiving sedatives or undergoing general anesthesia.

The diagnosis of SVCS is a clinical one. The most significant chest radiographic finding is widening of the superior mediastinum, most commonly on the right side. Pleural effusion occurs in only 25% of patients, often on the right side. However, a normal chest radiograph is still compatible with the diagnosis if other characteristic findings are present. Computed tomography (CT) provides the most reliable view of the mediastinal anatomy. The diagnosis of SVCS requires diminished or absent opacification of central venous structures with prominent collateral venous circulation. Magnetic resonance imaging (MRI) has no advantages over CT. Invasive procedures, including bronchoscopy, percutaneous needle biopsy, mediastinoscopy, and even thoracotomy, can be performed by a skilled clinician without any major risk of bleeding. For patients with a known cancer, a detailed workup usually is not necessary, and appropriate treatment may be started after obtaining a CT scan of the thorax. For those with no

C

FIGURE 88-1 *A.* Chest radiographs of a 59-year-old man with recurrent SVCS caused by non-small cell lung cancer showing right paratracheal mass with right pleural effusion. *B.* Computed tomography of same patient demonstrating obstruction of SVC with thrombosis (arrow) by the lung cancer (square) and collaterals (arrowheads). *C.* Balloon angioplasty (arrowhead) with walstent (arrow) in same patient.

history of malignancy, a detailed evaluation is essential to rule out benign causes and determine a specific diagnosis to direct the appropriate therapy.

TREATMENT

The one potentially life-threatening complication of a superior mediastinal mass is tracheal obstruction. Upper airway obstruction demands emergent therapy. Diuretics with a low salt diet, head elevation, and oxygen may produce temporary symptomatic relief. Glucocorticoids may be useful at shrinking lymphoma masses; they are of no benefit in patients with lung cancer.

Radiation therapy is the primary treatment for SVCS caused by non-small cell lung cancer and other metastatic solid tumors. Chemotherapy is effective when the underlying cancer is small cell carcinoma of the lung or lymphoma. Recurrent SVCS occurs in 10 to 30% of patients after initial therapy; it may be palliated with the use of intravascular self-expanding stents (Fig. 88-1). Early stenting may be necessary in patients with severe symptoms; however, the prompt increase in venous return after stenting may precipitate heart failure and pulmonary edema. Surgery may provide immediate relief for patients in whom a benign process is the cause.

Clinical improvement occurs in most patients, although this improvement may be due to the development of adequate collateral circulation. The mortality associated with SVCS does not relate to caval obstruction, but rather to the underlying cause.

SVCS and Central Venous Catheters in Adults The use of long-term central venous catheters has become common practice in patients with cancer. Major vessel thrombosis may occur. In these cases, catheter removal should be combined with anticoagulation to prevent embolization. SVCS in this setting, if detected early, can be treated by fibrinolytic therapy without sacrificing the catheter. Warfarin (1 mg/d) reduces the incidence of thrombosis without altering coagulation tests.

PERICARDIAL EFFUSION/TAMPONADE Malignant pericardial disease is found at autopsy in 5–10% of patients with cancer, most frequently with lung cancer, breast cancer, leukemias, and lymphomas. Cardiac tamponade as the initial presentation of extrathoracic malignancy is rare. The origin is not malignancy in about 50% of cancer patients with symptomatic pericardial disease, but can be related to irradiation, drug-induced pericarditis, hypothyroidism, idiopathic pericarditis, infection, or autoimmune diseases. Two types of radiation pericarditis occur: an acute inflammatory, effusive pericarditis occurring within months of irradiation, which usually resolves spontaneously, and a chronic effusive pericarditis that may appear up to 20 years after radiation therapy and is accompanied by a thickened pericardium.

Most patients with pericardial metastasis are asymptomatic. However, the common symptoms are dyspnea, cough, chest pain, orthopnea, and weakness. Pleural effusion, sinus tachycardia, jugular venous distension, hepatomegaly, peripheral edema, and cyanosis are the most frequent physical findings. Relatively specific diagnostic findings, such as paradoxical pulse, diminished heart sounds, pulsus alternans (pulse waves alternating between those of greater and lesser amplitude with successive beats), and friction rub are less common than with nonmalignant pericardial disease. Chest radiographs and ECG reveal abnormalities in 90% of patients, but half of these abnormalities are nonspecific. Echocardiography is the most helpful diagnostic test. Peri-

cardial fluid may be serous, serosanguineous, or hemorrhagic, and cytologic examination of pericardial fluid is diagnostic in most patients. False negative cytology may occur in patients with lymphoma and mesothelioma.

TREATMENT

Pericardiocentesis with or without the introduction of sclerosing agents, the creation of a pericardial window, complete pericardial stripping, cardiac irradiation, or systemic chemotherapy are effective treatments. Acute pericardial tamponade with life-threatening hemodynamic instability requires immediate drainage of fluid. This can be quickly achieved by pericardiocentesis. Alternatively, subxiphoid pericardiotomy can be performed in 45 min under local anesthesia. Thoracoscopic pericardial fenestration can be employed for benign causes; however, 60% of malignant pericardial effusions recur after this procedure.

INTESTINAL OBSTRUCTION Intestinal obstruction and reobstruction are common problems in patients with advanced cancer, particularly colorectal or ovarian carcinoma. However, other cancers, such as lung or breast cancer and melanoma, can metastasize within the abdomen, leading to intestinal obstruction. Typically, obstruction occurs at multiple sites. Melanoma has a predilection to involve the small bowel; this involvement may be isolated and resection may result in prolonged survival. Intestinal pseudoobstruction is caused by infiltration of the mesentery or bowel muscle by tumor, involvement of the celiac plexus, or paraneoplastic neuropathy in patients with small cell lung cancer. Paraneoplastic neuropathy is associated with IgG antibodies reactive to neurons of the myenteric and submucosal plexuses of the jejunum and stomach. Ovarian cancer can lead either to authentic luminal obstruction or to pseudoobstruction that results when circumferential invasion of a bowel segment arrests the forward progression of peristaltic contractions.

The onset of obstruction is usually insidious. Pain is the most common symptom and is usually colicky in nature. Pain can also be due to abdominal distention, tumor masses, or hepatomegaly. Vomiting can be intermittent or continuous. Patients with complete obstruction usually have constipation. Physical examination may reveal abdominal distention with tympany, ascites, visible peristalsis, high-pitched bowel sounds, and tumor masses. Erect plain abdominal films may reveal multiple air-fluid levels and dilation of the small or large bowel. Acute cecal dilation to more than 12 to 14 cm is considered a surgical emergency because of the high likelihood of rupture. CT is useful in differentiating benign from malignant causes of obstruction in patients who have undergone surgery for malignancy. Malignant obstruction is suggested by a mass at the site of obstruction or prior surgery, adenopathy, or an abrupt transition zone and irregular bowel thickening at the obstruction site. Benign obstruction is more likely when CT shows mesenteric vascular changes, a large volume of ascites, or a smooth transition zone and smooth bowel thickening at the obstruction site. The prognosis for the patient with cancer who develops intestinal obstruction is poor; median survival is 3 to 4 months. About 25–30% are found to have intestinal obstruction due to causes other than cancer. Adhesions from previous operations are a common benign cause. Ileus induced by vincristine is another reversible cause.

TREATMENT

The management of intestinal obstruction in patients with advanced malignancy depends on the extent of the underlying malignancy and the functional status of the major organs. The initial management should include surgical evaluation. Operation is not always successful and may lead to further complications with a substantial mortality rate (10 to 20%). Self-expanding metal stents placed in the gastric outlet, duodenum, proximal jejunum, colon, or rectum may palliate obstructive symptoms at those sites without major surgery. Patients known to have advanced intraabdominal malignancy should receive a prolonged course of conservative management, including nasogastric decompression. Treatment with antiemetics, antispasmodics, and analgesics may allow patients to remain outside the hospital. The somatostatin analogue octreotide may relieve obstructive symptoms through its inhibitory effect on gastrointestinal secretion.

URINARY OBSTRUCTION Urinary obstruction may occur in patients with prostatic or gynecologic malignancies, particularly cervical carcinoma, or metastatic disease from other primary sites such as carcinomas of the breast, stomach, lung, colon, and pancreas, and lymphomas. Radiation therapy to pelvic tumors may cause fibrosis and subsequent ureteral obstruction. Bladder outlet obstruction is usually due to prostate and cervical cancers and may lead to bilateral hydronephrosis and renal failure.

Flank pain is the most common symptom. Persistent urinary tract infection, persistent proteinuria, or hematuria in patients with cancer should raise suspicion of ureteral obstruction. Total anuria and/or anuria alternating with polyuria may occur. A slow, continuous rise in the serum creatinine level necessitates immediate evaluation. Renal ultrasound is the safest and cheapest way to identify hydronephrosis. The function of an obstructed kidney can be evaluated by a nuclear scan. CT can reveal the point of obstruction and identify a retroperitoneal mass or adenopathy.

TREATMENT

Obstruction associated with flank pain, sepsis, or fistula formation is an indication for immediate palliative urinary diversion. Internal ureteral stents can be placed under local anesthesia. Percutaneous nephrostomy offers an alternative approach for drainage. In the case of bladder outlet obstruction due to malignancy, a suprapubic cystostomy can be used for urinary drainage.

MALIGNANT BILIARY OBSTRUCTION This common clinical problem can be caused by a primary carcinoma arising in the pancreas, ampulla of Vater, bile duct, or liver or by metastatic disease to the periductal lymph nodes or liver parenchyma. The most common metastatic tumors causing biliary obstruction are gastric, colon, breast, and lung cancers. Jaundice, light-colored stools, dark urine, pruritus, and weight loss due to malabsorption are usual symptoms. Pain and secondary infection are uncommon in malignant biliary obstruction. Ultrasound, CT, or percutaneous transhepatic or endoscopic retrograde cholangiography will identify the site and nature of the biliary obstruction.

TREATMENT

Palliative intervention is indicated only in patients with disabling pruritus resistant to medical treatment, severe malabsorption, or infection. Stenting under radiographic control, surgical bypass, or radiation therapy with or without chemotherapy may alleviate the obstruction. The choice of modality should be based on the site of obstruction (proximal versus distal), the type of tumor (sensitive to radiotherapy, chemotherapy, or neither), and the general condition of the patient. In the absence of pruritus, biliary obstruction may be a largely asymptomatic cause of death.

SPINAL CORD COMPRESSION Spinal cord compression occurs in 5–10% of patients with cancer. Epidural tumor is the first manifestation of malignancy in about 10% of patients. The underlying cancer is usually identified during the initial evaluation; lung cancer is most commonly the primary malignancy.

Metastatic tumor involves the vertebral column more often than any other part of the bony skeleton. Lung, breast, and prostate cancer are the most frequent offenders. Multiple myeloma also has a high incidence of spine involvement. Lymphomas, melanoma, renal cell cancer, and genitourinary cancers also cause cord compression. The thoracic spine is the most common site (70%), followed by the lumbosacral spine (20%) and the cervical spine (10%). Involvement of multiple sites is most frequent in patients with breast and prostatic

carcinoma. Cord injury develops when metastases to the vertebral body or pedicle enlarge and compress the underlying dura. Another cause of cord compression is direct extension of a paravertebral lesion through the intervertebral foramen. These cases usually involve a lymphoma, myeloma, or pediatric neoplasm. Parenchymal spinal cord metastasis due to hematogenous spread is rare.

Expanding extradural tumors induce injury through several mechanisms. Obstruction of the epidural venous plexus leads to edema. Local production of inflammatory cytokines enhances blood flow and edema formation. Compression compromises blood flow leading to ischemia.

The most common initial symptom in patients with spinal cord compression is localized back pain and tenderness due to involvement of vertebrae by tumor. Pain is usually present for days or months before other neurologic findings appear. It is exacerbated by movement and by coughing or sneezing. It can be differentiated from the pain of disk disease by the fact that it worsens when the patient is supine. Radicular pain is less common than localized back pain and usually develops later. Radicular pain in the cervical or lumbosacral areas may be unilateral or bilateral. Radicular pain from the thoracic roots is often bilateral and is described by patients as a feeling of tight, band-like constriction around the thorax and abdomen. Typical cervical radicular pain radiates down the arm; in the lumbar region, the radiation is down the legs. Lhermitte's sign, a tingling or electric sensation down the back, upper and lower limbs upon flexing or extending the neck, may be an early sign of cord compression. Loss of bowel or bladder control may be the presenting symptom, but usually occurs late in the course.

On physical examination, pain induced by straight leg raising, neck flexion, or vertebral percussion may help to determine the level of cord compression. Patients develop numbness and paresthesias in the extremities or trunk. Loss of sensibility to pinprick is as common as loss of sensibility to vibration or position. The upper limit of the zone of sensory loss is often one or two vertebrae below the site of compression. Motor findings include weakness, spasticity, and abnormal muscle stretching. An extensor plantar reflex reflects significant compression. Deep tendon reflexes may be brisk. Motor and sensory loss usually precede sphincter disturbance. Patients with autonomic dysfunction may present with decreased anal tonus, decreased perineal sensibility, and a distended bladder. The absence of the anal wink reflex or the bulbocavernosus reflex confirms cord (conus or cauda equina) involvement. In doubtful cases, evaluation of post-voiding urinary residual volume can be helpful. A residual volume of more than 150 mL suggests bladder dysfunction. Autonomic dysfunction is an unfavorable prognostic factor. Patients with progressive neurologic symptoms should have frequent neurologic examinations and rapid therapeutic intervention. Other illnesses that may mimic cord compression include osteoporotic vertebral collapse, disc disease, pyogenic abscess or vertebral tuberculosis, radiation myelopathy, neoplastic leptomeningitis, benign tumors, epidural hematoma, and spinal lipomatosis.

Patients with cancer who develop back pain should be evaluated for spinal cord compression as quickly as possible (Fig. 88-2). Treatment is more often successful in patients who are ambulatory and still have sphincter control at the time treatment is initiated. Patients should have a neurologic examination and plain films of the spine. Those whose physical examination suggests cord compression should receive dexamethasone (24 mg intravenously every 6 h), starting immediately.

Erosion of the pedicles (the "winking owl" sign) is the earliest radiologic finding of vertebral tumor. Other radiographic changes include increased intrapedicular distance, vertebral destruction, lytic or sclerotic lesions, scalloped vertebral bodies, and vertebral body collapse. Vertebral collapse is not a reliable indicator of the presence of tumor; about 20% of cases of vertebral collapse, particularly those in older patients and postmenopausal women, are due not to cancer but to osteoporosis. Also, a normal appearance on plain films of the spine does not exclude the diagnosis of cancer. The role of bone scans in the detection of cord compression is not clear; this method is sensitive but less specific than spinal radiography.

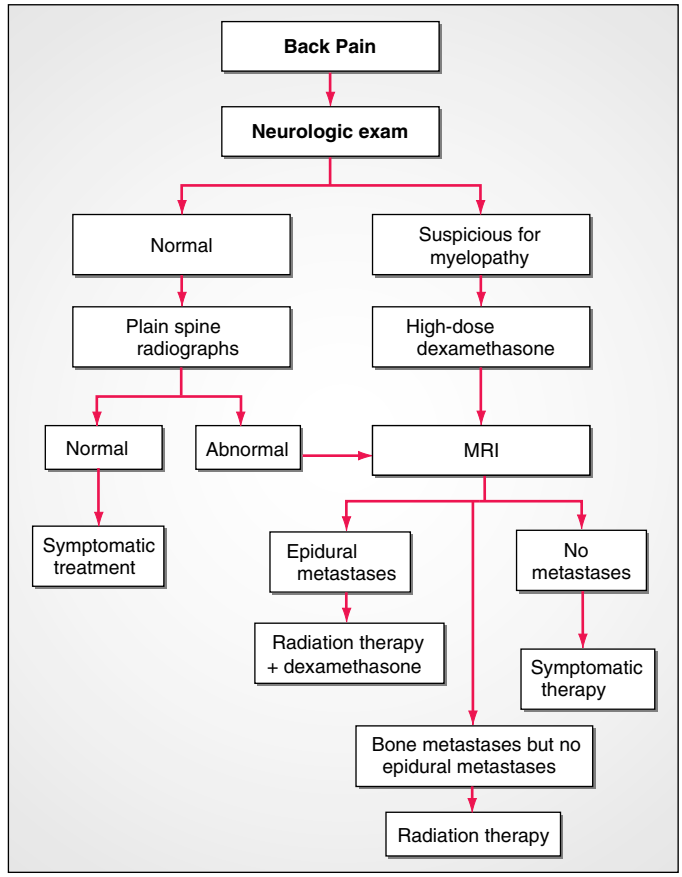

FIGURE 88-2 Management of cancer patients with back pain.

The full-length image of the cord provided by MRI is useful. Multiple epidural metastases are noted in 25% of patients with cord compression and their presence influences treatment plans. On T1-weighted images, good contrast is noted between the cord, cerebrospinal fluid, and extradural lesions. Owing to its sensitivity in demonstrating the replacement of bone marrow by tumor, MRI can show which parts of a vertebra are involved by tumor (the body, pedicle, lamina, spinous process). MRI also visualizes intraspinal extradural masses compressing the cord. T2-weighted images are most useful for the demonstration of intramedullary pathology. Gadolinium-enhanced MRI can help to delineate intramedullary disease. MRI is as good as or better than myelography plus postmyelogram CT in detecting metastatic epidural disease with cord compression. Myelography should be reserved for patients who have poor MR images or who cannot undergo MRI promptly. CT in conjunction with myelography enhances the detection of small areas of spinal destruction.

In patients with cord compression and an unknown primary tumor, a simple workup including chest radiography, mammography, measurement of prostate-specific antigen, and abdominal CT usually reveals the underlying malignancy.

TREATMENT

The treatment of patients with spinal cord compression is aimed at relief of pain and restoration of neurologic function (Fig. 88-2).

Radiation therapy plus glucocorticoids is generally the initial treatment of choice for spinal cord compression. Up to 75% of patients treated when still ambulatory remain ambulatory, but only 10% of patients with paraplegia recover walking capacity. Indications for surgical intervention include unknown etiology, failure of radiation therapy, a radioresistant tumor type (e.g., melanoma or renal cell cancer), pathologic fracture dislocation, and rapidly evolving neurologic symp-

toms. Until recently, laminectomy was the standard operation for metastatic spinal cord compression, although results were poor. At present, laminectomy should be used only for tissue diagnosis and for the removal of posteriorly localized epidural deposits in the absence of vertebral disease. Because most cases of epidural spinal cord compression are due to anterior or anterolateral extradural disease, resection of the anterior vertebral body along with the tumor, followed by spinal stabilization, has achieved good results and low mortality rate. Chemotherapy may have a role in patients with chemosensitive tumors who have had prior radiation therapy to the same region and who are not candidates for surgery. Most patients with prostate cancer who develop cord compression have already had hormonal therapy; however, for those who have not, androgen deprivation is combined with surgery and radiation therapy.

Patients with metastatic vertebral tumors may benefit from percutaneous vertebroplasty, the injection of acrylic cement into a collapsed vertebra to stabilize the fracture. Pain palliation is common and local antitumor effects have been noted. Cement leakage may cause symptoms in about 10% of patients.

The histology of the tumor is an important determinant of both recovery and survival. Rapid onset and quick progression are poor prognostic features.

INCREASED INTRACRANIAL PRESSURE About 25% of patients with cancer die with intracranial metastases. The cancers that most often metastasize to the brain are lung and breast cancers and melanoma. Brain metastases often occur in the presence of systemic disease, and they frequently cause major symptoms, disability, and early death.

The signs and symptoms of a metastatic brain tumor are similar to those of other intracranial expanding lesions: headache, nausea, vomiting, behavioral changes, seizures, and focal, progressive neurologic changes. Occasionally the onset is abrupt, resembling a stroke, with the sudden appearance of headache, nausea, vomiting, and neurologic deficits. This picture is usually due to hemorrhage into the metastasis. Melanoma, germ cell tumors, and renal cell cancers have a particularly high incidence of intracranial bleeding. The tumor mass and surrounding edema may cause obstruction of the circulation of cerebrospinal fluid, with resulting hydrocephalus. Patients with increased intracranial pressure may have papilledema with visual disturbances and neck stiffness. As the mass enlarges, brain tissue may be displaced through the fixed cranial openings, producing various herniation syndromes.

CT and MRI are equally effective in the diagnosis of brain metastases. CT with contrast should be used as a screening procedure. The CT scan shows brain metastases as multiple enhancing lesions of various sizes with surrounding areas of low-density edema. If a single lesion or no metastases are visualized by contrast-enhanced CT, MRI of the brain should be performed. Gadolinium-enhanced MRI is more sensitive than CT at revealing meningeal involvement and small lesions, particularly in the brainstem or cerebellum.

℞ TREATMENT

If signs and symptoms of brain herniation (particularly headache, drowsiness, and papilledema) are present, the patient should be intubated and hyperventilated to maintain P_{CO_2} between 25 and 30 mmHg and should receive infusions of mannitol (1 to 1.5 g/kg) every 6 h. Dexamethasone is the best initial treatment for all symptomatic patients with brain metastases (see above). Patients with multiple lesions should receive whole-brain radiation therapy. Patients with a single brain metastasis and with controlled extracranial disease may be treated with surgical excision followed by whole-brain radiation therapy, especially if they are younger than 60 years. Radioresistant tumors should be resected if possible. Stereotactic radiosurgery is an effective treatment for inaccessible or recurrent lesions. With a gamma knife or linear accelerator, multiple small, well-collimated beams of ionizing radiation destroy lesions seen on MRI. Some patients with increased intracranial pressure associated with hydrocephalus may benefit from shunt placement. If neurological deterioration is not reversed with medical therapy, ventriculotomy to remove cerebrospinal fluid (CSF) or craniotomy to remove tumors or hematomas may be necessary.

NEOPLASTIC MENINGITIS Tumor involving the leptomeninges is a complication of both primary tumors of the central nervous system (CNS) and tumors that metastasize to the CNS. The incidence is estimated at 3 to 8% of patients with cancer. Melanoma, breast and lung cancer, lymphoma (including AIDS-associated), and acute leukemia are the most common causes.

Patients typically present with multifocal neurologic signs and symptoms including headache, gait abnormality, mental changes, nausea, vomiting, seizures, back or radicular pain, and limb weakness. Signs include cranial nerve palsies, extremity weakness, paresthesia, and decreased deep tendon reflexes.

Diagnosis is made by demonstrating malignant cells in the cerebrospinal fluid (CSF); however, up to 40% of patients may have false negative CSF cytology. An elevated CSF protein level is nearly always present (except in HTLV-1-associated adult T cell leukemia). Patients with neurologic signs and symptoms consistent with neoplastic meningitis who have a negative CSF cytology but an elevated CSF protein level should have the spinal tap repeated at least three times for repeated cytologic examination before the diagnosis is rejected. MRI findings suggestive of neoplastic meningitis include leptomeningeal, subependymal, dural or cranial nerve enhancement, superficial cerebral lesions, and communicating hydrocephalus. Spinal cord imaging by MRI is a necessary component of the evaluation of non-leukemia neoplastic meningitis as ~20% of patients have cord abnormalities including intradural enhancing nodules that are diagnostic for leptomeningeal involvement. Cauda equina lesions are common but lesions may be seen anywhere in the spinal canal. Radiolabeled CSF flow studies are abnormal in up to 70% of patients with neoplastic meningitis; ventricular outlet obstruction, abnormal flow in the spinal canal, or impaired flow over the cerebral convexities may affect distribution of intrathecal chemotherapy resulting in decreased efficacy or increased toxicity. Radiation therapy may correct CSF flow abnormalities before use of intrathecal chemotherapy.

The development of neoplastic meningitis usually occurs in the setting of uncontrolled cancer outside the CNS; thus, prognosis is poor (median survival 10 to 12 weeks). However, treatment of the neoplastic meningitis may successfully alleviate symptoms and control the CNS spread.

℞ TREATMENT

Intrathecal chemotherapy, usually methotrexate, cytarabine, or thiotepa, is delivered by lumbar puncture or by an intraventricular reservoir (Ommaya) three times a week until the CSF is free of malignant cells. Then injections are given twice a week for a month and then weekly for a month. An extended release preparation of cytarabine (Depocyte) has a longer half-life and is more effective than regular formulations. Among solid tumors, breast cancer responds best to therapy. Patients with neoplastic meningitis from either acute leukemia or lymphoma may be cured of their CNS disease if the systemic disease can be eliminated.

SEIZURES Seizures occurring in a patient with cancer can be caused by the tumor itself, by metabolic disturbances, by radiation injury, by cerebral infarctions, by chemotherapy-related encephalopathies, or by CNS infections. Metastatic disease to the CNS is the most common cause of seizures in patients with cancer. However, seizures occur more frequently in primary brain tumors than in metastatic brain lesions. Seizures are a presenting symptom of CNS metastasis in 6 to 29% of cases. Approximately 10% of patients with CNS metastasis eventually develop seizures. The presence of frontal lesions correlates with early seizures, and the presence of hemispheric symptoms increases the risk for late seizures. Both early and late seizures are uncommon in patients with posterior fossa lesions. Seizures are also

common in patients with CNS metastases from melanoma. Very rarely, cytotoxic drugs such as etoposide, busulfan, and chlorambucil cause seizures.

TREATMENT

Patients in whom seizures due to CNS metastases have been demonstrated should receive anticonvulsive treatment with diphenylhydantoin. Prophylactic anticonvulsant therapy is not recommended unless the patient is at a high risk for late seizures (melanoma primary, hemorrhagic metastases, treatment with radiosurgery). In those patients, serum diphenylhydantoin levels should be monitored closely and the dosage adjusted according to serum levels. Phenytoin induces the hepatic metabolism of dexamethasone, reducing its half-life, while dexamethasone may decrease phenytoin levels. Most anti-seizure medications alter the metabolism of antitumor agents.

PULMONARY AND INTRACEREBRAL LEUKOCYTOSTASIS Hyperleukocytosis and the leukostasis syndrome associated with it is a potentially fatal complication of acute leukemia (particularly myeloid leukemia) that can occur when the peripheral blast cell count is greater than 100,000/mL. The frequency of hyperleukocytosis is 5–13% in AML and 10–30% in acute lymphoid leukemia; however, leukostasis is rare in lymphoid leukemia. At such high blast cell counts, blood viscosity is increased, blood flow is slowed by aggregates of tumor cells, and the primitive myeloid leukemic cells are capable of invading through endothelium and causing hemorrhage. Brain and lung are most commonly affected. Patients with brain leukostasis may experience stupor, headache, dizziness, tinnitus, visual disturbances, ataxia, confusion, coma, or sudden death. Administration of 600 cGy of whole-brain irradiation can protect against this complication and can be followed by rapid institution of antileukemic therapy. Pulmonary leukostasis may present as respiratory distress, hypoxemia, and progress to respiratory failure. Chest radiographs may be normal but usually show interstitial or alveolar infiltrates. Leukapheresis may be helpful in decreasing circulating blast counts. Treatment of the leukemia can result in pulmonary hemorrhage from lysis of blasts in the lung, called "leukemic cell lysis pneumopathy." Intravascular volume depletion and unnecessary blood transfusions may increase blood viscosity and worsen leukostasis syndrome. Leukostasis is not a feature of the high white cell counts associated with chronic lymphoid or chronic myeloid leukemia.

When acute promyelocytic leukemia is treated with differentiating agents like tretinoin and arsenic trioxide, cerebral or pulmonary leukostasis may occur. This complication can be largely avoided by using cytotoxic chemotherapy together with the differentiating agents.

HEMOPTYSIS Hemoptysis may be caused by nonmalignant conditions, but lung cancer accounts for a large proportion of cases. Up to 20% of patients with lung cancer have hemoptysis some time in their course. Endobronchial metastases from carcinoid tumors, breast, colon, kidney cancer, and melanoma may also cause hemoptysis. The volume of bleeding is often difficult to gauge. Massive hemoptysis is defined as more than 600 mL of blood produced in 48 h. When respiratory difficulty occurs, hemoptysis should be treated emergently. Often patients can tell where the bleeding is occurring. They should be placed bleeding side down, given supplemental oxygen, and subjected to emergency bronchoscopy. If the site of the lesion is detected, either the patient undergoes a definitive surgical procedure or the lesion is treated with a neodymium:yttrium-aluminum-garnet (Nd:YAG) laser. The surgical option is preferred. Bronchial artery embolization may control brisk bleeding in 75 to 90% of patients, permitting the definitive surgical procedure to be done more safely. Embolization without definitive surgery is associated with rebleeding in 20 to 50% of patients. Recurrent hemoptysis usually responds to a second embolization procedure. A post-embolization syndrome characterized by pleuritic pain, fever, dysphagia, and leukocytosis may occur; it lasts 5–7 days and resolves with symptomatic treatment. Bronchial or esophageal wall necrosis, myocardial infarction, and spinal cord infarction are rare complications.

Pulmonary hemorrhage with or without hemoptysis in hematologic malignancies is often associated with fungal infections, particularly *Aspergillus* sp. After granulocytopenia resolves, the lung infiltrates in aspergillosis may cavitate and cause massive hemoptysis. Thrombocytopenia and coagulation defects should be corrected, if possible. Surgical evaluation is recommended in patients with aspergillosis-related cavitary lesions.

AIRWAY OBSTRUCTION Generally, airway obstruction refers to a blockage at the level of the mainstem bronchi or above. It may result either from intraluminal tumor growth or from extrinsic compression of the airway. The most common cause of malignant upper airway obstruction is invasion from an adjacent primary tumor, most commonly lung cancer, followed by esophageal, thyroid, and mediastinal malignancies.Extrathoracic primary tumors such as renal cell, colon, or breast cancer can cause airway obtruction through endobronchial and/or mediastinal lymph node metastases. Patients may present with dyspnea, hemoptysis, stridor, wheezing, intractable cough, post-obstructive pneumonia, or hoarseness. Chest radiographs usually demonstrate obstructing lesions. CT scans provide more detailed information about the extent of tumor. Cool humidified oxygen, glucocorticoids, and ventilation with a mixture of helium and oxygen (Heliox) may provide temporary relief. If the obstruction is proximal to the larynx, a tracheostomy may be life-saving. For more distal obstructions, particularly intrinsic lesions incompletely obstucting the airway, bronchoscopy with laser treatment, photodynamic therapy, or stenting can produce immediate relief in most patients. However, radiation therapy (either external-beam irradiation or brachytherapy) given together with glucocorticoids may also open the airway. Symptomatic extrinsic compression may be palliated by stenting. Patients with primary airway tumors such as squamous cell carcinoma, carcinoid tumor, adenocystic carcinoma, or non-small cell lung cancer should have surgery.

METABOLIC EMERGENCIES

HYPERCALCEMIA Hypercalcemia is the most common paraneoplastic syndrome. →***Its pathogenesis and management are fully discussed in Chaps. 86 and 332.***

SYNDROME OF INAPPROPRIATE SECRETION OF ANTIDIURETIC HORMONE (SIADH) Hyponatremia is a common electrolyte abnormality in cancer patients, and SIADH is the most common cause of hyponatremia among patients with cancer. →***SIADH is discussed fully in Chaps. 86 and 319.***

LACTIC ACIDOSIS Lactic acidosis is a rare and potentially fatal metabolic complication of cancer. Lactic acidosis associated with sepsis and circulatory failure is a common preterminal event in many malignancies. Lactic acidosis in the absence of hypoxemia may occur in patients with leukemia, lymphoma, or solid tumors. Extensive involvement of the liver by tumor is present in most cases. Alteration of liver function may be responsible for the lactate accumulation. HIV-infected patients have an increased risk of aggressive lymphoma; lactic acidosis may occur in such patients either related to the rapid growth of the tumor or from toxicity of nucleoside reverse transcriptase inhibitors (components of HAART). Severe liver toxicity manifesting as acute lactic acidosis may be seen from nucleosides. Symptoms of lactic acidosis include tachypnea, tachycardia, change of mental status, and hepatomegaly. The serum level of lactic acid may reach 10 to 20 meq/L (90 to 180 mg/dL). Treatment is aimed at the underlying disease. The danger from lactic acidosis is from the acidosis, not the lactate. Sodium bicarbonate should be added if acidosis is very severe or if hydrogen ion production is very rapid and uncontrolled. The prognosis is poor.

HYPOGLYCEMIA Persistent hypoglycemia occasionally is associated with tumors other than pancreatic islet cell tumors. Usually these tumors are large, and often they are of mesenchymal origin or are hepatomas or adrenocortical tumors. Mesenchymal tumors are usually located in the retroperitoneum or thorax. In these patients, obtundation, confusion, and behavioral aberrations occur in the postabsorptive pe-

riod and may precede the diagnosis of the tumor. These tumors often secrete incompletely processed insulin-like growth factor II (IGF-II), a hormone capable of activating insulin receptors and causing hypoglycemia. Rarely, hypoglycemia is due to insulin secretion by a non-islet cell carcinoma. Also, the development of hepatic dysfunction from liver metastases and increased glucose consumption by the tumor can contribute to hypoglycemia. If the tumor cannot be resected, hypoglycemia symptoms may be relieved by the administration of glucose, glucocorticoids, or glucagon.

Hypoglycemia can be artifactual; hyperleukocytosis from leukemia, myeloproliferative diseases, leukemoid reactions, or colony stimulating factor treatment can increase glucose consumption in the test tube after blood is drawn, leading to pseudohypoglycemia.

ADRENAL INSUFFICIENCY In patients with cancer, adrenal insufficiency may go unrecognized because the symptoms, such as nausea, vomiting, anorexia, and orthostatic hypotension, are nonspecific and may be mistakenly attributed to progressive cancer or to cancer therapy. Primary adrenal insufficiency may develop owing to replacement of both glands by metastases (lung, breast, colon, or kidney cancer, lymphoma), to removal of both glands, or to hemorrhagic necrosis in association with sepsis or anticoagulation. Impaired adrenal steroid synthesis occurs in patients being treated for cancer with mitotane, ketoconazole, aminoglutethimide, or the investigational agent suramin or in those undergoing rapid reduction in glucocorticoid therapy. Rarely, metastatic replacement causes primary adrenal insufficiency as the first manifestation of an occult malignancy. Metastasis to the pituitary or hypothalamus is found at autopsy in up to 5% of patients with cancer, but associated secondary adrenal insufficiency is rare. Megesterol acetate, used to manage cancer and HIV-related cachexia, may suppress plasma levels of cortisol and adrenocorticotropic hormone (ACTH). Patients taking megesterol may develop adrenal insufficiency, and even those whose adrenal dysfunction is not symptomatic may have inadequate adrenal reserve if they become seriously ill.

Acute adrenal insufficiency is potentially lethal. Treatment of suspected adrenal crisis is initiated after the sampling of serum cortisol and ACTH levels (Chap. 321).

TREATMENT-RELATED EMERGENCIES

TUMOR LYSIS SYNDROME Tumor lysis syndrome is a well-recognized clinical entity that is characterized by various combinations of hyperuricemia, hyperkalemia, hyperphosphatemia, lactic acidosis, and hypocalcemia and is caused by the destruction of a large number of rapidly proliferating neoplastic cells. Frequently, acute renal failure develops as a result of the syndrome.

Tumor lysis syndrome is most frequently associated with the treatment of Burkitt's lymphoma, acute lymphoblastic leukemia, and other high-grade lymphomas, but it also may be seen with chronic leukemias and, rarely, with solid tumors. This syndrome has been seen in patients with chronic lymphocytic leukemia after treatment with fludarabine and cladribine. Tumor lysis syndrome usually occurs during or shortly (1 to 5 days) after chemotherapy. Rarely, spontaneous necrosis of malignancies causes tumor lysis syndrome.

Hyperuricemia may be present at the time of chemotherapy. Effective treatment kills malignant cells and leads to increased serum uric acid levels from the turnover of nucleic acids. Owing to the acidic local environment, uric acid can precipitate in the tubules, medulla, and collecting ducts of the kidney, leading to renal failure. Lactic acidosis and dehydration may contribute to the precipitation of uric acid in the renal tubules. The finding of uric acid crystals in the urine is strong evidence for uric acid nephropathy. The ratio of urinary uric acid to urinary creatinine is >1 in patients with acute hyperuricemic nephropathy and <1 in patients with renal failure due to other causes.

Hyperphosphatemia, which can be caused by the release of intracellular phosphate pools by tumor cell lysis, produces a reciprocal depression in serum calcium, which causes severe neuromuscular irritability and tetany. Deposition of calcium phosphate in the kidney and hyperphosphatemia may cause renal failure. Potassium is the principal intracellular cation, and massive destruction of malignant cells may lead to hyperkalemia. Hyperkalemia in patients with renal failure may rapidly become life-threatening. Hyperkalemia can cause ventricular arrhythmias and sudden death.

The likelihood that the tumor lysis syndrome will occur in patients with Burkitt's lymphoma is related to the tumor burden and renal function. Hyperuricemia and high serum levels of lactate dehydrogenase (LDH >1500 U/L), both of which correlate with total tumor burden, also correlate with the risk of tumor lysis syndrome. In patients at risk for tumor lysis, pretreatment evaluations should include a complete blood count, serum chemistry evaluation, and urine analysis. High leukocyte and platelet counts may artificially elevate potassium levels ("pseudohyperkalemia") due to lysis of these cells after the blood is drawn. In these cases, plasma potassium instead of serum potassium should be followed. In pseudohyperkalemia, no electrocardiographic abnormalities are present. In patients with abnormal baseline renal function, the kidneys and retroperitoneal area should be evaluated by sonography and/or CT to rule out obstructive uropathy. Urine output should be watched closely.

TREATMENT

Recognition of risk and prevention are the most important steps in the management of this syndrome (Fig. 88-3). The standard preventive approach consists of allopurinol, urinary alkalinization, and aggressive hydration. Intravenous allopurinol may be given in patients who cannot tolerate oral therapy. In some cases, uric acid levels cannot be lowered sufficiently with the standard preventive approach. Rasburicase (recombinant urate oxidase) can be effective in these instances.

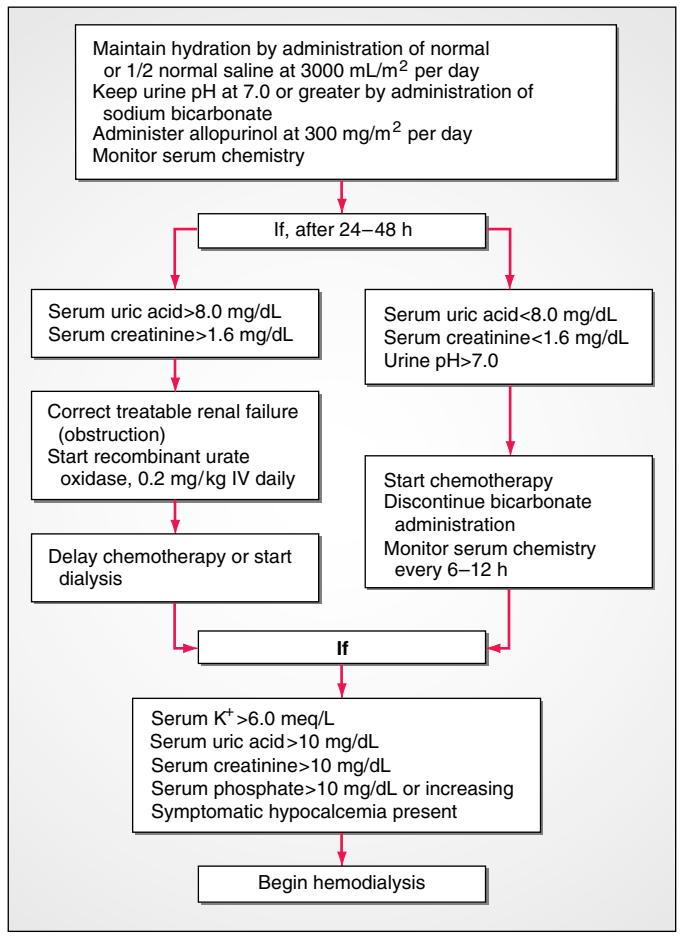

FIGURE 88-3 Management of patients at high risk for the tumor lysis syndrome.

Urate oxidase is missing from primates and catalyzes the conversion of poorly soluble uric acid to readily soluble allantoin. Rasburicase acts rapidly decreasing uric acid levels within hours; however, it may cause hypersensitivity reactions such as bronchospasm, hypoxemia, and hypotension. Rasburicase is contraindicated in patients with glucose-6-phosphate dehydrogenase deficiency who are unable to breakdown hydrogen peroxide, an end product of the urate oxidase reaction. Despite aggressive prophylaxis, tumor lysis syndrome and/or oliguric or anuric renal failure may occur. Care should be taken to prevent worsening of symptomatic hypocalcemia by induction of alkalosis during bicarbonate infusion. Administration of sodium bicarbonate may also lead to urinary precipitation of calcium phosphate, which is less soluble at alkaline pH. Dialysis is often necessary and should be considered early in the course. Hemodialysis is preferred. Hemofiltration offers a gradual, continuous method of removing cellular byproducts and fluid. The prognosis is excellent, and renal function recovers after the uric acid level is lowered to $\leq$10 mg/dL.

HUMAN ANTIBODY INFUSION REACTIONS The initial infusion of human or humanized antibodies (e.g., rituximab, gemtuzumab, trastuzumab) is associated with fever, chills, nausea, asthenia, and headache in up to half of treated patients. Bronchospasm and hypotension occur in 1% of patients. The pathogenesis is thought to be activation of immune effector processes (cells and complement). In the presence of high levels of circulating lymphoid tumor cells, thrombocytopenia, a rapid fall in circulating tumor cells, and mild electrolyte evidence of tumor lysis syndrome may also occur. In addition, increase of liver enzymes, D-dimer, LDH, and prolongation of the prothrombin time may occur. This syndrome is related to release of inflammatory cytokines, such as tumor necrosis factor-α and IL-6. Diphenhydramine and acetaminophen can often prevent or suppress the symptoms. If they occur, the infusion should be stopped and restarted at half the initial infusion rate after the symptoms have abated.

HEMOLYTIC-UREMIC SYNDROME Hemolytic-uremic syndrome (HUS) and, less commonly, thrombotic thrombocytopenic purpura (TTP) occurring after treatment with antineoplastic drugs have been described. Mitomycin is by far the most common agent causing this peculiar syndrome. Other chemotherapeutic agents, including cisplatin, bleomycin, and gemcitabine, have also been reported to be associated with this syndrome. It occurs most often in patients with gastric, colorectal, and breast carcinoma. In one series, 35% of patients were without evident cancer at the time this syndrome appeared. Secondary HUS/TTP has also been reported as a rare but sometimes fatal complication of bone marrow transplantation.

HUS usually has its onset 4 to 8 weeks after the last dose of chemotherapy, but it is not rare to detect it several months later. HUS is characterized by microangiopathic hemolytic anemia, thrombocytopenia, and renal failure. Dyspnea, weakness, fatigue, oliguria, and purpura are also common initial symptoms and findings. Systemic hypertension and pulmonary edema frequently occur. Severe hypertension, pulmonary edema, and rapid worsening of hemolysis and renal function may occur after a blood or blood product transfusion. Cardiac findings include atrial arrhythmias, pericardial friction rub, and pericardial effusion. Raynaud's phenomenon is part of the syndrome in patients treated with bleomycin.

Laboratory findings include severe to moderate anemia associated with red blood cell fragmentation and numerous schistocytes on peripheral smear. Reticulocytosis, decreased plasma haptoglobin, and an elevated lactic dehydrogenase (LDH) level document hemolysis. The serum bilirubin level is usually normal or slightly elevated. The Coombs test is negative. The white cell count is usually normal, and thrombocytopenia ($<$100,000/μL) is almost always present. Most patients have a normal coagulation profile, although some have mild elevations in thrombin time and in level of fibrin degradation products. The serum creatinine level is elevated at presentation and shows a pattern of subacute worsening within weeks of the initial azotemia. The urinalysis reveals hematuria, proteinuria, and granular or hyaline casts; and circulating immune complexes may be present.

The basic pathologic lesion appears to be deposition of fibrin in the walls of capillaries and arterioles, and these deposits are similar to those seen in HUS due to other causes. These microvascular abnormalities involve mainly the kidneys and rarely occur in other organs. The pathogenesis of chemotherapy-related HUS is unknown. Immune complexes have been proposed but not confirmed to be etiologic.

The case fatality rate is high; most patients die within a few months. Plasmapheresis and plasma exchange may normalize the hematologic abnormalities, but renal failure is not reversed in most patients. Immunoperfusion over a staphylococcal protein A column is the most successful treatment. About half of the patients treated with immunoperfusion respond with resolution of thrombocytopenia, improvement in anemia, and stabilization of renal failure. Treatment is well tolerated. It is not clear how the treatment works.

NEUTROPENIA AND INFECTION These remain the most common serious complications of cancer therapy. →***They are covered in detail in Chap. 72.***

PULMONARY INFILTRATES Patients with cancer may present with dyspnea associated with diffuse interstitial infiltrates on chest radiographs. Such infiltrates may be due to progression of the underlying malignancy, treatment-related toxicities, infection, and/or unrelated diseases. The cause may be multifactorial; however, most commonly they occur as a consequence of treatment. Infiltration of the lung by malignancy has been described in patients with leukemia, lymphoma, and breast and other solid cancers. Pulmonary lymphatics may be involved diffusely by neoplasm (pulmonary lymphangitic carcinomatosis), resulting in a diffuse increase in interstitial markings on chest radiographs. The patient is often mildly dyspneic at the onset, but pulmonary failure develops over a period of weeks. In some patients, dyspnea precedes changes on the chest radiographs and is accompanied by a nonproductive cough. This syndrome is characteristic of solid tumors. In patients with leukemia, diffuse microscopic neoplastic peribronchial and peribronchiolar infiltration is frequent but may be asymptomatic. However, some patients present with diffuse interstitial infiltrates, an alveolar capillary block syndrome, and respiratory distress. In these situations, glucocorticoids can provide symptomatic relief, but specific chemotherapy should always be started promptly.

Several cytotoxic agents, such as bleomycin, methotrexate, busulfan, and the nitrosoureas, may cause pulmonary damage. The most frequent presentations are interstitial pneumonitis, alveolitis, and pulmonary fibrosis. Some cytotoxic agents, including methotrexate and procarbazine, may cause an acute hypersensitivity reaction. Cytosine arabinoside has been associated with noncardiogenic pulmonary edema. Administration of multiple cytotoxic drugs, as well as radiation therapy and preexisting lung disease, may potentiate the pulmonary toxicity. Supplemental oxygen may potentiate the effects of drugs and radiation injury. Patients should always be managed with the lowest $F_{I_{O_2}}$ that is sufficient to maintain hemoglobin saturation.

The onset of symptoms may be insidious, with symptoms including dyspnea, nonproductive cough, and tachycardia. Patients may have bibasilar crepitant rales, end-inspiratory crackles, fever, and cyanosis. The chest radiograph generally shows an interstitial and sometimes an intraalveolar pattern that is strongest at the lung bases and may be symmetric. A small effusion may occur. Hypoxemia with decreased carbon monoxide diffusing capacity is always present. Glucocorticoids may be helpful in patients in whom pulmonary toxicity is related to radiation therapy or to chemotherapy. Treatment is otherwise supportive.

Radiation pneumonitis and/or fibrosis is a relatively frequent side effect of thoracic radiation therapy when the dosage exceeds 40 Gy; it may be acute or chronic. It has its onset usually from 2 to 6 months after completion of radiation therapy. The clinical syndrome, which varies in severity, consists of dyspnea, cough with scanty sputum, low-grade fever, and an initial hazy infiltrate on chest radiographs. The infiltrate and tissue damage usually are confined to the radiation field.

The patients subsequently may develop a patchy alveolar infiltrate and air bronchograms, which may progress to acute respiratory failure that is sometimes fatal. A lung biopsy may be necessary to make the diagnosis. Asymptomatic infiltrates found incidentally after radiation therapy need not be treated. However, prednisone should be administered to patients with fever or other symptoms. The dosage should be tapered slowly after the resolution of radiation pneumonitis, as abrupt withdrawal of glucocorticoids may cause an exacerbation of pneumonia. Delayed radiation fibrosis may occur years after radiation therapy and is signaled by dyspnea on exertion. Often it is mild, but it can progress to chronic respiratory failure. Therapy is supportive.

Classical radiation pneumonitis that leads to pulmonary fibrosis is due to radiation-induced production of local cytokines such as platelet-derived growth factor β, tumor necrosis factor, and transforming growth factor β in the radiation field. An immunologically mediated sporadic radiation pneumonitis occurs in about 10% of patients; bilateral alveolitis mediated by T cells results in infiltrates outside the radiation field. This form of radiation pneumonitis usually resolves without sequelae.

Pneumonia is a common problem in patients undergoing treatment for cancer. Bacterial pneumonia typically causes a localized infiltrate on chest radiographs. Therapy is tailored to the causative organism. When diffuse interstitial infiltrates appear in a febrile patient, the differential diagnosis is extensive and includes pneumonia due to infection with *Pneumocystis carinii*, cytomegalovirus, or intracellular pathogens such as *mycoplasma* and *Legionella*; effects of drugs or radiation; tumor progression; nonspecific pneumonitis; and fungal disease. Patients with cancer who are neutropenic and have fever and local infiltrates on chest radiograph should be treated with a third generation cephalosporin perhaps together with an aminoglycoside or imipenem. A new or persistent focal infiltrate not responding to broad spectrum antibiotics argues for initiation of empiric antifungal therapy. When diffuse bilateral infiltrates develop in patients with febrile neutropenia, broad spectrum antibiotics plus trimethoprim-sulfamethoxazole with or without erythromycin should be initiated. The empiric administration of trimethoprim-sulfamethoxazole plus erythromycin to patients without neutropenia and these antibiotics plus ceftazidime to patients with neutropenia covers nearly every treatable diagnosis (except tumor progression) and gives as good overall survival as a strategy based on early invasive intervention with bronchoalveolar lavage or open lung biopsy. If the patient does not improve in 4 days, open lung biopsy is the procedure of choice. Bronchoscopy with bronchoalveolar lavage may be used in patients who are poor candidates for surgery.

In patients with pulmonary infiltrates who are afebrile, heart failure and multiple pulmonary emboli form part of the differential diagnosis.

TYPHLITIS Neutropenic enterocolitis (typhlitis) is an inflammation and necrosis of the cecum and surrounding tissues that may complicate the treatment of acute leukemia. This complication has also been seen in patients with other forms of cancer treated with taxanes and in patients receiving high-dose chemotherapy. The patient develops right lower quadrant abdominal pain, often with rebound tenderness and a tense, distended abdomen, in a setting of fever and neutropenia. Watery diarrhea (often containing sloughed mucosa) and bacteremia are common, and bleeding may occur. Plain abdominal films are generally of little value in the diagnosis; CT scan may show marked bowel wall thickening, particularly in the cecum, with bowel wall edema. Patients with bowel wall thickness >10 mm on ultrasonogram have higher mortality rates. Rapid institution of broad-spectrum antibiotic coverage and nasogastric suction may reverse the disease. Surgical intervention should be considered if there is no improvement by 24 h after the start of antibiotic treatment. If the localized abdominal findings become diffuse, the prognosis is poor.

HEMORRHAGIC CYSTITIS Hemorrhagic cystitis can develop in patients receiving cyclophosphamide or ifosfamide. Both drugs are metabolized to acrolein, which is a strong chemical irritant that is excreted in the urine. Prolonged contact or high concentrations may lead to bladder irritation and hemorrhage. Symptoms include gross hematuria, frequency, dysuria, burning, urgency, incontinence, and nocturia. The best management is prevention. Maintaining a high rate of urine flow minimizes exposure. In addition, 2-mercaptoethanesulfonate (mesna) detoxifies the metabolites and can be coadministered with the instigating drugs. Mesna usually is given three times on the day of ifosfamide administration in doses that are each 20% of the total ifosfamide dose. If hemorrhagic cystitis develops, the maintenance of a high urine flow may be sufficient supportive care. If conservative management is not effective, irrigation of the bladder with an 0.37 to 0.74% formalin solution for 10 min stops the bleeding in most cases. *N*-acetylcysteine may also be an effective irrigant. Prostaglandins (carboprost tromethamine) can inhibit the progress. In extreme cases, ligation of the hypogastric arteries, urinary diversion, or cystectomy may be necessary.

Hemorrhagic cystitis also occurs in patients who undergo bone marrrow transplantation (BMT). In the BMT setting, early onset hemorrhagic cystitis is related to drugs in the treatment regimen (e.g. cyclophosphamide) and late onset hemorrhagic cystitis is usually due to the polyoma virus BKV or adenovirus type 11. Viral causes are usually detected by PCR-based diagnostic tests. Treatment of viral hemorrhagic cystitis is largely supportive with reduction in doses of immunosuppressive agents, if possible. No antiviral therapy is in use, though cidofovir is being tested.

89 LATE CONSEQUENCES OF CANCER AND ITS TREATMENT

Michael C. Perry, Dan L. Longo

Over 9 million Americans alive today have had cancer. Virtually all of these survivors will bear some mark of their diagnosis and its therapy, and many will experience long-term complications, including medical problems, psychosocial disturbances, sexual dysfunction, and inability to find employment or insurance.

Problems may be related to the cancer itself (e.g., patients with primary cancers of the head and neck are at increased risk for subsequent lung cancer), or to the normal aging process (surviving one cancer does not necessarily alter the risk of other common tumors that increase in frequency with age). However, many of the problems affecting cured patients are related to the treatments. Individuals carefully followed for periods up to 30 years have taught us the spectrum

TABLE 89-1 *Late Effects of Cancer Therapy*

Surgical Procedure	*Effect*
Amputation	Functional loss
Lymph node dissection	Risk of lymphedema
Ostomy	Psychosocial impact
Splenectomy	Risk of sepsis
Adhesions	Risk of obstruction
Bowel anastomoses	Malabsorption syndromes

Radiation Therapy	*Effect*
Organ	
Bone	Premature termination of growth, osteonecrosis
Soft tissues	Atrophy, fibrosis
Brain	Neuropsychiatric deficits, cognitive dysfunction
Thyroid	Hypothyroidism, Graves' disease, cancer
Salivary glands	Dry mouth, caries, dysgeusia
Eyes	Cataracts
Heart	Pericarditis, myocarditis, coronary artery disease
Lung	Pulmonary fibrosis
Kidney	Decreased function, hypertension
Liver	Decreased function
Intestine	Malabsorption, stricture
Gonads	Infertility, premature menopause
Any	Secondary neoplasia

Chemotherapy		*Effect*
Organ	Drug	
Bone	Glucocorticoids	Osteoporosis, avascular necrosis
Brain	Methotrexate, ara-C, others	Neuropsychiatric deficits, cognitive decline?
Peripheral nerves	Vincristine, platinum	Neuropathy, hearing loss
Eyes	Glucocorticoids	Cataracts
Heart	Anthracyclines, herceptin	Cardiomyopathy
Lung	Bleomycin	Pulmonary fibrosis
	Methotrexate	Pulmonary hypersensitivity
Kidney	Platinum, others	Decreased function, hypomagnesemia
Liver	Various	Altered function
Gonads	Alkylating agents, others	Infertility, premature menopause
Bone marrow	Various	Aplasia, myelodysplasia, secondary leukemia

of problems that can be encountered. Because of heterogeneity in treatment details and in completeness of follow-up, some treatment-related problems went undetected for many years. However, studies of long-term survivors of childhood cancers, acute leukemia, Hodgkin's disease, lymphomas, testicular cancer, and localized solid tumors have identified the features of cancer treatment that are associated with later morbidity and mortality. We have been somewhat slow to act in changing those aspects of primary treatment that contribute to these late problems. This reticence is due to the uncertainty associated with changing a treatment that is known to work before having a replacement that works as well.

The first task is always to eradicate the diagnosed malignancy. Late problems occurring in cured patients reflect the success of treatment. Such problems never develop in those who do not survive the cancer. Morbidity and mortality from iatrogenic disease should be avoided, if possible. However, the risk of late complications should not lead to the failure to apply potentially curative treatment. The challenge is to preserve or augment the cure rate while decreasing the risk of serious treatment-related illness.

The mechanisms of damage vary. Surgical procedures can create abnormal physiology (such as blind loops leading to malabsorption) or interfere with normal organ function (splenectomy leading to impaired immune response). Radiation therapy can damage organ function directly (salivary gland toxicity leading to dry mouth and dental caries), act as a carcinogen (second solid tumors in radiation ports), or promote accelerated aging-associated changes (atherosclerosis). Cancer chemotherapy can produce damage to the bone marrow and immune system and induce a spectrum of organ dysfunctions. Therapy may produce subclinical damage that may only become recognized in the presence of a second inciting factor (such as the increased incidence of melanoma in patients with dysplastic nevus syndrome treated for Hodgkin's disease with radiation therapy). Finally, although the mechanisms are not elucidated, cancer and its treatment are associated with psychosocial problems that can impair the survivor's ability to adapt to life after cancer.

Late effects by treatment modality are shown in Table 89-1. ***→Drug toxicities are discussed in Chap. 70; radiation toxicity is discussed in Chap. 71.***

CONSEQUENCES BY ORGAN SYSTEM ■ Cardiovascular Dysfunction Most anthracyclines damage the heart muscle. A dose-dependent dropout of myocardial cells is seen on endomyocardial biopsy, and eventually ventricular failure ensues. About 5% of patients who receive >550 mg/m^2 of doxorubicin will develop congestive heart failure (CHF). Coexisting cardiac disease, hypertension, advanced age, and concomitant therapy with thoracic radiation therapy or mitomycin may hasten the onset of CHF. Anthracycline-induced CHF is not readily reversible; mortality is as high as 50%, thus, prevention is the best approach. Mitoxantrone is a related drug that has less cardiac toxicity. Administration of doxorubicin by continuous infusion or encapsulated in liposomes appears to decrease the risk of heart damage. Dexrazoxane, an intracellular iron chelator, may protect the heart against anthracycline toxicity by preventing iron-dependent free-radical generation.

Mediastinal radiation therapy that includes the heart can induce acute pericarditis, chronic constrictive pericarditis, myocardial fibrosis, or accelerated premature coronary atherosclerosis. The incidence of acute pericarditis is 5 to 13%; patients may be asymptomatic or have dyspnea on exertion, fever, and chest pain. Onset is insidious, with a peak about 9 months after treatment. Pericardial effusion may be present. Chronic constrictive pericarditis can develop 5 to 10 years after treatment and usually presents with dyspnea on exertion. Myocardial fibrosis may present as unexplained CHF with diagnostic evaluation showing restrictive cardiomyopathy. Patients may have aortic insufficiency from valvular thickening or mitral regurgitation from papillary muscle dysfunction. Patients who receive mantle field radiation therapy have a threefold increased risk of *fatal* myocardial infarction. Similarly, radiation of the carotids is associated with premature atherosclerosis of the carotids and can produce central nervous system embolic disease. At very high doses, cyclosphosphamide can produce a hemorrhagic myocarditis. Herceptin has been associated with heart failure.

Pulmonary Dysfunction Pulmonary fibrosis from bleomycin is dose-related, with potential exacerbation by age, preexisting lung disease, thoracic radiation, high concentrations of inhaled oxygen, and the concomitant use of other chemotherapeutic agents. Several other chemotherapy agents and radiation therapy can cause pulmonary fibrosis, and at least five can cause pulmonary venoocclusive disease, especially following high-dose therapy such as that involved in stem cell/bone marrow transplantation.

Liver Dysfunction Clinically significant long-term damage to the liver from standard-dose chemotherapy is relatively infrequent and mostly confined to patients who have received chronic methotrexate for maintenance therapy of acute lymphoblastic leukemia. Radiation doses to the liver >1500 cGy can produce liver dysfunction. Although rarely seen with standard-dose chemotherapy, hepatic venoocclusive disease

is more common with high-dose therapy, such as that given to prepare patients for autologous or allogeneic stem cell transplantation. Endothelial damage is probably the inciting event.

Renal/Bladder Dysfunction Reduced renal function may be produced by cisplatin; it is usually asymptomatic but may render the patient more susceptible to other renal insults. Cyclophosphamide cystitis may eventually lead to the development of bladder cancer. Ifosfamide produces cystitis and a proximal tubular defect, a Fanconi-like syndrome that is usually, but not always, reversible.

Endocrine Dysfunction Long-term survivors of childhood cancer who received cranial irradiation are shorter, more likely to be obese, and have reductions in strength, exercise tolerance, and bone mineral density. The obesity may be related to alterations in leptin biology. Growth hormone deficiency is the most common hormone deficiency.

Thyroid disease is common in patients who have received radiation therapy to the neck, such as patients with Hodgkin's disease, with an incidence of up to 62% at 26 years post-therapy. Hypothyroidism is the most common abnormality, followed by Graves' disease, thyroiditis, and cancer. Such patients should have frequent thyroid-stimulating hormone (TSH) levels to detect hypothyroidism early and suppress the TSH drive, which may contribute to thyroid cancer.

Nervous System Dysfunction Although many patients experience peripheral neuropathy during chemotherapy, only a few have chronic problems, perhaps because they have other coexisting diseases such as diabetes mellitus. High doses of cisplatin can produce severe sensorimotor neuropathy. Vincristine may produce permanent numbness and tingling in the fingers and toes.

Neurocognitive sequelae from intrathecal chemotherapy, with or without radiation therapy, are recognized complications of the successful therapy of childhood acute lymphoblastic leukemia. Cognitive decline has been attributed to radiating the brain in the treatment of a variety of tumor types. In addition, cognitive decline can follow the use of adjuvant chemotherapy in women being treated for breast cancer. Because the agents are given at modest doses and are not thought to cross the blood-brain barrier, the mechanism of the cognitive decline is not defined.

Many patients suffer intrusive thoughts about cancer recurrence for many years after successful treatment. Adjustment to normal expectations can be difficult. Cancer survivors may often have more problems holding a job, staying in a stable relationship, and coping with the usual stresses of daily life.

A dose-related hearing loss can occur with the use of cisplatin, usually with doses >400 mg/m^2. This is irreversible, and patients should be screened with audiometric examinations periodically during such therapy.

Eyes Cataracts may be caused by chronic glucocorticoid use, radiation therapy to the head, and, rarely, by tamoxifen.

Sexual and Reproductive Dysfunction Reversible azoospermia can be caused by many chemotherapy agents. The gonads may also be permanently damaged by radiation therapy or by chemotherapeutic agents, particularly the alkylating agents. The extent of the damage depends upon the patient's age and the total dose administered. As a woman nears menopause, smaller amounts of chemotherapy will produce ovarian failure. In men, chemotherapy may produce infertility, but hormone production is not usually affected. Women, however, commonly lose both fertility and hormone production. The premature induction of menopause in a young woman can have serious medical and psychological consequences. Hormone therapy is controversial. Paroxetine may be useful in controlling hot flashes.

Musculoskeletal Dysfunction Late consequences of radiation therapy on the musculoskeletal system occur mostly in children and are related to the radiation dose, volume of tissue irradiated, and the age of the child at the time of therapy. Damage to the microvasculature of the epiphyseal growth zone may result in leg length discrepancy, scoliosis, and short stature.

Raynaud's Phenomenon Up to 40% of patients with testicular cancer treated with bleomycin may experience Raynaud's phenomenon varying in severity from mild and transient to severe. The mechanism is unknown.

Oral Complications Radiation therapy can damage the salivary glands, producing dry mouth. Without saliva, dental caries develop, and many patients have poor dentition. In rare patients, taste can be adversely affected and appetite can be suppressed.

SECOND MALIGNANCIES Second malignancies are a major cause of death for those cured of cancer. Second malignancies can be grouped into three categories: those associated with the primary cancer, those caused by radiation therapy, and those caused by chemotherapy.

Primary cancers increase the risk of secondary cancers in a number of settings. Patients with head and neck cancers are at increased risk of developing a lung cancer, and vice versa, probably because of shared risk factors, especially tobacco abuse. Patients with breast cancer are at increased risk of a second breast cancer in the contralateral breast. Patients with Hodgkin's disease are at increased risk of non-Hodgkin's lymphoma. Patients with genetic syndromes, such as multiple endocrine neoplasia type 1 or Lynch syndrome, are at increased risk of second cancers of specific types. In none of these examples does it appear that treatment of the primary cancer is the cause of the secondary cancer, but a role for treatment is difficult to exclude. These predispositions should result in heightened surveillance in persons at risk. Patients with head and neck cancer may have a reduced risk of developing lung cancer with retinoic acid treatment. Other cancer preventions have not been proved effective.

Patients treated with radiation therapy have an increasing and apparently life-long risk of developing second solid tumors, usually in or adjacent to the radiation field. The risk is modest in the first decade after treatment but reaches 1% per year in the second decade, such that populations followed for 25 years or more have a $\geq$25% chance of developing a second treatment-related tumor. Some organs differ in their susceptibility to radiation carcinogenesis with age; women receiving chest radiation therapy after age 30 have a small increased risk of breast cancer, but those $<$30 have a 19-fold increased risk. The chances of curing the second malignancies hinge on early diagnosis. Patients who were treated with radiation therapy should be carefully examined on an annual basis and evaluated for any abnormalities in organs and tissues that were in the radiation field. Symptoms in a patient cured of cancer should not be dismissed as they may be an early sign of second cancers.

Chemotherapy produces two clinical syndromes that can be fatal: myelodysplasia and acute myeloid leukemia. Two types of acute leukemia have been described. The first occurs in patients treated with alkylating agents, especially over a protracted period. The malignant cells frequently carry genetic deletions in chromosomes 5 or 7. The lifetime risk is about 2%; the risk is increased by the addition of radiation therapy and is about three times higher in people treated over age 40. It peaks in incidence 4 to 6 years after treatment; the risk returns to baseline if no disease has developed within 10 years of treatment. The second type of acute leukemia occurs after exposure to topoisomerase II inhibitors such as doxorubicin or etoposide. It is morphologically indistinguishable from the first but contains a characteristic chromosome translocation involving 10q23. The incidence is $<$1%, and it usually occurs 1.5 to 3 years after treatment. Both forms of acute leukemia are highly refractory to treatment, and no preventive strategy has been developed.

Hormonal manipulations can also cause second tumors. Tamoxifen induces endometrial cancer in about 1 to 2% of women taking it for 5 years or longer. Usually these tumors are found at an early stage; mortality from endometrial cancer is very low compared to the benefit from tamoxifen use as adjuvant therapy in women with breast cancer.

CONSEQUENCES BY CANCER TYPE ■ Pediatric Cancers Quality of life is often excellent, although the majority have at least one late effect. About

one-third of long-term survivors have moderate to severe problems. Cognitive function may be impaired. Late effects are worse for those with poor socioeconomic status. Functional impairments in the cardiovascular system due to radiation therapy and anthracyclines, and in the lungs due to radiation therapy, are rare. Scoliosis and/or delayed growth due to radiation of the skeleton is more common. Many survivors have psychosocial and sexual problems. Second malignant neoplasms are a significant cause of death.

Hodgkin's Disease The patient cured of Hodgkin's disease remains subject to long-term medical problems such as thyroid dysfunction, premature coronary artery disease, gonadal dysfunction, postsplenectomy sepsis, and second malignancies. The second malignancies encountered include myelodysplasia and acute myeloid leukemia, non-Hodgkin's lymphomas, breast cancer, lung cancer, and melanoma. The major risk factor for hematologic malignancies is treatment with alkylating agents plus radiation therapy, while solid tumors are more likely to be seen with the use of radiation therapy. Patients cured of Hodgkin's disease seem to have greater fatigue, more psychosocial and sexual problems, and report a poorer quality of life than patients cured of acute leukemia.

Non-Hodgkin's Lymphomas The patient cured of a non-Hodgkin's lymphoma may be at increased risk of myelodysplasia and acute leukemia if high doses or prolonged courses of alkylating agents were used. Chronic exposure to cyclophosphamide increases the risk of bladder cancer. Patients cured of lymphoma report a very good quality of life.

Acute Leukemia The late effects of anti-leukemic therapy include second malignancies (hematologic and solid tumors), neuropsychiatric difficulties, subnormal growth, thyroid abnormalities, and infertility.

Head and Neck Cancer Patients frequently have poor dentition, dry mouth, trismus, difficulty in eating, and poor nutrition. Those with nasopharyngeal cancer report the poorest long-term quality of life, possibly related to the volume of disease that is radiated.

Stem Cell Transplantation Cured patients are at risk of second cancers, especially if radiation therapy was part of the treatment. They are also subject to gonadal damage and infertility. Graft-versus-host disease is the leading factor contributing to the morbidity and mortality from allogeneic bone marrow transplantation, with an immune-mediated attack against the skin, liver, and gut epithelium. About half of patients report psychosexual problems.

Breast Cancer Patients treated with adjuvant chemotherapy and/or hormonal therapy for breast cancer are at risk for endometrial cancer from the use of tamoxifen. Those patients who have received chemotherapy may be at risk from doxorubicin- or radiation-induced cardiomyopathy and acute leukemia. Herceptin may contribute to heart failure. The development of premature ovarian failure from chemotherapy may cause hormone-deficient symptoms (hot flashes, decreased vaginal secretions, dyspareunia) and places women at risk for osteoporosis and cardiovascular death. Patients commonly report intrusive thoughts of cancer and psychological distress.

Testicular Cancer Depending on the modalities used for therapy, patients cured of testicular cancer can anticipate Raynaud's phenomenon, renal and/or pulmonary damage from chemotherapy, and retrograde ejaculation from retroperitoneal lymph node dissection. Sexual dysfunction is reported by 15% of patients cured of testicular cancer.

Colon Cancer To date the major threat to patients with colorectal cancer treated with chemotherapy and/or radiation therapy remains the risk of a second colorectal cancer. Quality of life is reported as high in long-term survivors.

Prostate Cancer Radical surgical treatment is often accompanied by impotence, and about 10 to 15% develop some urine incontinence. Use of radiation therapy increases the risk of second cancers.

OUTLOOK The challenge for the future is to integrate new chemotherapy and biologic agents and newer techniques of delivering radiation therapy in a fashion that increases cure rates and lowers the late effects of treatment. Additional populations at risk for late effects include those with cancers where therapy is becoming more effective, such as ovarian cancer, and cancers where chemotherapy and radiation therapy are used together in an organ-sparing approach, such as bladder, anal, and laryngeal cancers. Patients who have been cured of a cancer represent an important resource for cancer prevention studies.

90 IRON DEFICIENCY AND OTHER HYPOPROLIFERATIVE ANEMIAS

John W. Adamson

Anemias associated with normocytic and normochromic red cells and an inappropriately low reticulocyte response (reticulocyte index <2.5) are *hypoproliferative anemias*. This category includes early iron deficiency (before hypochromic microcytic red cells develop), acute and chronic inflammation (including many malignancies), renal disease, hypometabolic states such as protein malnutrition and endocrine deficiencies, and anemias from marrow damage. Marrow damage states are discussed in Chap. 94. Hypoproliferative anemias are the most common anemias and anemia associated with acute and chronic inflammation is the most common of these. The anemia of acute and chronic inflammation, like iron deficiency, is related in part to abnormal iron metabolism. The anemias associated with renal disease, inflammation, cancer, and hypometabolic states are characterized by an abnormal erythropoietin response to anemia.

IRON METABOLISM

Iron is a critical element in the function of all cells, although the amount of iron required by individual tissues varies during development. At the same time, the body must protect itself from free iron, which is highly toxic in that it participates in chemical reactions that generate free radicals such as singlet O_2 or OH^-. Consequently, elaborate mechanisms have evolved that allow iron to be made available for critical physiologic functions while at the same time conserving this element and handling it in such a way that toxicity is avoided.

The major role of iron in mammals is to carry O_2 as part of the heme protein that, in turn, is part of hemoglobin. O_2 is also bound by a heme protein in muscle, myoglobin. Iron is a critical element in iron-containing enzymes, including the cytochrome system in mitochondria; iron distribution in the body is shown in Table 90-1. Without

TABLE 90-1 *Body Iron Distribution*

	Iron Content, mg	
	Adult Male, 80 kg	*Adult Female, 60 kg*
Hemoglobin	2500	1700
Myoglobin/enzymes	500	300
Transferrin iron	3	3
Iron stores	600–1000	0–300

iron, cells lose their capacity for electron transport and energy metabolism; in erythroid cells hemoglobin synthesis is impaired, resulting in anemia and reduced O_2 delivery to tissue.

THE IRON CYCLE IN HUMANS Figure 90-1 outlines the major pathways of internal iron exchange in humans. Iron absorbed from the diet or released from stores circulates in the plasma bound to *transferrin*, the iron transport protein. Transferrin is a bilobed glycoprotein with two iron binding sites. Transferrin that carries iron exists in two forms—*monoferric* (one iron atom) or *diferric* (two iron atoms). The turnover (half-clearance time) of transferrin-bound iron is very rapid—typically 60 to 90 min. Because the overwhelming majority of iron transported by transferrin is delivered to the erythroid marrow, the clearance time of transferrin-bound iron from the circulation is affected most by the plasma iron level and the activity of the erythroid marrow. When erythropoiesis is markedly stimulated, the pool of erythroid cells requiring iron increases and the clearance time of iron from the circulation decreases. The half-clearance time of iron in the presence of iron deficiency is as short as 10 to 15 min; this value reflects the limits of iron delivery as a function of the cardiac output going to the bone marrow. With suppression of the erythroid marrow, the plasma iron level typically is increased and the half-clearance time is prolonged to as much as several hours. Normally, the iron bound to transferrin turns over 10 to 20 times per day. Assuming a normal plasma iron level of 80 to 100 μg/dL, the amount of iron passing through the transferrin pool is 20 to 24 mg/d.

The iron-transferrin complex circulates in the plasma until the iron-carrying transferrin interacts with specific *transferrin receptors* on the surface of marrow erythroid cells. Diferric transferrin has the highest affinity for transferrin receptors; apotransferrin (transferrin not carrying iron) has very little affinity. While transferrin receptors are found on cells in many tissues within the body—and all cells at some time during development will display transferrin receptors—the cell having the greatest number of receptors (300,000 to 400,000/cell) is the developing erythroblast.

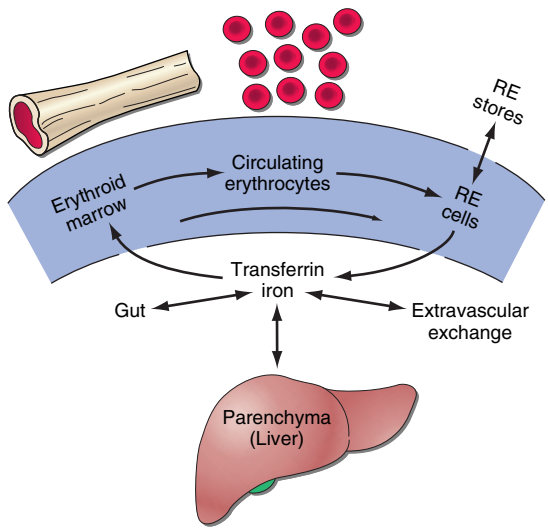

FIGURE 90-1 Internal iron exchange. Normally about 80% of iron passing through the plasma transferrin pool is recycled from broken-down red cells. Absorption of about 1 mg/d is required from the diet in men, 1.4 mg/d in women to maintain homeostasis. As long as transferrin saturation is maintained between 20 to 60% and erythropoiesis is not increased, iron stores are not required. However, in the event of blood loss, dietary iron deficiency, or inadequate iron absorption, up to 40 mg/d of iron can be mobilized from stores. RE, reticuloendothelial.

Once the iron-bearing transferrin interacts with its receptor, the iron-transferrin-receptor complex is internalized via clathrin-coated pits and transported to an acidic endosome, where the iron is released at the low pH. The iron is then made available for heme synthesis while the transferrin-receptor complex is recycled to the surface of the cell, where the bulk of the transferrin is released back into the circulation and the transferrin receptor reanchors into the cell membrane. At this point a certain amount of the transferrin receptor protein may be released into circulation. Within the erythroid cell, iron that is in excess of the amount needed for hemoglobin synthesis binds to a storage protein, *apoferritin*, forming *ferritin*. This mechanism of iron exchange also takes place in other cells of the body expressing transferrin receptors, especially liver parenchymal cells where the iron can be incorporated into heme-containing enzymes or stored. The iron incorporated into hemoglobin subsequently enters the circulation as new red cells are released from the bone marrow. The iron is then part of the red cell mass and will not become available for reutilization until the red cell dies.

In a normal individual, the average red cell life span is 120 days. Thus, 0.8 to 1.0% of red cells turn over each day. At the end of its life span, the red cell is recognized as senescent by the cells of the *reticuloendothelial (RE) system*, and the cell undergoes phagocytosis. Once within the RE cell, the hemoglobin from the ingested red cell is broken down, the globin and other proteins are returned to the amino acid pool, and the iron is shuttled back to the surface of the RE cell, where it is presented to circulating transferrin. The "harvesting" of iron from senescent red cells is both efficient and rapid, with newly recycled iron appearing in the circulation within 10 min of ingestion of the red cell. It is the efficient and highly conserved recycling of iron from senescent red cells that supports steady state (and even mildly accelerated) erythropoiesis.

Since each milliliter of red cells contains 1 mg of elemental iron, the amount of iron needed to replace those red cells lost through senescence amounts to 16 to 20 mg/d (assuming an adult with a red cell mass of 2 L). Any additional iron required for daily red cell production comes from the diet. Normally, an adult male will need to absorb at least 1 mg of elemental iron daily to meet needs, while females in the childbearing years will need to absorb an average of 1.4 mg/d. However, to achieve a maximum proliferative erythroid marrow response to anemia, additional iron must be available. With markedly stimulated erythropoiesis, demands for iron are increased by as much as six- to eightfold. With hemolytic anemias, the rate of red cell destruction is increased, but the iron recovered from the red cells is efficiently reutilized for hemoglobin synthesis. In contrast, with blood loss anemia the rate of red cell production is limited by the amount of iron that can be mobilized from ferritin and hemosiderin stores. Typically, the rate of mobilization under these circumstances will not support red cell production more than 2.5 to 3 times normal. If the delivery of iron to the stimulated marrow is suboptimal, the marrow's proliferative response is blunted and normal hemoglobin synthesis is impaired. The result is a hypoproliferative marrow accompanied by microcytic, hypochromic anemia.

While blood loss or hemolysis places a demand for iron to be supplied to the erythroid marrow, other conditions such as inflammation interfere with iron release from stores and can result in a rapid decrease in the serum iron (see below).

NUTRITIONAL IRON BALANCE The balance of iron metabolism in the organism is tightly controlled and designed to conserve iron for reutilization. There is no excretory pathway for iron, and the only mechanisms by which iron is lost from the body are blood loss (via gastrointestinal bleeding, menses, or other forms of bleeding) and the loss of epidermal cells from the skin and gut. Normally, the only route

by which iron comes into the body is via absorption from food (dietary iron intake) or from medicinal iron taken orally. Iron may also enter the body through red cell transfusions or injection of iron complexes. The margin between the amount of iron available for absorption and the requirement for iron in growing infants and the adult female is narrow. The narrowness of this margin accounts for the great prevalence of iron deficiency worldwide—currently estimated at one-half billion people.

External iron exchange—the amount of iron required from the diet to replace losses—averages about 10% of body iron content a year in men and 15% in women of childbearing age, equivalent to 1.0 and 1.4 mg of elemental iron daily, respectively. Dietary iron content is closely related to total caloric intake (approximately 6 mg of elemental iron per 1000 calories). Iron bioavailability is affected by the nature of the foodstuff, with heme iron (e.g., red meat) being most readily absorbed. In the United States, the average iron intake in an adult male is 15 mg/d with 6% absorption; for the average female, the daily intake is 11 mg/d with 12% absorption. An individual with iron deficiency can increase iron absorption to about 20% of the iron present in a meat-containing diet but only 5 to 10% of the iron in a vegetarian diet. As a result, nearly one-third of the female population in the United States has virtually no iron stores. Vegetarians are at an additional disadvantage because certain foodstuffs that include phytates and phosphates reduce iron absorption by about 50%. When ionizable iron salts are given together with food, the amount of iron absorbed is reduced. This is particularly true with iron in the ferric state. When the percentage of iron absorbed from individual food items is compared with the percentage for an equivalent amount of ferrous salt, iron in vegetables is only about one-twentieth as available, egg iron one-eighth, liver iron one-half, and heme iron one-half to two-thirds. Therefore, liver and heme iron are absorbed nearly as well as iron salt added to food, while the iron in vegetables and eggs is much less available.

Infants, children, and adolescents may be unable to maintain normal iron balance because of the demands of body growth and lower dietary intake of iron. In pregnancy during the last two trimesters, daily iron requirements increase to 5 to 6 mg. That is the reason why iron supplements are strongly recommended for pregnant women in developed countries. Enthusiasm for supplementing foods such as bread and cereals with iron has waned in the face of concerns that the very prevalent hemochromatosis gene would result in an unacceptable risk of iron overload.

Iron absorption takes place largely in the proximal small intestine and is a carefully regulated process. For absorption, iron must be taken up by the luminal cell. That process is facilitated by the acidic contents of the stomach, which maintains the iron in solution. At the brush border of the absorptive cell, the ferric iron is converted to the ferrous form by a ferrireductase. Transport across the membrane is accomplished by divalent metal transporter 1 (DMT 1, also known as Nramp 2 or DCT 1). DMT 1 is a general cation transporter. Once iron is inside the gut cell, the iron may be stored as ferritin or transported through the cell to be released at the basolateral surface to plasma transferrin. It is likely that another transporter acts here in concert with hephaestin, another ferroxidase. Hephaestin is similar to ceruloplasmin, the copper-carrying protein.

Iron absorption is influenced by a number of physiologic states. Erythroid hyperplasia, for example, stimulates iron absorption, even in the face of normal or increased iron stores. Patients with anemias associated with high levels of ineffective erythropoiesis absorb excess amounts of dietary iron. Over time, this may lead to iron overload and tissue damage. In iron deficiency, iron is much more efficiently absorbed from a given diet; the contrary is true in the presence of iron overload. This is possibly mediated through signals that become fixed before the jejunal crypt cell migrates up the villus to become an absorptive cell. The normal individual can reduce iron absorption in situations of excessive intake or medicinal iron intake; however, while the percentage of iron absorbed goes down, the absolute amount goes up. This accounts for the acute iron toxicity occasionally seen when children ingest large numbers of iron tablets. Under these circumstances, the amount of iron absorbed exceeds the transferrin binding capacity of the plasma, resulting in free iron that affects critical organs such as cardiac muscle cells.

IRON DEFICIENCY ANEMIA

STAGES OF IRON DEFICIENCY Iron deficiency anemia is the condition in which there is anemia and clear evidence of iron deficiency. However, iron deficiency occurs in steps (Fig. 90-2). These can be divided into three stages. The first stage is *negative iron balance*, in which the demands for (or losses of) iron exceed the body's ability to absorb iron from the diet. This stage can result from a number of physiologic mechanisms including blood loss, pregnancy (in which the demands for red cell production by the fetus outstrip the mother's ability to provide iron), rapid growth spurts in the adolescent, or inadequate dietary iron intake. Most commonly, the growth needs of the fetus or rapidly growing child exceed the individual's ability to absorb the iron necessary for hemoglobin synthesis from the diet. Blood loss in excess of 10 to 20 mL of red cells per day is greater than the amount of iron that the gut can absorb from a normal diet. Under these circumstances the iron deficit must be made up by mobilization of iron from RE storage sites. During this period measurements of iron stores—such as the serum ferritin level or the appearance of stainable iron on bone marrow aspirations—will decrease. As long as iron stores are present and can be mobilized, the serum iron, total iron-binding capacity (TIBC), and red cell protoporphyrin levels remain within normal limits. At this stage, red cell morphology and indices are normal.

When iron stores become depleted, the serum iron begins to fall. Gradually, the TIBC increases, as do red cell protoporphyrin levels. By definition, marrow iron stores are absent when the serum ferritin level is <15 μg/L. As long as the serum iron remains within the normal range, hemoglobin synthesis is unaffected despite the dwindling iron stores. Once the transferrin saturation falls to 15 to 20%, hemoglobin synthesis becomes impaired. This is a period of *iron-*

	Normal	Negative iron balance	Iron-deficient erythropoiesis	Iron-deficiency anemia
Marrow iron stores	1-3+	0-1+	0	0
Serum ferritin (μg/L)	50-200	<20	<15	<15
TIBC (μg/dL)	300-360	>360	>380	>400
SI (μg/dL)	50-150	NL	<50	<30
Saturation (%)	30-50	NL	<20	<10
Marrow sideroblasts (%)	40-60	NL	<10	<10
RBC protoporphyrin (μg/dL)	30-50	NL	>100	>200
RBC morphology	NL	NL	NL	Microcytic/ hypochromic

FIGURE 90-2 Laboratory studies in the evolution of iron deficiency. Measurements of marrow iron stores, serum ferritin, and total iron-binding capacity (TIBC) are sensitive to early iron-store depletion. Iron-deficient erythropoiesis is recognized from additional abnormalities in the serum iron (SI), percent transferrin saturation, the pattern of marrow sideroblasts, and the red cell protoporphyrin level. Patients with iron deficiency anemia demonstrate all the same abnormalities plus hypochromic microcytic anemia. (*From Hillman and Finch, with permission.*)

deficient erythropoiesis. Careful evaluation of the peripheral blood smear reveals the first appearance of microcytic cells, and if the laboratory technology is available, one finds hypochromic reticulocytes in circulation. Gradually, the hemoglobin and hematocrit begin to fall, reflecting *iron deficiency anemia*. The transferrin saturation at this point is 10 to 15%.

When moderate anemia is present (hemoglobin 10–13 g/dL), the bone marrow remains hypoproliferative. With more severe anemia (hemoglobin 7–8 g/dL), hypochromia and microcytosis become more prominent, misshapen red cells (poikilocytes) appear on the blood smear as cigar- or pencil-shaped forms and target cells, and the erythroid marrow becomes increasingly ineffective. Consequently, with severe prolonged iron deficiency anemia, erythroid hyperplasia of the marrow develops rather than hypoproliferation.

CAUSES OF IRON DEFICIENCY Conditions that increase demand for iron, increase iron loss, or decrease iron intake or absorption can produce iron deficiency (Table 90-2).

CLINICAL PRESENTATION OF IRON DEFICIENCY Certain clinical conditions carry an increased likelihood of iron deficiency. Pregnancy, adolescence, periods of rapid growth, and an intermittent history of blood loss of any kind should alert the clinician to possible iron deficiency. A cardinal rule is that the appearance of iron deficiency in an adult male means gastrointestinal blood loss until proven otherwise. Signs related to iron deficiency depend on the severity and chronicity of the anemia in addition to the usual signs of anemia—fatigue, pallor, and reduced exercise capacity. *Cheilosis* (fissures at the corners of the mouth) and *koilonychia* (spooning of the fingernails) are signs of advanced tissue iron deficiency. The diagnosis of iron deficiency is typically based on laboratory results.

LABORATORY IRON STUDIES ■ Serum Iron and Total Iron-Binding Capacity The serum iron level represents the amount of circulating iron bound to transferrin. The TIBC is an indirect measure of the circulating transferrin. The normal range for the serum iron is 50 to 150 μg/dL; the normal range for TIBC is 300 to 360 μg/dL. Transferrin saturation, which is normally 25 to 50%, is obtained by the following formula: serum iron × 100 ÷ TIBC. Iron deficiency states are associated with saturation levels below 18%. In evaluating the serum iron, the clinician should be aware that there is a diurnal variation in the value. A transferrin saturation of >50% indicates that a disproportionate amount of the iron bound to transferrin is being delivered to nonerythroid tissues. If this condition persists for an extended time, tissue iron overload may occur.

Serum Ferritin Free iron is toxic to cells, and the body has established an elaborate set of protective mechanisms to bind iron in various tissue compartments. Within cells, iron is stored complexed to protein as ferritin or hemosiderin. Apoferritin binds to free ferrous iron and stores it in the ferric state. As ferritin accumulates within cells of the RE system, protein aggregates are formed as hemosiderin. Iron in ferritin or hemosiderin can be extracted for release by the RE cells although hemosiderin is less readily available. Under steady state conditions, the serum ferritin level correlates with total body iron stores; thus, the serum ferritin level is the most convenient laboratory test to estimate iron stores. The normal value for ferritin varies according to the age and gender of the individual (Fig. 90-3). Adult males have serum ferritin values averaging about 100 μg/L, while adult females have levels averaging 30 μg/L. As iron stores are depleted, the serum ferritin falls to <15 μg/L. Such levels are virtually always diagnostic of absent body iron stores.

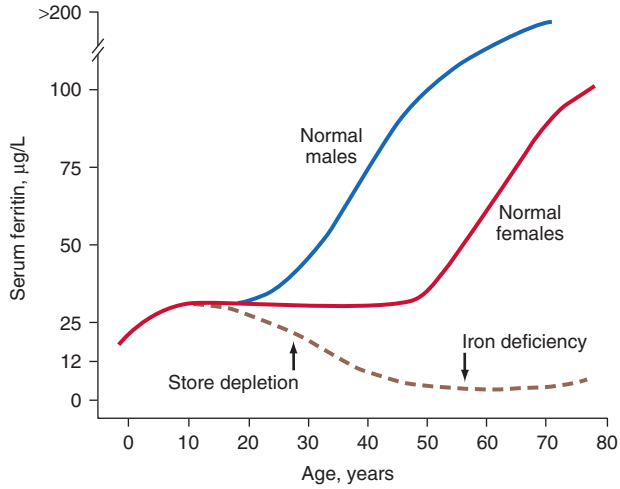

FIGURE 90-3 Serum ferritin levels as a function of sex and age. Iron store depletion and iron deficiency are accompanied by a fall in serum ferritin level below 20 μg/L. (*From Hillman and Ault, with permission.*)

Evaluation of Bone Marrow Iron Stores Although RE cell iron stores can also be estimated from the iron stain of a bone marrow aspirate or biopsy, the measurement of serum ferritin has largely supplanted bone marrow aspirates for determination of storage iron (Table 90-3). The serum ferritin level is a better indicator of iron overload than the marrow iron stain. However, in addition to storage iron the marrow iron stain provides information about the effective delivery of iron to developing erythroblasts. Normally, 20 to 40% of developing erythroblasts—called *sideroblasts*—will have visible ferritin granules in their cytoplasm. This represents iron in excess of that needed for hemoglobin synthesis. In states in which release of iron from storage sites is blocked, RE iron will be detectable, and there will be few or no sideroblasts. In the myelodysplastic syndromes, mitochondrial dysfunction occurs, and accumulation of iron in mitochondria appears in a necklace fashion around the nucleus of the erythroblast. Such cells are referred to as *ringed sideroblasts*.

Red Cell Protoporphyrin Levels Protoporphyrin is an intermediate in the pathway to heme synthesis. Under conditions in which heme synthesis is impaired, protoporphyrin accumulates within the red cell. This can reflect an inadequate iron supply to erythroid precursors to support hemoglobin synthesis. Normal values are less than 30 μg/dL of red cells. In iron deficiency, values in excess of 100 μg/dL are seen. The most common causes of increased red cell protoporphyrin levels are absolute or relative iron deficiency and lead poisoning.

TABLE 90-2 *Causes of Iron Deficiency*

Increased demand for iron and/or hematopoiesis
rapid growth in infancy or adolescence
pregnancy
erythropoietin therapy
Increased iron loss
chronic blood loss
menses
acute blood loss
blood donation
phlebotomy as treatment for polycythemia vera
Decreased iron intake or absorption
inadequate diet
malabsorption from disease (sprue, Crohn's disease)
malabsorption from surgery (post-gastrectomy)
acute or chronic inflammation

TABLE 90-3 *Iron Store Measurements*

Iron Stores	*Marrow Iron Stain, 0–4+*	*Serum Ferritin, μg/L*
0	0	<15
1–300 mg	Trace to 1+	15–30
300–800 mg	2+	30–60
800–1000 mg	3+	60–150
1–2 g	4+	>150
Iron overload	—	>500–1000

TABLE 90-4 *Diagnosis of Microcytic Anemia*

Tests	Iron Deficiency	Inflammation	Thalassemia	Sideroblastic Anemia
Smear	Micro/hypo	Normal micro/hypo	Micro/hypo with targeting	Variable
SI	<30	<50	Normal to high	Normal to high
TIBC	>360	<300	Normal	Normal
Percent saturation	<10	10–20	30–80	30–80
Ferritin (μg/L)	<15	30–200	50–300	50–300
Hemoglobin pattern	Normal	Normal	Abnormal	Normal

Note: SI, serum iron; TIBC, total iron-binding capacity.

Serum Levels of Transferrin Receptor Protein Because erythroid cells have the highest numbers of transferrin receptors on their surface of any cell in the body, and because transferrin receptor protein (TRP) is released by cells into the circulation, serum levels of TRP reflect the total erythroid marrow mass. Another condition in which TRP levels are elevated is absolute iron deficiency. Normal values are 4 to 9 μg/L determined by immunoassay. This laboratory test is becoming increasingly available and has been proposed to measure the serial expansion of the erythroid marrow in response to recombinant erythropoietin therapy.

DIFFERENTIAL DIAGNOSIS Other than iron deficiency, only three conditions need to be considered in the differential diagnosis of a hypochromic microcytic anemia (Table 90-4). The first is inherited defects in globin chain synthesis: the thalassemias. These are differentiated from iron deficiency most readily by serum iron values, since it is characteristic to have normal or increased serum iron levels and transferrin saturation with the thalassemias.

The second condition is chronic inflammatory disease with inadequate iron supply to the erythroid marrow. The distinction between true iron deficiency anemia and the anemia associated with chronic inflammatory states is among the most common diagnostic problems encountered by clinicians (see below). Usually the anemia of chronic disease is normocytic and normochromic. Again, the iron values usually make the differential diagnosis clear, as the ferritin level is normal or increased and the TIBC is typically below normal.

Finally, the myelodysplastic syndromes represent the third and most rare condition. Occasionally, patients with myelodysplasia have impaired hemoglobin synthesis with mitochondrial dysfunction resulting in impaired iron incorporation into heme. The iron values again reveal normal stores and more than an adequate supply to the marrow, despite the microcytosis and hypochromia.

TREATMENT

The severity and cause of iron deficiency anemia will determine the appropriate approach to treatment. As an example, symptomatic elderly patients with severe iron deficiency anemia and cardiovascular instability may require red cell transfusions. Younger individuals who have compensated for their anemia can be treated more conservatively with iron replacement. The foremost issue for the latter patient is the precise identification of the cause of the iron deficiency.

For the majority of cases of iron deficiency (pregnant women, growing children and adolescents, patients with infrequent episodes of bleeding, and those with inadequate dietary intake of iron), oral iron therapy will suffice. For patients with unusual blood loss or malabsorption, specific diagnostic tests and appropriate therapy take priority. Once the diagnosis of iron deficiency anemia and its cause is made, and a therapeutic approach is charted, there are three major approaches.

Red Cell Transfusion Transfusion therapy is reserved for those individuals who have symptoms of anemia, cardiovascular instability, and continued and excessive blood loss from whatever source, and those who require immediate intervention. The management of these patients is less related to the iron deficiency than it is to the consequences of the severe anemia. Not only do transfusions correct the anemia acutely, but the transfused red cells provide a source of iron for reutilization, assuming they are not lost through continued bleeding. Transfusion therapy will stabilize the patient while other options are reviewed.

Oral Iron Therapy In the patient with established iron deficiency anemia who is asymptomatic, treatment with oral iron is usually adequate. Multiple preparations are available ranging from simple iron salts to complex iron compounds designed for sustained release throughout the small intestine (Table 90-5). While the various preparations contain different amounts of iron, they are generally all absorbed well and are effective in treatment. Some come with other compounds designed to enhance iron absorption, such as ascorbic acid. It is not clear whether the benefits of such compounds justify their costs. Typically, for iron replacement therapy up to 300 mg of elemental iron per day is given, usually as three or four iron tablets (each containing 50 to 65 mg elemental iron) given over the course of the day. Ideally, oral iron preparations should be taken on an empty stomach, since foods may inhibit iron absorption. Some patients with gastric disease or prior gastric surgery require special treatment with iron solutions, since the retention capacity of the stomach may be reduced. The retention capacity is necessary for dissolving the shell of the iron tablet before the release of iron. A dose of 200 to 300 mg of elemental iron per day should result in the absorption of iron up to 50 mg/d. This supports a red cell production level of two to three times normal in an individual with a normally functioning marrow and appropriate erythropoietin stimulus. However, as the hemoglobin level rises, erythropoietin stimulation decreases, and the amount of iron absorbed is reduced. The goal of therapy in individuals with iron deficiency anemia is not only to repair the anemia, but also to provide stores of at least 0.5 to 1.0 g of iron. Sustained treatment for a period of 6 to 12 months after correction of the anemia will be necessary to achieve this.

Of the complications of oral iron therapy, gastrointestinal distress is the most prominent and is seen in 15 to 20% of patients. For these patients, abdominal pain, nausea, vomiting, or constipation often lead to noncompliance. Although small doses of iron or iron preparations with delayed release may help somewhat, the gastrointestinal side effects are a major impediment to the effective treatment of a number of patients.

The response to iron therapy varies, depending on the erythropoietin stimulus and the rate of absorption. Typically, the reticulocyte count should begin to increase within 4 to 7 days after initiation of therapy and peak at 1½ weeks. The absence of a response may be due to poor adsorption, noncompliance (which is common), or a confounding diagnosis. If iron deficiency persists, it may be necessary to switch to parenteral iron therapy.

Parenteral Iron Therapy Intravenous iron can be given to patients who are unable to tolerate oral iron, whose needs are relatively acute, or who need iron on an ongoing basis, usually due to persistent gastrointestinal blood loss. Parenteral iron use has been rising rapidly in the last several years with the recognition that recombinant erythropoietin therapy induces a large demand for iron—a demand that frequently

TABLE 90-5 *Oral Iron Preparations*

Generic Name	Tablet (Iron Content), mg	Elixir (Iron Content), mg in 5 mL
Ferrous sulfate	325 (65)	300 (60)
	195 (39)	90 (18)
Extended release	525 (105)	
Ferrous fumarate	325 (107)	
	195 (64)	100 (33)
Ferrous gluconate	325 (39)	300 (35)
Polysaccharide iron	150 (150)	100 (100)
	50 (50)	

cannot be met through the physiologic release of iron from RE sources. Concern has been raised about the safety of parenteral iron—particularly iron dextran. The serious adverse reaction rate to intravenous iron dextran is 0.7%. Fortunately, newer iron complexes are available in the United States that have a much lower rate of adverse effects. The most recently approved preparations are intravenous sodium ferric gluconate (Ferrlecit) and iron sucrose (Venofer).

Parenteral iron is used in two ways: one is to administer the total dose of iron required to correct the hemoglobin deficit and provide the patient with at least 500 mg of iron stores; the second is to give repeated small doses of parenteral iron over a protracted period. The latter approach is common in dialysis centers, where it is not unusual for 100 mg of elemental iron to be given weekly for 10 weeks to augment the response to recombinant erythropoietin therapy. The amount of iron needed by an individual patient is calculated by the following formula:

$$\text{Body weight (kg)} \times 2.3 \times (15 - \text{patient's hemoglobin, g/dL}) + 500 \text{ or } 1000 \text{ mg (for stores)}.$$

In administering intravenous iron dextran, anaphylaxis is a concern. Anaphylaxis is almost never seen with the newer preparations. The factors that have correlated with a serious anaphylactic-like reaction include a history of multiple allergies or a prior allergic reaction to dextran (in the case of iron dextran). Generalized symptoms appearing several days after the infusion of a large dose of iron can include arthralgias, skin rash, and low-grade fever. This may be dose-related, but it does not preclude the further use of parenteral iron in the patient. To date, patients with sensitivity to iron dextran have been safely treated with iron gluconate. If a large dose of iron dextran is to be given (>100 mg) the iron preparation should be diluted in 5% dextrose in water or 0.9% NaCl solution. The iron solution can then be infused over a 60- to 90-min period (for larger doses) or at a rate convenient for the attending nurse or physician. While a test dose (25 mg) of parenteral iron is recommended, in reality a slow infusion of a larger dose of parenteral iron solution will afford the same kind of early warning as a separately injected test dose. Early in the infusion of iron, if chest pain, wheezing, a fall in blood pressure, or other systemic manifestations occur, the infusion of iron—whether as a large solution or a test dose—should be interrupted immediately.

OTHER HYPOPROLIFERATIVE ANEMIAS

In addition to mild to moderate iron deficiency anemia, the hypoproliferative anemias can be divided into four categories: (1) chronic inflammation/infection; (2) renal disease; (3) endocrine and nutritional deficiencies (hypometabolic states); and (4) marrow damage (Chap. 94). With chronic inflammation, renal disease, or hypometabolism, endogenous erythropoietin production is inadequate for the degree of anemia observed. For the anemia of chronic inflammation (anemia of chronic disease), the erythroid marrow also responds inadequately to stimulation, due in part to defects in *iron reutilization*. As a result of the lack of adequate erythropoietin stimulation, an examination of the peripheral blood smear will disclose only an occasional polychromatophilic ("shift") reticulocyte. In the cases of iron deficiency or marrow damage, appropriate elevations in endogenous erythropoietin levels are typically found, and shift reticulocytes will be present on the blood smear.

ANEMIA OF ACUTE AND CHRONIC INFLAMMATION/INFECTION (THE ANEMIA OF CHRONIC DISEASE) The anemia of chronic disease—which encompasses inflammation, infection, tissue injury, and conditions associated with the release of proinflammatory cytokines (such as cancer)—is one of the most common forms of anemia seen clinically and is probably the most important in the differential diagnosis of iron deficiency, since many of the features of the anemia are brought about by inadequate iron delivery to the marrow, despite the presence of normal or increased iron stores. This is reflected by a low serum iron, increased red cell protoporphyrin, a hypoproliferative marrow, transferrin saturation in the range of 15 to 20%, and a normal or increased serum ferritin. The serum ferritin values are often the most distinguishing feature between true iron deficiency anemia and the iron-deficient erythropoiesis associated with inflammation. Typically, serum ferritin values increase threefold over basal levels in the face of inflammation. All of these changes are due to the effects of inflammatory cytokines and hepcidin, the storage iron regulator, acting at several levels of erythropoiesis (Fig. 90-4). Interleukin 1 (IL-1) directly decreases erythropoietin production in response to anemia. IL-1, acting through accessory cell release of interferon γ (IFN-γ), suppresses the response of the erythroid marrow to erythropoietin—an effect that can be overcome by increased erythropoietin administration in vitro and in vivo. In addition, tumor necrosis factor (TNF), acting through the release of IFN-γ by marrow stromal cells, also suppresses the response to erythropoietin. Hepcidin, made by the liver, is increased in inflammation and acts to suppress iron absorption and iron release from storage sites. The overall result is a chronic hypoproliferative anemia with classic changes in iron metabolism. The anemia is further compounded by a mild to moderate shortening in red cell survival.

With chronic inflammation/infection, the primary disease will determine the severity and characteristics of the anemia. For instance, many patients with cancer also have anemia that is typically normocytic and normochromic. In contrast, patients with long-standing active rheumatoid arthritis or chronic infections such as tuberculosis will have a microcytic, hypochromic anemia. In both cases, the bone marrow is hypoproliferative, but the differences in red cell indices reflect differences in the availability of iron for hemoglobin synthesis. Occasionally, conditions associated with chronic inflammation are also associated with chronic blood loss. Under these circumstances, a bone marrow aspirate stained for iron may be necessary to rule out absolute iron deficiency. However, the administration of iron in this case will correct the iron deficiency component of the anemia and leave the inflammatory component unaffected.

The anemia associated with acute infection or inflammation is typically mild but becomes more pronounced over time. Acute infection can produce a fall in hemoglobin levels of 2 to 3 g/dL within 1 or 2 days; this is largely related to the hemolysis of red cells near the end of their natural life span. The fever and cytokines released exert a selective pressure against cells with more limited capacity to maintain the red cell membrane. In most individuals the mild anemia is reasonably well tolerated, and symptoms, if present, are associated with the underlying disease. Occasionally, in patients with preexisting cardiac disease, moderate anemia (hemoglobin 10–11 g/dL) may be associated with angina, exercise intolerance, and shortness of breath. The red cell indices vary from normocytic, normochromic to microcytic, hypochromic. The serum iron values tend to correlate with the red cell indices. The erythropoietic profile that distinguishes the anemia of

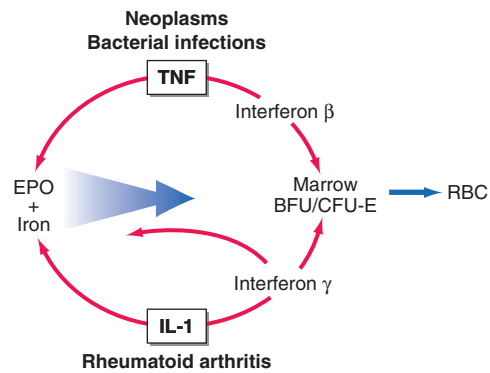

FIGURE 90-4 Suppression of erythropoiesis by inflammatory cytokines. Through the release of tumor necrosis factor (TNF) and interferon γ (IFN-γ) neoplasms and bacterial infections suppress erythropoietin (EPO) production, the release of iron from reticuloendothelial stores, and the proliferation of erythroid progenitors [erythroid burst-forming units and erythroid colony-forming units (BFU/CFU-E)]. The mediators in patients with vasculitis and rheumatoid arthritis include interleukin 1 (IL-1) and IFN-γ. The red arrows indicate sites of inflammatory cytokine inhibitory effects.

TABLE 90-6 *Diagnosis of Hypoproliferative Anemias*

Tests	Iron Deficiency	Inflammation	Renal Disease	Hypometabolic States
Anemia	Mild to severe	Mild	Mild to severe	Mild
MCV (fL)	60–90	80–90	90	90
Morphology	Normo-microcytic	Normocytic	Normocytic	Normocytic
SI	<30	<50	Normal	Normal
TIBC	>360	<300	Normal	Normal
Saturation (%)	<10	10–20	Normal	Normal
Serum ferritin (μg/L)	<15	30–200	115–150	Normal
Iron stores	0	2–4+	1–4+	Normal

Note: MCV, mean corpuscular volume; SI, serum iron; TIBC, total iron-binding capacity.

inflammation from the other causes of hypoproliferative anemias is shown in Table 90-6.

ANEMIA OF RENAL DISEASE Chronic renal failure is usually associated with a moderate to severe hypoproliferative anemia; the level of the anemia correlates with the severity of the renal failure. Red cells are typically normocytic and normochromic. Reticulocytes are decreased. The anemia is due to a failure to produce adequate amounts of erythropoietin and a reduction in red cell survival. In certain forms of acute renal failure, the correlation between the anemia and renal function is weaker. Patients with the hemolytic-uremic syndrome increase erythropoiesis in response to the hemolysis, despite renal failure requiring dialysis. Polycystic renal disease also shows a smaller degree of erythropoietin deficiency for a given level of renal failure. By contrast, patients with diabetes have more severe erythropoietin deficiency for a given level of renal failure.

Assessment of iron status provides information to distinguish the anemia of renal disease from the other forms of hypoproliferative anemia (Table 90-6) and to guide management. Patients with the anemia of renal disease usually present with normal serum iron, TIBC, and ferritin levels. However, those maintained on chronic hemodialysis may develop iron deficiency from blood loss through the dialysis procedure. Iron must be replenished in these patients to ensure an adequate response to erythropoietin therapy (see below).

ANEMIA IN HYPOMETABOLIC STATES Patients who are starving, particularly for protein, and those with a variety of endocrine disorders that produce lower metabolic rates may develop a mild to moderate hypoproliferative anemia. The release of erythropoietin from the kidney is sensitive to the need for O_2, not just O_2 levels. Thus, erythropoietin production is triggered at lower levels of O_2 tension in disease states (such as hypothyroidism and starvation) where metabolic activity, and thus O_2 demand, is decreased.

Endocrine Deficiency States The difference in the levels of hemoglobin between men and women is related to the effects of androgen and estrogen on erythropoiesis. Testosterone and anabolic steroids augment erythropoiesis; castration and estrogen administration to males decrease erythropoiesis. Patients who are hypothyroid or have deficits in pituitary hormones also may develop a mild anemia. Pathogenesis may be complicated by other nutritional deficiencies as iron and folic acid absorption can be affected by these disorders. Usually, correction of the hormone deficiency reverses the anemia.

Anemia may be more severe in Addison's disease, depending on the level of thyroid and androgen hormone dysfunction; however, anemia may be masked by decreases in plasma volume. Once such patients are given cortisol and volume replacement, the hemoglobin level may fall rapidly. Mild anemia complicating hyperparathyroidism may be due to decreased erythropoietin production as a consequence of the renal effects of hypercalcemia or to impaired proliferation of erythroid progenitors.

Protein Starvation Decreased dietary intake of protein may lead to mild to moderate hypoproliferative anemia; this form of anemia may be prevalent in the elderly. The anemia can be more severe in patients with a greater degree of starvation. In marasmus, where patients are both protein- and calorie-deficient, the release of erythropoietin is impaired in proportion to the reduction in metabolic rate; however, the degree of anemia may be masked by volume depletion and becomes apparent after refeeding. Deficiencies in other nutrients (iron, folate) may also complicate the clinical picture but may not be apparent at diagnosis. Changes in the erythrocyte indices on refeeding should prompt evaluation of iron, folate, and B_{12} status.

Anemia in Liver Disease A mild hypoproliferative anemia may develop in patients with chronic liver disease from nearly any cause. The peripheral blood smear may show spur cells and stomatocytes from the accumulation of excess cholesterol in the membrane from a deficiency of lecithin cholesterol acyltransferase. Red cell survival is shortened, and the production of erythropoietin is inadequate to compensate. In alcoholic liver disease, nutritional deficiencies can add complexity to the management. Folate deficiency from inadequate intake, as well as iron deficiency from blood loss and inadequate intake, can alter the red cell indices.

TREATMENT

Many patients with hypoproliferative anemias experience recovery of normal hemoglobin levels when the underlying disease is appropriately treated. For those in whom such reversals are not possible—such as patients with end-stage renal failure, cancer, and chronic inflammatory diseases—symptomatic anemia requires treatment. The two major forms of treatment are transfusions and erythropoietin.

Transfusions Thresholds for transfusion should be altered based on the patient's symptoms. In general, patients without serious underlying cardiovascular or pulmonary disease can tolerate hemoglobin levels above 8 g/dL and do not require intervention until the hemoglobin falls below that level. Patients with more physiologic compromise may need to have their hemoglobin levels kept above 11 g/dL. A typical unit of packed red cells increases the hemoglobin level by 1 g/dL. Transfusions are associated with certain infectious risks (Chap. 99), and chronic transfusions can produce iron overload.

Erythropoietin Erythropoietin is particularly useful in anemias in which endogenous erythropoietin levels are inappropriately low, such as the hypoproliferative anemias. Iron status must be evaluated and iron repleted to obtain optimal effects from erythropoietin. In patients with chronic renal failure, the usual dose of erythropoietin is 50 to 150 U/kg three times a week subcutaneously. Hemoglobin levels of 10 to 12 g/dL are usually reached within 4 to 6 weeks if iron levels are adequate; 90% of these patients respond. Once a target hemoglobin level is reached, the erythropoietin dose can be decreased. A fall in hemoglobin level occurring in the face of erythropoietin therapy usually signifies the development of an infection or iron depletion. Aluminum toxicity and hyperparathyroidism can also compromise the erythropoietin response. When an infection intervenes, it is best to interrupt the erythropoietin therapy and rely on transfusion to correct the anemia until the infection is adequately treated. The dose needed to correct the anemia in patients with cancer is higher, up to 300 U/kg three times a week, and only about 60% of patients respond.

ACKNOWLEDGMENT

Dr. Robert S. Hillman was the author of this chapter in the 14th edition, and material from his chapter has been retained.

91 HEMOGLOBINOPATHIES

Edward J. Benz

Hemoglobin is critical for normal oxygen delivery to tissues; it is also present in erythrocytes in such high concentrations that it can alter red cell shape, deformability, and viscosity. Hemoglobinopathies are disorders affecting the structure, function, or production of hemoglobin. These conditions are usually inherited and range in severity from asymptomatic laboratory abnormalities to death in utero. Different forms may present as hemolytic anemia, erythrocytosis, cyanosis, or vasoocclusive stigmata.

PROPERTIES OF THE HUMAN HEMOGLOBINS

HEMOGLOBIN STRUCTURE Different hemoglobins are produced during embryonic, fetal, and adult life (Fig. 91-1). Each consists of a tetramer of globin polypeptide chains: a pair of α-like chains 141 amino acids long and a pair of β-like chains 146 amino acids long. The major adult hemoglobin, HbA, has the structure $\alpha_2\beta_2$. HbF ($\alpha_2\gamma_2$) predominates during most of gestation, and HbA_2 ($\alpha_2\delta_2$) is a minor adult hemoglobin. Embryonic hemoglobins need not be considered here.

Each globin chain enfolds a single heme moiety, consisting of a protoporphyrin IX ring complexed with a single iron atom in the ferrous state (Fe^{2+}), positioned in a manner optimal for reversible binding of oxygen. Each heme moiety can bind a single oxygen molecule; every molecule of hemoglobin can thus transport up to four oxygen molecules.

The amino acid sequences of the various globins are highly homologous to one another. Each has a highly helical *secondary structure*. Their globular *tertiary structures* can cause the exterior surfaces to be rich in polar (hydrophilic) amino acids that enhance solubility and the interior to be lined with nonpolar groups, forming a hydrophobic pocket into which heme is inserted. The tetrameric *quaternary structure* of HbA contains two $\alpha\beta$ dimers. Numerous tight interactions (i.e., $\alpha_1\beta_1$ contacts) hold the α and β chains together. The complete tetramer is held together by interfaces (i.e., $\alpha_1\beta_2$ contacts) between the α-like chain of one dimer and the non-α chain of the other dimer.

The hemoglobin tetramer is highly soluble but individual globin chains are insoluble. Unpaired globin precipitates, forming inclusions that damage the cell. Normal globin chain synthesis is balanced so that each newly synthesized α or non-α globin chain will have an available partner with which to pair to form hemoglobin.

Solubility and reversible oxygen binding are the key properties deranged in hemoglobinopathies. Both depend most on the hydrophilic surface amino acids, the hydrophobic amino acids lining the heme pocket, a key histidine in the F helix, and the amino acids forming the $\alpha_1\beta_1$ and $\alpha_1\beta_2$ contact points. Mutations in these strategic regions tend to be the ones that alter clinical behavior.

FUNCTION OF HEMOGLOBIN To support oxygen transport, hemoglobin must bind O_2 efficiently at the partial pressure of oxygen (P_{O_2}) of the alveolus, retain it, and release it to tissues at the P_{O_2} of tissue capillary beds. Oxygen acquisition and delivery over a relatively narrow range of oxygen tensions depend on a property inherent in the tetrameric arrangement of heme and globin subunits within the hemoglobin molecule called *cooperativity* or *heme-heme interaction*.

At low oxygen tensions, the hemoglobin tetramer is fully deoxygenated (Fig. 91-2). Oxygen binding begins slowly as O_2 tension rises. However, as soon as some oxygen has been bound by the tetramer, an abrupt increase occurs in the slope of the curve. Thus, hemoglobin molecules that have bound some oxygen develop a higher oxygen affinity, greatly accelerating their ability to combine with more oxygen. This S-shaped oxygen equilibrium curve (Fig. 91-2), along which substantial amounts of oxygen loading *and unloading* can occur over a narrow range of oxygen tensions, is physiologically more useful than the high-affinity hyperbolic curve of individual monomers.

Oxygen affinity is modulated by several factors. The Bohr effect arises from the stabilizing action of protons on deoxyhemoglobin, which binds protons more readily than oxyhemoglobin because it is a weaker acid (Fig. 91-2). Thus, hemoglobin has a lower oxygen affinity at low pH, facilitating delivery to tissues. The major small molecule that alters oxygen affinity in humans is 2,3-bisphosphoglycerate (2,3-BPG, formerly 2,3-DPG), which lowers oxygen affinity when bound to hemoglobin. HbA has a reasonably high affinity for 2,3-BPG. HbF does not bind 2,3-BPG, so it tends to have a higher oxygen affinity in vivo. Hemoglobin also binds nitric oxide reversibly; this interaction may influence vascular tone, but its physiologic relevance remains unclear.

To understand hemoglobinopathies, it is important to understand

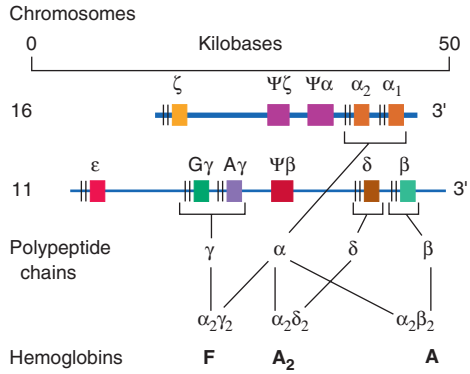

FIGURE 91-1 The globin genes. The α-like genes (α,ζ) are encoded on chromosome 16; the β-like genes ($\beta,\gamma,\delta,\varepsilon$) are encoded on chromosome 11. The ζ and ε genes encode embryonic globins.

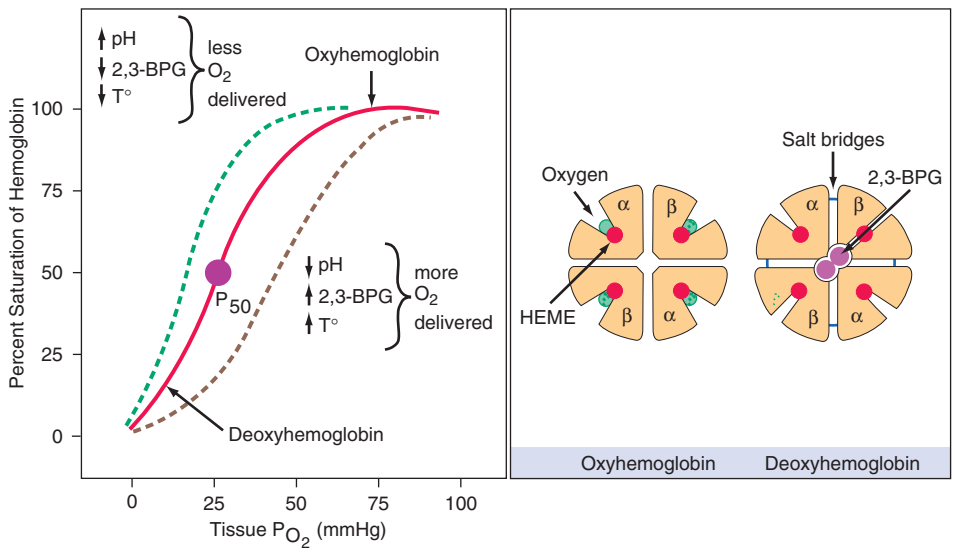

FIGURE 91-2 Hemoglobin-oxygen dissociation curve. The hemoglobin tetramer can bind up to four molecules of oxygen in the iron-containing sites of the heme molecules. As oxygen is bound, 2,3-BPG and CO_2 are expelled. Salt bridges are broken, and each of the globin molecules changes its conformation to facilitate oxygen binding. Oxygen release to the tissues is the reverse process, salt bridges being formed and 2,3-BPG and CO_2 bound. Deoxyhemoglobin does not bind oxygen efficiently until the cell returns to conditions of higher pH, the most important modulator of O_2 affinity (Bohr effect). When acid is produced in the tissues, the dissociation curve shifts to the right, facilitating oxygen release and CO_2 binding. Alkalosis has the opposite effect, reducing oxygen delivery.

that proper oxygen transport depends on the tetrameric structure of the proteins, the proper arrangement of the charged amino acids, and interaction with low-molecular-weight substances such as protons or 2,3-BPG.

DEVELOPMENTAL BIOLOGY OF HUMAN HEMOGLOBINS Red cells first appearing at about 6 weeks after conception contain the embryonic hemoglobins Hb Portland ($\zeta_2\gamma_2$), Hb Gower I ($\zeta_2\varepsilon_2$), and Hb Gower II ($\alpha_2\varepsilon_2$). At 10 to 11 weeks, fetal hemoglobin (HbF; $\alpha_2\gamma_2$) becomes predominant. The switch to nearly exclusive synthesis of adult hemoglobin (HbA; $\alpha_2\beta_2$) occurs at about 38 weeks (Fig. 91-1). Fetuses and newborns therefore require α-globin but not β-globin for normal gestation. Small amounts of HbF are produced during postnatal life. A few red cell clones called *F cells* are progeny of a small pool of immature committed erythroid precursors (BFU-e) that retain the ability to produce HbF. Profound erythroid stress, such as that seen in severe hemolytic anemias, after bone marrow transplant, or during chemotherapy, causes more of the F-potent BFU-e to be recruited. HbF levels thus tend to rise in some patients with sickle cell anemia or thalassemia. This phenomenon is also important because it probably explains the ability of hydroxyurea to increase levels of HbF in adults. Fetal globin genes can also be activated partially after birth by agents such as butyrate that inhibit histone deacetylase and modify the structure of chromatin.

GENETICS AND BIOSYNTHESIS OF HUMAN HEMOGLOBIN The human hemoglobins are encoded in two tightly linked gene clusters; the α-like globin genes are clustered on chromosome 16, and the β-like genes on chromosome 11 (Fig. 91-1). The α-like cluster consists of two α-globin genes and a single copy of the ζ gene. The non-α gene cluster consists of a single ε gene, the Gγ and Aγ fetal globin genes, and the adult δ and β genes.

Important regulatory sequences flank each gene. Immediately upstream are typical promoter elements needed for the assembly of the transcription initiation complex. Sequences in the 5′ flanking region of the γ and the β genes appear to be crucial for the correct developmental regulation of these genes, while elements that function like classic enhancers and silencers are in the 3′ flanking regions. The locus control region (LCR) elements located far upstream appear to control the overall level of expression of each cluster. These elements achieve their regulatory effects by interacting with *trans*-acting transcription factors. Some of these factors are ubiquitous (e.g., Sp1 and YY1), while others are more or less limited to erythroid cells (e.g., GATA-1, NFE-2, and EKLF). The LCR controlling the α globin gene cluster is modulated by a SWI/SNF-like protein called *ATRX*; this protein appears to influence chromatin remodeling and DNA methylation. The association of α thalassemia with mental retardation and myelodysplasia in some families appears to be related to mutations in the pathway governed by ATRX. The latter also appear to modulate genes specifically expressed during erythropoiesis, such as the genes that encode the enzymes for heme biosynthesis. This is relevant since normal red blood cell (RBC) differentiation also requires the coordinated expression of the globin genes with the genes responsible for heme and iron metabolism.

CLASSIFICATION OF HEMOGLOBINOPATHIES

There are five major classes of hemoglobinopathies (Table 91-1). *Structural hemoglobinopathies* occur when mutations alter the amino acid sequence of a globin chain, altering the physiologic properties of the variant hemoglobins and producing the characteristic clinical abnormalities. The variant hemoglobins relevant to this chapter polymerize abnormally, as in sickle cell anemia, or exhibit altered solubility or oxygen-binding affinity. *Thalassemia syndromes* arise from mutations that impair production or translation of globin mRNA, leading to deficient globin chain biosynthesis. Clinical abnormalities are attributable to the inadequate supply of hemoglobin and the imbalances in the production of individual globin chains, leading to premature destruction of erythroblasts and red cells. *Thalassemic hemoglobin variants* combine features of thalassemia (e.g., abnormal globin biosynthesis) and of structural hemoglobinopathies (e.g., an abnormal amino acid sequence). *Hereditary persistence of fetal hemoglobin* (HPFH) is characterized by synthesis of high levels of fetal hemoglobin in adult life. *Acquired hemoglobinopathies* include modifications of the hemoglobin molecule by toxins (e.g., acquired methemoglobinemia) and abnormal hemoglobin synthesis (e.g., high levels of HbF production in preleukemia and α thalassemia in myeloproliferative disorders).

TABLE 91-1 Classification of Hemoglobinopathies

I. Structural hemoglobinopathies—hemoglobins with altered amino acid sequences that result in deranged function or altered physical or chemical properties
  A. Abnormal hemoglobin polymerization—HbS, hemoglobin sickling
  B. Altered O_2 affinity
    1. High affinity—polycythemia
    2. Low affinity—cyanosis, pseudoanemia
  C. Hemoglobins that oxidize readily
    1. Unstable hemoglobins—hemolytic anemia, jaundice
    2. M hemoglobins—methemoglobinemia, cyanosis
II. Thalassemias—defective biosynthesis of globin chains
  A. α Thalassemias
  B. β Thalassemias
  C. $\delta\beta$, $\gamma\delta\beta$, $\alpha\beta$ Thalassemias
III. Thalassemic hemoglobin variants—structurally abnormal Hb associated with coinherited thalassemic phenotype
  A. HbE
  B. Hb Constant Spring
  C. Hb Lepore
IV. Hereditary peristence of fetal hemoglobin—persistence of high levels of HbF into adult life
V. Acquired hemoglobinopathies
  A. Methemoglobin due to toxic exposures
  B. Sulfhemoglobin due to toxic exposures
  C. Carboxyhemoglobin
  D. HbH in erythroleukemia
  E. Elevated HbF in states of erythroid stress and bone marrow dysplasia

EPIDEMIOLOGY Hemoglobinopathies are especially common in areas in which malaria is endemic. This clustering of hemoglobinopathies is assumed to reflect a selective survival advantage for the abnormal red cells, which presumably provide a less hospitable environment during the obligate intraerythrocytic stages of the parasitic life cycle. Very young children with α thalassemia are *more* susceptible to infection with the nonlethal *Plasmodium vivax*. Thalassemia might then favor a natural protection against infection with the more lethal *P. falciparum*.

Thalassemias are the most common genetic disorders in the world, affecting nearly 200 million people worldwide. About 15% of American blacks are silent carriers for α thalassemia; α-thalassemia trait (minor) occurs in 3% of American blacks and in 1 to 15% of persons of Mediterranean origin. β Thalassemia has a 10 to 15% incidence in individuals from the Mediterranean and Southeast Asia and 0.8% in American blacks. The number of severe cases of thalassemia in the United States is about 1000. Sickle cell disease is the most common structural hemoglobinopathy occurring in heterozygous form in about 8% of American blacks and in homozygous form in 1 in 400. Between 2 and 3% of American blacks carry a hemoglobin C allele.

INHERITANCE AND ONTOGENY Hemoglobinopathies are autosomal codominant traits—compound heterozygotes who inherit a different abnormal mutant allele from each parent exhibit composite features of each. For example, patients inheriting sickle β thalassemia exhibit features of β thalassemia and sickle cell anemia. The α chain is present in HbA, HbA_2, and HbF; α-chain mutations thus cause abnormalities in all three. The α-globin hemoglobinopathies are symptomatic in utero and after birth because normal function of the α-globin gene is required throughout gestation and adult life. In contrast, infants with

β-globin hemoglobinopathies tend to be asymptomatic until 3 to 9 months of age, when HbA has largely replaced HbF.

DETECTION AND CHARACTERIZATION OF HEMOGLOBINOPATHIES—GENERAL METHODS

Of the many methods available for hemoglobin analysis, electrophoretic techniques are used for routine clinical purposes. Electrophoresis at pH 8.6 on cellulose acetate membranes is especially simple, inexpensive, and reliable for initial screening. Agar gel electrophoresis at pH 6.1 in citrate buffer is often used as a complementary method because each method detects different variants. Comparison of results obtained in each system usually allows unambiguous diagnosis, but some important variants are electrophoretically silent. These mutant hemoglobins can usually be characterized by more specialized techniques such as isoelectric focusing and/or high pressure liquid chromatography (HPLC).

Quantitation of the hemoglobin profile is often desirable. HbA_2 is frequently elevated in β-thalassemia trait and depressed in iron deficiency. HbF is elevated in HPFH, some β-thalassemia syndromes, and occasional periods of erythroid stress or marrow dysplasia. For characterization of sickle cell trait, sickle thalassemia syndromes, or HbSC disease, and for monitoring the progress of exchange transfusion therapy to lower the percentage of circulating HbS, quantitation of individual hemoglobins is also required. In most laboratories, quantitation is performed only if the test is specifically ordered.

Because some variants can comigrate with HbA or HbS (sickle hemoglobin), electrophoretic assessment should always be regarded as incomplete unless functional assays for hemoglobin sickling, solubility, or oxygen affinity are also performed, as dictated by the clinical presentation. The best sickling assays involve measurement of the degree to which the hemoglobin sample becomes insoluble, or gelated, as it is deoxygenated (i.e., sickle solubility test). Unstable hemoglobins are detected by their precipitation in isopropanol or after heating to 50°C. High-O_2 affinity and low-O_2 affinity variants are detected by quantitating the P_{50}, the partial pressure of oxygen at which the hemoglobin sample becomes 50% saturated with oxygen. Direct tests for the percent carboxyhemoglobin and methemoglobin, employing spectrophotometric techniques, can readily be obtained from most clinical laboratories on an urgent basis.

Complete characterization, including amino acid sequencing or gene cloning and sequencing, is available from several investigational laboratories around the world. The advent of the polymerase chain reaction (PCR), allele-specific oligonucleotide hybridization, and automated DNA sequencing has made it possible to identify globin gene mutations in a few days.

Laboratory evaluation remains an adjunct, rather than the primary diagnostic aid. Diagnosis is best established by recognition of a characteristic history, physical findings, peripheral blood smear morphology, and abnormalities of the complete blood cell count (e.g., profound microcytosis with minimal anemia in thalassemia trait).

STRUCTURALLY ABNORMAL HEMOGLOBINS

SICKLE CELL SYNDROMES The sickle cell syndromes are caused by a mutation in the β-globin gene that changes the sixth amino acid from glutamic acid to valine. HbS ($\alpha_2\beta_2^{6\ Glu\rightarrow Val}$) polymerizes reversibly when deoxygenated to form a gelatinous network of fibrous polymers that stiffen the erythrocyte membrane, increase viscosity, and cause dehydration due to potassium leakage and calcium influx (Fig. 91-3). These changes also produce the characteristic sickle shape. Sickled cells lose the pliability needed to traverse small capillaries. They possess altered sticky membranes (especially reticulocytes) that are abnormally adherent to the endothelium of small venules. These abnormalities provoke unpredictable episodes of microvascular vasoocclusion and premature RBC destruction (hemolytic anemia). Hemolysis occurs because the abnormal erythrocytes are destroyed by the spleen. The rigid adherent cells also clog small capillaries and venules, causing tissue ischemia, acute pain, and gradual end-organ damage. This venoocclusive component usually dominates the clinical course. Prominent manifestations include episodes of ischemic pain (i.e., painful crises) and ischemic malfunction or frank infarction in the spleen, central nervous system, bones, liver, kidneys, and lungs (Fig. 91-3).

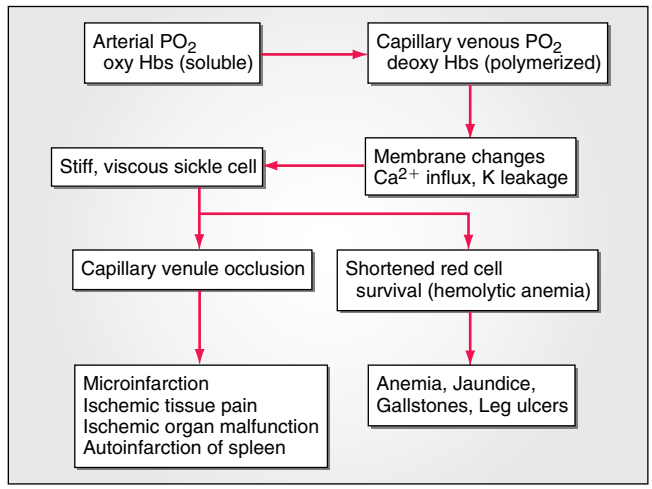

FIGURE 91-3 Pathophysiology of sickle cell crisis.

Several sickle syndromes occur as the result of inheritance of HbS from one parent and another hemoglobinopathy, such as β thalassemia or HbC ($\alpha_2\beta_2^{6\ Glu\rightarrow Lys}$), from the other parent. The prototype disease, sickle cell anemia, is the homozygous state for HbS (Table 91-2).

Clinical Manifestations of Sickle Cell Anemia Most patients with sickling syndromes suffer from hemolytic anemia, with hematocrits from 15 to 30%, and significant reticulocytosis. Anemia was once thought to exert protective effects against vasoocclusion by reducing blood viscosity. However, natural history and drug therapy trials suggest that an *increase* in the hematocrit and feedback inhibition of reticulocytosis might be beneficial, even at the expense of increased blood viscosity. The role of adhesive reticulocytes in vasoocclusion might account for these paradoxical effects.

Granulocytosis is common. The white count can fluctuate substan-

TABLE 91-2 Clinical Features of Sickle Hemoglobinopathies

Condition	Clinical Abnormalities	Hemoglobin Level g/L (g/dL)	MCV, fL	Hemoglobin Electrophoresis
Sickle cell trait	None; rare painless hematuria	Normal	Normal	Hb S/A:40/60
Sickle cell anemia	Vasoocclusive crises with infarction of spleen, brain, marrow, kidney, lung; aseptic necrosis of bone; gallstones; priapism; ankle ulcers	70–100 (7–10)	80–100	Hb S/A:100/0 Hb F:2–25%
S/β^0 thalassemia	Vasoocclusive crises; aseptic necrosis of bone	70–100 (7–10)	60–80	Hb S/A:100/0 Hb F:1–10%
S/β^+ thalassemia	Rare crises and aseptic necrosis	100–140 (10–14)	70–80	Hb S/A:60/40
Hemoglobin SC	Rare crises and aseptic necrosis; painless hematuria	100–140 (10–14)	80–100	Hb S/A:50/0 Hb C:50%

tially and unpredictably during and between painful crises, infectious episodes, and other intercurrent illnesses.

Vasoocclusion causes protean manifestations. Intermittent episodes of vasoocclusion in connective and musculoskeletal structures produce painful ischemia manifested by acute pain and tenderness, fever, tachycardia, and anxiety. These recurrent episodes, called *painful crises*, are the most common clinical manifestation. Their frequency and severity vary greatly. Pain can develop almost anywhere in the body and may last from a few hours to 2 weeks. Repeated crises requiring hospitalization (>3 per year) correlate with reduced survival in adult life, suggesting that these episodes are associated with accumulation of chronic end-organ damage. Provocative factors include infection, fever, excessive exercise, anxiety, abrupt changes in temperature, hypoxia, or hypertonic dyes.

Repeated microinfarction can destroy tissues having microvascular beds that promote sickling. Thus, the spleen is frequently lost within the first 18 to 36 months of life, causing susceptibility to infection, particularly by pneumococci. Acute venous obstruction of the spleen (*splenic sequestration crisis*), a rare occurrence in early childhood, may require emergency transfusion and/or splenectomy to prevent trapping of the entire arterial output in the obstructed spleen. Occlusion of retinal vessels can produce hemorrhage, neovascularization, and eventual detachments. Renal papillary necrosis invariably produces isosthenuria. More widespread renal necrosis leads to renal failure in adults, a common late cause of death. Bone and joint ischemia can lead to aseptic necrosis, especially of the femoral or humeral heads; chronic arthropathy; and unusual susceptibility to osteomyelitis, which may be caused by organisms, such as *Salmonella*, rarely encountered in other settings. The *hand-foot syndrome* is caused by painful infarcts of the digits and dactylitis. Stroke is especially common in children, a small subset of whom tend to suffer repeated episodes; stroke is less common in adults and is often hemorrhagic. A particularly painful complication in males is priapism, due to infarction of the penile venous outflow tracts; permanent impotence is a frequent consequence. Chronic lower leg ulcers probably arise from ischemia and superinfection in the distal circulation.

Acute chest syndrome is a distinctive manifestation characterized by chest pain, tachypnea, fever, cough, and arterial oxygen desaturation. It can mimic pneumonia, pulmonary emboli, bone marrow infarction and embolism, myocardial ischemia, or in situ lung infarction. Acute chest syndrome is thought to reflect in situ sickling within the lung producing pain and temporary pulmonary dysfunction. It is frequently difficult or impossible to distinguish among other possibilities. Pulmonary infarction and pneumonia are the most frequent underlying or concomitant conditions in patients with this syndrome. Repeated episodes of acute chest pain correlate with reduced survival. Acutely, reduction in arterial oxygen saturation is especially ominous because it promotes sickling on a massive scale. Chronic acute or subacute pulmonary crises lead to pulmonary hypertension and cor pulmonale, an increasingly common cause of death as patients survive further into adult life.

Sickle cell syndromes are remarkable for their clinical heterogeneity. Some patients remain virtually asymptomatic into or even through adult life, while others suffer repeated crises requiring hospitalization from early childhood. Patients with sickle thalassemia and sickle-HbE tend to have similar, slightly milder, symptoms, perhaps because of the ameliorating effects of production of other hemoglobins within the RBC. Hemoglobin SC disease, one of the more common variants of sickle cell anemia, is frequently marked by lesser degrees of hemolytic anemia and a greater propensity for the development of retinopathy and aseptic necrosis of bones. In most respects, however, the clinical manifestations resemble sickle cell anemia. Some rare hemoglobin variants actually aggravate the sickling phenomenon.

Clinical Manifestations of Sickle Cell Trait Sickle cell trait is usually asymptomatic. Anemia and painful crises are exceedingly rare. An uncommon, but highly distinctive, symptom is painless hematuria often occurring in adolescent males, probably due to papillary necrosis. Isosthenuria is a more common manifestation of the same process. Sloughing of papillae with ureteral obstruction has been reported, as have isolated cases of massive sickling or sudden death due to exposure to high altitudes or extraordinary extremes of exercise and dehydration.

Diagnosis Sickle cell syndromes are readily suspected on the basis of characteristic hemolytic anemia, red cell morphology (Fig. 91-4), and intermittent episodes of ischemic pain. Diagnosis is confirmed by hemoglobin electrophoresis and the sickling tests already discussed. Thorough characterization of the exact hemoglobin profile of the patient is important, because sickle thalassemia and hemoglobin SC disease are correlated with alterations in prognosis or clinical features. Diagnosis is usually established in childhood, but occasional patients, often with compound heterozygous states, do not develop symptoms until the onset of puberty, pregnancy, or early adult life. Genotyping of family members and potential parental partners is critical for genetic counseling. Details of the childhood history establish prognosis and eligibility for aggressive or experimental therapies. Factors associated with increased morbidity and reduced survival are more than three crises requiring hospitalization per year, a chronic neutrophilia, a history of splenic sequestration or hand-foot syndrome, and second episodes of acute chest syndrome. Patients with a history of cerebrovascular accidents are at higher risk for repeated episodes and require especially close monitoring.

TREATMENT

Patients with sickle cell syndromes require ongoing continuity of care. Familiarity with the pattern of symptoms provides the best safeguard against excessive use of the emergency room, hospitalization, and habituation to addictive narcotics. Additional preventive measures include regular slit-lamp examinations to monitor development of retinopathy; antibiotic prophylaxis appropriate for splenectomized patients during dental or other invasive procedures; and vigorous oral hydration during or in anticipation of periods of extreme exercise, exposure to heat or cold, emotional stress, or infection. Pneumococcal and *Haemophilus influenzae* vaccines are less effective in splenectomized individuals. Thus, patients with sickle cell anemia should be vaccinated early in life.

The management of acute painful crisis includes vigorous hydration, thorough evaluation for underlying causes (such as infection), and aggressive analgesia administered by a standing order and/or patient-controlled analgesia (PCA) pump. Morphine (0.1 to 0.15 mg/kg every 3 to 4 h) or meperidine (0.75 to 1.5 mg/kg every 2 to 4 h) should control severe pain. Meperidine should be used only for acute short-term pain control; as a chronic analgesic, it is unsuitable. Bone pain may respond as well to ketorolac (30 to 60 mg initial dose, then 15 to 30 mg every 6 to 8 h). Inhalation of nitrous oxide can provide short-term pain relief, but great care must be exercised to avoid hypoxia and respiratory depression. Nitrous oxide also elevates O_2 affinity, reducing O_2 delivery to tissues. Its use should be restricted to experts. Many crises can be managed at home with oral hydration and oral analgesia. Use of the emergency room should be reserved for especially severe symptoms or circumstances in which other processes, e.g., infection, are strongly suspected. Nasal oxygen should be employed as appropriate to protect arterial saturation. Most crises resolve in 1 to 7 days.

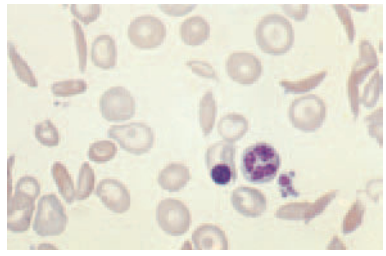

FIGURE 91-4 Sickle cell anemia. The elongated and crescent-shaped red blood cells seen on this smear represent circulating irreversibly sickled cells. Target cells and a nucleated red blood cell are also seen.

Use of blood transfusion should be reserved for extreme cases: no evidence exists for a beneficial effect in shortening the duration of the crisis.

No tests are definitive to diagnose acute painful crisis. Critical to good management is an approach that recognizes that most patients reporting crisis symptoms do indeed have crisis or another significant medical problem. Diligent diagnostic evaluation for underlying causes is imperative, even though these are found infrequently. In adults, the possibility of aseptic necrosis or sickle arthropathy must be considered, especially if pain and immobility become repeated or chronic at a single site. Nonsteroidal anti-inflammatory agents are often effective for sickle cell arthropathy.

Acute chest syndrome is a medical emergency that may require management in an intensive care unit. Hydration should be monitored carefully to avoid the development of pulmonary edema, and oxygen therapy should be especially vigorous for protection of arterial saturation. Diagnostic evaluation for pneumonia and pulmonary embolism should be especially thorough, since these may occur with atypical symptoms. Critical interventions are transfusion to maintain a hematocrit >30, and emergency exchange transfusion if arterial saturation drops to <90%. As patients with sickle cell syndrome increasingly survive into their fifth and sixth decades, end-stage renal failure and pulmonary hypertension are becoming increasingly prominent causes of end-stage morbidity. Anecdotal evidence suggests that a sickle cell cardiomyopathy and/or premature coronary artery disease may compromise cardiac function in later years. Sickle cell patients have received kidney transplants, but they often experience an increase in the frequency and severity of crises, possibly due to increased infection as a consequence of immunosuppression.

The most significant advance in the therapy of sickle cell anemia has been the introduction of hydroxyurea as a mainstay of therapy for patients with severe symptoms. Hydroxyurea (10 to 30 mg/kg per day) increases fetal hemoglobin and may also exert beneficial affects on red cell hydration, vascular wall adherence, and suppression of the granulocyte and reticulocyte counts; indeed, dosage is titrated to maintain a white count between 5000 and 8000 cells/μL. White cells and reticulocytes may play a major role in the pathogenesis of sickle cell crisis, and their suppression may be an important benefit of hydroxyurea therapy.

Hydroxyurea should be considered in patients experiencing repeated episodes of acute chest syndrome or with more than three crises per year requiring hospitalization. The utility of this agent for reducing the incidence of other complications (priapism, retinopathy) is under evaluation, as are the long-term side effects. The preponderance of evidence, however, is that hydroxyurea offers broad benefits to most patients whose disease is severe enough to impair their functional status. One long-term study suggests that hydroxyurea may improve survival. A number of experts are advocating more widespread use of this agent. HbF levels increase in most patients within a few months.

The antitumor drug, 5-azacytidine, was the first agent found to elevate HbF. It never achieved widespread use because of concerns about acute toxicity and carcinogenesis. However, low doses of the related agent, 5-deoxyazacytidine (decitabine) can elevate HbF with acceptable toxicity.

Bone marrow transplantation can provide definitive cures but is known to be effective and safe only in children. Prognostic features justifying bone marrow transplant are the presence of repeated crises early in life, a high neutrophil count, or the development of hand-foot syndrome. Children at risk for stroke can now be identified through the use of Doppler ultrasound techniques. Prophylactic exchange transfusion appears to substantially reduce the risk of stroke in this population. Children who do suffer a cerebrovascular accident should be maintained for at least 3 to 5 years on a program of vigorous exchange transfusion, since the risk of second strokes is extremely high in this population.

Gene therapy for sickle cell anemia is being intensively pursued, but no safe measures are currently available. Agents blocking RBC dehydration or vascular adhesion, such as clotrimazole or magnesium, may have value as an adjunct to hydroxyurea therapy, pending the completion of ongoing trials. Combinations of clotrimazole and magnesium are being evaluated in clinical trials.

UNSTABLE HEMOGLOBINS Amino acid substitutions that reduce solubility or increase susceptibility to oxidation produce unstable hemoglobins that precipitate, forming inclusion bodies injurious to the red cell membrane. Representative mutations are those that interfere with contact points between the α and β subunits [e.g., Hb Philly ($\beta^{35Tyr\rightarrow Phe}$)], alter the helical segments [e.g., Hb Genova ($\beta^{28Leu\rightarrow Pro}$)], or disrupt interactions of the hydrophobic pockets of the globin subunits with heme [e.g., Hb Koln ($\beta^{98Val\rightarrow Met}$)] (Table 91-3). The inclusions, called *Heinz bodies*, are clinically detectable by staining with supravital dyes such as crystal violet (Heinz body test). Removal of these inclusions by the spleen generates pitted, rigid cells that have shortened life spans, producing hemolytic anemia of variable severity, sometimes requiring chronic transfusion support. Splenectomy may be needed to correct the anemia. Leg ulcers and premature gallbladder disease due to bilirubin turnover are frequent stigmata.

Unstable hemoglobins occur sporadically, often by spontaneous new mutations. Heterozygotes are often symptomatic because a significant Heinz body burden can develop even when the unstable variant accounts for a portion of the total hemoglobin. Symptomatic unstable hemoglobins tend to be β-globin variants, because sporadic mutations affecting only one of the four α globins would generate only 20 to 30% abnormal hemoglobin.

HEMOGLOBINS WITH ALTERED OXYGEN AFFINITY *High-affinity hemoglobins* [e.g., Hb Yakima ($\beta^{99\ Asp\rightarrow His}$)] bind oxygen more readily but deliver less O_2 to tissues at normal capillary P_{O_2} levels (Fig. 91-2). Mild tissue hypoxia ensues, stimulating RBC production and erythrocytosis (Table 91-3). In extreme cases, the hematocrits can rise to 60 to 65%, increasing blood viscosity and producing typical symptoms (headache, somnolence, or dizziness). Phlebotomy may be required. Typical mutations alter interactions within the heme pocket or disrupt the Bohr effect or salt-bond site. Mutations that impair the interaction of HbA with 2,3-BPG can increase O_2 affinity because 2,3-BPG binding lowers O_2 affinity.

Low-affinity hemoglobins [e.g., Hb Kansas ($\beta^{102Asn\rightarrow Lys}$)] bind sufficient oxygen in the lungs, despite their lower oxygen affinity, to achieve nearly full saturation. At capillary oxygen tensions, they lose sufficient amounts of oxygen to maintain homeostasis at a low hematocrit (Fig. 91-2) (*pseudoanemia*). Capillary hemoglobin desaturation can also be sufficient to produce clinically apparent cyanosis. Despite these findings, patients usually require no specific treatment.

METHEMOGLOBINEMIAS Methemoglobin is generated by oxidation of the heme iron moieties to the ferric state, causing a characteristic bluish-brown muddy color resembling cyanosis. Methemoglobin has such

TABLE 91-3 *Representative Abnormal Hemoglobins with Altered Synthesis or Function*

Designation	Mutation	Population	Main Clinical Effects[a]
Sickle or S	$\beta^{6Glu\rightarrow Val}$	African	Anemia, ischemic infarcts
C	$\beta^{6Glu\rightarrow Lys}$	African	Mild anemia; interacts with HbS
E	$\beta^{26Glu\rightarrow Lys}$	Southeast Asian	Microcytic anemia, splenomegaly, thalassemic phenotype
Köln	$\beta^{98Val\rightarrow Met}$	Sporadic	Hemolytic anemia, Heinz bodies when splenectomized
Yakima	$\beta^{99Asp\rightarrow His}$	Sporadic	Polycythemia
Kansas	$\beta^{102Asn\rightarrow Lys}$	Sporadic	Mild anemia
M. Iwata	$\alpha^{87His\rightarrow Tyr}$	Sporadic	Methemoglobinemia

[a] See text for details.

high oxygen affinity that virtually no oxygen is delivered to tissues. Levels >50 to 60% are often fatal.

Congenital methemoglobinemia arises from globin mutations that stabilize iron in the ferric state [e.g., HbM Iwata ($\alpha^{87\ His \rightarrow Tyr}$), Table 91-3] or from mutations that impair the enzymes that reduce methemoglobin to hemoglobin (e.g., methemoglobin reductase, NADP diaphorase). Acquired methemoglobinemia is caused by toxins that oxidize heme iron, notably nitrate and nitrite-containing compounds.

DIAGNOSIS AND MANAGEMENT OF PATIENTS WITH UNSTABLE HEMOGLOBINS, HIGH-AFFINITY HEMOGLOBINS, AND METHEMOGLOBINEMIA *Unstable hemoglobin variants* should be suspected in patients with nonimmune hemolytic anemia, jaundice, splenomegaly, or premature biliary tract disease. Severe hemolysis usually presents during infancy as neonatal jaundice or anemia. Milder cases may present in adult life with anemia or only as unexplained reticulocytosis, hepatosplenomegaly, premature biliary tract disease, or leg ulcers. Because spontaneous mutation is common, family history of anemia may be absent. The peripheral blood smear often shows anisocytosis, abundant cells with punctate inclusions, and irregular shapes (i.e., poikilocytosis).

The two best tests for diagnosing unstable hemoglobins are the Heinz body preparation and the isopropanol or heat stability test. Many unstable Hb variants are electrophoretically silent. A normal electrophoresis does not rule out the diagnosis.

Severely affected patients may require transfusion support for the first 3 years of life, because splenectomy before age 3 is associated with a significantly higher immune deficit. Splenectomy is usually effective thereafter, but occasional patients may require lifelong transfusion support. Even after splenectomy, patients can develop cholelithiasis and leg ulcers. Splenectomy can also be considered in patients exhibiting severe secondary complications of chronic hemolysis, even if anemia is absent. Precipitation of unstable hemoglobins is aggravated by oxidative stress, e.g., infection, antimalarial drugs.

High-O_2 affinity hemoglobin variants should be suspected in patients with erythrocytosis. The best test for confirmation is measurement of the P_{50}. A high-O_2 affinity Hb causes a significant left shift (i.e., lower numeric value of the P_{50}); confounding conditions, e.g., tobacco smoking or carbon monoxide exposure, can also lower the P_{50}.

High-affinity hemoglobins are often asymptomatic; rubor or plethora may be telltale signs. When the hematocrit reaches to 55 to 60%, symptoms of high blood viscosity and sluggish flow (headache, lethargy, dizziness, etc.) may be present. These persons may benefit from judicious phlebotomy. Erythrocytosis represents an appropriate attempt to compensate for the impaired oxygen delivery by the abnormal variant. Overzealous phlebotomy may stimulate increased erythropoiesis or aggravate symptoms by thwarting this compensatory mechanism. The guiding principle of phlebotomy should be to improve oxygen delivery by reducing blood viscosity and increasing blood flow rather than restoration of a normal hematocrit. Modest iron deficiency may aid in control.

Low-affinity hemoglobins should be considered in patients with cyanosis or a low hematocrit with no other reason apparent after thorough evaluation. The P_{50} test confirms the diagnosis. Counseling and reassurance are the interventions of choice.

Methemoglobin should be suspected in patients with hypoxic symptoms who appear cyanotic but have a Pa_{O_2} sufficiently high that hemoglobin should be fully saturated with oxygen. A history of nitrite or other oxidant ingestions may not always be available; some exposures may be unapparent to the patient, and others may result from suicide attempts. The characteristic muddy appearance of freshly drawn blood can be a critical clue. The diagnostic test of choice is measurement of the methemoglobin content, which is usually available on an emergency basis.

Methemoglobinemia often causes symptoms of cerebral ischemia at levels >15%; levels >60% are usually lethal. Intravenous injection of 1 mg/kg of methylene blue is effective emergency therapy. Milder cases and follow-up of severe cases can be treated orally with methylene blue (60 mg three to four times each day) or ascorbic acid (300 to 600 mg/d).

THALASSEMIA SYNDROMES

The thalassemia syndromes are inherited disorders of α- or β-globin biosynthesis. The reduced supply of globin diminishes production of hemoglobin tetramers, causing hypochromia and microcytosis. Unbalanced accumulation of α and β subunits occurs because the synthesis of the unaffected globins proceeds at a normal rate. Unbalanced chain accumulation dominates the clinical phenotype. Clinical severity varies widely, depending on the degree to which the synthesis of the affected globin is impaired, altered synthesis of other globin chains, and coinheritance of other abnormal globin alleles.

CLINICAL MANIFESTATIONS OF β-THALASSEMIA SYNDROMES Mutations causing thalassemia can affect any step in the pathway of globin gene expression: transcription, processing of the mRNA precursor, translation, and posttranslational metabolism of the β-globin polypeptide chain. The most common forms arise from mutations that derange splicing of the mRNA precursor or prematurely terminate translation of the mRNA.

Hypochromia and microcytosis characterize all forms of β thalassemia because of the reduced amounts of hemoglobin tetramers (Fig. 91-5). In heterozygotes (β-thalassemia trait), this is the only abnormality seen. Anemia is minimal. In more severe homozygous states, unbalanced α- and β-globin accumulation causes accumulation of highly insoluble unpaired α chains. They form toxic inclusion bodies that kill developing erythroblasts in the marrow. Few of the proerythroblasts beginning erythroid maturation survive. The few RBCs surviving bear a burden of inclusion bodies that are detected in the spleen, shortening the RBC life span and producing severe hemolytic anemia. The resulting profound anemia stimulates erythropoietin release and compensatory erythroid hyperplasia, but the marrow response is sabotaged by ineffective erythropoiesis. Anemia persists. Erythroid hyperplasia can become exuberant and produce masses of extramedullary erythropoietic tissue in the liver and spleen.

Massive bone marrow expansion deranges growth and development. Children develop characteristic chipmunk facies due to maxillary marrow hyperplasia and frontal bossing, thinning and pathologic fracture of long bones and vertebrae due to cortical invasion by erythroid elements, and profound growth retardation. Hemolytic anemia causes hepatosplenomegaly, leg ulcers, gallstones, and high-output congestive heart failure. The conscription of caloric resources to support erythropoiesis leads to inanition, susceptibility to infection, endocrine dysfunction, and in the most severe cases, death during the first decade of life. Chronic transfusions with RBCs improves oxygen delivery, suppresses the excessive ineffective erythropoiesis, and prolongs life, but the inevitable side effects, notably iron overload, usually prove fatal by age 30.

Severity is highly variable. Known modulating factors are those that ameliorate the burden of unpaired α-globin inclusions. Alleles associated with milder synthetic defects and coinheritance of α-thalassemia trait reduce clinical severity by reducing accumulation of excess α globin. HbF persists to various degrees in β thalassemias. γ-Globin gene chains can substitute for β chains, simultaneously generating more hemoglobin and reducing the burden of α-globin inclu-

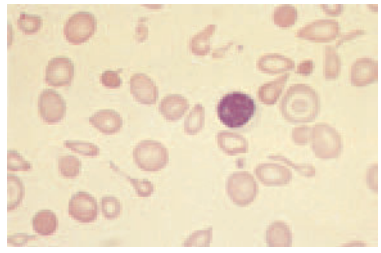

FIGURE 91-5 β-Thalassemia intermedia. Microcytic and hypochromic red blood cells are seen that resemble the red blood cells of severe iron deficiency anemia. Many elliptical and teardrop-shaped red blood cells are noted.

sions. The terms *β-thalassemia major* and *β-thalassemia intermedia* are used to reflect the clinical heterogeneity. Patients with β-thalassemia major require intensive transfusion support to survive. Patients with β-thalassemia intermedia have a somewhat milder phenotype and can survive without transfusion. The terms *β-thalassemia minor* and *β-thalassemia trait* describe asymptomatic heterozygotes for β-thalassemia.

TABLE 91-4 *The α Thalassemias*

Condition	Hemoglobin A, %	Hemoglobin H (β^4), %	Hemoglobin level, g/L (g/dL)	MCV, fL
Normal	97	0	150 (15)	90
Silent thalassemia: $-\alpha/\alpha\alpha$	98–100	0	150 (15)	90
Thalassemia trait:	85–95	Rare red blood cell inclusions	120–130 (12–13)	70–80
$-\alpha/-\alpha$ homozygous α-thal-2[a] or $--/\alpha\alpha$ heterozygous α-thal-1[a]				
Hemoglobin H disease:	70–95	5–30	60–100 (6–10)	60–70
$--/-\alpha$ heterozygous α-thal-1/α-thal-2				
Hydrops fetalis:	0	5–10[b]	Fatal in utero or at birth	
$--/--$ homozygous α-thal-1				

[a] When both α alleles on one chromosome are deleted, the locus is called α-thal-1; when only a single α allele on one chromosome is deleted, the locus is called α-thal-2.
[b] 90–95% of the hemoglobin is hemoglobin Barts (tetramers of γ chains).

α-THALASSEMIA SYNDROMES The four classic α-thalassemias, most common in Asians, are α-thalassemia-2 trait, in which one of the four α-globin loci is deleted; α-thalassemia-1 trait, with two deleted loci; HbH disease, with three loci deleted; and hydrops fetalis with Hb Bart's, with all four loci deleted (Table 91-4). Nondeletion forms of α-thalassemia also exist.

α-Thalassemia-2 trait is an asymptomatic, silent carrier state. *α-Thalassemia-1 trait* resembles β-thalassemia minor. Offspring doubly heterozygous for α-thalassemia-2 and α-thalassemia-1 exhibit a more severe phenotype called HbH disease. Heterozygosity for a deletion that removes both genes from the same chromosome (*cis* deletion) is common in Asians and Mediterranean individuals, as is homozygosity for α-thalassemia-2 (*trans* deletion). Both produce asymptomatic hypochromia and microcytosis.

In *HbH disease,* HbA production is only 25 to 30% of normal. Fetuses accumulate some unpaired β chains. In adults, unpaired β chains accumulate and are soluble enough to form β_4 tetramers called HbH. HbH forms few inclusions in erythroblasts but does not precipitate in circulating red cells. Patients with HbH disease have thalassemia intermedia characterized by moderately severe hemolytic anemia but milder ineffective erythropoiesis. Survival into mid-adult life without transfusions is common.

The homozygous state for the α-thalassemia-1 *cis* deletion (hydrops fetalis) causes total absence of α-globin synthesis. No physiologically useful hemoglobin is produced beyond the embryonic stage. Excess γ globin forms tetramers called *Hb Barts* (γ_4), which has an extraordinarily high oxygen affinity. It delivers almost no O_2 to fetal tissues, causing tissue asphyxia, edema (hydrops fetalis), congestive heart failure, and death in utero. α-Thalassemia-2 trait is common (15 to 20%) among people of African descent. The *cis* α-thalassemia-1 deletion is almost never seen, however. Thus, α-thalassemia-2 and the *trans* form of α-thalassemia-1 are very common, but HbH disease and hydrops fetalis are almost never encountered.

It has been known for some time that some patients with myelodysplasia or erythroleukemia produce red cell clones containing HbH. It now appears that this phenomenon is due to mutations in the ATRX pathway that affect the LCR of the α-globin gene cluster.

DIAGNOSIS AND MANAGEMENT OF THALASSEMIAS The diagnosis of β-thalassemia major is readily made during childhood on the basis of severe anemia accompanied by the characteristic signs of massive ineffective erythropoiesis: hepatosplenomegaly, profound microcytosis, a characteristic blood smear (Fig. 91-5), and elevated levels of HbF, HbA_2, or both. Many patients require chronic hypertransfusion therapy designed to maintain a hematocrit of at least 27 to 30% so that erythropoiesis is suppressed. Splenectomy is required if the annual transfusion requirement (volume of RBCs per kilogram of body weight per year) increases by >50%. Folic acid supplements may be useful. Vaccination with Pneumovax in anticipation of eventual splenectomy is advised, as is close monitoring for infection, leg ulcers, and biliary tract disease. Early endocrine evaluation is required for glucose intolerance, thyroid dysfunction, and delayed onset of puberty or secondary sexual characteristics. Many patients develop endocrine deficiencies as a result of iron overload.

Patients with β-thalassemia intermedia exhibit similar stigmata but can survive without chronic hypertransfusion. Management is particularly challenging because a number of factors can aggravate the anemia, including infection, onset of puberty, and development of splenomegaly and hypersplenism. Some patients may eventually benefit from splenectomy. The expanded erythron can cause absorption of excessive dietary iron and hemosiderosis, even without transfusion.

β-Thalassemia minor (i.e., thalassemia trait) usually presents as profound microcytosis and hypochromia with target cells, but only minimal or mild anemia. The mean corpuscular volume is rarely >75 fL; the hematocrit is rarely <30 to 33%. Hemoglobin electrophoresis classically reveals an elevated HbA_2 (3.5 to 7.5%), but some forms are associated with normal HbA_2 and/or elevated HbF. Genetic counseling and patient education are essential. Patients with β-thalassemia trait should be warned that their blood picture resembles iron deficiency and can be misdiagnosed. They should eschew routine use of iron but know that iron deficiency requiring supplementation can develop, as in other persons, during pregnancy or from chronic bleeding.

Persons with α-thalassemia trait may exhibit mild hypochromia and microcytosis usually without anemia. HbA_2 and HbF levels are normal. Affected individuals usually require only genetic counseling. HbH disease resembles β-thalassemia intermedia, with the added complication that the HbH molecule behaves like a moderately unstable hemoglobin. Patients with HbH disease should undergo splenectomy if excessive anemia or a transfusion requirement develops. Oxidative drugs should be avoided. Iron overload leading to death can occur in more severely affected patients.

PREVENTION Antenatal diagnosis of thalassemia syndromes is now widely available. DNA diagnosis is based on PCR amplification of fetal DNA, obtained by amniocentesis or chorionic villus biopsy followed by hybridization to allele-specific oligonucleotides probes. The probes can be designed to detect simultaneously the subset of mutations that account for 95 to 99% of the α- or β-thalassemias that occur in a particular ethnic group.

THALASSEMIC STRUCTURAL VARIANTS

Thalassemic structural variants are characterized by both defective synthesis and abnormal structure.

HEMOGLOBIN LEPORE Hb Lepore [$\alpha_2(\delta\beta)_2$] arises by an unequal crossover and recombination event that fuses the proximal end of the δ-gene with the distal end of the closely linked β-gene. The resulting chromosome contains only the fused δβ gene. The Lepore (δβ) globin is synthesized poorly because the fused gene is under the control of the weak δ-globin promoter. Hb Lepore alleles have a phenotype like β-thalassemia, except for the added presence of 2 to 20% Hb Lepore. Compound heterozygotes for Hb Lepore and a classic β-thalassemia allele may also have severe thalassemia.

HEMOGLOBIN E HbE (i.e., $\alpha_2\beta_2^{26Glu\rightarrow Lys}$) is extremely common in Cambodia, Thailand, and Vietnam. The gene has become far more prevalent in the United States as a result of immigration of Asian persons, especially in California, where HbE is the most common variant de-

tected. HbE is mildly unstable but not enough to affect RBC life span significantly. The high frequency of the HbE gene may be a result of the thalassemia phenotype associated with its inheritance. Heterozygotes resemble individuals with mild β-thalassemia trait. Homozygotes have somewhat more marked abnormalities but are asymptomatic. Compound heterozygotes for HbE and a β-thalassemia gene can have β-thalassemia intermedia or β-thalassemia major, depending on the severity of the coinherited thalassemic gene.

The β^E allele contains only a single base change, in codon 26, that causes the amino acid substitution. However, this mutation activates a cryptic RNA splice site generating a structurally abnormal globin mRNA that cannot be translated from about 50% of the initial pre-mRNA molecules. The remaining 40 to 50% that are normally spliced generate functional mRNA that is translated into β^E-globin because the mature mRNA carries the base change that alters codon 26.

Genetic counseling of the persons at risk for HbE should be concerned with the interaction of HbE with β thalassemia rather than HbE homozygosity, a condition associated with asymptomatic microcytosis, hypochromia, and hemoglobin levels rarely $<$10 g/dL.

HEREDITARY PERSISTENCE OF FETAL HEMOGLOBIN HPFH is characterized by continued synthesis of high levels of HbF in adult life. No deleterious effects are apparent, even when all of the hemoglobin produced is HbF. These rare patients demonstrate convincingly that prevention or reversal of the fetal to adult hemoglobin switch would provide efficacious therapy for sickle cell anemia and β thalassemia.

ACQUIRED HEMOGLOBINOPATHIES The two most important acquired hemoglobinopathies are carbon monoxide poisoning and methemoglobinemia, which is covered elsewhere in this chapter. Carbon monoxide has a higher affinity for hemoglobin than does oxygen; it can replace oxygen and diminish O_2 delivery. Chronic elevation of carboxyhemoglobin levels to 10 or 15%, as occurs in smokers, can lead to secondary polycythemia. Carboxyhemoglobin is cherry red in color and masks the development of cyanosis usually associated with poor O_2 delivery to tissues.

Abnormalities of hemoglobin biosynthesis have also been described in blood dyscrasias. In some patients with myelodysplasia, erythroleukemia, or myeloproliferative disorders, a mild form of HbH disease may also be seen. The abnormalities are not severe enough to alter the course of the underlying disease.

MANAGEMENT OF TRANSFUSIONAL HEMOSIDEROSIS

Chronic blood transfusion can lead to bloodborne infection, alloimmunization, febrile reactions, and lethal iron overload. A unit of packed RBCs contains 250 to 300 mg iron (1 mg/mL). The iron assimilated by single transfusion of two units of packed RBCs is thus equal to a 1- to 2-year intake of iron. Iron accumulates in chronically transfused patients because no mechanisms exist for increasing iron excretion: an expanded erythron causes especially rapid development of iron overload because accelerated erythropoiesis promotes excessive absorption of dietary iron. Vitamin C should not be supplemented because it generates free radicals in iron excess states.

Patients who receive $>$100 units of packed RBCs usually develop hemosiderosis. The ferritin level rises, followed by early endocrine dysfunction (glucose intolerance and delayed puberty), cirrhosis, and cardiomyopathy. Liver biopsy shows both parenchymal and reticuloendothelial iron. The superconducting quantum-interference device (SQUID) is accurate at measuring hepatic iron but not widely available. Cardiac toxicity is often insidious. Early development of pericarditis is followed by dysrhythmia and pump failure. The onset of heart failure is ominous, often presaging death within a year (Chap. 336).

The decision to start long-term transfusion support should also prompt one to institute therapy with iron-chelating agents. The only approved and available iron chelator, desferoxamine (Desferal), is expensive and poorly absorbed from the gastrointestinal tract. Its iron-binding kinetics require chronic slow infusion via a metering pump. The constant presence of the drug improves the efficiency of chelation and protects tissues from occasional releases of the most toxic fraction of iron—low-molecular-weight iron—which may not be sequestered by protective proteins. Oral iron-chelating agents such as deferiprone showed initial promise, but long-term trials have raised serious doubts about their efficacy and safety. Newer oral agents are in clinical trials.

Desferoxamine is relatively nontoxic. Occasional cataracts, deafness, and local skin reactions, including urticaria, occur. Skin reactions can usually be managed with antihistamines. Negative iron balance can be achieved, even in the face of a high transfusion requirement, but this alone does not prevent long-term morbidity and mortality in chronically transfused patients. Irreversible end-organ deterioration develops at relatively modest levels of iron overload, even if symptoms do not appear for many years thereafter. To enjoy a significant survival advantage, chelation must begin before 5 to 8 years of age in β thalassemia major.

EXPERIMENTAL THERAPIES

BONE MARROW TRANSPLANTATION, GENE THERAPY, AND MANIPULATION OF HbF Bone marrow transplantation provides stem cells able to express normal hemoglobin; it has been used in a large number of patients with β thalassemia and a smaller number of patients with sickle cell anemia. Early in the course of disease, before end-organ damage occurs, transplantation is curative in 80 to 90% of patients. In highly experienced centers, the treatment-related mortality is $<$10%. Since survival into adult life is possible with conventional therapy, the decision to transplant is best made in consultation with specialized centers.

Gene therapy of thalassemia and sickle cell disease has proved to be an exceptionally elusive goal. Uptake of gene vectors into the nondividing hematopoietic stem cells has been disappointingly inefficient. Lentiviral-type vectors that can transduce nondividing cells may solve this problem.

Reestablishing high levels of fetal hemoglobin synthesis should ameliorate the symptoms of β thalassemia. Cytotoxic agents such as hydroxyurea and cytarabine promote high levels of HbF synthesis, probably by stimulating proliferation of the primitive HbF-producing progenitor cell population (i.e., F cell progenitors). Unfortunately, no regimen has yet been identified that ameliorates the clinical manifestations of β thalassemia. Butyrates stimulate HbF production, but only transiently. Pulsed or intermittent administration has recently been found to sustain HbF induction in the majority of patients with sickle cell disease. It is unclear whether butyrates will have similar activity in patients with β thalassemia.

APLASTIC AND HYPOPLASTIC CRISIS IN PATIENTS WITH HEMOGLOBINOPATHIES

Patients with hemolytic anemias sometimes exhibit an alarming decline in hematocrit during and immediately after acute illnesses. Bone marrow suppression occurs in almost everyone during acute inflammatory illnesses. In patients with short RBC life spans, suppression can affect RBC counts more dramatically. These hypoplastic crises are usually transient and self-correcting before intervention is required.

Aplastic crisis refers to a profound cessation of erythroid activity in patients with chronic hemolytic anemias. It is associated with a rapidly falling hematocrit. Episodes are usually self-limited. Aplastic crises are caused by infection with a particular strain of parvovirus, B19A. Children infected with this virus usually develop permanent immunity. Aplastic crises do not often recur and are rarely seen in adults. Management requires close monitoring of the hematocrit and reticulocyte count. If anemia becomes symptomatic, transfusion support is indicated. Most crises resolve spontaneously within 1 to 2 weeks.

92 MEGALOBLASTIC ANEMIAS

Bernard M. Babior, H. Franklin Bunn

The megaloblastic anemias are disorders caused by impaired DNA synthesis. Cells primarily affected are those having relatively rapid turnover, especially hematopoietic precursors and gastrointestinal epithelial cells. Cell division is sluggish, but cytoplasmic development progresses normally, so megaloblastic cells tend to be large, with an increased ratio of RNA to DNA. Megaloblastic erythroid progenitors tend to be destroyed in the marrow. Thus, marrow cellularity is often increased but production of red blood cells (RBC) is decreased, an abnormality termed *ineffective erythropoiesis* (Chap. 52).

Most megaloblastic anemias are due to a deficiency of cobalamin (vitamin B_{12}) and/or folic acid. The various clinical entities associated with megaloblastic anemia are listed in Table 92-1.

PHYSIOLOGIC AND BIOCHEMICAL CONSIDERATIONS

FOLIC ACID Folic acid is the common name for pteroylmonoglutamic acid. It is synthesized by many different plants and bacteria. Fruits and vegetables constitute the primary dietary source of the vitamin. Some forms of dietary folic acid are labile and may be destroyed by cooking. The minimum daily requirement is normally about 50 μg, but this may be increased severalfold during periods of enhanced metabolic demand such as pregnancy.

The assimilation of adequate amounts of folic acid depends on the nature of the diet and its means of preparation. Folates in various foodstuffs are largely conjugated to a chain of glutamic acid residues. This highly polar side chain impairs the intestinal absorption of the vitamin. However, conjugases (γ-glutamyl carboxypeptidases) in the lumen of the gut convert polyglutamates to mono- and diglutamates, which are readily absorbed in the proximal jejunum.

Plasma folate is primarily in the form of N^5-methyltetrahydrofolate, a monoglutamate, which is transported into cells by a carrier that is specific for the tetrahydro forms of the vitamin. Once in the cell, the N^5-methyl group is removed in a cobalamin-requiring reaction (see below), and the folate is then reconverted to the polyglutamate form. Conjugation to polyglutamate may be useful for retention of folate within the cell.

A folate-binding protein occurs in plasma, milk, and other body fluids. The function of this folate binder and its membrane-bound precursor is unknown. Neither the binder nor its precursor is related to the tetrahydrofolate carrier.

Normal individuals have about 5 to 20 mg folic acid in various body stores, half in the liver. In light of the minimum daily requirement, it is not surprising that a deficiency will occur within months if dietary intake or intestinal absorption is curtailed.

The prime function of folate compounds is to transfer 1-carbon moieties such as methyl and formyl groups to various organic compounds (Fig. 92-1). The sources of these 1-carbon moieties is usually serine, which reacts with tetrahydrofolate to produce glycine and $N^{5,10}$-methylenetetrahydrofolate. An alternative source is formiminoglutamic acid, an intermediate in histidine catabolism, which gives up its formimino group to tetrahydrofolate to yield N^5-formiminotetrahydrofolate and glutamic acid. These derivatives provide entry into an interconvertible donor pool consisting of tetrahydrofolate derivatives carrying various 1-carbon moieties. The constituents of this pool can donate their 1-carbon moieties to appropriate acceptor compounds to form metabolic intermediates, which are ultimately converted to build-

TABLE 92-1 Classification of the Megaloblastic Anemias

COBALAMIN DEFICIENCY

I. Inadequate intake: vegans (rare)
II. Malabsorption
  A. Defective release of cobalamin from food
    1. Gastric achlorhydria
    2. Partial gastrectomy
    3. Drugs that block acid secretion
  B. Inadequate production of intrinsic factor (IF)
    1. Pernicious anemia
    2. Total gastrectomy
    3. Congenital absence or functional abnormality of IF (rare)
  C. Disorders of terminal ileum
    1. Tropical sprue
    2. Nontropical sprue
    3. Regional enteritis
    4. Intestinal resection
    5. Neoplasms and granulomatous disorders (rare)
    6. Selective cobalamin malabsorption (Imerslund's syndrome) (rare)
  D. Competition for cobalamin
    1. Fish tapeworm (*Diphyllobothrium latum*)
    2. Bacteria: "blind loop" syndrome
  E. Drugs: *p*-aminosalicylic acid, colchicine, neomycin
III. Other
  A. Nitrous oxide
  B. Transcobalamin II deficiency (rare)
  C. Congenital enzyme defects (rare)

FOLIC ACID DEFICIENCY

I. Inadequate intake: unbalanced diet (common in alcoholics, teenagers, some infants)
II. Increased requirements
  A. Pregnancy
  B. Infancy
  C. Malignancy
  D. Increased hematopoiesis (chronic hemolytic anemias)
  E. Chronic exfoliative skin disorders
  F. Hemodialysis
III. Malabsorption
  A. Tropical sprue
  B. Nontropical sprue
  C. Drugs: Phenytoin, barbiturates, (?) ethanol
IV. Impaired metabolism
  A. Inhibitors of dihydrofolate reductase: methotrexate, pyrimethamine, triamterene, pentamidine, trimethoprim
  B. Alcohol
  C. Rare enzyme deficiencies: dihydrofolate reductase, others

OTHER CAUSES

I. Drugs that impair DNA metabolism
  A. Purine antagonists: 6-mercaptopurine, azathioprine, etc.
  B. Pyrimidine antagonists: 5-fluorouracil, cytosine arabinoside, etc.
  C. Others: procarbazine, hydroxyurea, acyclovir, zidovudine
II. Metabolic disorders (rare)
  A. Hereditary orotic aciduria
  B. Lesch-Nyhan syndrome
  C. Others
III. Megaloblastic anemia of unknown etiology
  A. Refractory megaloblastic anemia
  B. Di Guglielmo's syndrome[a]
  C. Congenital dyserythropoietic anemia

[a] A form of acute myeloid leukemia with atypical, dysplastic changes in erythroid series.

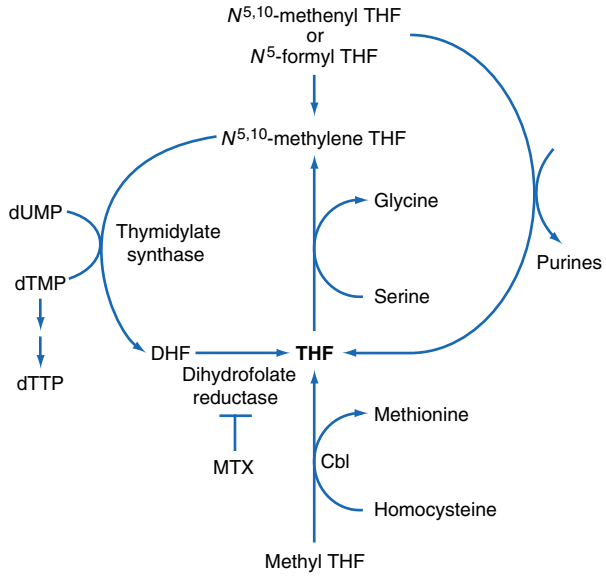

FIGURE 92-1 Folate metabolism. Folate is essential for the de novo synthesis of purines, deoxythymidylate monophosphate (dTMP), and methionine, serving as an intermediate carrier of 1-carbon fragments used in the biosynthesis of these compounds. Its active form is tetrahydrofolate (THF). THF acquires the 1-carbon fragment principally from serine, which is converted to glycine in the course of the reaction. For purine synthesis, the 1-carbon fragment is first oxidized to the level of formic acid, then transferred to substrate. For methionine synthesis, a cobalamin-requiring reaction, the 1-carbon fragment is first reduced to the level of a methyl group, then transferred to homocysteine. In these reactions the cofactor is released as THF, which can immediately participate in another 1-carbon transfer cycle. During the production of dTMP from dUMP, however, the 1-carbon fragment is reduced from formaldehyde to a methyl group in the course of the transfer reaction. The hydrogen atoms used for this reduction come from the cofactor, which is therefore released, not as THF, but as dihydrofolate (DHF). To participate further in the 1-carbon transfer cycle, the DHF has to be re-reduced to THF, a reaction catalyzed by dihydrofolate reductase.

ing blocks used in the synthesis of macromolecules. The most important building blocks are (1) purines, in which the C-2 and C-8 atoms are introduced in folate-dependent reactions; (2) deoxythymidylate monophosphate (dTMP), synthesized from $N^{5,10}$-methylenetetrahydrofolate and deoxyuridylate monophosphate (dUMP); and (3) methionine, formed by the transfer of a methyl group from N^5-methyltetrahydrofolate to homocysteine (two of these three reactions are shown in Fig. 92-1).

In all but one of the 1-carbon transfer reactions, tetrahydrofolate is produced. It can immediately accept a 1-carbon moiety and reenter the donor pool. The single exception is the thymidylate synthase reaction (dUMP → dTMP), in which dihydrofolate is the product (Fig. 92-1). This must be reduced to tetrahydrofolate by the enzyme dihydrofolate reductase before it can reenter the donor pool. A number of drugs are able to inhibit dihydrofolate reductase (Table 92-1), thereby diverting folate from the donor pool and producing what amounts to a state of folate deficiency in the face of normal tissue folate concentrations.

COBALAMIN This vitamin is a complex organometallic compound in which a cobalt atom is situated within a corrin ring, a structure similar to the porphyrin from which heme is formed. Unlike heme, however, cobalamin cannot be synthesized in the human body and must be supplied in the diet. The only dietary source of cobalamin is animal products: meat and dairy foods. The minimum daily requirement for cobalamin is about 2.5 μg.

During gastric digestion, cobalamin in food is released and forms a stable complex with gastric R binder, one of a closely related group of glycoproteins of unknown function that are found in secretions (e.g., saliva, milk, gastric juice, bile), phagocytes, and plasma. On entering the duodenum, the cobalamin–R binder complex is digested, releasing the cobalamin, which then binds to intrinsic factor (IF), a 50-kDa glycoprotein produced by the parietal cells of the stomach. The secretion of IF generally parallels that of hydrochloric acid. The cobalamin-IF complex is resistant to proteolytic digestion and travels to the distal ileum, where specific receptors on the mucosal brush border bind and absorb the cobalamin-IF complex. Thus, IF, like iron-binding transferrin, is a cell-directed carrier protein. The receptor-bound cobalamin-IF complex is taken into the ileal mucosal cell, where the IF is destroyed and the cobalamin is transferred to another transport protein, transcobalamin (TC) II. The cobalamin–TC II complex is then secreted into the circulation, from which it is rapidly taken up by the liver, bone marrow, and other cells. The pathway of cobalamin absorption is shown in Fig. 92-2. Normally, about 2 mg cobalamin is stored in the liver, and another 2 mg is stored elsewhere in the body. In view of the minimum daily requirement, about 3 to 6 years would be required for a normal individual to become deficient in cobalamin if absorption were to cease abruptly.

Although TC II is the acceptor for newly absorbed cobalamin, most circulating cobalamin is bound to TC I, a glycoprotein closely related to gastric R binder. TC I appears to be derived in part from leukocytes. The paradox that most circulating cobalamin is bound to TC I rather than TC II, even though TC II initially carries all the cobalamin that is absorbed by the intestine, is explained by the fact that cobalamin bound to TC II is rapidly cleared from the blood ($t_{1/2}$ about 1 h), while clearance of cobalamin bound to TC I requires many days. The function of TC I is unknown.

Cobalamin is an essential cofactor for two enzymes in human cells: methionine synthase and methylmalonyl–coenzyme A (CoA) synthase. Cobalamin exists in two metabolically active forms, identified by the alkyl group attached to the sixth coordination position of the cobalt atom: methylcobalamin and adenosylcobalamin. The vitamin preparation that is used therapeutically is cyanocobalamin (also called vitamin B_{12}). Cyanocobalamin has no known physiologic role and must be converted to a biologically active form before it can be used by tissues.

Methylcobalamin is the form required for methionine synthase,

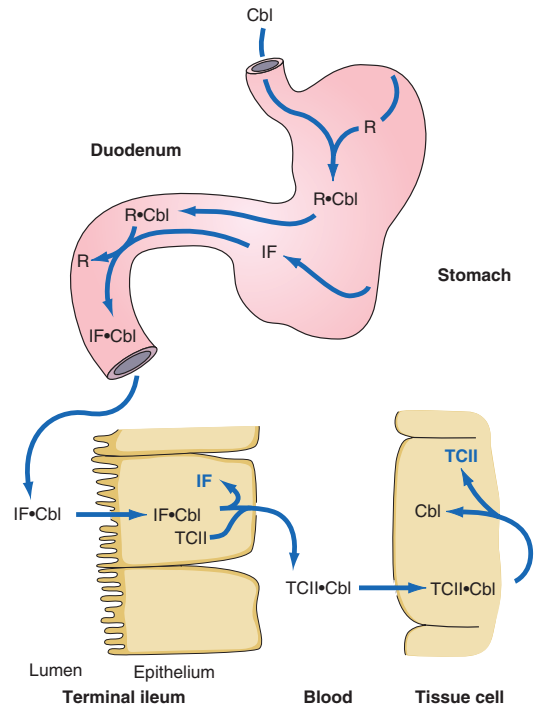

FIGURE 92-2 The assimilation of cobalamin. On entering the stomach, dietary cobalamin (Cbl) forms a complex with R binding protein. As this protein is digested in the small intestine, cobalamin is transferred to intrinsic factor (IF). This complex passes through the intestine until it reaches specific receptors on the mucosa of the distal ileum. The internalized Cbl is then transferred to transcobalamin II (TC II), which circulates in the plasma until it binds to receptors on cells throughout the body and is internalized.

which catalyzes the conversion of homocysteine to methionine (Fig. 92-1). When this reaction is impaired, folate metabolism is deranged; it is this derangement that underlies the defect in DNA synthesis and the megaloblastic maturation pattern in patients who are deficient in cobalamin. In cobalamin deficiency, the unconjugated N^5-methyltetrahydrofolate newly taken from the bloodstream cannot be converted to other forms of tetrahydrofolate by methyl transfer. This is the so-called folate trap hypothesis. Because N^5-methyltetrahydrofolate is a poor substrate for the conjugating enzyme, it largely remains in the unconjugated form and slowly leaks from the cell. Tissue folate deficiency therefore develops, and this results in megaloblastic hematopoiesis. This hypothesis explains why tissue folate stores in cobalamin deficiency are substantially reduced, with a disproportionate reduction in conjugated, as compared with unconjugated, folates, despite normal or supranormal serum folate levels. It also explains why large doses of folate can produce a partial hematologic remission in patients with cobalamin deficiency.

Megaloblastic changes in both cobalamin and folate deficiency as well as in methotrexate treatment are related to a deficiency in production of dTMP. In addition, the excess deoxyuridylate that accumulates can be phosphorylated and mistakenly incorporated into DNA in place of thymidylate; base pairing can be affected by this U-for-T substitution.

Plasma homocysteine levels are elevated in both folate and cobalamin deficiency, and high levels of plasma homocysteine appear to be a risk factor for venous and arterial thrombosis. It is not yet known if hyperhomocysteinemia due to folate or cobalamin deficiency predisposes to thrombosis or alters its response to treatment.

Impairment in the conversion of homocysteine to methionine may also contribute to the neurologic complications of cobalamin deficiency (see below). The methionine formed in this reaction is needed for the production of choline and choline-containing phospholipids. Nervous system damage is postulated to result at least in part from interference with these processes due to decreased methionine production in cobalamin deficiency.

Adenosylcobalamin is required for the conversion of methylmalonyl CoA to succinyl CoA. Lack of this cofactor leads to large increases in the tissue levels of methylmalonyl CoA and its precursor, propionyl CoA. As a consequence, nonphysiologic fatty acids containing an odd number of carbon atoms are synthesized and incorporated into neuronal lipids. This biochemical abnormality may also contribute to the neurologic complications of cobalamin deficiency (see below).

CLINICAL DISORDERS

CLASSIFICATION OF MEGALOBLASTIC ANEMIAS (Table 92-1) The cause of megaloblastic anemia varies in different parts of the world. In temperate zones, folate deficiency in alcoholics and cobalamin deficiency due to pernicious anemia or achlorhydria are the common types of megaloblastic anemias. In certain areas close to the equator, tropical sprue is endemic and an important cause of megaloblastic anemia, while in Scandinavia, infestations by the fish tapeworm, *Diphyllobothrium latum*, may be a cause.

The dietary intake of cobalamin is more than adequate for the body's requirements, except in complete vegetarians (vegans) and their breast-fed infants. Thus deficiency of cobalamin is almost always due to malabsorption. Malabsorption can occur at several levels. In contrast, the dietary intake of folic acid is marginal in many parts of the world. Furthermore, because the body's stores of folate are relatively low, folic acid deficiency can arise rather suddenly during periods of decreased dietary intake or increased metabolic demand. Finally, folic acid deficiency may be due to malabsorption. Often two or more of these factors coexist in a given patient.

Combined deficiencies of cobalamin and folic acid are not uncommon. Patients with tropical sprue are often deficient in both vitamins. The biochemical lesion that results in megaloblastic maturation of bone marrow cells also causes structural and functional abnormalities of the rapidly proliferating epithelial cells of the intestinal mucosa. Thus severe deficiency of one vitamin can lead to malabsorption of the other. Furthermore, as discussed above, a deficiency of cobalamin causes a secondary reduction in cellular folic acid.

Finally, megaloblastic anemias may occasionally be induced by factors unrelated to a vitamin deficiency. Most such cases are caused by drugs that interfere with DNA synthesis. Less commonly, megaloblastic maturation is a feature of certain acquired hematopoietic stem cell defects. Rarest of all are specific congenital enzyme deficiencies.

COBALAMIN DEFICIENCY The clinical features of cobalamin deficiency involve the blood, the gastrointestinal tract, and the nervous system.

The hematologic manifestations are almost entirely the result of anemia, although very rarely purpura may appear, due to thrombocytopenia. Symptoms of anemia may include weakness, light-headedness, vertigo, and tinnitus, as well as palpitations, angina, and the symptoms of congestive failure. On physical examination, the patient with florid cobalamin deficiency is pale, with slightly icteric skin and eyes. Elevated bilirubin levels are related to high erythroid cell turnover in the marrow. The pulse is rapid, and the heart may be enlarged; auscultation will usually reveal a systolic flow murmur.

The gastrointestinal manifestations reflect the effect of cobalamin deficiency on the rapidly proliferating gastrointestinal epithelium. The patient sometimes complains of a sore tongue, which on inspection will be smooth and beefy red. Anorexia with moderate weight loss may also be evident, possibly accompanied by diarrhea and other gastrointestinal symptoms. These latter manifestations may be caused in part by megaloblastosis of the small intestinal epithelium, which results in malabsorption.

The neurologic manifestations often fail to remit fully on treatment. The initial pathology is demyelination, followed by axonal degeneration and eventual neuronal death; the final stage, of course, is irreversible. Sites of involvement include peripheral nerves; the spinal cord, where the posterior and lateral columns undergo demyelination; and the cerebrum itself. Signs and symptoms include numbness and paresthesia in the extremities (the earliest neurologic manifestations), weakness, and ataxia. There may be sphincter disturbances. Reflexes may be diminished or increased. The Romberg and Babinski's signs may be positive, and position and vibration senses are usually diminished. Disturbances of mentation will vary from mild irritability and forgetfulness to severe dementia or frank psychosis. It should be emphasized that *neurologic disease may occur in a patient with a normal hematocrit* and normal RBC indices. Although it has many benefits, folate supplementation of food may increase the likelihood of neurologic presentations of cobalamin deficiency.

In the classic patient, in whom hematologic problems predominate, the blood and bone marrow show characteristic megaloblastic changes (described under "Diagnosis," below). The anemia may be very severe—hematocrits of 15 to 20 are not infrequent—but is surprisingly well tolerated by the patient because it develops slowly.

Defective Release of Cobalamin from Food Cobalamin in food is tightly bound to enzymes in meat and is split from these enzymes by hydrochloric acid and pepsin in the stomach. People >70 years commonly have achlorhydria. Therefore, they are unable to release cobalamin from food sources but retain the ability to absorb crystalline B_{12}, the form most commonly found in multivitamins. The exact incidence of the defect in cobalamin release from food has not been well defined; estimates vary from 10 to >50% of those over age 70 years. Only a minority of these persons go on to develop frank cobalamin deficiency, but many have biochemical changes, including low levels of cobalamin bound to TC II and elevated homocysteine levels, that augur cobalamin deficiency (see below).

Similarly, patients on drugs that suppress gastric acid production, such as omeprazole, may also fail to release cobalamin from food. However, the proton pump inhibitors do not inhibit IF secretion by parietal cells.

Pernicious Anemia Pernicious anemia, considered the most common cause of cobalamin deficiency, is caused by the absence of IF, due to either atrophy of the mucosa or autoimmune destruction of parietal cells. It is most frequently seen in individuals of northern European descent and African Americans and is much less common in southern Europeans and Asians. Men and women are equally affected. It is a disease of the elderly, the average patient presenting near age 60; it is rare under age 30, although typical pernicious anemia can be seen in children under age 10 (juvenile pernicious anemia). Inherited conditions in which a histologically normal stomach secretes either an abnormal IF or none at all will induce cobalamin deficiency in infancy or early childhood.

The incidence of pernicious anemia is substantially increased in patients with other diseases thought to be of immunologic origin, including Graves' disease, myxedema, thyroiditis, idiopathic adrenocortical insufficiency, vitiligo, and hypoparathyroidism. Patients with pernicious anemia also have abnormal circulating antibodies related to their disease: 90% have antiparietal cell antibody, which is directed against the H^+,K^+-ATPase, while 60% have anti-IF antibody. Antiparietal cell antibody is also found in 50% of patients with gastric atrophy without pernicious anemia, as well as in 10 to 15% of an unselected patient population, but anti-IF antibody is usually absent from these patients. Relatives of patients with pernicious anemia have an increased incidence of the disease, and even clinically unaffected relatives may have anti-IF antibody in their serum. Finally, treatment with glucocorticoids may reverse the disease.

Cytotoxic T cells may also contribute to the destruction of parietal cells in pernicious anemia. Pernicious anemia is unusually common in patients with agammaglobulinemia, supporting a role for the cellular immune system in its pathogenesis. In contrast, *Helicobacter pylori* does not cause parietal cell destruction in pernicious anemia.

The most characteristic finding in pernicious anemia is gastric atrophy affecting the acid- and pepsin-secreting portion of the stomach; the antrum is spared. Other pathologic changes are secondary to the deficiency of cobalamin; these include megaloblastic alterations in the gastric and intestinal epithelium and the neurologic changes described above. The abnormalities in the gastric epithelium appear as cellular atypia in gastric cytology specimens, a finding that must be carefully distinguished from the cytologic abnormalities seen in gastric malignancy.

The *clinical manifestations* are primarily those of cobalamin deficiency, as described above. The disease is of insidious onset and progresses slowly. Laboratory examination will reveal hypergastrinemia and pentagastrin-fast achlorhydria as well as the hematologic and other laboratory abnormalities discussed under "Diagnosis."

Through appropriate replacement therapy, patients with pernicious anemia should experience complete and lifelong correction of all abnormalities that are due to cobalamin deficiency, except to the extent that irreversible changes in the nervous system may have occurred before treatment. These patients, however, are unusually subject to gastric polyps and have about twice the normal incidence of cancer of the stomach. Thus, patients should be followed with frequent stool guaiac examinations and endoscopy when indicated.

Postgastrectomy Following total gastrectomy or extensive damage to gastric mucosa as, for example, by ingestion of corrosive agents, megaloblastic anemia will develop because the source of IF has been removed. In all such patients, the absorption of orally administered cobalamin is impaired. Megaloblastic anemia may also follow partial gastrectomy, but the incidence is lower than after total gastrectomy. The cause of cobalamin deficiency after partial gastrectomy is not clear; defective release of cobalamin from food and intestinal overgrowth of bacteria have been suggested, but response to antibiotics is not common.

Intestinal Organisms Megaloblastic anemia may occur with intestinal stasis due to anatomic lesions (strictures, diverticula, anastomoses, "blind loops") or pseudoobstruction (diabetes mellitus, scleroderma, amyloid). This anemia is caused by colonization of the small intestine by large masses of bacteria that consume intestinal cobalamin before absorption. Steatorrhea may also be seen under these circumstances because bile salt metabolism is disturbed when the intestine is heavily colonized with bacteria. Hematologic responses have been observed after administration of oral antibiotics such as tetracycline and ampicillin. Megaloblastic anemia is seen in persons harboring the fish tapeworm, *D. latum*, due to competition by the worm for cobalamin. Destruction of the worm eliminates the problem.

Ileal Abnormalities Cobalamin deficiency is common in tropical sprue, while it is an unusual complication of nontropical sprue (gluten-sensitive enteropathy; Chap. 275). Virtually any disorder that compromises the absorptive capacity of the distal ileum can result in cobalamin deficiency. Specific entities include regional enteritis, Whipple's disease, and tuberculosis. Segmental involvement of the distal ileum by disease can cause megaloblastic anemia without any other manifestations of intestinal malabsorption such as steatorrhea. Cobalamin malabsorption is also seen after ileal resection. The Zollinger-Ellison syndrome (intense gastric hyperacidity due to a gastrin-secreting tumor) may cause cobalamin malabsorption by acidifying the small intestine, retarding the transfer of the vitamin from R binder to IF and impairing the binding of the cobalamin-IF complex to the ileal receptors. Chronic pancreatitis may also cause cobalamin malabsorption by impairing the transfer of the vitamin from R binder to IF. This abnormality can be detected by tests of cobalamin absorption (see below, Schilling test), but it is invariably mild and never causes clinical cobalamin deficiency. Finally, a rare congenital disorder, Imerslund-Gräsbeck disease, involves a selective defect in cobalamin absorption accompanied by proteinuria. Affected individuals have a mutation in cubulin, a receptor that mediates intestinal absorption of the cobalamin-IF complex.

Nitrous Oxide Inhalation of nitrous oxide as an anesthetic destroys endogenous cobalamin. As ordinarily used, the magnitude of the effects are not sufficient to cause clinical cobalamin deficiency, but repeated or protracted exposure ($>$6 h), particularly in older patients with borderline cobalamin stores, can lead to severe megaloblastic anemia and/or acute neurologic deficits.

FOLIC ACID DEFICIENCY Since January 1998, folic acid has been added to all enriched grain products by order of the U.S. Food and Drug Administration; accordingly, the incidence of folic acid deficiency has fallen markedly. Patients with folic acid deficiency are more often malnourished than those with cobalamin deficiency. The gastrointestinal manifestations are similar to but may be more widespread and more severe than those of pernicious anemia. Diarrhea is often present, and cheilosis and glossitis are also encountered. However, in contrast to cobalamin deficiency, neurologic abnormalities do not occur.

The hematologic manifestations of folic acid deficiency are the same as those of cobalamin deficiency. Folic acid deficiency can generally be attributed to one or more of the following factors: inadequate intake, increased demand, or malabsorption.

Inadequate Intake Alcoholics may become folate deficient because their main source of caloric intake is alcoholic beverages. Distilled spirits are virtually devoid of folic acid, while beer and wine do not contain enough of the vitamin to satisfy the daily requirement. In addition, alcohol may interfere with folate metabolism. Narcotic addicts are also prone to become folate deficient because of malnutrition. Many indigent and elderly individuals who subsist primarily on canned foods or "tea and toast" and occasional teenagers whose diet consists of "junk food" develop folate deficiency.

Increased Demand Tissues with a relatively high rate of cell division such as the bone marrow or gut mucosa have a large requirement for folate. Therefore, patients with chronic hemolytic anemias or other causes of very active erythropoiesis may become deficient. Pregnant women formerly were at risk to become deficient in folic acid because of the high demand of the developing fetus. Deficiency in the first

weeks of pregnancy can cause neural tube defects in newborns. Often the pregnancy was not detected until the defect had developed; thus, provision of folate supplementation to women after they learned they were pregnant was ineffective. However, folate food supplementation has decreased neural tube defects by >50%. Folate deficiency may also occur during the growth spurts of infancy and adolescence. Patients on chronic hemodialysis may require supplementary folate to replace that lost in the dialysate.

Malabsorption Folic acid deficiency is a common accompaniment of tropical sprue. Both the gastrointestinal symptoms and malabsorption are improved by the administration of either folic acid or antibiotics by mouth. Patients with nontropical sprue (gluten-sensitive enteropathy) may also develop significant folic acid deficiency that parallels other parameters of malabsorption. Similarly, folate deficiency in alcoholics may be due in part to malabsorption. In addition, other primary small-bowel disorders are sometimes associated with folate deficiency (Chap. 275).

DRUGS Next to deficiency of folate or cobalamin, the most common cause of megaloblastic anemia is drugs. Agents that cause megaloblastic anemia do so by interfering with DNA synthesis, either directly or by antagonizing the action of folate. They can be classified as follows:

1. *Direct inhibitors of DNA synthesis*. They include purine analogues (6-thioguanine, azathioprine, 6-mercaptopurine), pyrimidine analogues (5-fluorouracil, cytosine arabinoside), and other drugs that interfere with DNA synthesis by a variety of mechanisms (hydroxyurea, procarbazine). The antiviral agent zidovudine (AZT), used for treating HIV, often causes severe megaloblastic anemia.
2. *Folate antagonists*. The most toxic of these is methotrexate, a powerful inhibitor of dihydrofolate reductase, which is used in the treatment of certain malignancies and rheumatologic disorders. Much less toxic but still capable of inducing a megaloblastic anemia are several weak dihydrofolate reductase inhibitors used to treat a variety of nonmalignant conditions. These drugs include pentamidine, trimethoprim, triamterene, and pyrimethamine.
3. *Others*. A number of drugs antagonize folate by mechanisms that are poorly understood but are thought to involve an effect on absorption of the vitamin by the intestine. In this category are the anticonvulsants phenytoin, primidone, and phenobarbital. Megaloblastic anemia induced by these agents is mild.

OTHER MECHANISMS ■ Hereditary Megaloblastic anemia may be seen in several hereditary disorders. Orotic aciduria is a deficiency of orotidylic decarboxylase and phosphorylase, leading to a defect in pyrimidine metabolism and characterized by retarded growth and development as well as by the excretion of large amounts of orotic acid. Congenital folate malabsorption causes megaloblastic anemia, accompanied by ataxia and mental retardation. A thiamine-responsive megaloblastic anemia accompanied by nerve deafness and diabetes mellitus has been reported in several children. Megaloblastic changes as well as multinuclearity of RBC precursors are seen in the marrow of certain patients with congenital dyserythropoietic anemia, a group of inherited disorders characterized by mild to moderate anemia and a benign course.

TC II deficiency, like the congenital abnormalities in cobalamin absorption, causes pronounced deficiency in cobalamin in infancy or early childhood. Megaloblastic anemia is not seen in hereditary TC I deficiency.

Refractory Megaloblastic Anemia Megaloblastic erythropoiesis may sometimes be seen in myelodysplasia. Megaloblastic changes are restricted to the RBC series (see below). Myelodysplasia often produces a distinct morphologic picture most apparent in orthochromatic normoblasts in which a megaloblastic nucleus is associated with severely hypochromic cytoplasm. This variant has been called "megaloblastoid" and refers to the presence of both nuclear and cytoplasmic maturation defects. "Megaloblastoid" does not mean "mildly megaloblastic." As with other forms of myelodysplasia, refractory megaloblastic anemia is associated with an increased incidence of acute leukemia.

Megaloblastic changes are seen in erythremic myelosis and acute erythroleukemia, where RBC precursors are prominently involved. Here, the marrow is characterized by bizarre erythroid maturation, with multinuclearity and multipolar mitotic figures in the RBC precursors (Chap. 96).

MEGALOBLASTIC DISEASE WITHOUT ANEMIA Megaloblastic disease is easily overlooked in nonanemic patients. It can present in one of two ways.

Acute Megaloblastic Disease Occasionally, a full-blown megaloblastic state can develop over the course of just a few days. This is usually seen following nitrous oxide anesthesia but may occur in any patient with a serious illness requiring intensive care, especially a patient receiving multiple transfusions, dialysis, or total parenteral nutrition. An acute megaloblastic state can also be precipitated by the administration of a weak antifolate (e.g., trimethoprim) to a patient with marginal tissue folate stores.

The condition resembles an immune cytopenia, with a rapidly developing thrombocytopenia and/or leukopenia in the absence of anemia. The blood smear may be completely normal, but the marrow is floridly megaloblastic. Acute megaloblastic anemia responds rapidly to treatment with folate plus cobalamin in the usual therapeutic doses.

Cobalamin Deficiency without Anemia Cobalamin deficiency without hematologic abnormalities is surprisingly common, especially in the elderly. The risk of a nonhematologic presentation for cobalamin deficiency is increased by the folate food fortification because folate can mask the hematologic effects of cobalamin deficiency. Between 10 and 30% of persons over age 70 years have metabolic evidence of cobalamin deficiency, either elevated homocysteine levels, low cobalamin-TC II levels, or both. Only 10% of these patients have defective production of IF, and the remainder often have atrophic gastritis and cannot release cobalamin from their food (see above). Serum cobalamin levels may be normal or low, but serum levels of methylmalonic acid are almost invariably increased due to a deficiency of cobalamin at the tissue level. The neuropsychiatric abnormalities tend to improve, and serum methylmalonic acid levels generally return to normal after treatment with cobalamin. Neurologic defects do not always reverse with cobalamin supplementation.

DIAGNOSIS The finding of significant macrocytosis [mean corpuscular volume (MCV) > 100 fL] suggests the presence of a megaloblastic anemia. Other causes of macrocytosis include hemolysis, liver disease, alcoholism, hypothyroidism, and aplastic anemia. If the macrocytosis is marked (MCV > 110 fL), the patient is much more likely to have a megaloblastic anemia. Macrocytosis is less marked with concurrent iron deficiency or thalassemia. The reticulocyte index is low, and the leukocyte and platelet count may also be decreased, particularly in severely anemic patients. The blood smear (Fig. 92-3) demonstrates marked anisocytosis and poikilocytosis, together with macroovalocytes, which are large, oval, fully hemoglobinized erythrocytes typical of megaloblastic anemias. There is some basophilic stippling, and an occasional nucleated RBC may be seen. In the white blood cell series, the neutrophils show hypersegmentation of the nucleus (Fig. 92-4). This is such a characteristic finding that a single cell with a nucleus of six lobes or more should raise the immediate suspicion of a meg-

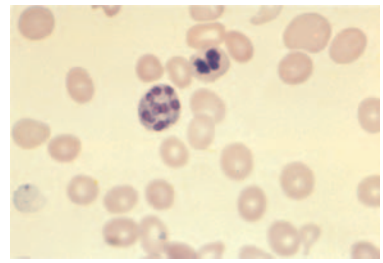

FIGURE 92-3 Megaloblastic anemia. Oval macrocytes, well filled with hemoglobin, are admixed with lesser numbers of large red blood cells, some of which are teardrop-shaped. Note also hypersegmented granulocyte.

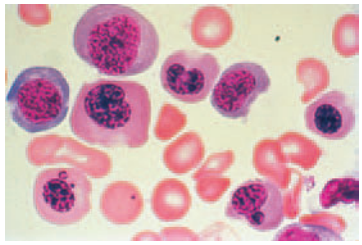

FIGURE 92-4 This marrow section demonstrates nuclear-cytoplasmic dissociation. Nuclei of late stage (orthochromatic) erythroblasts have loose chromatin more characteristic of more immature cells while their cytoplasms are nearly filled with hemoglobin. Slow nuclear maturation is related to a decrese in DNA synthesis related to an insufficient supply of thymidylate. An inadequate supply of reduced folate (usually folate or B12 deficiency) or drugs that inhibit DNA synthesis can produce this picture. (*From RS Hillman, MD, and KA Ault, MD, courtesy of the American Society of Hematology Slide Bank.*)

aloblastic anemia. A rare myelocyte may also be seen. Bizarre, misshapen platelets are also observed. The bone marrow is hypercellular with a decreased myeloid/erythroid ratio and abundant stainable iron. RBC precursors are abnormally large and have nuclei that appear much less mature than would be expected from the development of the cytoplasm (nuclear-cytoplasmic asynchrony). The nuclear chromatin is more dispersed than expected, and it condenses in a peculiar fenestrated pattern that is very characteristic of megaloblastic erythropoiesis. Abnormal mitoses may be seen. Granulocyte precursors are also affected, many being larger than normal, including giant bands and metamyelocytes. Megakaryocytes are decreased and show abnormal morphology.

Megaloblastic anemias are characterized by ineffective erythropoiesis (Chap. 52). In a severely megaloblastic patient, as many as 90% of the RBC precursors may be destroyed before they are released into the bloodstream, compared with 10 to 15% in normal individuals. Enhanced intramedullary destruction of erythroblasts results in an increase in unconjugated bilirubin and lactic acid dehydrogenase (isoenzyme 1) in plasma.

In evaluating a patient with megaloblastic anemia, it is important to determine whether there is a specific vitamin deficiency by measuring serum cobalamin and folate levels. The normal range of cobalamin in serum is 300 to 900 pg/mL; values <200 pg/mL indicate clinically significant deficiency. Measurements of cobalamin bound to TC II would be a more physiologic measure of cobalamin status, but such assays are not yet routinely available. The normal serum concentration of folic acid ranges from 6 to 20 ng/mL; values ≤4 ng/mL are generally considered to be diagnostic of folate deficiency. Unlike serum cobalamin, serum folate levels may reflect recent alterations in dietary intake. Measurement of RBC folate level provides useful information because it is not subject to short-term fluctuations in folate intake and is better than serum folate as an index of folate stores.

Once cobalamin deficiency has been established, its pathogenesis can be delineated by means of a Schilling test. A patient is given radioactive cobalamin by mouth, followed shortly thereafter by an intramuscular injection of unlabeled cobalamin. The proportion of the administered radioactivity excreted in the urine during the next 24 h provides an accurate measure of absorption of cobalamin, assuming that a complete urine sample has been collected. Because cobalamin deficiency is almost always due to malabsorption (Table 92-1), this first stage of the Schilling test should be abnormal (i.e., small amounts of radioactivity in the urine). The patient is then given labeled cobalamin bound to IF. Absorption of the vitamin will now approach normal if the patient has pernicious anemia or some other type of IF deficiency. If cobalamin absorption is still decreased, the patient may have bacterial overgrowth (blind loop syndrome) or ileal disease (including an ileal absorptive defect secondary to the cobalamin deficiency itself). Cobalamin malabsorption due to bacterial overgrowth can frequently be corrected by the administration of antibiotics. The Schilling test can provide equally reliable information after the patient has had adequate therapy with parenteral cobalamin.

A normal Schilling test in a patient with documented cobalamin deficiency may indicate poor absorption of the vitamin when mixed with food. This can be established by repeating the Schilling test with radioactive cobalamin scrambled with an egg.

Serum methylmalonic acid and homocysteine levels are also useful in the diagnosis of megaloblastic anemias. Both are elevated in cobalamin deficiency, while elevated levels of homocysteine but not methylmalonic acid are seen in folate deficiency. These tests measure tissue vitamin stores and may demonstrate a deficiency even when the more traditional but less reliable folate and cobalamin levels are borderline or even normal. Patients (particularly older patients) without anemia and with normal serum cobalamin levels but elevated levels of serum methylmalonic acid may develop neuropsychiatric abnormalities. Treatment of patients with this "subtle" cobalamin deficiency will usually prevent further deterioration and may result in improvement.

TREATMENT

Cobalamin Deficiency Apart from specific therapy related to the underlying disorder (e.g., antibiotics for intestinal overgrowth with bacteria), the mainstay of treatment for cobalamin deficiency is replacement therapy. Because the defect is nearly always malabsorption, patients are generally given parenteral treatment, specifically in the form of intramuscular cyanocobalamin. Parenteral treatment begins with 1000 μg cobalamin per week for 8 weeks, followed by 1000 μg cyanocobalamin intramuscularly every month for the rest of the patient's life. Cobalamin deficiency can also be managed very effectively by oral replacement therapy with 2 mg crystalline B_{12} per day; however, compliance is a greater concern with oral than intramuscular treatment.

The response to treatment is gratifying. Shortly after treatment is begun, and several days before a hematologic response is evident in the peripheral blood, the patient will experience an increase in strength and an improved sense of well-being. Marrow morphology begins to revert toward normal within a few hours after treatment is initiated. Reticulocytosis begins 4 to 5 days after therapy is started and peaks at about day 7 (Fig. 92-5), with subsequent remission of the anemia over the next several weeks. If a reticulocytosis does not occur, or if it is less brisk than expected from the level of the hematocrit, a search should be made for other factors contributing to the anemia (e.g., infection, coexisting iron and/or folate deficiency, or hypothyroidism). Hypokalemia and salt retention may occur early in the course of therapy. Thrombocytosis may also be seen.

In most cases, replacement therapy is all that is needed for the treatment of cobalamin deficiency. Occasionally, however, a patient with a severe anemia will have such a precarious cardiovascular status that emergency transfusion is necessary. This must be done with great

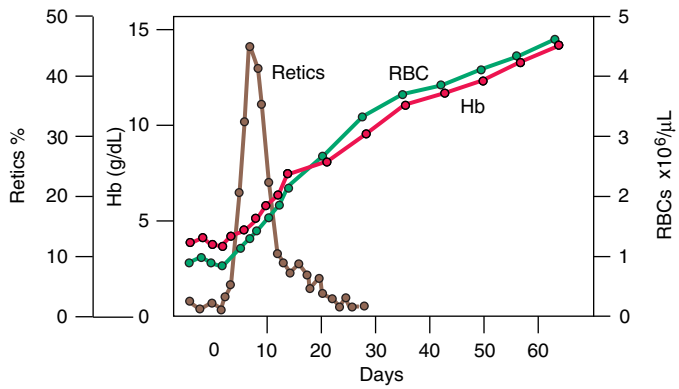

FIGURE 92-5 Hematologic response of a patient with pernicious anemia to an intramuscular injection of 100 μg cobalamin on day 0. Retics, reticulocytes; RBC, red blood cell; Hb, hemoglobin. (*From A Erslev, TG Gabuzda, Pathophysiology of Blood, Philadelphia, Saunders, 1975, with permission.*)

care, because such patients may develop heart failure from fluid overload. Blood must be administered slowly in the form of packed RBCs, with very close observation. A small volume of packed RBCs will frequently be enough to ameliorate the acute cardiovascular problems. If necessary, blood may be administered by exchanging patient blood (mostly plasma) for packed cells.

With lifelong treatment, patients should experience no further manifestations of cobalamin deficiency, although neurologic symptoms may not be fully corrected even by optimal therapy. The potential for late development of gastric carcinoma in pernicious anemia necessitates careful follow-up of the patient.

Folate, particularly in large doses, can correct the megaloblastic anemia of cobalamin deficiency without altering the neurologic abnormalities. The neurologic manifestations may even be aggravated by folate therapy. Cobalamin deficiency can thus be masked in patients who are taking large doses of folate. For this reason, a hematologic response to folate must never be used to rule out cobalamin deficiency in a given patient; cobalamin deficiency can be excluded only by appropriate laboratory evaluation.

In light of the high frequency of defective cobalamin absorption in older people and the possible increased risk that overt cobalamin deficiency will present with neurologic rather than hematologic symptoms (because of folate food fortification), some experts have recommended the use of 0.1 mg oral crystalline cobalamin prophylaxis daily in people over age 65 years.

Folate Deficiency Like cobalamin deficiency, folate deficiency is treated by replacement therapy. The usual dose of folic acid is 1 mg/d, by mouth, but higher doses (up to 5 mg/d) may be required for folate deficiency due to malabsorption. Parenteral folate is rarely necessary. The hematologic response is similar to that seen after replacement therapy for cobalamin deficiency, i.e., a brisk reticulocytosis after about 4 days, followed by correction of the anemia over the next 1 to 2 months. The duration of therapy depends on the basis of the deficiency state. Patients with a continuously increased requirement (such as patients with hemolytic anemia) or those with malabsorption or chronic malnutrition should continue to receive oral folic acid indefinitely. In addition, the patient should be encouraged to maintain an optimal diet containing adequate amounts of folate.

Other Causes of Megaloblastic Anemia Megaloblastic anemia due to drugs can be treated, if necessary, by reducing the dose of the drug or eliminating it altogether. The effects of folate antagonists that inhibit dihydrofolate reductase can be counteracted by folinic acid [5-formyl tetrahydrofolate (THF)] in a dose of 100 to 200 mg/d (Fig. 92-1), which circumvents the block in folate metabolism by providing a form of folate that can be converted to 5,10-methylene THF. For the megaloblastic forms of sideroblastic anemia, pyridoxine in pharmacologic doses (as high as 300 mg/d) should be tried. Simple supportive measures are all that appear to be in order for treatment of refractory megaloblastic anemia. Acute erythroleukemia is treated like other types of acute myeloid leukemia (Chap. 96).

93 HEMOLYTIC ANEMIAS AND ACUTE BLOOD LOSS

H. Franklin Bunn, Wendell Rosse

The loss of red cells either through hemorrhage or, less commonly, through premature destruction of the red cells (hemolysis) may cause anemia. Hemolysis or blood loss normally leads to an increase in red cell production, detected by an increase in reticulocyte index.

HEMOLYTIC ANEMIAS

Red blood cells (RBC) normally survive 90 to 120 days in the circulation. The life span of RBC may be shortened in a number of disorders, often resulting in anemia if the bone marrow is not able to replenish adequately the prematurely destroyed RBC.

In all patients with hemolytic anemia, a careful history and physical examination provide important clues to the diagnosis. The patient may complain of fatigue and other symptoms of anemia (Chap. 52). Less commonly, jaundice and even red-brown urine (hemoglobinuria) are reported. A complete drug and toxin exposure history and the family history often provide crucial information. The physical examination may show jaundice of skin and mucosae. Splenomegaly is encountered in a variety of hemolytic anemias. Other historic and physical findings are associated with specific hemolytic anemias (see below).

Laboratory tests may be used initially to demonstrate the presence of hemolysis (Table 93-1) and define its cause. An elevated reticulocyte count in the patient with anemia is the most useful indicator of hemolysis, reflecting erythroid hyperplasia of the bone marrow; biopsy of the bone marrow is often unnecessary. Reticulocytes are also elevated in patients with active blood loss, those with myelophthisis, and those who are recovering from suppression of erythropoiesis (Chap. 52). The morphology of the RBC may provide evidence both of hemolysis and of its cause; the characteristic abnormalities and their associated causes and syndromes are listed in Table 93-2. While the findings on the peripheral blood smear alone are rarely pathognomonic, they may provide important clues to the presence of hemolysis and to diagnosis.

Hemolysis results in increased heme catabolism and enhanced formation of unconjugated bilirubin. The plasma level of unconjugated bilirubin may be high enough to produce readily apparent jaundice (detectable usually when serum bilirubin is >34 μmol/L or 2 mg/dL).

TABLE 93-1 *Laboratory Evaluation of Hemolysis*

TABLE 93-2 *Red Blood Cell Morphology in the Diagnosis of Hemolytic Anemia*

Morphology	Cause	Syndromes
Spherocytes	Loss of membrane	Hereditary spherocytosis, immunohemolytic anemia
Target cells	Increased ratio of RBC surface area to volume	Hemoglobin disorders: thalassemias, hemoglobin S, C, etc.; liver disease
Schistocytes	Traumatic disruption of membrane	Microangiopathy, intravascular prostheses
Sickled cells	Polymerization of hemoglobin S	Sickle cell syndromes
Acanthocytes	?Abnormal membrane lipids	Severe liver disease (spur cell anemia)
Agglutinated cells	Presence of IgM antibody	Cold agglutinin disease
Heinz bodies	Precipitated hemoglobin	Unstable hemoglobin, oxidant stress

The unconjugated (indirect) bilirubin level can be further elevated by a commonly encountered defect in conjugation of bilirubin (Gilbert's syndrome) (Chap. 284). In patients with hemolysis, the level of unconjugated bilirubin never exceeds 70 to 85 μmol/L (4 to 5 mg/dL) unless liver function is impaired.

In the absence of tissue damage in other organs, serum enzyme levels can be useful in the diagnosis and monitoring of patients with hemolysis. Lactate dehydrogenase (LDH), particularly LDH-2, is elevated by accelerated RBC destruction. Serum AST (SGOT) may be somewhat elevated, whereas ALT (SGPT) is not.

Haptoglobin is an α globulin that is present in high concentration ($\sim$1.0 g/L) in the serum. It binds specifically to the globin in hemoglobin. The hemoglobin-haptoglobin complex is cleared rapidly by the mononuclear phagocyte system. Thus patients with significant hemolysis, either intravascular or extravascular, have low or absent levels of serum haptoglobin. The fact that haptoglobin synthesis is decreased in patients with hepatocellular disease and increased in inflammatory states must be considered in the interpretation of serum haptoglobin.

Intravascular hemolysis (which is uncommon) results in the release of hemoglobin into the plasma. In these cases, plasma hemoglobin is increased in proportion to the degree of hemolysis (plasma hemoglobin may be falsely elevated due to lysis of RBC in vitro). If the haptoglobin-binding capacity of the plasma is exceeded, free hemoglobin tetramer dissociates into dimers that pass through renal glomeruli. This filtered hemoglobin is reabsorbed by the proximal tubule, where it is catabolized in situ, and the heme iron is incorporated into storage proteins (ferritin and hemosiderin). The presence of hemosiderin in the urine, detected by staining the sediment with Prussian blue, indicates that a significant amount of circulating free hemoglobin has been filtered by the kidneys. When the absorptive capacity of the tubular cells is exceeded, hemoglobinuria ensues and indicates severe intravascular hemolysis. Hemoglobinuria must be distinguished from hematuria (in which case RBC are seen on urine examination) and from myoglobinuria due to rhabdomyolysis; in all three cases, the urine is positive with the benzidine reaction, commonly used in analysis of urine. After centrifugation of an anticoagulated blood specimen, the plasma of patients with hemoglobinuria has a reddish-brown color, whereas that of patients with myoglobinuria is normal in color. Because of its higher molecular weight, hemoglobin has lower glomerular permeability than myoglobin and is less rapidly cleared by the kidneys.

CLASSIFICATION The hemolytic anemias can be grouped into three categories (Table 93-3). Accelerated RBC destruction can be caused by (1) a molecular defect (hemoglobinopathy or enzymopathy) inside the red cell, (2) an abnormality in membrane structure and function, or (3) an environmental factor such as mechanical trauma or an autoantibody. In *intracorpuscular types* of hemolysis, the patient's RBC have an abnormally short life span in a normal recipient (with a compatible blood type), while compatible normal RBC survive normally in the patient. The opposite is true in *extracorpuscular* types of hemolysis. Finally, hemolytic disorders can be either inherited or acquired.

TABLE 93-3 *Classification of Hemolytic Anemias*

Intracorpuscular	1. Abnormalities of RBC interior a. Enzyme defects b. Hemoglobinopathies (Chap. 91)	Hereditary
	2. RBC membrane abnormalities a. Hereditary spherocytosis, etc. b. Paroxysmal nocturnal hemoglobinuria c. Spur cell anemia	
Extracorpuscular	3. Extrinsic factors a. Hypersplenism b. Antibody: immune hemolysis c. Microangiopathic hemolysis d. Infections, toxins, etc.	Acquired

INHERITED HEMOLYTIC ANEMIAS The inherited hemolytic anemias are due to inborn defects in one of three main components of red cells: the membrane, enzymes, or hemoglobin. These defects are often known at the genomic level, but their identification still largely depends on their clinical and laboratory manifestations.

Red Cell Membrane Disorders These are usually readily detected by morphologic abnormalities of the RBC on the blood film. The three inherited RBC membrane abnormalities are hereditary spherocytosis, hereditary elliptocytosis (including hereditary pyropoikilocytosis), and hereditary stomatocytosis.

HEREDITARY SPHEROCYTOSIS Hereditary spherocytosis is characterized by spherical RBC due to a molecular defect in one of the proteins in the cytoskeleton of the RBC membrane; this leads to a loss of membrane and hence decreased ratio of surface area to volume and consequently spherocytosis. Usually an autosomal dominant trait, this disorder has an incidence of 1:1000 to 1:4500. In $\sim$20% of patients, the absence of hematologic abnormalities in family members suggests either autosomal recessive inheritance or a spontaneous mutation. The disorder is sometimes clinically apparent in early infancy but often escapes detection until adult life.

Clinical Manifestations The major clinical features of hereditary spherocytosis are anemia, splenomegaly, and jaundice. Jaundice may be intermittent and tends to be less pronounced in early childhood. Because of the increased bile pigment production, pigmented gallstones are common, even in childhood. Compensatory erythroid hyperplasia of the bone marrow occurs, with the extension of red marrow into the midshafts of long bones and occasionally with extramedullary erythropoiesis, at times leading to the formation of paravertebral masses visible on chest x-ray. Because the bone marrow's capacity to increase erythropoiesis nearly matches the rate of hemolysis, anemia is usually mild or moderate and may even be absent in an otherwise healthy individual. Compensation may be temporarily interrupted by episodes of relative erythroid hypoplasia precipitated by infections, particularly parvovirus. Splenomegaly is very common. The hemolytic rate may increase transiently during systemic infections, which induce further splenic enlargement. Chronic leg ulcers, similar to those observed in sickle cell anemia, occur occasionally.

The characteristic erythrocyte abnormality is the spherocyte (Fig. 93-1). The mean corpuscular volume (MCV) is usually normal or slightly decreased, and the mean corpuscular hemoglobin concentration (MCHC) is increased to 350 to 400 g/L. Spheroidicity may be quantitatively assessed by measurement of the osmotic fragility of the RBC on exposure to hyposmotic solutions causing a net influx of water (Fig. 93-2). On microscopic examination, spherocytes are usually detected as small cells without central pallor.

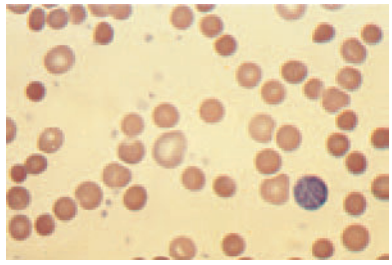

FIGURE 93-1 *Hereditary spherocytosis* Small, densely staining red blood cells are seen that have lost their central area of pallor (microspherocytes). Microspherocytes may also be found in other hemolytic disorders (Fig. 93-5).

Pathogenesis The molecular abnormality in hereditary spherocytosis primarily involves the proteins responsible for tethering the lipid bilayer to the underlying cytoskeletal network. About 50% of patients have a defect in ankyrin, the protein that forms a bridge between protein 3 and spectrin (Fig. 93-3). Homozygotes who have a recessive inheritance pattern for ankyrin deficiency have more severe anemia than heterozygotes with the more common dominant form. About 25% of patients have a mutation of protein 3, resulting in a deficiency of that protein and mild anemia with dominant inheritance. Most of the remaining 25% have mutations of spectrin, leading to impaired synthesis or self-association. β-spectrin mutants are generally mild, with dominant inheritance, while α-spectrin deficiency is severe, with a recessive inheritance pattern. Less often, deficiency of palladin (protein 4.2) is a cause of hereditary spherocytosis. Because the lipid bilayer is not well anchored when these proteins are defective, part of it is lost by vesiculation, resulting in a more spherical and less deformable cell. Because of their shape and rigidity, spherocytes are trapped in the spleen where their increased metabolic rate cannot be sustained, causing a further loss of surface membrane. This "conditioning" produces a subpopulation of hyperspheroidal RBC in the peripheral blood.

Diagnosis Hereditary spherocytosis must be distinguished primarily from the spherocytic hemolytic anemias associated with RBC antibodies. The family history of anemia and/or splenectomy is helpful, when present. The diagnosis of immune spherocytosis is usually readily established by a positive direct Coombs test (see below). Spherocytes are also seen in association with hemolysis induced by splenomegaly in patients with cirrhosis, in clostridial infections, and in certain snake envenomations (due to the action of phospholipases on the membrane). A few spherocytes are seen in the course of a wide variety of hemolytic disorders, particularly glucose-6-phosphate dehydrogenase (G6PD) deficiency.

TREATMENT

Splenectomy is recommended in patients with moderate or severe hemolysis. Although the RBC defect and its consequent morphology persist, anemia is ameliorated. The operative risk is low, particularly if performed by laparoscopy. RBC survival after splenectomy is normal or nearly so; if it is not, an accessory spleen or another diagnosis should be sought. Because of the potential for gallstones and for episodes of bone marrow hypoplasia or hemolytic crises, splenectomy should be performed in symptomatic individuals; cholecystectomy should not be performed without splenectomy, as intrahepatic gallstones may result. Splenectomy in children should be postponed until age 4, if possible, to minimize the risk of severe infections with gram-positive encapsulated organisms. Pneumococcal, meningococcal, and *Haemophilus influenzae* vaccines should be administered at least 2 weeks before splenectomy. In patients with severe hemolysis, folic acid (1 mg/d) should be administered prophylactically.

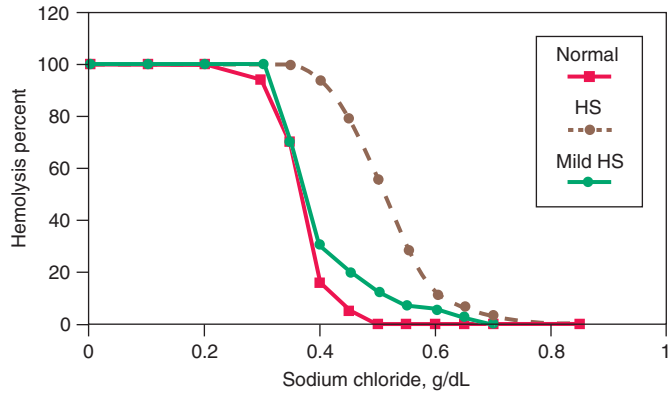

FIGURE 93-2 Osmotic fragility of RBC in hereditary spherocytosis (HS). The results from two patients are compared to those from a normal individual.

HEREDITARY ELLIPTOCYTOSIS AND HEREDITARY PYROPOIKILOCYTOSIS *Hereditary elliptocytosis* is an autosomal dominant trait and affects 1 per 4000 to 5000 people, a frequency similar to that of hereditary spherocytosis (rarely, patients with myelodysplastic disorders of the bone marrow may have acquired elliptocytosis). In most affected individuals, a structural abnormality of erythrocyte spectrin leads to impaired assembly of the cytoskeleton. In some families, affected individuals have a deficiency of erythrocyte membrane protein 4.1, which stabilizes the interaction of spectrin and actin in the cytoskeleton (Fig. 93-3). In Southeast Asia, the incidence of hereditary ovalocytosis is high; a small internal deletion of protein 3 makes the membrane rigid and confers resistance against malaria.

The great majority of patients manifest only mild hemolysis, with little or no anemia. RBC destruction occurs predominantly in an enlarged spleen. Hemolysis is corrected by splenectomy.

The blood smear reveals elongated or oval red cells (elliptocytes). Patients with marked hemolysis have microovalocytes, bizarre-shaped RBC, and RBC fragments, all of which increase in number after splenectomy. The degree of hemolysis does not correlate with the percentage of elliptocytes.

Hereditary pyropoikilocytosis is a rare disorder related to hereditary elliptocytosis and is characterized by bizarre-shaped, microcytic RBC that undergo disruption at temperatures of 44 to 45°C (in contrast,

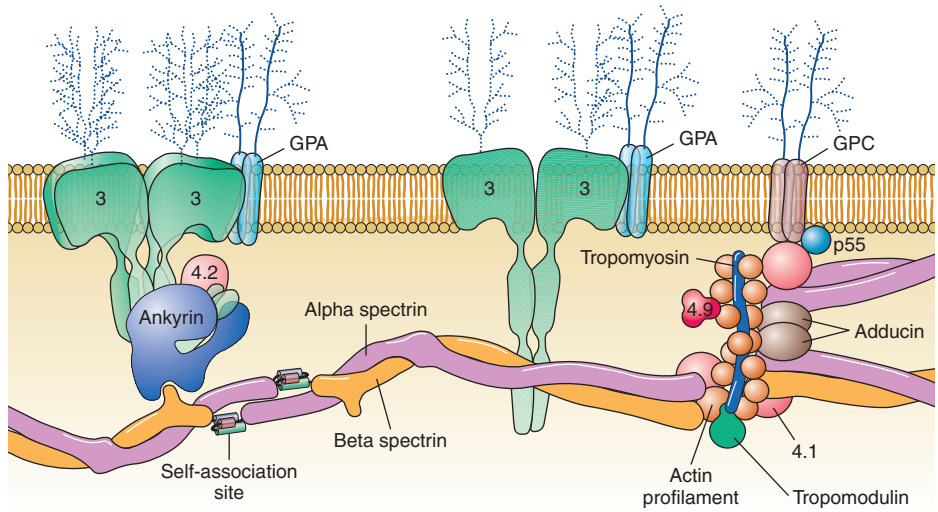

FIGURE 93-3 Diagram of a cross-section of the RBC membrane. Spectrin, actin, tropomyosin, adducin, and protein 4.1 form a meshwork that laminates the inner surface of the membrane. In contrast, other proteins such as the glycophorins (GPA and GPC) and protein 3 (anion transport channel) traverse the lipid bilayer. Long polysaccharide chains are covalently attached to these proteins on the outer surface of the cell and also to glycolipid. Ankyrin and protein 4.2 form a bridge between spectrin and a fraction of the anion transport proteins. Protein 4.1 binds to GPC. *[From Lux SE, Palek J, in Blood: Principles and Practice of Hemotology, RI Handin et al (eds). Philadelphia, Lippincott, 1995.]*

normal RBC are stable up to 49°C). This condition results from a deficiency of spectrin and an abnormality of spectrin self-assembly. Hemolysis is usually severe, is recognized in childhood, and is partially responsive to splenectomy.

HEREDITARY STOMATOCYTOSIS Stomatocytes are cup-shaped RBC that have a slitlike central zone of pallor on blood smears. The disorder is inherited in an autosomal dominant pattern. RBC have an increased permeability to sodium and potassium, which is compensated for by an increased active transport of these cations. In some patients, the RBC are swollen with an excess of ions and water and a decreased mean corpuscular hemoglobin concentration (overhydrated stomatocytes, "hydrocytosis"); many of these patients lack the RBC membrane protein 7.2 (stomatin). RBC lacking Rh proteins (Rh_{null} cells) are also stomatocytic and have a shortened life span. In other patients, the RBC are shrunken, with a decreased ion and water content, appearing as target cells on blood smears. Most patients have splenomegaly and mild anemia. Splenectomy decreases but does not totally correct the hemolytic process.

Red Cell Enzyme Defects During its maturation, the RBC loses its nucleus, ribosomes, and mitochondria and thus its capability for protein synthesis and oxidative phosphorylation. The mature circulating RBC has a relatively simple pattern of intermediary metabolism (Fig. 93-4) in keeping with its modest metabolic obligations. ATP must be generated from the Embden-Meyerhof pathway to drive the cation pump that maintains the ionic milieu in the RBC. Smaller amounts of energy are needed for the preservation of hemoglobin iron in the ferrous (Fe^{2+}) state and perhaps for the renewal of the lipids in the RBC membrane. About 10% of the glucose consumed by the RBC is metabolized via the hexose-monophosphate shunt (Fig. 93-4), which protects both hemoglobin and the membrane from oxidants, including certain drugs.

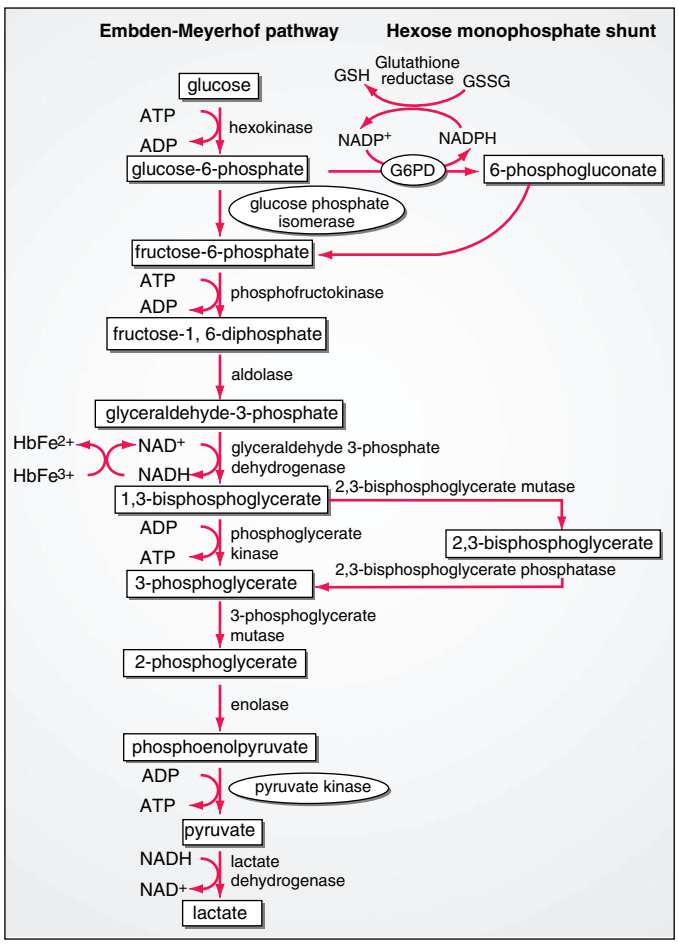

FIGURE 93-4 RBC metabolism. The Embden-Meyerhof pathway (glycolysis) generates ATP for energy and membrane maintenance. The generation of NADPH maintains hemoglobin in a reduced state. The hexose monophosphate shunt generates NADPH that is used to reduce glutathione, which protects the red cell against oxidant stress. Regulation of 2,3-bisphosphoglycerate levels is a critical determinant of oxygen affinity of hemoglobin. Enzyme deficiency states in order of prevalence: glucose-6-phosphate dehydrogenase (G6PD) ⋙ pyruvate kinase > glucose-6-phosphate isomerase > rare deficiencies of other enzymes in the pathway. The more common enzyme deficiencies are encircled.

DEFECTS IN THE EMBDEN-MEYERHOF PATHWAY Most of the glycolytic enzyme defects are inherited in an autosomal recessive pattern. Since the gene frequency for this group of defects is low, true heterozygotes are often the offspring of a consanguineous mating. More often, affected individuals are compound homozygotes. Patients with severe hemolysis usually present during early childhood with anemia, jaundice, and splenomegaly. The RBC are often relatively deficient in ATP, resulting in a leak of potassium ion out of these cells. These RBC are rigid and thus more readily sequestered by the mononuclear phagocyte system.

Some of these glycolytic enzyme deficiencies such as pyruvate kinase (PK) deficiency and hexokinase deficiency are localized to the RBC, with no apparent metabolic abnormality in other cells. In other disorders, the enzyme deficiency is more widespread.

About 95% of the clinically significant defects in the glycolytic pathway are due to PK deficiency, and about 4% are due to glucose phosphate isomerase deficiency. The remainder, shown in Fig. 93-4, are extremely rare. Most have been encountered in isolated families; clinical manifestations are variable.

Laboratory Findings Patients have a normocytic (or slightly macrocytic), normochromic anemia with reticulocytosis. In those with PK deficiency, bizarre erythrocytes, including spiculated cells, are noted on the peripheral smear, especially after splenectomy. Spherocytes are usually absent; the term *congenital nonspherocytic hemolytic anemia* has been applied to these disorders. The diagnosis of this group of anemias depends on specific enzymatic assays. Abnormalities in enzymatic properties may be useful in distinguishing among enzyme mutants. DNA sequencing is the only definitive way to identify a mutant.

TREATMENT

Most patients do not require therapy. Those with severe hemolysis should be given folic acid (1 mg/d). Blood transfusions may be necessary during a hypoplastic crisis. Women with PK deficiency may become very anemic during pregnancy, sometimes leading to the diagnosis for the first time. Patients with PK or glucose phosphate isomerase deficiency may benefit from splenectomy.

DEFECTS IN THE HEXOSE-MONOPHOSPHATE SHUNT Normal RBC are well protected against oxidant stress. When the cells are exposed to a drug or toxin that generates oxygen radicals, glucose metabolism via the hexose-monophosphate shunt is normally increased severalfold. Reduced glutathione is regenerated, protecting the sulfhydryl groups of hemoglobin and the RBC membrane from oxidation. Individuals with an inherited defect in the hexose-monophosphate shunt are unable to maintain an adequate level of reduced glutathione in their RBC, hemoglobin sulfhydryl groups become oxidized, and the hemoglobin precipitates within the RBC, forming Heinz bodies.

G6PD Deficiency This is by far the most common congenital shunt defect, affecting more than 200 million people throughout the world; like hemoglobin S, it partially protects the patient from malaria by providing a defective home for the merozoite. Over 400 variants of G6PD have been described, resulting in considerable clinical heterogeneity among affected individuals. Most are missense mutations resulting in altered enzymatic properties.

The normal G6PD is designated as type B. About 20% of individuals of African descent have a G6PD (designated A+) that differs by a single amino acid and is electrophoretically distinguishable but functionally normal. Among the clinically significant G6PD variants, the

most common, the so-called A− type, is due to two base substitutions and is encountered primarily in individuals of central African descent. The A− G6PD has the same electrophoretic mobility as the A+ type, but it is unstable and has abnormal kinetic properties. This variant is found in about 11% of African-American males. A second relatively common G6PD variant is encountered among groups of Mediterranean origin, particularly Sardinians and Sephardic Jews; this variant is more severe than the A− variant and may result in nonspherocytic hemolytic anemia in the absence of known oxidative stress. A third relatively common and slightly less severe variant occurs in southern Chinese populations.

The G6PD gene is located on the X chromosome; thus the deficiency state is a sex-linked trait. Affected males (hemizygotes) inherit the abnormal gene from their mothers who are usually carriers (heterozygotes). Because of inactivation of one of the two X chromosomes (Lyon hypothesis: Chap. 56), the heterozygote has two populations of RBC: normal and deficient in G6PD. Most female carriers have no problems. Those who happen to have a high proportion of deficient cells resemble the male hemizygotes. G6PD activity normally declines ~50% during the 120-day life span of the RBC. This decay is moderately accelerated in A− RBC and markedly so in RBC containing the Mediterranean variant. Individuals with the A− variant normally have a slightly shortened RBC survival time, but they are not anemic. Clinical problems arise only when the affected individual is subjected to some type of environmental stress. Most often, hemolytic episodes are triggered by viral and bacterial infections. The mechanism is unknown. In addition, drugs or toxins that pose an oxidant threat to the RBC (most commonly sulfa drugs, antimalarials, and nitrofurantoin) cause hemolysis in individuals deficient in G6PD (Table 93-4). Although aspirin is frequently mentioned as a likely offender, it has no deleterious effect in A− individuals. Accidental ingestion of toxic compounds such as naphthalene (moth balls) may cause severe hemolysis. Metabolic acidosis can precipitate an episode of hemolysis in individuals deficient in G6PD.

Clinical and Laboratory Features The patient may experience an acute hemolytic crisis within hours of exposure to the oxidant stress, leading to hemoglobinuria and peripheral vascular collapse in severe cases. Since only the older population of RBC is rapidly destroyed, the hemolytic crisis is usually self-limited, even if the exposure to the oxidant continues. Among black males with the A− variant, the RBC mass decreases by a maximum of 25 to 30%. The oxidation of hemoglobin leads to the formation of Heinz bodies, visualized by means of a supravital stain such as crystal violet. However, Heinz bodies are usually not seen after the first day or so, since these inclusions are readily removed by the spleen. Their removal leads to the formation of "bite cells" (RBC that have lost a peripheral portion of the cell). Multiple bites cause the formation of fragments. A few spherocytes also may be present. Individuals with the Mediterranean type G6PD have much lower overall enzyme activity than those with the A− variant and, therefore, have more severe clinical manifestations. A minority of patients are exquisitely sensitive to fava beans and develop a fulminant hemolytic crisis after exposure. The oxidants in *Vicia fava* are two β-glycosides whose aglycones, when autooxidized, produce oxygen free radicals. The incidence of favism is highly variable due to variations in concentration, in absorption, or in metabolism of the aglycones. Favism is seldom encountered in individuals with the A− variant.

The *diagnosis* of G6PD deficiency should be considered in any individual, particularly a male of African or Mediterranean descent, who experiences an acute hemolytic episode. The patient should be questioned about possible exposure to oxidant agents. The diagnosis can be established by a number of tests that assess either the enzyme activity or the effects of its deficiency. However, the test may yield a false-negative result during a hemolytic episode when the old RBC deficient in the enzyme have already lysed.

TABLE 93-4 Drugs Causing Hemolysis in Subjects Deficient in G6PD

Antimalarials: Primaquine, pamaquine, dapsone
Sulfonamides: Sulfamethoxazole
Nitrofurantoin
Analgesics: Acetanilid
Miscellaneous: Vitamin K (water-soluble form), doxorubicin, methylene blue, nalidixic acid, furazolidone, niridazole, phenazopyridine

TREATMENT

Since hemolysis in patients deficient in A− G6PD is usually self-limited, no specific treatment is necessary. Splenectomy does not benefit Mediterranean patients with chronic hemolysis. Blood transfusions are rarely indicated. Adequate urine flow should be maintained if hemoglobinuria develops during an acute hemolytic episode.

Hemolytic episodes can be prevented by warning patients about risks posed by oxidant drugs and fava beans and by prompt treatment of infections.

Other Defects of the Hexose-Monophosphate Shunt A few kindreds have been found to have congenital deficiency in RBC glutathione due to a defect in either of the two enzymes responsible for the synthesis of this tripeptide. Affected individuals have a hemolytic anemia with Heinz bodies that is aggravated by oxidant drugs.

OTHER ENZYME DEFECTS Hemolytic anemia may sometimes be caused by abnormalities in enzymes of nucleotide metabolism. Individuals with pyrimidine 5′-nucleotidase deficiency have marked coarse basophilic stippling in their RBC because the mRNA of the cell is not properly metabolized. Hemolytic anemia also has been noted in individuals whose RBC have supranormal levels of adenosine deaminase and relatively low levels of ATP.

Hemoglobinopathies Hemolysis is a component of anemias related to some hemoglobinopathies (Chap. 91).

ACQUIRED HEMOLYTIC ANEMIAS In most patients with acquired hemolytic anemia, RBC are made normally but are prematurely destroyed because of damage acquired in the circulation. (The exceptions are rare disorders characterized by acquired dysplasia of the cells of the bone marrow and the production of structurally and functionally abnormal RBC.) The damage that occurs may be mediated by antibodies or toxins or may be due to abnormalities in the circulation, including an overactive mononuclear phagocyte system or traumatic lysis by natural or artificial impediments to circulation. The acquired hemolytic anemias are classified into five categories (Table 93-5).

TABLE 93-5 Causes of Acquired Hemolytic Anemia

I. Entrapment
II. Immune
A. Warm-reactive (IgG) antibody
B. Cold-reactive IgM antibody (cold agglutinin disease)
C. Cold-reactive IgG antibody (paroxysmal cold hemoglobinuria)
D. Drug-dependent antibody
1. Autoimmune
2. Haptene
III. Traumatic hemolytic anemia
A. Impact hemolysis
B. Macrovascular defects—prostheses
C. Microvascular causes
1. Thrombotic thrombocytopenic purpura/hemolytic-uremic syndrome
2. Other causes of microvascular abnormalities
3. Disseminated intravascular hemolysis
IV. Hemolytic anemia due to toxic effects on the membrane
A. Spur cell anemia
B. External toxins
1. Animal or spider bites
2. Metals (e.g., copper)
3. Organic compounds
V. Paroxysmal nocturnal hemoglobinuria

Hypersplenism The spleen is particularly efficient in trapping and destroying RBC that have minimal defects. This unique ability of the spleen to filter mildly damaged RBC results from its unusual vascular anatomy (Chap. 54). Almost all the blood circulating through the spleen flows rapidly from arterioles in the white pulp to sinuses in the spleen's red pulp and then into the venous system. In contrast, a small portion of splenic blood flow (normally 1 to 2%) passes into the "marginal zone" of the lymphatic white pulp. Although the cells that occupy this zone are not phagocytic, they serve as a mechanical filter that hinders the progress of severely damaged blood cells. As RBC leave this zone and enter the red pulp, they flow into narrow cords, rich in macrophages, that end blindly but communicate with sinuses through small openings between the lining cells of the sinuses. These openings, averaging 3 μm in diameter, test the ability of RBC (4.5 μm in diameter) to undergo deformation. RBC that cannot re-enter the vascular sinuses are engulfed by phagocytic cells and destroyed (see Fig. 54-1).

The normal spleen retains reticulocytes for 1 to 2 days but otherwise poses no threat to normal RBC until they become senescent. However, in the face of splenomegaly, increased destruction of the cells of the blood, including the RBC, may take place due to pooling of the blood in a relatively nutrient-poor environment full of phagocytic cells. Splenic sequestration that causes cytopenia is called hypersplenism. In infiltrative diseases of the spleen, substantial splenomegaly may exist with no apparent hemolysis; inflammatory and congestive splenomegaly is commonly associated with modest shortening of RBC survival time, along with more marked granulocytopenia and thrombocytopenia. Patients with cytopenia(s) sufficient to produce symptoms generally benefit from splenectomy.

Immunologic Causes of Hemolysis Immune hemolysis in the adult is usually induced by IgG or IgM antibodies reacting specifically with antigens associated with the patient's RBC (often called "autoantibodies") or with alloantigens on transfused RBC (alloantibodies) (Chap. 99).

The Coombs antiglobulin test is the major tool for diagnosing autoimmune hemolysis. This test relies on the ability of antibodies specific for immunoglobulins (especially IgG) or complement components (especially C3) to agglutinate RBC coated with these proteins. With specific anti-IgG and anti-C3, the *direct Coombs test* detects IgG or C3 on the patient's RBC, which indicates the presence of immune hemolysis and may help define its cause (Table 93-6). Rarely, neither IgG nor complement may be found on the RBC of the patient (Coombs-negative immune hemolytic anemia).

Antibodies in the serum of the patient that recognize RBC antigens can be detected by reacting the serum with normal RBC bearing the antigen. With the exception of cold-reacting antibodies and some drug-related antibodies (see below), this is of value primarily in compatibility testing for transfusion.

"WARM" ANTIBODIES Antibodies that react at body temperature (warm antibodies) are nearly always IgG, rarely IgM or IgA. Autologous warm antibodies cause *autoimmune hemolytic (or immunohemolytic) anemia, warm antibody type*.

Clinical Manifestations Immunohemolytic anemia of the warm antibody type occurs at all ages, but it is more common in adults, particularly women. In approximately one-fourth of patients this disorder occurs as a complication of an underlying disease affecting the immune system, especially lymphoid neoplasms (Chap. 97); collagen vascular diseases, especially systemic lupus erythematosus (SLE); and congenital immunodeficiency diseases (Table 93-7). A wide variety of drugs may stimulate antibody formation, resulting in a similar syndrome (see below).

The presentation and course of IgG immunohemolytic anemia are quite variable. In its mildest form, the only manifestation is a positive direct Coombs test. In this instance, insufficient antibody is present on the RBC surface to permit the reticuloendothelial system to recognize the cell as abnormal. Most symptomatic patients have a moderate to severe anemia [hemoglobin levels 60 to 100 g/L and reticulocyte counts 10 to 30% (200 to 600 $\times$ $10^3/\mu$L)], spherocytosis (Fig. 93-5), and splenomegaly. Occasionally, venous thrombosis occurs.

Severe immunohemolytic anemia presents with fulminant hemolysis associated with hemoglobinemia, hemoglobinuria, and shock; this syndrome may be rapidly fatal unless aggressively treated.

The direct Coombs test is positive in 98% of patients; usually IgG is detected with or without C3. The pattern of IgG and C3 fixation on the patient's RBC may indicate the origin of the disorder.

Immune thrombocytopenia also may be present (*Evans syndrome*), a disorder in which separate antibodies are directed against platelets and RBC.

Pathogenesis IgG antibodies lyse RBC by two mechanisms: (1) immune adherence of RBC to phagocytes mediated by the antibody and by complement components that become fixed to the membrane (by far the more important mechanism of destruction), and (2) complement activation. IgG antibodies bind to Fc receptors on macrophages, activating those cells to engulf the coated RBC. If internalization is only partial, a portion of the RBC membrane is removed, resulting in the formation of spherocytes, which are destroyed in the spleen. Complement-mediated immune adherence involves the interaction of C3b and C4b with receptors on the macrophage; while much less likely to lead to RBC lysis, this mechanism markedly increases the immune adherence due to IgG. Immune adherence, particularly that due to the IgG antibody, is also enhanced by the transit of RBC into splenic cords and sinuses, which brings cells into direct contact with phagocytic cells.

TABLE 93-6 *Use of the Direct Coombs Test in Diagnosing the Cause of Autoimmune Hemolytic Anemia*

Reaction with		
Anti-IgG	Anti-C3	Causes
Yes	No	Antibodies to Rh proteins, hemolysis caused by α-methyldopa or penicillin
Yes	Yes	Antibodies to glycoprotein antigens, SLE
No	Yes	Cold-reacting antibodies (agglutinins or Donath-Landsteiner antibody), most drug-related antibodies, IgM antibodies, IgG antibodies of low affinity, activation of complement by immune complexes

TREATMENT

Patients having a mild degree of hemolysis usually do not require therapy. In those with clinically significant hemolysis, initial therapy consists of glucocorticoids (e.g., prednisone, 1.0 mg/kg per day). A rise in hemoglobin is frequently noted within 3 or 4 days and occurs

TABLE 93-7 *Hemolysis due to Antibodies*

WARM-ANTIBODY IMMUNOHEMOLYTIC ANEMIA

1. Idiopathic
2. Lymphomas: Chronic lymphocytic leukemia, non-Hodgkin's lymphomas, Hodgkin's disease (infrequent)
3. SLE and other collagen-vascular diseases
4. Drugs
   a. α-Methyldopa type (autoantibody to Rh antigens)
   b. Penicillin type (stable hapten)
   c. Quinidine type (unstable hapten)
5. Postviral infections
6. Other tumors (rare)

COLD-ANTIBODY IMMUNOHEMOLYTIC ANEMIA

1. Cold agglutinin disease
   a. Acute: *Mycoplasma* infection, infectious mononucleosis
   b. Chronic: Idiopathic, lymphoma
2. Paroxysmal cold hemoglobinuria

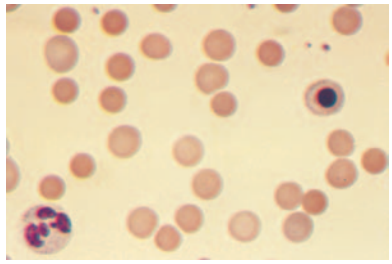

FIGURE 93-5 *Immunohemolytic anemia* Microspherocytes are seen on this blood smear along with several macrocytes with a slight purple tinge (polychromasia). The latter represent new red blood cells released early from the bone marrow. The microspherocytes seen in immunohemolytic anemia may be indistinguishable from the microspherocytes seen in hereditary spherocytosis (Fig. 93-1).

in most patients within 1 to 2 weeks. Prednisone is continued until the hemoglobin level has risen to normal values, and thereafter it is tapered rapidly to about 20 mg/d, then slowly over the course of several months. An algorithm for this tapering process is given in Fig. 93-6. For chronic therapy with prednisone, alternate-day administration is preferred. More than 75% of patients achieve an initial significant and sustained reduction in hemolysis; however, in half these patients the disease recurs, either during glucocorticoid tapering or after its cessation. Glucocorticoids have two modes of action: an immediate effect due to inhibiting clearance of IgG-coated RBC by the mononuclear phagocyte system and a later effect due to inhibiting antibody synthesis. Splenectomy is recommended for patients who cannot tolerate or fail to respond to glucocorticoid therapy.

Patients who have been refractory to glucocorticoid therapy and to splenectomy are treated with immunosuppressive drugs. A success rate of ~50% has been reported. Intravenous gamma globulin may cause rapid cessation of hemolysis; however, it is not nearly as effective in this disorder as in immune thrombocytopenia.

Patients with severe anemia may require blood transfusions. Because the antibody in this disease is usually a "panagglutinin," reacting with nearly all normal donor cells, compatible cross-matching is impossible. The goal in selecting blood for transfusion is to avoid administering RBC with antigens to which the patient may have alloantibodies. A common procedure is to adsorb the panagglutinin

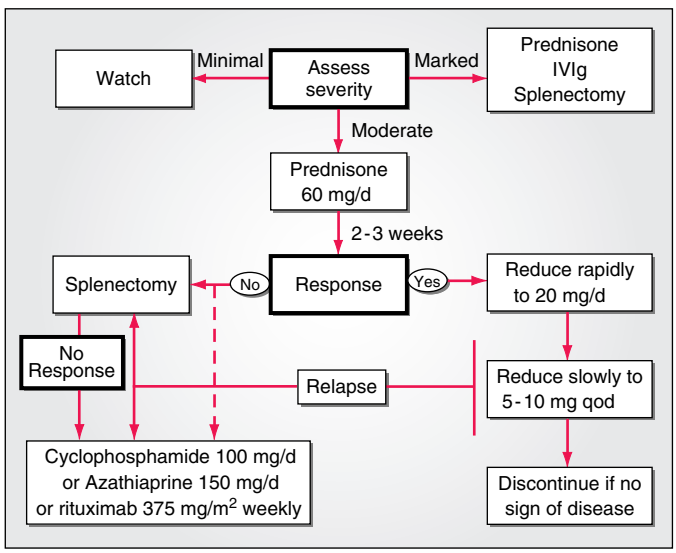

FIGURE 93-6 Algorithm for the treatment of patients with IgG-mediated immune hemolytic anemia. The patient with minimal disease may be watched carefully. The patient with very severe disease may need all modalities of treatment applied at once. The more common patient with moderate disease may be treated with prednisone at a high dose; if no response is seen, then either splenectomy is performed or an immunosuppressive agent is given. If a response is seen, the dose of prednisone is reduced over time. If relapse occurs during this process, splenectomy or chemotherapy may be needed.

present in the patient's serum with the patient's own RBC from which antibody has been previously eluted. Serum cleared of autoantibody can then be tested for the presence of alloantibody to donor blood groups. ABO-compatible RBC matched in this fashion are administered slowly, with watchfulness for signs of an immediate-type hemolytic transfusion reaction.

Prognosis Immune hemolytic anemia is often transient in children, particularly when it follows a viral infection, but is usually chronic in adults, lasting many years with exacerbations and remissions. In most patients, hemolysis is controlled by glucocorticoid therapy alone, by splenectomy, or by a combination. Fatalities occur among three rare subsets of patients: (1) those with overwhelming hemolysis who die from anemia; (2) those whose host defenses are impaired by glucocorticoids, splenectomy, and/or immunosuppressive agents; and (3) those with major thrombotic events coincident with active hemolysis.

When immunohemolysis develops as a complication of an underlying disorder, the prognosis is often determined by the primary disease.

IMMUNOHEMOLYTIC ANEMIA SECONDARY TO DRUGS Drugs cause immunohemolytic anemia by two mechanisms of action: (1) they induce a disorder identical in almost every respect to warm-antibody immunohemolytic anemia [e.g., α-methyldopa (an antihypertensive; Chap. 230)], or (2) they become associated as haptens with the RBC surface and induce the formation of an antibody directed against the RBC-drug complex (e.g., penicillin, quinidine).

A positive direct Coombs test is observed in up to 10% of patients receiving α-methyldopa therapy in doses of 2 g/d or higher. A small minority of these patients develop spherocytosis and hemolysis, which may be severe. The autoantibodies cross-react with the normal Rh protein.

In most other cases of drug-induced hemolysis, the antibody is directed against the combination of the drug and the membrane glycoprotein to which it is attached. The hemolytic reaction in vivo is dependent on the presence of the drug and usually ceases shortly after the drug has been discontinued. Penicillin and its congeners may cause this type of reaction if the drug is given in very high doses (10 million units per day or more). The direct Coombs test is positive only with anti-IgG; the indirect Coombs test is positive only when the normal cells have been coated with penicillin. Complement is not usually fixed, and the hemolysis in vivo is usually not severe. Since the antibody is usually IgG, spherocytosis and splenic destruction may occur.

Most other drugs (such as quinine, quinidine, sulfonamides, sulfonureas, phenacetin, stibophen, and dipyrone) do not adhere as tightly to their glycoproteins, and the drug-antibody complexes are removed during the washing steps of the direct and indirect Coombs reactions. These antibodies (particularly IgM) are usually able to fix complement, and C3d and C4d remain on the RBC surface; thus the direct Coombs test is positive with anti-C3 but not anti-IgG. The antibody is detected in the *indirect* Coombs test only when the drug is added to the incubation mixture. Hemolysis may be quite severe, sometimes resulting in signs of intravascular hemolysis; resolution is usually prompt after the drug is discontinued.

IMMUNE HEMOLYSIS DUE TO COLD-REACTIVE ANTIBODIES Antibodies that react with polysaccharide antigens are usually IgM and bind antigen better at temperatures lower than 37°C, hence the name *cold-reactive antibodies*. Uncommonly, the antibody is IgG (the Donath-Landsteiner antibody of paroxysmal cold hemoglobinuria).

IgM cold-reacting antibodies readily agglutinate RBC and are called *cold agglutinins*. They arise in two clinical settings: (1) monoclonal antibodies, the product of lymphocytic neoplasia or paraneoplasia; and (2) polyclonal antibodies in response to infection. In many elderly patients, the "neoplasm" is benign monoclonal gammopathy that does not progress, and the paraprotein remains its only manifes-

tation. Occasionally, cold agglutinins are found in patients with nonlymphoid neoplasms.

Transient cold agglutinins occur commonly in two infections: *Mycoplasma pneumoniae* infection and infectious mononucleosis. In both, the titer of antibody is usually too low to cause clinical symptoms, but its presence is of diagnostic value; only occasionally is hemolysis present. Cold agglutinins are less frequently encountered in a number of other viral infections. Their manifestations are usually benign.

The specificity of the antibody may be of diagnostic value. Cold agglutinins reacting more strongly with adult RBC than fetal (cord) RBC are called *anti-I*; these antibodies are seen in benign lymphoproliferation (chronic cold agglutinin monoclonal gammopathy) and in Mycoplasma infections. Those reacting more strongly with cord RBC cells are called *anti-i*; these antibodies are seen in aggressive lymphomas and in infectious mononucleosis. Rarely, the antibody may react with other antigens that are equally expressed on adult and cord RBC. The clinical manifestations elicited by the antibody on exposure to cold are of two sorts: intravascular agglutination (acrocyanosis) and hemolysis. Acrocyanosis is the marked purpling of the extremities, ears, and nose when the blood becomes cold enough to agglutinate in the veins; it clears on warming and does not have the vasospastic characteristics of Raynaud's phenomenon (Chap. 232). Patients may also have symptoms when swallowing cold food or drinks.

The hemolysis is usually not severe and is manifested by a mild reticulocytosis, agglutination on the blood film, and agglutination during analysis of the blood by particle analysis (giving rise to a falsely high mean corpuscular volume). The degree of hemolysis depends on several variables.

1. *Antibody titer*. The titer in symptomatic patients is usually above 1:2000 dilution of serum and may range to as high as 1:50,000. When collecting samples, great care must be taken to keep the serum separated from the cells while the sample is maintained at 37°C so that the antibody will not adsorb onto the patient's own cells.
2. *Thermal amplitude of the antibody* (the highest temperature at which the antibody will react with the RBC). For most antibodies, this is 23 to 30°C. Those with a higher thermal amplitude (up to 37°C) are more hemolytic, since it is more likely that these temperatures will be encountered during RBC circulation.
3. *Environmental temperature*. Since the reaction can occur only at temperatures below body temperature, frequency and degree of exposure to cold are major determinants of the rate of hemolysis.

The hemolysis that occurs is due primarily to the hemolytic action of complement, since there are no functional Fc receptors for the IgM antibody on phagocytes. Complement is readily fixed; a single molecule of IgM is enough to effect binding of C1 and initiate the cascade. However, normal human RBC are remarkably resistant to the hemolytic action of complement because of several defense mechanisms. Therefore, severe hemolysis with hemoglobinuria occurs only with massive activation of the antibody, such as by sudden cooling. The activation of complement is always marked by the accumulation of a degradation product of C3, C3dg, on the surface; this product is what is detected with appropriate antisera in the direct Coombs test in all patients with significant cold agglutinin disease.

The cutaneous manifestations are best treated by maintaining the patient in a warm environment. Splenectomy is usually not of value in this disorder. Glucocorticoids are of limited value, although patients with the panthermal variety of cold agglutinin disease may respond. Chlorambucil and cyclophosphamide are commonly used to treat patients who have hemolysis associated with monoclonal gammopathy, but their efficacy is usually marginal. Rituximab (anti-CD20) has been effective in some cases. Successful treatment of the neoplasm responsible for the cold agglutinin often lowers the antibody titer and the severity of hemolysis.

Chronic cold agglutinin disease tends to be unremitting. The overall prognosis is dominated by the underlying lymphoma, if present. In those patients in whom cold agglutinin disease appears to arise spontaneously, malignant lymphoma may develop after several years.

PAROXYSMAL COLD HEMOGLOBINURIA (PCH) Now a rare disorder, PCH was more frequent when tertiary syphilis was prevalent; now, most cases are either secondary to a viral infection or are autoimmune. PCH results from the formation of the Donath-Landsteiner antibody, an IgG antibody that is directed against the P antigen (Chap. 99) and that can induce complement-mediated lysis. Attacks are precipitated by exposure to cold and are associated with hemoglobinemia and hemoglobinuria; chills and fever; back, leg, and abdominal pain; headache; and malaise. Recovery from the acute episode is prompt, and between episodes patients are usually asymptomatic. When this syndrome accompanies acute viral infections (e.g., measles and mumps in children), it is self-limited but may be severe. Although the direct Coombs test may show complement to be present (seldom IgG), this test may be negative. The diagnosis is made by demonstrating cold-reacting IgG antibodies either by lytic tests (when the titer is very high) or by special antiglobulin tests. When PCH is secondary to syphilis, it responds to therapy for syphilis. Chronic autoimmune PCH may respond to prednisone or cytotoxic therapy (azathioprine or cyclophosphamide) but does not respond to splenectomy. The natural history of this disease often extends over many years.

Hemolysis Due to Trauma in the Circulation RBC may be fragmented by mechanical trauma as they circulate; this circumstance leads to intravascular hemolysis and in most cases to RBC fragments called *schistocytes*. Schistocytes are identified by the sharp points that result from the faulty resealing of the fractured membrane (Fig. 93-7). Mechanical trauma leading to hemolysis occurs in three clinical settings: (1) when RBC flow through small vessels over the surface of bony prominences and are subject to external impact during various physical activities, (2) when RBC flow across a pressure gradient created by an abnormal heart valve or valve prosthesis (macrovascular), and (3) when the deposition of fibrin or small platelet thrombi in the microvasculature exposes RBC to a physical impediment that fragments them (microvascular) (Table 93-8).

EXTERNAL IMPACT Hemoglobinemia and hemoglobinuria have been observed in a small proportion of individuals who have undergone a prolonged march or a prolonged run, most typically on a hard surface and while wearing thin-soled shoes. Hemolysis can be prevented by the insertion of a soft inner sole in the runner's shoes. No abnormality of RBC has been demonstrated, even during the acute episode.

MACROVASCULAR TRAUMATIC HEMOLYSIS Hemolysis associated with fragmented RBC (Fig. 93-7) occurs in approximately 10% of patients with artificial aortic valve prostheses. In contrast, traumatic hemolysis is rare in recipients of porcine valves. Severe hemolysis may occur after repair of ostium primum or endocardial cushion defects with a prosthetic patch. Mitral valve prostheses may produce hemolysis, but since the pressure gradient across these valves is lower than across aortic prostheses, the incidence is lower. A moderately shortened RBC survival time with little or no anemia occurs in some patients with severe calcific aortic stenosis. Indeed, almost any intracardiac lesion that alters hemodynamics may lead to some shortening of RBC survival. Traumatic hemolysis has been observed in patients who have undergone aortofemoral bypass.

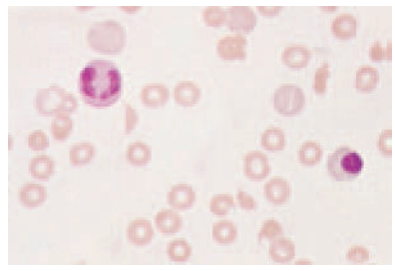

FIGURE 93-7 The helmet-shaped red blood cell and the small triangular-shaped red blood cells seen on this smear represent morphologic evidence of mechanical damage to red blood cells within the blood vessels.

TABLE 93-8 *Changes in RBC and Platelets Induced by Intravascular Trauma*

Etiology	Fragments	Hemolysis	Thrombocytopenia
Impact: march hemoglobinuria, etc.	0	+	0
Cardiac (turbulence):			
Aortic valve prosthesis	++++	++++	0
Mitral valve prosthesis	++	++	0
Calcific aortic stenoses	+	±	0
Vessel disease[a]	+++	+	+
Thrombotic thrombocytopenic purpura	++++	++++	++++
Hemolytic-uremic syndrome	++++	++++	++++
Adenocarcinoma	++++	++++	++++
Disseminated intravascular coagulation	++	±	++++

[a] Malignant hypertension, eclampsia, renal graft rejection, hemangiomas, immune disease (scleroderma).

Clinical Manifestations In severe cases, hemoglobin levels fall to 50 to 70 g/L with reticulocytosis, fragmented RBC in the peripheral blood, depressed haptoglobin, elevated serum LDH, and hemoglobinemia and hemoglobinuria. Iron loss (as hemoglobin or hemosiderin) in the urine may lead to iron deficiency. The direct Coombs test may rarely become positive.

TREATMENT

Iron deficiency should be corrected by the administration of oral iron. The elevated hemoglobin that results may permit a decrease in the cardiac output and a slowing of the hemolytic rate. Limitation in physical activity also lessens the hemolytic rate. When these measures fail, any paravalvular leak must be repaired or the prosthetic valve replaced.

MICROVASCULAR TRAUMATIC HEMOLYSIS If fibrin or platelet microthrombi are deposited in arteriolar sites, RBC may be trapped on the meshwork and fragmented by high shear forces.

Abnormalities of the Vessel Wall Disorders such as malignant hypertension, eclampsia [hemolysis, elevated liver enzymes, low platelets (HELLP) syndrome], renal allograft rejection, disseminated cancer, hemangiomas, or disseminated intravascular coagulation (DIC) may cause traumatic hemolysis (Chaps. 101, 102). The degree of hemolysis induced by this family of disorders is usually quite mild, but a large number of fragments may be seen in the peripheral blood. In some patients, thrombocytopenia may be severe. Therapy is best directed at the primary disease. Thus, reversal of renal graft rejection, treatment of malignant hypertension and eclampsia, control of cancer, and the like lead to a cessation of hemolysis. The relative importance of the primary vascular abnormality versus fibrin deposition is unclear.

THROMBOTIC THROMBOCYTOPENIA PURPURA (TTP) This disorder is characterized by arteriolar lesions in various organs that contain platelet thrombi and produce thrombocytopenia and hemolytic anemia due to fragmentation of RBC (see Chap. 101).

HEMOLYTIC-UREMIC SYNDROME This disorder is similar to TTP and is characterized by the same arteriolar lesions, which may be confined to the kidney, and by similar laboratory findings (see Chap. 101).

DISSEMINATED INTRAVASCULAR COAGULATION Inappropriate activation of the clotting system with deposition of fibrin in small vessels may lead to RBC fragmentation in the microvasculature. RBC fragmentation occurs in about one-fourth of patients with DIC (Chap. 102). The degree of hemolysis is much less in DIC than in either TTP or the hemolytic-uremic syndrome, and anemia with reticulocytosis is rare.

Environmental Alteration of the Red Cell Membrane by "Toxic" Effects A variety of infections may be associated with severe hemolysis. The microbes that cause bartonellosis (Chap. 144), as well as malaria and babesiosis (Chap. 195), directly parasitize RBC. *Clostridium welchii* (Chap. 126) produces a phospholipase that can cleave the phosphoryl bond of lecithin, thereby lysing human RBC. A mild, transient hemolysis frequently accompanies bacteremia with diverse organisms such as pneumococci, staphylococci, and *Escherichia coli*.

Hemolysis may result from the direct action of snake and spider venoms on the RBC. Although cobra venom is directly lytic in vitro, the clinical disease induced by the bite of the cobra is one of moderate hemolysis associated with spherocytosis. Spider bites, particularly the bite of the brown recluse spider, induce acute intravascular hemolysis associated with spherocytosis and fragments of complement components on the RBC. The hemolysis continues for several days up to 1 week.

Copper has a direct hemolytic effect on RBC. Hemolysis has been observed after exposure of individuals to copper salts (such as during hemodialysis). Transient episodes of hemolysis occur in patients with Wilson's disease (Chap. 339).

The RBC membrane is unstable at temperatures above 49°C due to denaturation of the cytoskeletal protein spectrin. The RBC undergoes a process of budding, cleavage, and resealing above this temperature. Patients with extensive burns have prominent spherocytosis, hemoglobinemia, and sometimes hemoglobinuria.

Spur Cell Anemia Hemolytic anemia with bizarre-shaped RBC occurs in about 5% of patients with severe hepatocellular disease, particularly advanced Laennec's cirrhosis.

Clinical Manifestations Anemia is more severe than that observed in otherwise uncomplicated cirrhosis. Splenomegaly is always present and is greater than in patients who have cirrhosis without spur cell anemia. The RBC are irregularly shaped with multiple spicules, and a small number of bizarre-shaped fragments are commonly seen on peripheral blood smears (see Fig. 98-3).

Pathogenesis The surface membrane of a spur cell contains 50 to 70% excess cholesterol, but its total phospholipid content is normal. Cholesterol out of proportion to phospholipid decreases the membrane fluidity and cell deformability. These rigid, cholesterol-laden RBC cannot pass through the filtering system of the spleen, further impeded by congestive splenomegaly in cirrhosis. In contrast, the target-shaped RBC is more common in liver disease and has an excess of both cholesterol and phospholipid.

Diagnosis Patients with spur cell anemia have severe hemolysis and characteristic RBC morphology. Spur cells or acanthocytes have irregular spikes (irregular in length of projections and their spacing) and must be distinguished from regularly spaced, crenated RBC (echinocytes). Echinocytes are a frequent artifact on portions of some blood smears, and they are uniformly present in some patients with uremia ("burr cells") (Fig. 93-8). Small, dense, crenated spheres (spheroechinocytes) are sometimes seen in congenital nonspherocytic hemolytic anemia due to enzyme deficiencies in the Embden-Meyerhof pathway (see above). RBC of similar morphology are seen in patients with abetalipoproteinemia. However, hemolysis is minimal.

TREATMENT

Transfusion therapy is of limited benefit. Lipid-lowering agents have been unsuccessful. Splenectomy has been reported to prevent both the

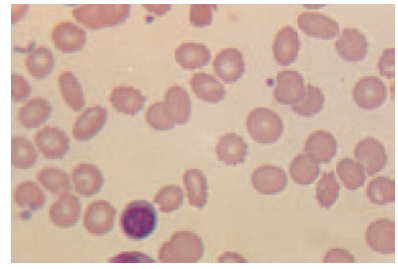

FIGURE 93-8 The red blood cells in uremia may acquire numerous, regularly spaced, small spiny projections. Such cells, called burr cells or echinocytes, are readily distinguishable from irregularly spiculated acanthocytes or spur cells.

conditioning of RBC in the spleen and their premature destruction. However, splenectomy carries a high risk in patients with severe liver disease complicated by portal hypertension and coagulation defects. It must be reserved for patients in whom hemolysis is a major problem and who are relatively good surgical risks.

Prognosis Spur cell anemia occurs during the late stages of cirrhosis, and >90% of patients succumb to their underlying liver disease within 1 year of the diagnosis of spur cell anemia.

Paroxysmal Nocturnal Hemoglobinuria (PNH) This hemolytic disorder is distinctive because it is an intracorpuscular defect acquired at the stem cell level.

Clinical Manifestations The three common manifestations of PNH are hemolytic anemia, venous thrombosis, and deficient hematopoiesis. Anemia is highly variable, with hematocrit values ranging from ≤20% to normal. RBC are normochromic and normocytic unless iron deficiency has occurred from chronic iron loss in the urine.

Clinical hemoglobinuria is intermittent in most patients and never occurs in some, but hemosiderinuria is usually present. Since hemolysis is due to abnormalities of the RBC leading to sensitivity to the hemolytic action of complement, it is manifest when complement is activated, for example, by infection.

Granulocytopenia and thrombocytopenia are common and reflect impaired hematopoiesis. The life span of the platelet is normal. However, the activation of complement indirectly stimulates platelet aggregation and hypercoagulability; this probably accounts for the tendency toward thrombosis seen in PNH.

Venous thrombosis is a common complication of patients of European origin, affecting ~40% at one time or another; it is less common in Asian patients. It occurs primarily in intra-abdominal veins (hepatic, portal, mesenteric) and results in Budd-Chiari syndrome, congestive splenomegaly, and abdominal pain. It may occur in cerebral venous sinuses and is a common cause of death in patients with PNH.

The bone marrow may appear normocellular, but in vitro marrow progenitor assays are abnormal. In about 15 to 30% of long-term survivors of aplastic anemia, PNH cells appear in the circulation; in some patients, the manifestations of PNH become dominant. Patients with PNH may have aplastic periods lasting from weeks to years. PNH may be seen in association with other stem cell disorders, including myelofibrosis and (rarely) other myelodysplastic or myeloproliferative disorders.

Pathogenesis PNH is an acquired clonal disease, arising from an inactivating somatic mutation in a single hematopoietic stem cell of a gene on the X-chromosome (*pig-A*) necessary for the biosynthesis of the glycosylphosphatidylinositol (GPI) anchor. This anchor attaches a number of proteins to the external membrane surface, and its partial or complete absence results in the absence of those proteins; to date, about 20 proteins have been found to be missing on the blood cells of patients with PNH. Two of these are the complement defense proteins CD55 [PNH decay accelerating factor (DAF)] and CD59, which block complement activation on the cell surface. Their absence accounts for the sensitivity of RBC to complement lysis and for the tendency of platelets to abnormally initiate clotting. The normal clones of stem cells do not completely disappear, and the proportion of cells that are abnormal varies among patients and over time in a single patient.

Diagnosis PNH should be suspected in anyone with otherwise unexplained hemolytic anemia, especially with leukopenia and/or thrombocytopenia and with evidence of intravascular hemolysis (hemoglobinemia, hemoglobinuria, hemosiderinuria, elevated LDH). Anyone recovering from aplastic anemia should be examined at intervals for the appearance of the diagnostic cells. The diagnosis is often delayed because (1) it is not considered, (2) hemoglobinuria is confused with hematuria, (3) elevation of the LDH is attributed to liver disease, and (4) the diagnostic tests [the acidified serum lysis test (Ham test) and the sucrose lysis test] are not reliable.

For many years, the diagnosis of PNH depended on the demonstration of the lysis of RBC after complement activation either by acid (Ham test) or by reduction in ionic strength (sucrose lysis test). These tests are inferior to the analysis of GPI-linked proteins (e.g., CD59, DAF) on RBC and granulocytes by flow cytometry.

Rx TREATMENT

Transfusion therapy is useful in PNH not only for raising the hemoglobin level but also for suppressing the marrow production of RBC during episodes of sustained hemoglobinuria. Washed RBC are the preferred source to prevent exacerbation of hemolysis. Therapy with androgens sometimes results in a rise in hemoglobin level. Glucocorticoids reduce the rate of hemolysis in moderate doses (15 to 30 mg prednisone) on alternate days.

Iron deficiency is common. Iron replacement may exacerbate hemolysis because of the formation of many new RBC, which may be sensitive to complement. This occurrence may be minimized by giving prednisone (60 mg/d) or by suppressing the bone marrow with transfusions.

Acute thrombosis in PNH, particularly Budd-Chiari syndrome and cerebral thrombosis, should be treated with thrombolytic agents. Heparin therapy should be instituted rapidly and maintained using low-molecular-weight heparin, at least for several weeks to months and perhaps indefinitely in severe cases. Anyone who has had a major thrombosis should chronically receive at least warfarin therapy. Antithymocyte globulin (total dose, 150 mg/kg over 4 to 10 days) is often of use in treating marrow hypoplasia; prednisone counteracts the immune-complex disease that results from the administration of this foreign protein.

In patients with either hypoplasia or thrombosis who have an appropriate sibling donor, marrow transplantation should be considered early in the course of the disease. The usual conditioning programs are sufficient to eradicate the aberrant clone.

ANEMIA OF ACUTE BLOOD LOSS

The normal capacity to compensate for acute blood loss involves cardiovascular mechanisms, an adjustment in the oxygen affinity of hemoglobin, and an increase in erythropoiesis in the marrow. The signs and symptoms of blood loss relate to the volume of the blood loss and the time frame over which the hemorrhage occurs (Table 93-9). Losses of up to 20% of the blood volume are normally tolerated by redistribution of blood flow mediated by reflex venospasm, but the presence of fever or pain may interfere with this compensation. With larger losses, blood volume redistribution is not adequate to maintain normal blood pressure: initially, hypotension is only seen on standing, but with greater losses the patient has hypotension in sitting or supine positions. If the blood loss is more gradual, plasma volume increases, but albumin production usually lags behind the fluid shifts. It may take 2 to 3 days for the liver to generate the albumin lost in a 1500-mL bleed.

TABLE 93-9 Signs and Symptoms of Acute Blood Loss

Blood Loss			
%,[a]	Volume, mL	Symptoms	Signs
<20	<1000	Restlessness	+/− Vasovagal reaction
20–30	1000–1500	Anxiety, DOE	Orthostatic hypotension, tachycardia on exertion
30–40	1500–2000	Syncope on sitting or standing	Orthostatic hypotension, tachycardia at rest
>40	>2000	Confusion, shortness of breath	Shock, poor perfusion

[a] Based on an estimated total blood volume of 5000 mL (70-kg adult).

The most rapid hematologic adjustment to acute blood loss is an increase in oxygen delivery to the tissues. This is first mediated by the Bohr effect, in which the more acidic milieu of the hypoperfused hypoxic tissues shifts the hemoglobin-oxygen dissociation curve to the right. Over several hours the RBC increase their production of 2,3-bisphosphoglycerate, which also enhances the unloading of oxygen to tissues. These two mechanisms can substantially increase the capacity of RBC to deliver oxygen to the tissues.

The marrow response to hemorrhage is related to the erythropoietin response to decreased oxygen tension. A normal response depends on the production of erythropoietin, the presence of normal erythroid progenitors in the marrow, and an adequate supply of iron. If these three elements are normal, reticulocytes begin to increase in the first 2 days based on early release of reticulocytes from the marrow. However, it takes 3 to 6 days for erythroid hyperplasia to appear and 7 to 10 days before the erythropoietic response is maximal, producing reticulocyte counts up to 20 to 30%, a reticulocyte index of ≥3, and a marked increase in the marrow erythroid/granulocytic ratio.

DIAGNOSIS Usually it is clear that a patient is bleeding; however, in some cases, large volumes of blood loss can occur internally from the gastrointestinal tract (esophageal varices, cancer in the stomach or colon), a ruptured spleen, fractures and other trauma, or other lesions that can cause massive hemorrhage into the peritoneal cavity, the pleural cavity, or the retroperitoneal space. Patients who have bled sufficiently to develop hypotension generally develop anemia, which is apparent only after volume replacement. The granulocyte count may increase to ≥20,000 cells/μL and include immature cell types such as metamyelocytes and myelocytes. Epinephrine-induced demargination of peripheral granulocytes and release of cells from the marrow may account for this change. Nucleated RBC may appear in the circulation, and platelet counts may exceed $1 \times 10^6/\mu L$. The basis for the increased platelet count is unclear. Hemorrhage in an internal cavity is accompanied by a rise in unconjugated bilirubin and a fall in serum haptoglobin.

TREATMENT

Treatment of the underlying cause of the hemorrhage is of paramount importance. If the patient is severely anemic or sufficiently hypovolemic, packed RBC should be transfused. In less severe cases, if the patient has normal kidneys (and presumably a normal erythropoietin response to anemia), normal bone marrow function, and an adequate supply of iron, no specific therapy for the anemia is required.

94 APLASTIC ANEMIA, MYELODYSPLASIA, AND RELATED BONE MARROW FAILURE SYNDROMES

Neal S. Young

The hypoproliferative anemias associated with marrow damage include aplastic anemia, myelodysplasia (MDS), pure red cell aplasia (PRCA), and myelophthisis. Anemia in these disorders, which is normochromic, normocytic or macrocytic, and characterized by low reticulocyte count, is not a solitary or even the major finding in these diseases, which are better described as marrow failure states. In bone marrow failure, pancytopenia—anemia, leukopenia, and thrombocytopenia (sometimes in various combinations)—results from deficient hematopoiesis, as distinguished from blood count depression due to peripheral destruction of red cells (hemolytic anemias), platelets (idiopathic thrombocytopenic purpura or due to splenomegaly), and granulocytes (as in the immune leukopenias).

Hematopoietic failure syndromes are classified by dominant morphologic features of the bone marrow (Table 94-1). While practical distinction among these syndromes usually is clear, they can occur secondary to other diseases, and some processes are so closely related that the differential diagnosis may be arbitrary. Patients may seem to suffer from two or three related diseases simultaneously, or one diagnosis may appear to evolve into another. Finally, many of these syndromes share an immune-mediated pathophysiologic mechanism of marrow destruction and some element of genomic instability resulting in a higher rate of malignant transformation.

APLASTIC ANEMIA

DEFINITION Aplastic anemia is pancytopenia with bone marrow hypocellularity. Acquired aplastic anemia is distinguished from iatrogenic marrow aplasia, the common occurrence of marrow hypocellularity after intensive cytotoxic chemotherapy for cancer. Aplastic anemia can also be constitutional: the genetic diseases Fanconi's anemia and dyskeratosis congenita, while frequently associated with typical physical anomalies and the development of pancytopenia early in life, can also present as marrow failure in normal-appearing adults. Acquired aplastic anemia is often stereotypical in its manifestations, with the abrupt onset of low blood counts in a previously well young adult; seronegative hepatitis or a course of an incriminated medical drug may precede the onset. The diagnosis in these instances is

TABLE 94-1 Differential Diagnosis of Pancytopenia

PANCYTOPENIA WITH HYPOCELLULAR BONE MARROW
Acquired aplastic anemia
Constitutional aplastic anemia (Fanconi's anemia, dyskeratosis congenita)
Some myelodysplasia syndromes
Rare aleukemic leukemia (AML)
Some acute lymphoid leukemia
Some lymphomas of bone marrow
PANCYTOPENIA WITH CELLULAR BONE MARROW

Primary bone marrow diseases	Secondary to systemic diseases
Myelodysplasia syndromes	Systemic lupus erythematosus
Paroxysmal nocturnal hemoglobinuria	Hypersplenism
Myelofibrosis	B_{12}, folate deficiency
Some aleukemic leukemia	Overwhelming infection
Myelophthisis	Alcohol
Bone marrow lymphoma	Brucellosis
Hairy cell leukemia	Sarcoidosis
	Tuberculosis
	Leishmaniasis

HYPOCELLULAR BONE MARROW ± CYTOPENIA
Q fever
Legionnaires' disease
Anorexia nervosa, starvation
Mycobacteria

uncomplicated. Sometimes blood count depression is moderate or incomplete, resulting in anemia, leukopenia, and thrombocytopenia in some combination. Aplastic anemia is related to both paroxysmal nocturnal hemoglobinuria (PNH; Chap. 93) and to MDS, and in some cases a clear distinction among these disorders may not be possible.

EPIDEMIOLOGY The incidence of acquired aplastic anemia in Europe and Israel is 2 cases per million persons annually. In Thailand and China, rates of 5 to 7 per million have been established. In general, men and women are affected with equal frequency, but there is a biphasic age distribution, with the major peak in the teens and twenties and a second rise in the elderly.

ETIOLOGY The origins of aplastic anemia have been inferred from several recurring clinical associations (Table 94-2); unfortunately, these relationships are neither a reliable guide in an individual patient nor necessarily etiologic. In addition, while most cases of aplastic anemia are idiopathic, little other than history separates these cases from those with a presumed etiology such as a drug exposure.

Radiation Marrow aplasia is a major acute sequela of radiation. Radiation damages DNA; tissues dependent on active mitosis are particularly susceptible. Nuclear accidents can involve not only power plant workers but also employees of hospitals, laboratories, and industry (food sterilization, metal radiography, etc.), as well as innocents exposed to stolen, misplaced, or misused sources. While the radiation dose can be approximated from the rate and degree of decline in blood counts, dosimetry by reconstruction of the exposure can help to estimate the patient's prognosis and also to protect medical personnel from contact with radioactive tissue and excreta. MDS and leukemia, but probably not aplastic anemia, are late effects of irradiation.

Chemicals Benzene is a notorious cause of bone marrow failure. Vast quantities of epidemiologic, clinical, and laboratory data link benzene to aplastic anemia, acute leukemia, and blood and marrow abnormalities. The occurrence of leukemia is roughly correlated with cumulative exposure, but susceptibility must also be important, as only a minority of even heavily exposed workers develop benzene myelotoxicity. The employment history is important, especially in industries where benzene is used for a secondary purpose, usually as a solvent. Benzene-related blood diseases have declined with regulation of industrial exposure. Although benzene is no longer generally available as a household solvent, exposure to its metabolites occurs in the normal diet and in the use of lead-free gasoline. The association between marrow failure and other chemicals is much less well substantiated.

Drugs (See Table 94-3) Many chemotherapeutic drugs have marrow suppression as a major toxicity; effects are dose-dependent and will occur in all recipients. In contrast, idiosyncratic reactions to a large and diverse group of drugs may lead to aplastic anemia without a clear dose-response relationship. These associations rested largely on accumulated case reports until a large international study in Europe in the 1980s quantitated drug relationships, especially for nonsteroidal analgesics, sulfonamides, thyrostatic drugs, some psychotropics, penicillamine, allopurinol, and gold. Not all associations necessarily reflect causation: a drug may have been used to treat the first symptoms of bone marrow failure (antibiotics for fever or the preceding viral illness) or provoked the first symptom of a preexisting disease (petechiae by nonsteroidal anti-inflammatory agents administered to the thrombocytopenic patient). In the context of total drug use, idiosyncratic reactions, while individually devastating, are rare events. Chlor-

TABLE 94-2 *Classification of Aplastic Anemia and Single Cytopenias*

Acquired	*Inherited*
APLASTIC ANEMIA	
Secondary	Fanconi's anemia
Radiation	Dyskeratosis congenita
Drugs and chemicals	Shwachman-Diamond syndrome
Regular effects	Reticular dysgenesis
Idiosyncratic reactions	Amegakaryocytic thrombocytopenia
Viruses	Familial aplastic anemias
Epstein-Barr virus (infectious mononucleosis)	Preleukemia (monosomy 7, etc.)
Hepatitis (non-A, non-B, non-C hepatitis)	Nonhematologic syndrome (Down's, Dubowitz, Seckel)
Parvovirus B19 (transient aplastic crisis, PRCA)	
HIV-1 (AIDS)	
Immune diseases	
Eosinophilic fasciitis	
Hypoimmunoglobulinemia	
Thymoma/thymic carcinoma	
Graft-versus-host disease in immunodeficiency	
Paroxysmal nocturnal hemoglobinuria	
Pregnancy	
Idiopathic	
CYTOPENIAS	
PRCA (see Table 94-4)	Congenital PRCA (Diamond-Blackfan anemia)
Neutropenia/Agranulocytosis	
Idiopathic	Kostmann's Syndrome
Drugs, toxins	Shwachman-Diamond syndrome
Pure white cell aplasia	Reticular dysgenesis
Thrombocytopenia	
Drugs, toxins	Amegakaryocytic thrombocytopenia
Idiopathic amegakaryocytic	Thrombocytopenia with absent radii

Note: PRCA, pure red cell aplasia.

TABLE 94-3 *Some Drugs and Chemicals Associated with Aplastic Anemia*

Agents that regularly produce marrow depression as major toxicity in commonly employed doses or normal exposures:
- Cytotoxic drugs used in cancer chemotherapy: *alkylating agents*, antimetabolites, antimitotics, some antibiotics

Agents that frequently but not inevitably produce marrow aplasia:
- *Benzene*

Agents associated with aplastic anemia but with a relatively low probability:
- *Chloramphenicol*
- Insecticides
- Antiprotozoals: *quinacrine* and chloroquine, mepacrine
- Nonsteroidal anti-inflammatory drugs (including *phenylbutazone*, indomethacin, ibuprofen, sulindac, aspirin)
- Anticonvulsants (*hydantoins*, *carbamazapine*, phenacemide, felbamate)
- Heavy metals (*gold*, arsenic, bismuth, mercury)
- Sulfonamides: some antibiotics, antithyroid drugs (methimazole, methylthiouracil, propylthiouracil), antidiabetes drugs (tolbutamide, chlorpropamide), carbonic anhydrase inhibitors (acetazolamide and methazolamide)
- Antihistamines (*cimetidine*, chlorpheniramine)
- D-Penicillamine
- Estrogens (in pregnancy and in high doses in animals)

Agents whose association with aplastic anemia is more tenuous:
- Other antibiotics (streptomycin, tetracycline, methicillin, mebendazole, trimethoprim/sulfamethoxazole, flucytosine)
- Sedatives and tranquilizers (chlorpromazine, prochlorperazine, piperacetazine, chlordiazepoxide, meprobamate, methyprylon)
- Allopurinol
- Methyldopa
- Quinidine
- Lithium
- Guanidine
- Potassium perchlorate
- Thiocyanate
- Carbimazole

Note: Terms set in italic show the most consistent association with aplastic anemia.

amphenicol, the most infamous culprit, reportedly produced aplasia in only about 1/60,000 therapy courses, and even this number is almost certainly an overestimate (risks are almost invariably exaggerated when based on collections of cases; although the introduction of chloramphenicol was perceived to have created an epidemic of aplastic anemia, its diminished use was not followed by a changed frequency of marrow failure). Risk estimates are usually lower when determined in population-based studies; furthermore, the low absolute risk is also made more obvious: even a 10- or 20-fold increase in risk translates, in a rare disease, to but a handful of drug-induced aplastic anemia cases among hundreds of thousands of exposed patients.

Infections Hepatitis is the most common preceding infection, and posthepatitis marrow failure accounts for about 5% of etiologies in most series. Patients are usually young men who have recovered from a bout of liver inflammation 1 to 2 months earlier; the subsequent pancytopenia is very severe. The hepatitis is seronegative (non-A, non-B, non-C, non-G) and presumably due to a novel, as yet undiscovered, virus. Fulminant liver failure in childhood also follows seronegative hepatitis, and marrow failure occurs at a high rate in these patients. Marrow failure can rarely follow infectious mononucleosis, and Epstein-Barr virus has been found in the marrow of a few aplastic anemia patients, some without a suggestive preceding history. Parvovirus B19, the cause of transient aplastic crisis in hemolytic anemias and of some pure red cell aplasia (see below), does not usually cause generalized bone marrow failure. Blood count depression is frequent in the course of many viral and bacterial infections but is moderate and resolves with the infection.

Immunologic Diseases Aplasia is a major consequence and the cause of death in *transfusion-associated graft-versus-host disease*, which can occur after infusion of unirradiated blood products to an immunodeficient recipient. Aplastic anemia is strongly associated with the rare collagen vascular syndrome called *eosinophilic fasciitis*, which is characterized by painful induration of subcutaneous tissues (Chap. 303). Pancytopenia with marrow hypoplasia can also occur in systemic lupus erythematosus.

Pregnancy Aplastic anemia very rarely may occur and recur during pregnancy and resolve with delivery or with spontaneous or induced abortion.

Paroxysmal Nocturnal Hemoglobinuria An acquired mutation in the *PIG-A* gene in a hematopoietic stem cell is required for the development of PNH, but *PIG-A* mutations probably occur commonly in normal individuals. If the PIG-A mutant stem cell proliferates, the result is a clone of progeny deficient in glycosylphosphatidylinositol-linked cell surface membrane proteins (Chap. 93). Such PNH cells are now most accurately enumerated using fluorescence-activated flow cytometry of CD55 or CD59 expression on granulocytes rather than Ham or sucrose lysis tests on red cells. Small clones of deficient cells can be detected in about half of patients with aplastic anemia at the time of presentation [and PNH cells are also seen in MDS (see below)]; frank hemolysis and thrombotic episodes occur in patients with PNH clones. Functional studies of bone marrow from PNH patients, even those with mainly hemolytic manifestations, show evidence of defective hematopoiesis. Patients with an initial clinical diagnosis of PNH, especially younger individuals, may later develop frank marrow aplasia and pancytopenia; patients with an initial diagnosis of aplastic anemia may suffer from hemolytic PNH years after recovery of blood counts. One explanation for the aplastic anemia/PNH syndrome is selection of the deficient clones, because they are favored for proliferation in the peculiar environment of immune-mediated marrow destruction.

Congenital Disorders Fanconi's anemia, an autosomal recessive disorder, manifests as congenital developmental anomalies, progressive pancytopenia, and an increased risk of malignancy. Chromosomes in Fanconi's anemia are peculiarly susceptible to DNA cross-linking agents, the basis for a diagnostic assay. Patients with Fanconi's anemia typically have short stature, café au lait spots, and anomalies involving the thumb, radius, and genitourinary tract. At least eight different genetic defects have been defined by complementation analysis. The most common, type A Fanconi's anemia, is due to a mutation in *FANCA*. The Fanconi's anemia genes play a role in the cellular response to DNA damage, a response that includes BRCA1, ATM, and NBS1.

Dyskeratosis congenita is characterized by mucous membrane leukoplasia, dystrophic nails, reticular hyperpigmentation, and the development of aplastic anemia during childhood. The common X-linked variety is due to mutations in the *DKC1* (*dyskerin*) gene; the more unusual autosomal dominant type has been linked to *hTERC*, the RNA component of the telomerase complex. These two gene products cooperate in maintaining telomere length. In Shwachman-Diamond syndrome, marrow failure is seen with pancreatic insufficiency and malabsorption.

PATHOPHYSIOLOGY Bone marrow failure results from severe damage to the hematopoietic cell compartment. In aplastic anemia, replacement of the bone marrow by fat is apparent in the morphology of the biopsy specimen (Fig. 94-1) and magnetic resonance imaging (MRI) of the spine; cells bearing the CD34 antigen, a marker of early hematopoietic cells, are greatly diminished; and in functional studies, committed and primitive progenitor cells are virtually absent—in vitro assays have suggested that the stem cell pool is reduced to $\leq$1% of normal in severe disease at the time of presentation. Qualitative abnormalities, such as limited number of operating stem cell clones or shortened telomere length, may follow from the quantitative deficiency, reflecting the shrunken and stressed state of hematopoiesis. An intrinsic stem cell defect exists for constitutional aplastic anemia, as cells from patients with Fanconi's anemia exhibit chromosome damage and death on exposure to certain chemical agents. Aplastic anemia does not appear to result from defective stroma or growth factor production.

Drug Injury Extrinsic damage to the marrow follows massive physical or chemical insults such as high doses of radiation and toxic chemicals. For the more common idiosyncratic reaction to modest doses of medical drugs, altered drug metabolism has been invoked as a likely mechanism. The metabolic pathways of many drugs and chemicals, especially if they are polar and have limited water solubility, involve enzymatic degradation to highly reactive electrophilic compounds; these intermediates are toxic because of their propensity to bind to cellular macromolecules. For example, derivative hydroquinones and quinolones are responsible for benzene-induced tissue injury. Excessive generation of toxic intermediates or failure to detoxify the intermediates may be genetically determined and apparent only on specific drug challenge; the complexity and specificity of the pathways imply multiple susceptibility loci and would provide an explanation for the rarity of idiosyncratic drug reactions.

Immune-Mediated Injury The recovery of marrow function in some patients prepared for bone marrow transplantation with antilymphocyte globulin (ALG) first suggested that aplastic anemia might be immune-mediated. Consistent with this hypothesis was the frequent failure of simple bone marrow transplantation from a syngeneic twin, without conditioning cytotoxic chemotherapy, which also argued both *against* simple stem cell absence as the cause and *for* the presence of a host factor producing marrow failure. Laboratory data support an important role for the immune system in aplastic anemia. Blood and bone marrow cells of patients can suppress normal hematopoietic progenitor cell growth, and removal of T cells from aplastic anemia bone marrow improves colony formation in vitro. Increased numbers of activated cytotoxic T cells are observed in aplastic anemia patients and usually decline with successful immunosuppressive therapy; cytokine measurements show a T_H1 immune response (interferon γ, interleukin 2, and tumor necrosis factor). Interferon and tumor necrosis factor induce Fas expression on CD34 cells, leading to apoptotic cell death; localization of activated T cells to bone marrow and local production of their soluble factors are probably important in stem cell destruction.

Early immune system events in aplastic anemia are not well un-

derstood. Analysis of T cell receptor expression suggests an oligoclonal, antigen-driven cytotoxic T cell response. Many different exogenous antigens appear capable of initiating a pathologic immune response, but at least some of the T cells may recognize true self-antigens. The rarity of aplastic anemia despite common exposures (medicines, hepatitis virus) suggests that genetically determined features of the immune response can convert a normal physiologic response into a sustained abnormal autoimmune process.

CLINICAL FEATURES ■ History Aplastic anemia can appear with seeming abruptness or have a more insidious onset. Bleeding is the most common early symptom; a complaint of days to weeks of easy bruising, oozing from the gums, nose bleeds, heavy menstrual flow, and sometimes petechiae will have been noticed. With thrombocytopenia, massive hemorrhage is unusual, but small amounts of bleeding in the central nervous system can result in catastrophic intracranial or retinal hemorrhage. Symptoms of anemia are also frequent, including lassitude, weakness, shortness of breath, and a pounding sensation in the ears. Infection is an unusual first symptom in aplastic anemia (unlike in agranulocytosis, where pharyngitis, anorectal infection, or frank sepsis occur early). A striking feature of aplastic anemia is the restriction of symptoms to the hematologic system, and patients often feel and look remarkably well despite drastically reduced blood counts. Systemic complaints and weight loss should point to other etiologies of pancytopenia. Prior drug use, chemical exposure, and preceding viral illnesses must often be elicited with repeated questioning. A family history of hematologic diseases or blood abnormalities may indicate a constitutional etiology of marrow failure.

Physical Examination Petechiae and ecchymoses are typical, and retinal hemorrhages may be present. Pelvic and rectal examinations should be performed with great gentleness to avoid trauma; these will often show bleeding from the cervical os and blood in the stool. Pallor of the skin and mucous membranes is common except in the most acute cases or those already transfused. Infection on presentation is unusual but may occur if the patient has been symptomatic for a few weeks. Lymphadenopathy and splenomegaly are highly atypical of aplastic anemia. Café au lait spots and short stature suggest Fanconi's anemia; peculiar nails and leukoplakia suggest dyskeratosis congenita.

LABORATORY STUDIES ■ Blood The smear shows large erythrocytes and a paucity of platelets and granulocytes. Mean corpuscular volume (MCV) is commonly increased. Reticulocytes are absent or few, and lymphocyte numbers may be normal or reduced. The presence of immature myeloid forms suggests leukemia or MDS; nucleated red blood cells suggest marrow fibrosis or tumor invasion; abnormal platelets suggest either peripheral destruction or MDS.

Bone Marrow The bone marrow is usually readily aspirated but appears dilute on smear, and the fatty biopsy specimen may be grossly pale on withdrawal; a "dry tap" suggests fibrosis or myelophthisis. In severe aplasia the smear of the aspirated specimen shows only red cells, residual lymphocytes, and stromal cells; the biopsy, which should be >1 cm in length, is superior for determination of cellularity and shows mainly fat under the microscope, with hematopoietic cells occupying <25% of the marrow space. In the most serious cases the biopsy is virtually 100% fat. The correlation between marrow cellularity and disease severity is imperfect. Some patients with moderate disease by blood counts will have empty iliac crest biopsies, while "hot spots" of hematopoiesis may be seen in severe cases. If an iliac crest specimen is inadequate, cells may also be obtained by aspiration from the sternum. Residual hematopoietic cells should have normal morphology, except for mildly megaloblastic erythropoiesis; megakaryocytes are invariably greatly reduced and usually absent. Areas adjacent to the spicule should be searched for myeloblasts. Granulomas (in cellular specimens) may indicate an infectious etiology of the marrow failure.

Ancillary Studies Chromosome breakage studies of peripheral blood using diepoxybutane (DEB) or mito-

FIGURE 94-1 *A*. Normal bone marrow biopsy. *B*. Normal bone marrow aspirate smear. The marrow is normally 30 to 70% cellular, and there is a heterogeneous mix of myeloid, erythroid, and lymphoid cells. *C*. Aplastic anemia biopsy. *D*. Marrow smear in aplastic anemia. The marrow shows replacement of hematopoietic tissue by fat and only residual stromal and lymphoid cells.

mycin C should be performed on children and younger adults to exclude Fanconi's anemia. Chromosome studies of bone marrow cells are often revealing in MDS and should be negative in typical aplastic anemia. Flow cytometric assays have replaced the Ham test for the diagnosis of PNH. Serologic studies may show evidence of viral infection, especially Epstein-Barr virus and HIV. Posthepatitis aplastic anemia is typically seronegative. The spleen size should be determined by scanning if the physical examination of the abdomen is unsatisfactory. MRI may be helpful to assess the fat content on a few vertebrae in order to distinguish aplasia from MDS.

DIAGNOSIS The diagnosis of aplastic anemia is usually straightforward, based on the combination of pancytopenia with a fatty, empty bone marrow. Aplastic anemia is a disease of the young and should be a leading diagnosis in the pancytopenic adolescent or young adult. When pancytopenia is secondary, the primary diagnosis is usually obvious from either history or physical examination: the massive spleen of alcoholic cirrhosis, the history of metastatic cancer or systemic lupus erythematosus, or obvious miliary tuberculosis on chest radiograph (Table 94-1).

Diagnostic problems can occur with atypical presentations and among related hematologic diseases. While pancytopenia is most common, some patients with bone marrow hypocellularity have depression of only one or two of three blood lines, sometimes showing later progression to more recognizable aplastic anemia. The bone marrow in constitutional aplastic anemia is indistinguishable morphologically from the aspirate in acquired disease. The diagnosis can be suggested by family history, abnormal blood counts since childhood, or the presence of associated physical anomalies. Aplastic anemia may be difficult to distinguish from the hypocellular variety of MDS: MDS is favored by finding morphologic abnormalities, particularly of megakaryocytes and myeloid precursor cells, and typical cytogenetic abnormalities (see below).

PROGNOSIS The natural history of severe aplastic anemia is rapid deterioration and death. Provision first of red blood cell and later platelet transfusions and effective antibiotics were of some benefit, but few patients showed spontaneous recovery. The major prognostic determinant is the blood count; severe disease is defined by the presence of two of three parameters: absolute neutrophil count $<500/\mu L$, platelet count $<20{,}000/\mu L$, and corrected reticulocyte count $<1\%$ (or absolute reticulocyte count $<60{,}000/\mu L$). Survival of patients who fulfill these criteria is about 20% at 1 year after diagnosis with only supportive care; patients with very severe disease, defined by an absolute neutrophil count $<200/\mu L$, fare even more poorly. Treatment has markedly improved survival in this disease.

℞ TREATMENT

Severe acquired aplastic anemia can be cured by replacement of the absent hematopoietic cells (and the immune system) by stem cell transplant, or it can be ameliorated by suppression of the immune system to allow recovery of the patient's residual bone marrow function. Hematopoietic growth factors have limited usefulness and glucocorticoids are of no value. Suspect exposures to drugs or chemicals should be discontinued; however, spontaneous recovery of severe blood count depression is rare, and a waiting period before beginning treatment may not be advisable unless the blood counts are only modestly depressed.

Bone Marrow Transplantation This is the best therapy for the young patient with a fully histocompatible sibling donor (Chap. 100). Human leukocyte antigen (HLA) typing should be ordered as soon as the diagnosis of aplastic anemia is established in a child or younger adult. In transplant candidates, transfusion of blood from family members should be avoided so as to prevent sensitization to histocompatibility antigens; while transfusions in general should be minimized, limited numbers of blood products probably do not seriously affect outcome.

For allogeneic transplant from fully matched siblings, long-term survival rates for children are 80% or better. Transplant morbidity and mortality are increased among adults, due mainly to the higher risk of chronic graft-versus-host disease and serious infections. Graft rejection was historically a major determinant of outcome in bone marrow transplant for aplastic anemia; high rates of primary or secondary graft failure may be related to the pathophysiology of marrow failure as well as to alloimmunization from transfusions.

Most patients do not have a suitable sibling donor. Occasionally, a full phenotypic match can be found within the family and serve as well. Far more available are other alternative donors, either unrelated but histocompatible volunteers, or closely but not perfectly matched family members. Survival using alternative donors is about half that of conventional sibling transplants. These patients will be at risk for late complications, especially a higher rate of cancer, if radiation is used as a component of conditioning. Most older adults who undergo alternative donor transplants succumb to transplant-related complications.

Immunosuppression Used alone, ALG or antithymocyte globulin (ATG) induces hematologic recovery (independence from transfusion and a leukocyte count adequate to prevent infection) in about 50% of patients. The addition of cyclosporine to either ALG or ATG has further increased response rates to about 70% and especially improved outcomes for children and for severely neutropenic patients. Combined treatment is now standard for patients with severe disease. Hematologic response strongly correlates with survival. Improvement in granulocyte number is generally apparent within 2 months of treatment. Most recovered patients continue to have some degree of blood count depression, the MCV remains elevated, and the bone marrow cellularity returns toward normal only very slowly, if at all. Relapse (recurrent pancytopenia) is frequent, often occurring as cyclosporine is discontinued; most, but not all, patients respond to reinstitution of immunosuppression, but some responders become dependent on continued cyclosporine administration. Development of MDS, with typical marrow morphologic or cytogenetic abnormalities, occurs in about 15% of treated patients, usually but not invariably associated with a return of pancytopenia, and some patients develop leukemia. Although the laboratory diagnosis of PNH can generally be made at the time of presentation of aplastic anemia by flow cytometry, recovered patients showing frank hemolysis should be retested for PNH. Bone marrow examinations should be performed if there is an unfavorable change in blood counts.

Horse ATG is given at 40 mg/kg per day for 4 days; rabbit ALG is administered at 3.5 mg/kg per day for 5 days. For ATG, anaphylaxis is a rare but occasionally fatal complication; allergy should be tested by a skin-prick test with an undiluted solution and immediate observation; desensitization is feasible. ATG binds to peripheral blood cells; therefore, platelet and granulocyte numbers may fall further during active treatment. Serum sickness, a flulike illness with a characteristic cutaneous eruption and arthralgia, often develops about 10 days after initiating treatment. Most patients are given methylprednisolone, 1 mg/kg per day for 2 weeks, to ameliorate the immune consequences of heterologous protein infusion. Excessive or extended glucocorticoid therapy is associated with avascular joint necrosis. Cyclosporine is administered orally at an initial dose of 12 mg/kg per day in adults (15 mg/kg per day in children), with subsequent adjustment according to blood levels obtained every 2 weeks. Trough levels should be between 150 and 200 ng/mL. The most important side effects of chronic cyclosporine treatment are nephrotoxicity, hypertension, seizures, and opportunistic infections, especially *Pneumocystis carinii* (prophylactic treatment with monthly inhaled pentamidine is recommended).

Most patients with aplastic anemia lack a suitable marrow donor and immunosuppression is the treatment of choice. Long-term survival is equivalent with transplantation and immunosuppression. However, successful transplant cures marrow failure, while patients who recover adequate blood counts after immunosuppression remain at risk of relapse and malignant evolution. Because of the excellent results in chil-

dren, allogeneic transplant should be performed in the pediatric population if a suitable sibling donor is available. Increasing age and the severity of neutropenia are the most important factors weighing in the decision between transplant and immunosuppression in adults who have a matched family donor: older patients do better with ATG and cyclosporine, whereas transplant is preferred if granulocytopenia is profound. Some reluctant patients may be treated by immunosuppression; transplant is used for failure to recover blood counts or occurrence of late complications.

Outcomes following both transplant and immunosuppression have improved with time. High doses of cyclophosphamide, without stem cell rescue, have been reported to produce durable hematologic recovery, without relapse or evolution to MDS, but this treatment can produce sustained severe fatal neutropenia and response is often delayed. Several new immunosuppressive drugs in clinical trial may further improve outcome.

Other Therapies The effectiveness of androgens has not been verified in controlled trials, but occasional patients will respond or even demonstrate blood count dependence on continued therapy. For patients with moderate disease or those with severe pancytopenia in whom immunosuppression has failed, a 3- to 4-month trial is appropriate. Hematopoietic growth factors, granulocyte colony-stimulating factor (G-CSF), granulocyte-macrophage CSF (GM-CSF), and interleukin 3 are not recommended as initial therapy for severe aplastic anemia, and even their role as adjuncts to immunosuppression is not well defined. Some patients may respond to combinations of growth factors after immunosuppression has failed. Splenectomy may occasionally increase blood counts in relapsed or refractory cases.

Supportive Care Meticulous medical attention is required so that the patient may survive to benefit from definitive therapy or, having failed treatment, to maintain a reasonable existence in the face of pancytopenia. First and most important, infection in the presence of severe neutropenia must be aggressively treated by prompt institution of parenteral, broad-spectrum antibiotics, usually ceftazidime or a combination of an aminoglycoside, cephalosporin, and semisynthetic penicillin. Therapy is empirical and must not await results of culture, although specific foci of infection such as oropharyngeal or anorectal abscesses, pneumonia, sinusitis, and typhlitis (necrotizing colitis) should be sought on physical examination and with radiographic studies. When indwelling plastic catheters become contaminated, vancomycin should be added. Persistent or recrudescent fever implies fungal disease: *Candida* or *Aspergillus* are common, especially after several courses of antibacterial antibiotics, and a progressive course may be averted by timely initiation of antifungal therapy. Granulocyte transfusions using G-CSF–mobilized peripheral blood have been effective in the treatment of overwhelming or refractory infections in a few patients. Hand washing, the single best method of preventing the spread of infection, remains a neglected practice. Nonabsorbed antibiotics for gut decontamination are poorly tolerated and not of proven value. Total reverse isolation does not reduce mortality from infections.

Both platelet and erythrocyte numbers can be maintained by transfusion. Alloimmunization limits the usefulness of platelet transfusions and can be avoided or minimized by several strategies, including use of single donors to reduce exposure and physical or chemical methods to diminish leukocytes in the product; HLA-matched platelets are often effective in patients refractory to random donor products. Inhibitors of fibrinolysis such as aminocaproic acid have not been shown to relieve mucosal oozing; the use of low-dose glucocorticoids to induce "vascular stability" is unproven. Whether platelet transfusions are better used prophylactically or only as needed remains unclear. Any rational regimen of prophylaxis requires transfusions once or twice weekly in order to maintain the platelet count $>10{,}000/\mu L$ (oozing from the gut, and presumably also from other vascular beds, increases precipitously at counts $<5000/\mu L$). Menstruation should be suppressed either by oral estrogens or nasal follicle-stimulating hormone/luteinizing hormone (FSH/LH) antagonists. Aspirin and other nonsteroidal anti-inflammatory agents inhibit platelet function and must be avoided.

Red blood cells should be transfused to maintain a normal level of activity, usually at a hemoglobin value of 70 g/L (90 g/L if there is underlying cardiac or pulmonary disease); a regimen of 2 units every 2 weeks will replace normal losses in a patient without a functioning bone marrow. In chronic anemia, the iron chelator deferoxamine should be added at around the fiftieth transfusion in order to avoid secondary hemochromatosis.

PURE RED CELL APLASIA

Other, more restricted forms of marrow failure occur, in which only a single circulating cell type is affected and the aregenerative marrow shows corresponding absence or decreased numbers of specific precursor cells: aregenerative anemia as in PRCA (see below), thrombocytopenia with amegakaryocytosis (Chap. 101), and neutropenia without marrow myeloid cells in agranulocytosis (Chap. 55). In general, and in contrast to aplastic anemia and MDS, the unaffected lineages appear quantitatively and qualitatively normal. Agranulocytosis, the most frequent of these syndromes, is usually a complication of medical drug use (with agents similar to those related to aplastic anemia), either by a mechanism of direct chemical toxicity or by immune destruction. Agranulocytosis has an incidence similar to aplastic anemia but is especially frequent among the elderly and in women. The syndrome should resolve with discontinuation of exposure, but significant mortality is attached to neutropenia in the older and often previously unwell patient. Both pure white cell aplasia (agranulocytosis without incriminating drug exposure) and amegakaryocytic thrombocytopenia are exceedingly rare and, like PRCA, appear to be due to destructive antibodies or lymphocytes and can respond to immunosuppressive therapies. In all the single lineage failure syndromes, progression to pancytopenia or leukemia is unusual.

DEFINITION AND DIFFERENTIAL DIAGNOSIS PRCA is characterized by anemia, reticulocytopenia, and absent or rare erythroid precursor cells in the bone marrow. The classification of PRCA is shown in Table 94-4. In adults, PRCA is acquired. An identical syndrome can occur constitutionally: Diamond-Blackfan anemia, or congenital PRCA, is diagnosed at birth or in early childhood and often responds to glucocorticoid treatment. Temporary red cell failure occurs in transient aplastic crisis of hemolytic anemias, due to acute parvovirus infection

TABLE 94-4 Classification of Pure Red Cell Aplasia

Self-limited
Transient erythroblastopenia of childhood
Transient aplastic crisis of hemolysis (acute B19 parvovirus infection)
Fetal red blood cell aplasia
Nonimmune hydrops fetalis (in utero B19 parvovirus infection)
Hereditary pure red cell aplasia
Congenital pure red cell aplasia (Diamond-Blackfan syndrome)
Acquired pure red cell aplasia
Thymoma and malignancy
Thymoma
Lymphoid malignancies (and more rarely other hematologic diseases)
Paraneoplastic to solid tumors
Connective tissue disorders with immunologic abnormalities
Systemic lupus erythematosus, juvenile rheumatoid arthritis, rheumatoid arthritis
Multiple endocrine gland insufficiency
Virus
Persistent B19 parvovirus, hepatitis, adult T cell leukemia virus, Epstein-Barr virus
Pregnancy
Drugs
Especially phenytoin, azathioprine, chloramphenicol, procaineamide, isoniazid
Idiopathic

(Chap. 168), and in transient erythroblastopenia of childhood, which affects normal children.

CLINICAL ASSOCIATIONS AND ETIOLOGY PRCA has important associations with immune system diseases. A small minority of cases occur with a thymoma. More frequently, red cell aplasia can be the major manifestation of large granular lymphocytosis or may occur in chronic lymphocytic leukemia. Some patients may be hypogammaglobulinemic. As with agranulocytosis, PRCA can be due to an idiosyncratic reaction to a drug.

Like aplastic anemia, PRCA results from diverse mechanisms. Antibodies to red blood cell precursors are frequently present in the blood, but T cell inhibition is probably the more common immune mechanism. Cytotoxic lymphocyte activity restricted by histocompatibility locus or specific for human T cell leukemia/lymphoma virus I–infected cells, as well as natural killer cell activity inhibitory of erythropoiesis, have been demonstrated in particularly well-studied individual cases.

Persistent Parvovirus B19 Infection Chronic parvovirus infection is an important, treatable cause of PRCA. This common virus causes a benign exanthem of childhood (fifth disease) and a polyarthralgia syndrome in adults. In patients with underlying hemolysis (or any condition that increases demand for red blood cell production), parvovirus infection can cause a transient aplastic crisis and an abrupt but temporary worsening of the anemia due to failed erythropoiesis. In normal individuals, acute infection is resolved by production of neutralizing antibodies to the virus, but in the setting of congenital, acquired, or iatrogenic immunodeficiency, persistent viral infection may occur. The bone marrow shows red cell aplasia and the presence of giant pronormoblasts (Fig. 94-2), which is the cytopathic sign of B19 parvovirus infection. Viral tropism for human erythroid progenitor cells is due to its use of erythrocyte P antigen as a cellular receptor for entry. Direct cytotoxicity of virus causes anemia if demands on

Tumor cells present on a touch preparation made from the marrow biopsy of a patient with metastatic carcinoma.

erythrocyte production are high; in normal individuals, the temporary cessation of red cell production is not clinically apparent, and skin and joint symptoms are mediated by immune complex deposition.

TREATMENT

History, physical examination, and routine laboratory studies may disclose an underlying disease or a suspect drug exposure. Thymoma should be sought by radiographic procedures. Tumor excision is indicated, but anemia does not necessarily improve with surgery. The diagnosis of parvovirus infection requires detection of viral DNA sequences in the blood (IgG and IgM antibodies are commonly absent). The presence of erythroid colonies has been considered predictive of response to immunosuppressive therapy in idiopathic PRCA.

Red cell aplasia is compatible with long survival with supportive care alone: a combination of erythrocyte transfusions and iron chelation. For persistent B19 parvovirus infection, almost all patients respond to intravenous immunoglobulin therapy (for example, 0.4 g/kg daily for 5 days), although relapse and retreatment may be expected, especially in patients with AIDS. The majority of patients with idiopathic PRCA respond favorably to immunosuppression. Most first receive a course of glucocorticoids, followed in the absence of a response by cyclosporine, ATG, azathioprine, or cyclophosphamide.

MYELODYSPLASIA

DEFINITION The myelodysplasias (MDS) are a heterogeneous group of hematologic disorders broadly characterized by cytopenias associated with a dysmorphic (or abnormal appearing) and usually cellular bone marrow, and consequent ineffective blood cell production. A clinically useful nosology of these entities was first developed by the French-American-British Cooperative Group in 1983. Five entities were defined: refractory anemia (RA), refractory anemia with ringed sideroblasts (RARS), refractory anemia with excess blasts (RAEB), refractory anemia with excess blasts in transformation (RAEB-t), and chronic myelomonocytic leukemia (CMML). The World Health Organization classification (2002) recognizes that the distinction between RAEB-t and acute myeloid leukemia is arbitrary and groups them together as acute leukemia, notes that CMML behaves as a myeloproliferative disease, and separates refractory anemias with dysmorphic change restricted to erythroid lineage from those with multilineage changes (Table 94-5).

EPIDEMIOLOGY Idiopathic MDS is a disease of the elderly; the mean age at onset is 68 years. There is a slight male preponderance. MDS is a relatively common form of bone marrow failure, with reported incidence rates of 35 to >100 per million persons in the general population and 120 to >500 per million in the elderly. MDS is rare in children, but monocytic leukemia can be seen. Therapy-related MDS is not age-related and may occur in as many as 15% of patients within a decade following intensive combined modality treatment for cancer. Rates of MDS have increased over time, due to the recognition of the syndrome by physicians and the aging of the population.

ETIOLOGY AND PATHOPHYSIOLOGY MDS is caused by environmental exposures such as radiation and benzene; other risk factors have been reported inconsistently. Secondary MDS occurs as a late toxicity of cancer treatment, usually with a combination of radiation and the radiomimetic alkylating agents such as busulfan, nitrosourea, or procarbazine (with a latent period of 5 to 7 years) or the DNA topoisomerase inhibitors (2 years). Both acquired aplastic anemia following immunosuppressive treatment and Fanconi's anemia can evolve into MDS.

MDS is a clonal hematopoietic stem cell disorder leading to impaired cell proliferation and differentiation. Cytogenetic abnormalities are found in about half of patients, and some of the same specific lesions are also seen in frank leukemia; aneuploidy is more frequent

TABLE 94-5 *World Health Organization Classification of Myelodysplastic Syndromes*

Disease	Frequency	Blood Findings	Bone Marrow Findings	Prognosis
Refractory anemia (RA)	5–10%	Anemia No or rare blasts	Erythroid dysplasia only <5% blasts <15% ringed sideroblasts	Protracted course Leukemic transformation in ~6%
Refractory anemia with ringed sideroblasts (RARS)	10–12%	Anemia No blasts	Erythroid dysplasia only ≥15% ringed sideroblasts <5% blasts	Protracted course Leukemia in ~1–2%
Refractory cytopenia with multilineage dysplasia (RCMD)	24%	Cytopenias (2 or 3 lineages) No or rare blasts No Auer rods <1 × 10^9/L monocytes	Dysplasia in ≥10% of cells in ≥2 lineages <5% blasts No Auer rods <15% ringed sideroblasts	Variable clinical course Leukemia in ~11%
RCMD with ringed sideroblasts (RCMD-RS)	15%	Cytopenias (2 or 3 lineages) No or rare blasts No Auer rods <1 × 10^9/L monocytes	Dysplasia in ≥10% of cells in ≥2 lineages ≥15% ringed sideroblasts <5% blasts No Auer rods	
Refractory anemia with excess blasts-1 (RAEB-1)	40% (RAEB-1 +2)	Cytopenias <5% blasts No Auer rods <1 × 10^9/L monocytes	Unilineage or multilineage dysplasia 5–9% blasts No Auer rods	Progressive BM failure Leukemia in ~25%
Refractory anemia with excess blasts-2 (RAEB-2)		Cytopenias 5–19% blasts ±Auer rods <1 × 10^9/L monocytes	Unilineage or multilineage dysplasia 10–19% blasts ±Auer rods	Progressive BM failure Leukemia in ~33%
Myelodysplastic syndrome, unclassified (MDS-U)	Unknown	Cytopenias No or rare blasts No Auer rods	Dysplasia in myeloid or platelet lineage <5% blasts No Auer rods	Unknown
MDS with isolated del(5q)	Unknown	Anemia <5% blasts Platelets nl or increased	Nl or increased megakaryocytes with hypolobated nuclei <5% blasts No Auer rods Isolated del(5q)	Long survival

than translocations. Both presenting and evolving hematologic manifestations result from the accumulation of multiple genetic lesions, loss of tumor suppressor genes, activating oncogene mutations, or other harmful alterations. Cytogenetic abnormalities are not random (loss of all or part of 5, 7, and 20, trisomy of 8) and may be related to etiology (11q23 following topoisomerase II inhibitors); chronic myelomonocytic leukemia is often associated with t(5;12) that creates a chimeric *tel-PDGFβ* gene. The type and number of cytogenetic abnormalities strongly correlate with the probability of leukemic transformation and survival. Mutations of N-*ras* (an oncogene), *p53* and *IRF-1* (tumor suppressor genes), *Bcl-2* (an antiapoptotic gene), and others have been reported in some patients but may occur relatively late in the sequence leading to leukemic transformation. Apoptosis of marrow cells is increased in MDS, presumably due to these acquired genetic alterations or possibly to an overlaid immune response. Sideroblastic anemia may be related to mutations in mitochondrial genes. Ineffective erythropoiesis and disordered iron metabolism are the functional consequences of the genetic alterations.

TABLE 94-6 *International Prognostic Scoring System*

	Score Value				
Prognostic Variable	*0*	*0.5*	*1.0*	*1.5*	*2.0*
Bone marrow blasts (%)	<5%	5–10%		11–20%	21–30%
Karyotype[a]	Good	Intermediate	Poor		
Cytopenia[b] (lineages affected)	0 or 1	2 or 3			
Risk Group Scores	**Score**				
Low	0				
Intermediate-1	0.5–1.0				
Intermediate-2	1.5–2.0				
High	≥2.5				

[a] Good, normal, -Y, del(5q), del (20q); intermediate, all other abnormalities; poor, complex (≥3 abnormalities) or chromosome 7 abnormalities.
[b] Cytopenias defined as Hb <100 g/L, platelet count < 100,000/μL, absolute neutrophil count <1500/μL.

CLINICAL FEATURES Anemia dominates the early course. Most symptomatic patients complain of the gradual onset of fatigue and weakness, dyspnea, and pallor, but at least half the patients are asymptomatic and their MDS is discovered only incidentally on routine blood counts. Previous chemotherapy or radiation exposure is an important historic fact. Fever and weight loss should point to a myeloproliferative rather than myelodysplastic process. Children with Down syndrome are susceptible to MDS, and a family history may indicate a hereditary form of sideroblastic anemia or Fanconi's anemia.

The physical examination is remarkable for signs of anemia; about 20% of patients have splenomegaly. Some unusual skin lesions, including Sweet's syndrome (febrile neutrophilic dermatosis), occur with MDS. Autoimmune syndromes are not infrequent.

LABORATORY STUDIES ■ Blood Anemia is present in the majority of cases, either alone or as part of bi- or pancytopenia; isolated neutropenia or thrombocytopenia is more unusual. Macrocytosis is common, and the smear may be dimorphic with a distinctive population of large red blood cells. Platelets are also large and lack granules. In functional studies, they may show marked abnormalities, and patients may have bleeding symptoms despite seemingly adequate numbers. Neutrophils are hypogranulated; have hyposegmented, ringed, or abnormally segmented nuclei; contain Dohle bodies; and may be functionally deficient. Circulating myeloblasts usually correlate with marrow blast numbers, and their quantitation is important for classification and prognosis. The total white blood cell count is usually normal or low, except in chronic myelomonocytic leukemia. As in aplastic anemia, MDS also can be associated with a clonal population of PNH cells.

Bone Marrow The bone marrow is usually normal or hypercellular but in 20% of cases is sufficiently hypocellular to be confused with aplasia. No single characteristic feature of marrow morphology distinguishes MDS, but the following are commonly observed: dyserythropoietic changes (especially nuclear abnormalities) and ringed sideroblasts in the erythroid lineage; hypogranulation and hyposegmentation in granulocytic precursors, with an increase in myeloblasts; and megakaryocytes showing reduced numbers of disorganized nuclei. Megaloblastic nuclei associated with defective hemoglobinization in the erythroid lineage are common. Prognosis strongly correlates with the proportion of marrow blasts. Cytogenetic analysis and fluorescent in situ hybridization can identify genetic lesions.

DIFFERENTIAL DIAGNOSIS Deficiencies of vitamin B_{12} or folate should be excluded by appropriate blood tests; vitamin B_6 deficiency can be assessed by a therapeutic trial of pyridoxine if the bone marrow shows ringed sideroblasts. Marrow dysplasia can be observed in acute viral infections, drug reactions, or chemical toxicity but should be transient. More difficult are the distinctions between hypocellular MDS and aplasia or between refractory anemia with excess blasts and early acute leukemia. The World Health Organization considers the presence of 20% blasts in the marrow as the criterion that separates acute myeloid leukemia from MDS.

PROGNOSIS The median survival varies greatly from years for patients with 5q– or sideroblastic anemia to a few months in refractory anemia with excess blasts or severe pancytopenia associated with monosomy 7; an International Prognostic Scoring System (Table 94-6) assists in making predictions. Most patients die as a result of complications of pancytopenia and not due to leukemic transformation; perhaps one-third will succumb to other diseases unrelated to their MDS. Precipitous worsening of pancytopenia, acquisition of new chromosomal abnormalities on serial cytogenetic determination, and increase in the number of blasts are all poor prognostic indicators. The outlook in therapy-related MDS, regardless of type, is poor, and most patients will progress within a few months to refractory acute myeloid leukemia.

℞ TREATMENT

The therapy of MDS is generally unsatisfactory. Only stem cell transplantation offers cure: survival rates of 50% at 3 years have been reported, but older patients are particularly prone to develop treatment-related mortality and morbidity. Results of transplant using matched unrelated donors are comparable, although most series contain younger and more highly selected cases. MDS associated with trisomy 8 may respond to cyclosporine.

MDS has been regarded as particularly refractory to cytotoxic chemotherapy regimens but is probably no more resistant to effective treatment than acute myeloid leukemia in the elderly, in whom drug toxicity is often fatal and remissions, if achieved, are brief. Low doses of cytotoxic drugs have been administered for their "differentiating" potential. 5-azacytidine inhibits DNA methylation and may induce the expression of genes; its use in MDS can improve blood counts and modestly improves survival compared to best supportive care. Amifostine, an organic thiophosphonate that blocks apoptosis, can improve blood counts but has significant toxicities. Both azacytidine and amifostine are approved by the U.S. Food and Drug Administration for use in MDS. ATG may improve blood counts in one-third of MDS patients; those who are young, HLA-D2 positive, and have a PNH clone are more likely to respond.

Hematopoietic growth factors can improve blood counts but, as in most other marrow failure states, have been most beneficial to patients with the least severe pancytopenia. G-CSF treatment alone failed to improve survival in a controlled trial. Erythropoietin alone or in combination with G-CSF can improve hemoglobin levels, especially in those with low serum erythropoietin levels who have no or only a modest need for transfusions.

The same principles of supportive care described for aplastic anemia apply to MDS. Because many patients will be anemic for years,

erythrocyte transfusion support should be accompanied by iron chelation in order to prevent secondary hemochromatosis.

MYELOPHTHISIC ANEMIAS

Fibrosis of the bone marrow (see Fig. 95-2), usually accompanied by a characteristic blood smear picture called *leukoerythroblastosis*, can occur as a primary hematologic disease, called *myelofibrosis* or *myeloid metaplasia* (Chap. 95), and as a secondary process, called *myelophthisis*. Myelophthisis, or secondary myelofibrosis, is reactive. Fibrosis can be a response to invading tumor cells, usually of an epithelial cancer of breast, lung, and prostate or neuroblastoma. Marrow fibrosis may occur with infection of mycobacteria (both *Mycobacterium tuberculosis* and *M. avium*), fungi, or HIV, and in sarcoidosis. Intracellular lipid deposition in Gaucher disease and obliteration of the marrow space related to absence of osteoclast remodeling in congenital osteopetrosis also can produce fibrosis. Secondary myelofibrosis is a late consequence of radiation therapy or treatment with radiomimetic drugs. Usually, the infectious or malignant underlying processes are obvious. Marrow fibrosis can also be a feature of a variety of hematologic syndromes, especially chronic myeloid leukemia, multiple myeloma, lymphomas, myeloma, and hairy cell leukemia.

The pathophysiology has three distinct features: proliferation of fibroblasts in the marrow space (myelofibrosis); the extension of hematopoiesis into the long bones and, most particularly, into extramedullary sites usually the spleen, liver, and lymph nodes (myeloid metaplasia); and ineffective erythropoiesis. The etiology of fibrosis is unknown but most likely involves dysregulated production of growth factors: platelet-derived growth factor and transforming growth factor β have been implicated. Abnormal regulation of other hematopoietins would lead to localization of blood-producing cells in nonhematopoietic tissues and uncoupling of the usually balanced processes of stem cell proliferation and differentiation. Myelofibrosis is remarkable for pancytopenia despite extraordinarily large numbers of circulating hematopoietic progenitor cells.

Anemia is dominant in secondary myelofibrosis, usually normocytic and normochromic. The diagnosis is suggested by the characteristic leukoerythroblastic smear (see Fig. 95-1). Erythrocyte morphology is highly abnormal, with circulating nucleated red blood cells, teardrops, and shape distortions. White blood cell numbers are often elevated, sometimes mimicking a leukemoid reaction, with circulating myelocytes, promyelocytes, and myeloblasts. Platelets may be abundant and are often giant size. Inability to aspirate the bone marrow, the characteristic "dry tap," can allow a presumptive diagnosis in the appropriate setting before the biopsy is decalcified.

The course of secondary myelofibrosis is determined by its cause, usually a metastatic tumor or an advanced hematologic malignancy. Treatable causes must be excluded, especially tuberculosis and fungus. Transfusion support can relieve symptoms.

95 POLYCYTHEMIA VERA AND OTHER MYELOPROLIFERATIVE DISEASES

Jerry L. Spivak

Polycythemia vera, chronic idiopathic myelofibrosis, essential thrombocytosis, and chronic myeloid leukemia (CML) are commonly classified together under the rubric *the chronic myeloproliferative disorders*, because their pathophysiology involves the clonal expansion of a multipotent hematopoietic progenitor cell with the overproduction of one or more of the formed elements of the blood. These entities may transform into acute leukemia naturally or as a consequence of mutagenic treatment. However, while polycythemia vera, idiopathic myelofibrosis, essential thrombocytosis, and CML share similar phenotypic characteristics, CML is genotypically distinct from the other three disorders because it alone is associated with translocation of genetic material between the long arms of chromosomes 9 and 22, resulting in the production of the unique fusion protein, bcr-abl.

The new World Health Organization classification of myeloid neoplasms has expanded the list of chronic myeloproliferative disorders to include the exceedingly rare entities chronic neutrophilic leukemia, chronic eosinophilic leukemia, and the hypereosinophilic syndrome. In addition, a category of myelodysplastic/myeloproliferative diseases was created to encompass juvenile myelomonocytic leukemia, atypical chronic myeloid leukemia [lacking t(9;22)], and chronic myelomonocytic leukemia. The word "chronic" was also added to idiopathic myelofibrosis to distinguish this disorder from the rarer syndrome of acute panmyelosis with myelofibrosis, a rare form of acute leukemia.

These classification changes were made in recognition of the considerable overlap in clinical presentation and hematopathology that characterizes the chronic myeloproliferative disorders. Systemic mastocytosis, while having phenotypic overlap with the chronic myeloproliferative diseases, was given its own category in recognition of the many distinct clinical syndromes that characterize mast cell proliferation. In this chapter, only polycythemia vera, chronic idiopathic myelofibrosis, and essential thrombocytosis will be discussed as their clinical overlap is substantial and their clinical course distinct from the other myeloproliferative disorders. →***CML is discussed in Chap. 96.***

POLYCYTHEMIA VERA

Polycythemia vera is a clonal disorder involving a multipotent hematopoietic progenitor cell in which there is accumulation of phenotypically normal red cells, granulocytes, and platelets in the absence of a recognizable physiologic stimulus. The most common of the chronic myeloproliferative disorders, polycythemia vera occurs in about 2 per 100,000 persons, sparing no adult age group. Vertical transmission has been documented, establishing a genetic basis for the disorder. A slight overall male predominance has been observed, but females predominate within the reproductive age range.

ETIOLOGY The etiology of polycythemia vera is unknown. Although nonrandom chromosome abnormalities such as 20q−, trisomy 8 or 9 have been documented in a small percentage of untreated polycythemia vera patients, no consistent cytogenetic abnormality has been associated with the disorder and no specific genetic defect has yet been identified. Impaired posttranslational processing of the thrombopoietin receptor, Mpl, has been noted in polycythemia vera patients; the extent of the defect correlated with disease duration and splenomegaly. While this defect is specific for polycythemia vera and is not found in secondary erythrocytosis, its role in the pathophysiology of the disorder is still undefined. Polycythemia vera leukocytes also overexpress mRNA for *PRV*-1. In contrast to normal erythroid progenitor cells, polycythemia vera erythroid progenitor cells can grow in vitro in the absence of erythropoietin due to hypersensitivity to insulin-like growth factor I. However, this phenotypic abnormality is not specific for polycythemia vera and has been documented in essential thrombocytosis

and secondary erythrocytosis. Polycythemia vera erythroid progenitor cells are more resistant to apoptosis induced by erythropoietin deprivation, due to upregulation of bcl-X_L, an antiapoptotic protein. Polycythemia vera erythroid progenitors do not divide more rapidly than their normal counterparts, but they accumulate because they do not die normally. Additionally, the transformed hematopoietic progenitor cells in polycythemia vera, as in other neoplastic disorders, exhibit clonal dominance and suppress the proliferation of normal hematopoietic progenitor cells by an unknown mechanism. Consequently, the circulating formed elements of the blood represent only progeny of the transformed clone.

CLINICAL FEATURES Although massive splenomegaly may be the initial presenting sign in polycythemia vera, most often the disorder is first recognized by the discovery of a high hemoglobin or hematocrit, but with the exception of aquagenic pruritus, no symptoms distinguish polycythemia vera from other causes of erythrocytosis.

Uncontrolled erythrocytosis can lead to neurologic symptoms such as vertigo, tinnitus, headache, and visual disturbances. Systolic hypertension also accompanies the elevated red cell mass. In some patients, venous or arterial thrombosis may be the presenting manifestation of polycythemia vera. Intraabdominal venous thrombosis is particularly common and may be catastrophic when there is sudden compromise of the hepatic vein. Polycythemia vera should be suspected in any patient who develops the Budd-Chiari syndrome. Digital ischemia may also occur. Easy bruising, epistaxis, or gastrointestinal hemorrhage may be observed, and polycythemia vera patients are frequently hypermetabolic. Hyperuricemia with secondary gout, uric acid stones, and acid-peptic disease also complicate the disorder. Because isolated erythrocytosis is a common initial presentation for polycythemia vera but no clonal marker is available for the disease, the first task of the physician is to distinguish this autonomous clonal form of erythrocytosis from the many other types of erythrocytosis, most of which are correctable (Table 95-1).

Erythropoiesis is normally regulated by the glycoprotein hormone erythropoietin. Erythropoietin, which in adults is produced primarily in the kidneys and to a small extent in the liver, promotes the proliferation of erythroid progenitor cells, maintains their survival, and facilitates their differentiation. Because erythropoietin acts as a survival factor, it is constitutively produced and, like the red cell mass, its level is constant as long as tissue oxygenation is adequate. The plasma erythropoietin level, like the red cell mass, differs among individuals but in adults is not affected by either age or gender. Erythropoietin production is regulated at the level of gene transcription. Hypoxia is the only physiologic stimulus that increases the number of cells producing erythropoietin, and thus the production of erythropoietin is independent of its plasma level. In the absence of renal or hepatic disease, plasma erythropoietin levels reflect erythropoietin production, and therefore the assay for plasma erythropoietin is a surrogate assay for tissue hypoxia. Erythropoietin is active at the picomolar level, and its production is tightly regulated. Thus, the plasma erythropoietin level does not rise outside the normal range until the hemoglobin level falls below 105 g/L. This is not meant to imply that an increase in erythropoietin production does not occur as the hemoglobin level falls below normal, but because the normal range for plasma erythropoietin is wide (4 to 26 mU/mL), unless the patient's baseline level is known, any increase will not be recognized until the hemoglobin falls below 105 g/L. Thereafter, there is a log-linear inverse correlation between the plasma erythropoietin and hemoglobin levels. With erythrocytosis, erythropoietin production is suppressed; this suppression reflects not only the increase in tissue oxygen transport associated with the increase in red cell number but also additional negative-feedback mechanisms unrelated to oxygen transport but related to the increase in blood viscosity and an increase in red cell precursors capable of metabolizing erythropoietin. The summation of these mechanisms accounts for the paradoxical observation that many patients with hypoxic erythrocytosis due to cyanotic congenital heart disease or obstructive lung disease have a "normal" plasma erythropoietin level. The plasma erythropoietin level is a useful diagnostic test in patients with isolated erythrocytosis, because an elevated level excludes polycythemia vera as the cause for the erythrocytosis.

TABLE 95-1 *Causes of Absolute Erythrocytosis*

Hypoxia	Tumors
Carbon monoxide intoxication	Hypernephroma
High altitude	Hepatoma
Pulmonary disease	Cerebellar hemangioblastoma
High-affinity hemoglobin	Adrenal adenoma
Sleep-apnea syndrome	Pheochromocytoma
Respiratory center dysfunction	Meningioma
Supine hypoventilation	Uterine fibromyoma
Right-to-left cardiac shunts	Familial (with normal hemoglobin function)
Renal disease	VHL mutations
Renal cysts	Erythropoietin receptor mutations
Hydronephrosis	BPG mutase deficiency
Renal artery stenosis	Bartter's syndrome
Focal glomerulonephritis	Androgen therapy
Renal transplantation	Recombinant erythropoietin therapy
	Polycythemia vera

Note: BPG, bisphosphoglycerate; VHL, von Hippel–Lindau.

DIAGNOSIS When confronted with an elevated hemoglobin or hematocrit level, it is important to obtain previous values to determine the duration of this abnormality. Because the hemoglobin or hematocrit level is affected by the plasma volume, and hematocrit and red cell mass are not linearly related, a red cell mass determination must also be performed to distinguish absolute erythrocytosis from relative erythrocytosis due to a reduction in plasma volume alone (also known as *stress* or *spurious erythrocytosis* or *Geisböck's syndrome*). Red cell mass determination is important because in polycythemia vera, in contrast to erythropoietin-driven erythrocytosis, the plasma volume is frequently elevated, masking not only the true extent of red cell mass expansion but often its presence. Indeed, a significant proportion of patients with polycythemia vera have a hematocrit within the normal range, particularly patients with a substantial splenomegaly. Failure to recognize this phenomenon is undoubtedly the basis for many of the reported instances of hepatic or portal vein thrombosis in patients with an "undefined" myeloproliferative disorder.

Red cell mass is reliably determined by isotope dilution using the patient's ^{51}Cr-tagged red cells; extrapolations made after determining only the plasma volume are unacceptable. Furthermore, to allow ample time for equilibration of the labeled red cells, measurements should be made over a period of $\geq$90 min.

Once the presence of absolute erythrocytosis has been established, its cause must be determined. An elevated plasma erythropoietin level suggests either an hypoxic cause for erythrocytosis or autonomous erythropoietin production, in which case assessment of pulmonary function and an abdominal computed tomography scan to evaluate renal and hepatic anatomy are appropriate. A normal erythropoietin level does not exclude an hypoxic cause for erythrocytosis. In polycythemia vera, in contrast to hypoxic erythrocytosis, the arterial oxygen saturation is normal. However, a normal oxygen saturation does not exclude a high-affinity hemoglobin as a cause for erythrocytosis, and it is here that documentation of previous hemoglobin levels and a family study become important. Because there is no clonal marker for polycythemia vera, clinical guidelines have been proposed to define the disease. A modified version is provided in Table 95-2. However, these guidelines do not establish clonality, and in some patients the underlying disorder only becomes apparent over time. Diagnostic ambiguity does not preclude the initiation of therapy.

Other laboratory studies that may aid in diagnosis include the red cell count, mean corpuscular volume, and red cell distribution width (RDW). Only three situations cause microcytic erythrocytosis: β-thalassemia trait, hypoxic erythrocytosis, and polycythemia vera. However, with β-thalassemia trait the RDW is normal, whereas with hy-

TABLE 95-2 Suggested Criteria for the Clinical Diagnosis of Polycythemia Vera[a]

Elevated red cell mass
Normal arterial oxygen saturation
Splenomegaly
In the absence of splenomegaly:
Leukocytosis and thrombocytosis

[a] It must be emphasized that these criteria do not establish clonality.

poxic erythrocytosis and polycythemia vera, the RDW is usually elevated. A properly made blood smear from a patient with erythrocytosis will be virtually unreadable due to the marked elevation in red cell count, but no specific morphologic abnormalities are seen in the leukocytes or platelets in polycythemia vera. However, when these are also elevated the diagnosis is assured. In many patients, the leukocyte alkaline phosphatase level is also increased, as is the uric acid level. Elevated serum vitamin B_{12} or B_{12}-binding capacity may be present. In patients with associated acid-peptic disease, occult gastrointestinal bleeding may lead to presentation with hypochromic, microcytic anemia.

A bone marrow aspirate and biopsy will provide no specific diagnostic information, and unless there is a need to establish the presence of myelofibrosis or exclude some other disorder, these procedures need not be done. Although the presence of a cytogenetic abnormality such as trisomy 8 or 9 or 20q− in the setting of an expanded red cell mass supports a clonal etiology, no specific cytogenetic abnormality is associated with polycythemia vera, and the absence of a cytogenetic marker does not exclude the diagnosis.

COMPLICATIONS The major clinical complications of polycythemia vera relate directly to the increase in blood viscosity associated with elevation of the red cell mass and indirectly to the increased turnover of red cells, leukocytes, and platelets and the attendant increase in uric acid and cytokine production. The latter appears to be responsible for the increase in peptic ulcer disease and for the pruritus associated with this disorder, although little formal proof for this has been obtained. A sudden massive increase in spleen size is another problem and can be associated with splenic infarction or progressive cachexia. Myelofibrosis and myeloid metaplasia can also develop with transfusion-dependent anemia, but the frequency is low in those not receiving chemotherapy or irradiation. Although acute nonlymphocytic leukemia is reported to be increased in polycythemia vera, the incidence of acute leukemia in patients not exposed to chemotherapy or radiation is low and the development of leukemia is not related to disease duration, suggesting that the treatment exposure may be a more important risk factor than the disease itself.

Erythromelalgia is a curious syndrome of unknown etiology primarily involving the lower extremities and manifested usually by erythema, warmth, and pain of the affected appendage and occasionally digital infarction. It occurs with a variable frequency in patients with a myeloproliferative disorder and is usually responsive to salicylates. Some of the central nervous system symptoms observed in patients with polycythemia vera may represent a variant of erythromelalgia.

If left uncontrolled, erythrocytosis can lead to intravascular thrombosis involving vital organs such as the liver, heart, brain, or lungs. Patients with massive splenomegaly are particularly prone to thrombotic events because the associated increase in plasma volume masks the true extent of the red cell mass elevation as measured by the hematocrit or hemoglobin level. A "normal" hematocrit or hemoglobin level in a polycythemia vera patient with massive splenomegaly should be considered as indicative of an elevated red cell mass until proven otherwise.

℞ TREATMENT

Polycythemia vera is generally an indolent disorder whose clinical course can run many decades, and its medical management should reflect the tempo of the disorder. Maintenance of the hemoglobin level at ≤140 g/L in men and ≤120 g/L in women is mandatory to avoid the thrombotic complications. Thrombosis due to erythrocytosis is the most significant complication of this disorder. Phlebotomy serves initially to reduce hyperviscosity by bringing the red cell mass into the normal range. Periodic phlebotomies thereafter serve to maintain the red cell mass within the range of normal and to induce a state of iron deficiency, which prevents an accelerated reexpansion of the red cell mass. In most polycythemia vera patients, once an iron-deficient state is achieved, phlebotomy is usually required only at 3-month intervals. Although both phlebotomy and iron deficiency, in addition to the disease itself, tend to increase the platelet count, thrombocytosis is not correlated with thrombosis in polycythemia vera, in contrast to the strong correlation between erythrocytosis and thrombosis in this disease. The use of salicylates as a tonic against thrombosis in polycythemia vera patients is potentially harmful, and salicylates should be employed only to treat erythromelalgia. Anticoagulants are not routinely indicated and are difficult to monitor owing to the artifactual imbalance between the test tube anticoagulant and plasma that occurs when blood from these patients is assayed for prothrombin or partial thromboplastin activity. Asymptomatic hyperuricemia requires no therapy, but allopurinol should be administered to avoid further elevation of the uric acid when chemotherapy is employed to reduce splenomegaly, leukocytosis, or pruritus. Generalized pruritus intractable to antihistamines can be a major problem in polycythemia vera, and hydroxyurea, interferon (IFN)-α, and psoralens with ultraviolet light in the A range (PUVA) therapy are methods of palliation. Asymptomatic thrombocytosis requires no therapy. Symptomatic splenomegaly can be treated with hydroxyurea or IFN-α, although each can be associated with significant side effects. Anagrelide, a quinazolin derivative and platelet antiaggregant that also lowers the platelet count, can control thrombocytosis and is preferable to hydroxyrurea or IFN-α. A reduction in platelet number may be necessary in the treatment of erythromelalgia if salicylates are not effective or if the thrombocytosis is associated with migraine-like symptoms. Alkylating agents and sodium phosphate P32 (^{32}P) are leukemogenic in polycythemia vera, and their use should be avoided. If a cytotoxic agent must be used, hydroxyurea is preferred, but it also may be leukemogenic. Chemotherapy should be used for as short a time as possible. In some patients, massive splenomegaly unresponsive to reduction by hydroxyurea or IFN-α therapy and associated with intractable weight loss will require splenectomy. Allogeneic bone marrow transplantation may be curative in young patients.

Patients with polycythemia vera can be expected to live long and useful lives when their red cell mass is effectively managed with phlebotomy. Chemotherapy is never indicated to control the red cell mass unless venous access is impossible.

CHRONIC IDIOPATHIC MYELOFIBROSIS

Chronic idiopathic myelofibrosis (other designations include *agnogenic myeloid metaplasia* or *myelofibrosis with myeloid metaplasia*) is a clonal disorder of a multipotent hematopoietic progenitor cell of unknown etiology characterized by marrow fibrosis, myeloid metaplasia with extramedullary hematopoiesis, and splenomegaly. Chronic idiopathic myelofibrosis is uncommon; in the absence of a specific clonal marker, establishing this diagnosis is difficult because myelofibrosis and myeloid metaplasia with splenomegaly are also features of both polycythemia vera and CML. Furthermore, myelofibrosis and splenomegaly occur in a variety of benign and malignant disorders (Table 95-3), many of which are amenable to specific therapies not effective in chronic idiopathic myelofibrosis. In contrast to the other chronic myeloproliferative disorders and so-called acute or malignant myelofibrosis, which can occur at any age, chronic idiopathic myelofibrosis primarily afflicts individuals in their sixth decade or later.

ETIOLOGY The etiology of chronic idiopathic myelofibrosis is unknown. Although nonrandom chromosome abnormalities such as 20q−, 13q−, and trisomy 1q are not uncommon, no specific cytoge-

TABLE 95-3 *Causes of Myelofibrosis*

Carcinoma metastatic to the marrow	Polycythemia vera
Infection	Chronic idiopathic myelofibrosis
Lymphoma	Systemic mastocytosis

Acute leukemia (lymphoid or myeloid)	Systemic lupus erythematosus
Hairy cell leukemia	Renal osteodystrophy
Multiple myeloma	HIV infection
Chronic myeloid leukemia	Hyperparathyroidism
	Gray-platelet syndrome

netic abnormality has been identified. The degree of myelofibrosis and the extent of extramedullary hematopoiesis are not related. Fibrosis in this disorder is associated with overproduction of transforming growth factor β and thrombopoietin. Importantly, fibroblasts in chronic idiopathic myelofibrosis are not part of the neoplastic clone.

CLINICAL FEATURES No specific signs or symptoms are associated with chronic idiopathic myelofibrosis. Most patients are asymptomatic at presentation and usually detected by the discovery of splenic enlargement and/or abnormal blood counts during a routine examination. A blood smear reveals the characteristic features of extramedullary hematopoiesis: teardrop-shaped red cells, nucleated red cells, myelocytes, and promyelocytes; myeloblasts may also be present but have no prognostic significance (Fig. 95-1). Anemia, usually mild initially, is the rule, while the leukocyte and platelet counts are either normal or increased but either can be depressed. Mild hepatomegaly may accompany the splenomegaly, and both the lactate dehydrogenase and serum alkaline phosphatase levels can be elevated. The level of leukocyte alkaline phosphatase can be low, normal, or elevated. Marrow may be unaspirable due to the myelofibrosis (Fig. 95-2), and bone x-rays may reveal osteosclerosis. Exuberant extramedullary hematopoiesis can cause ascites, pulmonary hypertension, intestinal or ureteral obstruction, intracranial hypertension, pericardial tamponade, spinal cord compression, or skin nodules. Splenic enlargement can be sufficiently rapid to cause splenic infarctions with fever and pleuritic chest pain. Hyperuricemia and secondary gout may ensue.

DIAGNOSIS While the clinical picture described above is characteristic of chronic idiopathic myelofibrosis, all of the clinical features described can be observed in polycythemia vera or CML. Massive splenomegaly commonly masks erythrocytosis in polycythemia vera, and reports of intraabdominal thromboses in chronic idiopathic myelofibrosis likely represent instances of unrecognized polycythemia vera. Furthermore, many other disorders have features that overlap with chronic idiopathic myelofibrosis but respond to distinctly different therapies. Therefore, the diagnosis of chronic idiopathic myelofibrosis is one of exclusion, which requires that the disorders listed in Table 95-3 be ruled out.

The presence of teardrop-shaped red cells, nucleated red cells, myelocytes, and promyelocytes establishes the presence of extramedullary hematopoiesis; the presence of leukocytosis, thrombocytosis with large and bizarre platelets, as well as circulating myeloblasts suggests

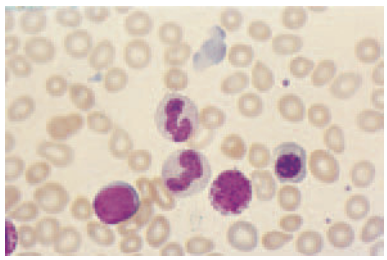

FIGURE 95-1 Teardrop-shaped red blood cells indicative of membrane damage from collagen fibers, a nucleated red blood cell indicative of premature release of erythroid precursors, and immature myeloid cells indicative of extramedullary hematopoiesis are noted. This peripheral blood smear is related to marrow fibrosis, either primary myelofibrosis or secondary myelophthisis.

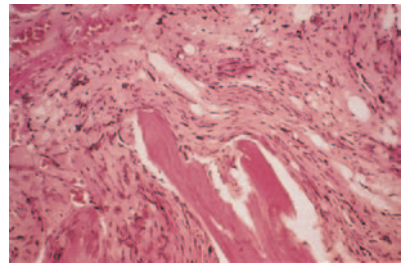

FIGURE 95-2 This marrow section shows the marrow cavity replaced by fibrous tissue composed of reticulin fibers and collagen. When this fibrosis is due to a primary hematologic process, it is called *myelofibrosis*. When the fibrosis is secondary to a tumor or a granulomatous process, it is called *myelophthisis*.

the presence of a myeloproliferative disorder as opposed to a secondary form of myelofibrosis (Table 95-3). Marrow is usually not aspirable due to increased marrow reticulin, but marrow biopsy will reveal a hypercellular marrow with trilineage hyperplasia and, in particular, increased megakaryocytes, but there are no characteristic morphologic abnormalities that distinguish idiopathic myelofibrosis from the other chronic myeloproliferative disorders. Splenomegaly due to extramedullary hematopoiesis may be sufficiently massive to cause portal hypertension and variceal formation. In some patients, exuberant extramedullary hematopoiesis can dominate the clinical picture. An intriguing feature of chronic idiopathic myelofibrosis is the occurrence of autoimmune abnormalities such as immune complexes, antinuclear antibodies, rheumatoid factor, or a positive Coombs' test. Whether these represent a host reaction to the disorder or are involved in its pathogenesis is unknown. Cytogenetic analysis of blood or marrow is useful both to exclude CML and for prognostic purposes, because complex karyotype abnormalities portend a poor prognosis in chronic idiopathic myelofibrosis.For unknown reasons, the number of circulating CD34+ cells is markedly increased in chronic idiopathic myelofibrosis.

COMPLICATIONS Chronic idiopathic myelofibrosis has a median survival of only 5 years (range 1 to 15 years), a duration much shorter than for polycythemia vera or essential thrombocytosis. The natural history of chronic idiopathic myelofibrosis is one of inexorable marrow failure with transfusion-dependent anemia and increasing organomegaly. Patients are prone to deep-seated tissue infections, particularly of the lungs. As with CML, chronic idiopathic myelofibrosis can evolve from a chronic phase to an accelerated phase with constitutional symptoms and increasing marrow failure. About 10% of patients develop an aggressive form of acute leukemia for which therapy is usually ineffective. Important prognostic factors for disease acceleration include anemia; thrombocytopenia; age; the presence of complex cytogenetic abnormalities; and constitutional symptoms such as unexplained fever, night sweats, or weight loss. Any nonrandom cytogenetic abnormality is associated with a shortened life span, and the presence or development of multiple cytogenetic abnormalities is highly indicative of disease acceleration.

℞ TREATMENT

No specific therapy exists for chronic idiopathic myelofibrosis. Anemia may be exacerbated by deficiency of folic acid or iron, and in rare instances, pyridoxine therapy has been effective. However, anemia is more often due to ineffective erythropoiesis not compensated for by the extramedullary hematopoiesis in the spleen and liver; neither androgens nor erythropoietin has been consistently effective therapy. Erythropoietin may worsen splenomegaly. A red cell splenic sequestration study can establish the presence of hypersplenism, for which splenectomy is indicated. Splenectomy may also be necessary if splenomegaly impairs alimentation and should be performed before cachexia sets in. In this situation, splenectomy should not be avoided because of concern over rebound thrombocytosis, loss of hematopoietic capacity, or compensatory hepatomegaly. However, for unexplained reasons, splenectomy increases the risk of blastic transformation. Allopurinol can control significant hyperuricemia, and

hydroxyurea has proved useful for controlling organomegaly. The role of IFN-α is undefined, and its side effects are more pronounced in the older individuals who are affected with this disorder, but reversal of myelofibrosis has been observed. Glucocorticoids are used to control autoimmune complications and may ameliorate anemia alone or in combination with thalidomide. Allogeneic bone marrow transplantation should be considered in younger patients.

ESSENTIAL THROMBOCYTOSIS

Essential thrombocytosis (other designations include *essential thrombocythemia*, *idiopathic thrombocytosis*, *primary thrombocytosis*, *hemorrhagic thrombocythemia*) is a clonal disorder of unknown etiology involving a multipotent hematopoietic progenitor cell and is manifested clinically by the overproduction of platelets without a definable cause. Essential thrombocytosis is an uncommon disorder, but its exact frequency is unknown. No clonal marker distinguishes it from the more common nonclonal, reactive forms of thrombocytosis (Table 95-4). Clinical recognition of thrombocytosis is unlikely in the largely asymptomatic persons affected by this disorder. As a consequence, essential thrombocytosis was formerly considered to be a disease of the elderly and to be responsible for significant morbidity due to hemorrhage or thrombosis. However, with the widespread application of platelet counting, it is now clear that essential thrombocytosis can occur at any age in adults and often occurs without symptoms or disturbances of hemostasis. There is an unexplained female predominance, in contrast to the reactive forms of thrombocytosis where no sex bias exists. Because no clonal marker is available for the disorder, clinical criteria have been proposed to distinguish it from the other chronic myeloproliferative disorders, which may also present with thrombocytosis but have differing prognoses and treatment (Table 95-5). These criteria do not establish clonality; therefore, they are truly useful only in identifying disorders such as CML, polycythemia vera, or myelodysplasia, which can masquerade as essential thrombocytosis, as opposed to establishing the presence of essential thrombocytosis. Furthermore, as with "primary" erythrocytosis, nonclonal, benign forms of thrombocytosis exist (such as hereditary overproduction of thrombopoietin) that are not widely recognized because we currently lack the diagnostic tools to do so.

ETIOLOGY Megakaryocytopoiesis and platelet production depend upon thrombopoietin and its receptor, Mpl. As in the case of early erythroid and myeloid progenitor cells, early megakaryocytic progenitors require the presence of interleukin (IL) 3 and stem cell factor for optimal proliferation, and their subsequent development is enhanced by IL-6 and -11. However, megakaryocyte maturation and differentiation require thrombopoietin.

Megakaryocytes are unique among hematopoietic progenitor cells because they undergo endomitotic as opposed to mitotic reduplication of their genome. In the absence of thrombopoietin, endomitotic megakaryocytic reduplication and, by extension, the cytoplasmic development necessary for platelet production are impaired. Like erythropoietin, thrombopoietin is produced in both the liver and the kidneys,

TABLE 95-4 Causes of Thrombocytosis

Iron-deficiency anemia	Idiopathic myelofibrosis
Hyposplenism	Essential thrombocytosis
Postsplenectomy[a]	Chronic myeloid leukemia
Malignancy	Idiopathic sideroblastic anemia
Collagen vascular disease	Myelodysplasia (5q− syndrome)
Inflammatory bowel disease	Postsurgery
Infection	Rebound (cessation of ethanol intake, correction of vitamin B_{12} or folate deficiency)
Hemolysis	
Hemorrhage	
Polycythemia vera	

[a] If the platelet count is greater than $2 \times 10^6/\mu L$, the etiology is most likely a myeloproliferative disorder.

TABLE 95-5 Suggested Criteria for the Clinical Diagnosis of Essential Thrombocytosis[a]

Platelet count $\geq 500{,}000/\mu L$
Absence of a known cause of reactive thrombocytosis (see Table 95-4)
Absence of the Ph chromosome and the bcr-abl gene rearrangement
Normal red cell mass
Presence of marrow iron
Absence of myelofibrosis
Absence of myelodysplasia clinically and by cytogenetic analysis
Splenomegaly

[a] The concept that a platelet count greater than $1 \times 10^6/\mu L$ distinguishes essential thrombocytosis from other causes of thrombocytosis has no clinical validity.

and an inverse correlation exists between the platelet count and plasma thrombopoietic activity. Like erythropoietin, plasma levels of thrombopoietin are controlled in part by the size of its progenitor cell pool. In contrast to erythropoietin, but like its myeloid counterparts granulocyte and granulocyte-macrophage colony-stimulating factors, thrombopoietin not only enhances the proliferation of its target cells but also enhances the reactivity of their end-stage product, the platelet. In addition to its role in thrombopoiesis, thrombopoietin enhances the survival of multipotent hematopoietic stem cells.

The clonality of essential thrombocytosis was established by the use of the isoenzymes of glucose-6-phosphate dehydrogenase in patients who are hemizygous for this gene, by the use of X-linked DNA polymorphisms, and by the identification of nonrandom, although variable, cytogenetic abnormalities. The multipotent hematopoietic progenitor cell involved in this disorder can vary; in some patients lymphocytes contained the same clonal marker as the megakaryocytes, erythrocytes, and myeloid cells, whereas in others the lymphocytes were not involved. Similar observations have been made in polycythemia vera. Furthermore, a number of families have been described in which essential thrombocytosis was inherited, in one instance as an autosomal dominant trait. In one kindred, in addition to essential thrombocytosis, idiopathic myelofibrosis and polycythemia vera were also individually documented.

CLINICAL FEATURES Clinically, essential thrombocytosis is most often identified incidentally when a platelet count is obtained during the course of a routine evaluation. Occasionally, review of previous platelet counts will reveal that an elevation was present but overlooked. No symptoms or signs are specific for essential thrombocytosis, but patients do have hemorrhagic and thrombotic tendencies expressed as easy bruising for the former or microvascular occlusions for the latter, which may be manifested by erythromelalgia, migraine, or transient ischemic attacks. Physical examination is generally unremarkable except occasionally for mild splenomegaly. Massive splenomegaly is more characteristic of the other myeloproliferative disorders, particularly polycythemia vera or idiopathic myelofibrosis.

Anemia is unusual, but a mild neutrophilic leukocytosis is not. The blood smear, however, is most remarkable for the number of platelets present, some of which may be very large. The leukocyte alkaline phosphatase score is either normal or elevated. The large mass of circulating platelets may prevent the accurate measurement of serum potassium due to the release of platelet potassium upon blood clotting. This hyperkalemia is a laboratory artifact and is not associated with any electrocardiographic abnormalities. Similarly, arterial oxygen measurements can be inaccurate unless the blood is collected on ice. The prothrombin and partial thromboplastin times are normal, while abnormalities of platelet function such as a prolonged bleeding time and impaired platelet aggregation can be present. However, in spite of much study, characteristic platelet function abnormalities are not yet defined, and no platelet function test predicts clinically significant bleeding or thrombosis.

The elevated platelet count may hinder the collection of a marrow aspirate, but marrow biopsy usually reveals both megakaryocyte hyperplasia and hypertrophy, as well as an overall increase in marrow cellularity. A slight increase in marrow reticulin may be present, but

if extensive, another diagnosis should be considered. The absence of stainable iron demands an explanation, because iron deficiency alone can cause thrombocytosis and absent marrow iron is a feature of polycythemia vera.

While nonrandom cytogenetic abnormalities have been identified in essential thrombocytosis, no consistently identifiable abnormality is notable, even involving chromosomes 3 and 1 where the genes for thrombopoietin and its receptor Mpl, respectively, are located.

DIAGNOSIS Thrombocytosis is encountered in a variety of clinical disorders (Table 95-4) in which production of cytokines is increased. Thus, the first obligation when confronted with a high platelet count is to determine if it is a consequence of another disorder. Cytogenetic evaluation is mandatory to determine if the thrombocytosis is due to CML or a myelodysplastic disorder such as the 5q− syndrome. Because the bcr-abl translocation can be present in the absence of the Ph chromosome, fluorescence in situ hybridization (FISH) analysis for bcr-abl expression should be performed in all patients with thrombocytosis rather than a cytogenetic study. Anemia and ringed sideroblasts are not features of essential thrombocytosis, but they are features of idiopathic refractory sideroblastic anemia, in which thrombocytosis can also occur. The presence of massive splenomegaly should suggest the possibility of another myeloproliferative disorder, and in this setting a red cell mass determination is mandatory because substantial splenomegaly can mask the presence of erythrocytosis. What appears to be essential thrombocytosis can evolve into polycythemia vera, revealing the true nature of the underlying myeloproliferative disorder.

COMPLICATIONS Perhaps no other condition in clinical medicine has caused otherwise astute physicians to intervene inappropriately more often than thrombocytosis, particularly if the platelet count is $>1 \times 10^6/\mu L$. It is commonly believed that a high platelet count must cause intravascular stasis and thrombosis; however, no controlled clinical study has ever established this association.

To the contrary, very high platelet counts are associated primarily with hemorrhage due to acquired von Willebrand disease, while platelet counts of $<1 \times 10^6/\mu L$ are more often associated with thrombosis. This is not meant to imply that an elevated platelet count cannot cause symptoms in a patient with essential thrombocytosis, but rather that the focus should be on the patient, not the platelet count. For example, some of the most dramatic neurologic problems in essential thrombocytosis are migraine-related and may respond only to lowering of the platelet count; other symptoms may be a manifestation of erythromelalgia and respond simply to platelet cyclooxygenase inhibitors such as aspirin, without a reduction in platelet number. Still others may represent an interaction between an atherosclerotic vascular system and a high platelet count, and others may have no relationship to the platelet count whatsoever. Progress in distinguishing essential thrombocytosis from polycythemia vera and in defining new causes of hypercoagulability (such as factor V Leiden) make the older literature on thrombocytosis less reliable.

Rx TREATMENT

An elevated platelet count in an asymptomatic patient requires no therapy, and before any therapy is initiated in a patient with thrombocytosis, the cause of symptoms must be clearly identified to be a consequence of the elevated platelet count. Platelet pheresis has not been proven efficacious and cannot be recommended. Furthermore, patients with essential thrombocytosis treated with ^{32}P, hydroxyurea, or alkylating agents are placed at risk of developing acute leukemia without any proof of benefit from such therapy. If platelet reduction is deemed necessary on the basis of neurologic symptoms refractory to salicylates, IFN-α or anagrelide, a quinazolin derivative, can reduce the platelet count, but neither is uniformly effective nor without significant side effects. Hydroxyurea should be considered only if these agents are not effective or tolerable. Bleeding associated with thrombocytosis usually responds to ϵ-aminocaproic acid, which can be given prophylactically before and after elective surgery. As more clinical experience is acquired, it appears that essential thrombocytosis is more benign than previously thought, and that evolution to acute leukemia is more likely to be a consequence of prior therapy than of the disease itself. In managing patients with thrombocytosis, the physician's first obligation is to do no harm.

96 ACUTE AND CHRONIC MYELOID LEUKEMIA

Meir Wetzler, John C. Byrd, Clara D. Bloomfield

The myeloid leukemias are a heterogeneous group of diseases characterized by infiltration of the blood, bone marrow, and other tissues by neoplastic cells of the hematopoietic system. In 2004, the estimated number of new myeloid leukemia cases in the United States was 16,520. These leukemias comprise a spectrum of malignancies that, untreated, range from rapidly fatal to slowly growing. Based on their untreated course, the myeloid leukemias have traditionally been designated acute or chronic.

ACUTE MYELOID LEUKEMIA

INCIDENCE The incidence of acute myeloid leukemia (AML) is ~3.6 per 100,000 people per year, and the age-adjusted incidence is higher in men than in women (4.4 versus 3.0). AML incidence increases with age; it is 1.7 in individuals <65 years and 16.2 in those >65. A significant increase in AML incidence has occurred over the past 10 years.

ETIOLOGY Heredity, radiation, chemical and other occupational exposures, and drugs have been implicated in the development of AML. No direct evidence suggests a viral etiology.

Heredity Certain syndromes with somatic cell chromosome aneuploidy, e.g., Down (chromosome 21 trisomy), Klinefelter (XXY and variants), and Patau (chromosome 13 trisomy), are associated with an increased incidence of AML. Inherited diseases with excessive chromatin fragility, e.g., Fanconi anemia, Bloom syndrome, ataxia telangiectasia, and Kostmann syndrome, are also associated with AML.

Radiation Survivors of the atomic bomb explosions in Japan had an increased incidence of myeloid leukemias that peaked 5 to 7 years after exposure. Therapeutic radiation alone seems to add little risk of AML but can increase the risk in people exposed to alkylating agents.

Chemical and Other Exposures Exposure to benzene, which is used as a solvent in the chemical, plastic, rubber, and pharmaceutical industries, is associated with an increased incidence of AML. Smoking and exposure to petroleum products, paint, embalming fluids, ethylene oxide, herbicides, and pesticides, have also been associated with an increased risk of AML.

Drugs Anticancer drugs are the leading cause of treatment-associated AML. Alkylating agent–associated leukemias occur on average 4 to 6 years after exposure, and affected individuals have aberrations in chromosomes 5 and 7. Topoisomerase II inhibitor–associated leukemias occur 1 to 3 years after exposure, and affected individuals often have aberrations involving chromosome 11q23. Chloramphenicol, phenylbutazone, and, less commonly, chloroquine and methoxypsoralen can result in bone marrow failure that may evolve into AML.

CLASSIFICATION

The categorization of acute leukemia into biologically distinct groups is based on morphology, cytochemistry, and immunophenotype as well as cytogenetic and molecular techniques.

Morphologic and Cytochemical Classification The diagnosis of AML is established by the presence of ≥20% myeloblasts in blood and/or bone marrow according to the World Health Organization (WHO) classification. Myeloblasts have nuclear chromatin that is uniformly fine or lacelike in appearance and large nucleoli (2 to 5 per cell). If specific cytoplasmic granules, Auer rods, or the nuclear folding and clefting characteristic of monocytoid cells are not present, the morphologic features observed under light microscopy may not be sufficient to clarify the diagnosis. A positive myeloperoxidase reaction in >3% of the blasts may be the only feature distinguishing AML from acute lymphoblastic leukemia (ALL).

Until 2000, the diagnosis of AML was established by the presence of ≥30% myeloblasts in the marrow and further classified based on morphology and cytochemistry according to the French, American, and British (FAB) schema, which includes eight major subtypes, M0 to M7 (Table 96-1). The WHO classification modified the FAB schema by reducing the number of blasts required for a diagnosis and incorporating molecular (including cytogenetic), morphologic (multilineage dysplasia), and clinical features (such as prior hematologic disorder) in defining disease entities (Table 96-1).

Immunophenotypic Classification The phenotype of human myeloid leukemia cells can be studied by multiparameter flow cytometry after the cells are labeled with monoclonal antibodies to cell-surface antigens. For example, M0, which is characterized by immature morphology and no lineage-specific cytochemical reactions, is diagnosed by flow cytometric demonstration of the myeloid-specific antigens cluster designation (CD) 13 or 33. Similarly, M7 can often be diagnosed only by expression of the platelet-specific antigens CD41 and/or CD61 or by electron microscopic demonstration of myeloperoxidase.

Chromosomal Classification Chromosomal analysis of the leukemic cell provides the most important pretreatment prognostic information in AML. Two cytogenetic abnormalities have been invariably associated with a specific FAB group: t(l5;17)(q22;q12) with M3 and inv(16)(p13q22) with M4Eo, and many chromosomal abnormalities have been associated primarily with one FAB group, including t(8;21)(q22;q22) with M2, and t(9;11)(p22;q23), and other translocations involving 11q23, with M5. As a result of their prognostic significance and association with specific morphologic features, the WHO classification incorporates cytogenetics (Table 96-1). Many of the recurring chromosomal abnormalities in AML have been associated with specific clinical characteristics. More commonly associated with younger age are t(8;21) and t(l5;17), and with older age, del(5q) and del(7q). Myeloid sarcomas (see below) are associated with t(8;21) and disseminated intravascular coagulation (DIC) with t(15;17).

Molecular Classification Molecular study of many recurring cytogenetic abnormalities has revealed genes that may be involved in leukemogenesis. The 15;17 translocation encodes a chimeric protein, Pml/Rarα, which is formed by the fusion of the retinoic acid receptor-α (*RARα*) gene from chromosome 17 and the promyelocytic leukemia (*PML*) gene from chromosome 15. The *RARα* gene encodes a member of the nuclear hormone receptor family of transcription factors. After binding retinoic acid, *RARα* can promote expression of a variety of genes. The 15;17 translocation juxtaposes *PML* with *RARα* in a head-to-tail configuration that is under the transcriptional control of *PML*. Three different breakpoints in the *PML* gene lead to various fusion proteins. The Pml-Rarα fusion protein tends to suppress gene transcription and blocks differentiation of the cells. Pharmacologic doses of the Rarα ligand, all-*trans*-retinoic acid (tretinoin), relieve the block and promote differentiation (see below).

The inv(16), characteristic of M4Eo or AML with abnormal bone marrow eosinophils, and the t(8;21) both involve subunits of the transcription factor complex core-binding factor (Cbf), also known as polyomavirus enhancer binding protein 2 (Pebp2). This transcription factor contains two subunits, an α subunit, the Am11 protein, and a β subunit, the Pebp2 protein, and is involved in the expression of a number of differentiation-dependent genes in myeloid cells. The inv(16) results in a fusion of the core-binding factor β (*CBFB*) gene on the q arm (encodes Pebp2 protein) and the myosin heavy chain *(MYH11)* gene on the p arm. The 8;21 translocation involves the core binding factor α (*CBFA*) gene on chromosome 21, called the *AML1* (also *RUNX1*) gene, joining the *ETO* gene on chromosome 8. Similar to the t(15;17) gene product, the Am11/Eto protein acts to block transcription of *CBFA-CBFB*-controlled genes.

Most translocations that involve 11q23 rearrange the myeloid-lymphoid [or mixed-lineage leukemia (*MLL*)] gene. The *MLL* gene has

TABLE 96-1 Acute Myeloid Leukemia (AML) Classification Systems

French-American-British (FAB) Classification[a]
- M0: Minimally differentiated leukemia
- M1: Myeloblastic leukemia without maturation
- M2: Myeloblastic leukemia with maturation
- M3: Hypergranular promyelocytic leukemia
- M4: Myelomonocytic leukemia
- M4Eo: Variant: Increase in abnormal marrow eosinophils
- M5: Monocytic leukemia
- M6: Erythroleukemia (DiGuglielmo's disease)
- M7: Megakaryoblastic leukemia

World Health Organization Classification[b]
- I. AML with recurrent genetic abnormalities
  - AML with t(8;21)(q22;q22);*AML1*(*CBFα*)/*ETO*
  - AML with abnormal bone marrow eosinophils [inv(16)(p13q22) or t(16;16)(p13;q22);*CBFβ*/*MYH11*]
  - Acute promyelocytic leukemia [AML with t(15;17)(q22;q12) (*PML*/*RARα* and variants]
  - AML with 11q23 (*MLL*) abnormalities
- II. AML with multilineage dysplasia
  - Following a myelodysplastic syndrome or myelodysplastic syndrome/myeloproliferative disorder
  - Without antecedent myelodysplastic syndrome
- III. AML and myelodysplastic syndromes, therapy-related
  - Alkylating agent–related
  - Topoisomerase type II inhibitor–related
  - Other types
- IV. AML not otherwise categorized
  - AML minimally differentiated
  - AML without maturation
  - AML with maturation
  - Acute myelomonocytic leukemia
  - Acute monoblastic and monocytic leukemia
  - Acute erythroid leukemia
  - Acute megakaryoblastic leukemia
  - Acute basophilic leukemia
  - Acute panmyelosis with myelofibrosis
  - Myeloid sarcoma

two regions that encompass multiple zinc fingers and has at least two additional potential DNA-binding motifs. Abnormalities in the *MLL* gene are relatively common in patients with AML who do not have 11q23 rearrangements cytogenetically.

The above molecular aberrations are increasingly being used for diagnosis and detection of residual disease after treatment. Molecular aberrations are also being identified that are useful for classifying risk of relapse in patients without cytogenetic abnormalities. A partial tandem duplication (PTD) of the *MLL* gene is found in 5 to 10% of patients with normal cytogenetics and results in short remission duration. Flt3 (FMS-like tyrosine kinase 3) is a tyrosine kinase receptor important in the development of myeloid and lymphoid lineages. Activating mutations of *FLT3* are present in ~30% of adult AML patients due to internal tandem duplications (ITD) in the juxtamembrane domain or mutations of the activating loop of the kinase. Continuous activation of Flt3 and downstream target kinases, including signal transducer and activator of transcription protein 5, Ras/mitogen-activated protein kinase, and phosphatidylinositol 3-kinase/Akt, provides increased proliferation and antiapoptotic signals to the myeloid progenitor cell. Several clinical studies have demonstrated that presence of *FLT3* ITD in patients with normal cytogenetics predicts for short remission duration and inferior survival.

CLINICAL PRESENTATION ■ Symptoms Patients with AML most often present with nonspecific symptoms that begin gradually or abruptly and are the consequence of anemia, leukocytosis, leukopenia or leukocyte dysfunction, or thrombocytopenia. Nearly half have had symptoms for ≥3 months before the leukemia was diagnosed.

Half mention fatigue as the first symptom, but most complain of fatigue or weakness at the time of diagnosis. Anorexia and weight loss are common. Fever with or without an identifiable infection is the initial symptom in ~10% of patients. Signs of abnormal hemostasis (bleeding, easy bruising) are noted first in 5% of patients. On occasion, bone pain, lymphadenopathy, nonspecific cough, headache, or diaphoresis is the presenting symptom.

Rarely patients may present with symptoms from a mass lesion located in the soft tissues, breast, uterus, ovary, cranial or spinal dura, gastrointestinal tract, lung, mediastinum, prostate, bone, or other organs. The mass lesion represents a tumor of leukemic cells and is called a *granulocytic sarcoma*, or *chloroma*. Typical AML may occur simultaneously, later, or not at all in these patients. This rare presentation is more common in patients with 8;21 translocations.

Physical Findings Fever, splenomegaly, hepatomegaly, lymphadenopathy, sternal tenderness, and evidence of infection and hemorrhage are often found at diagnosis. Significant gastrointestinal bleeding, intrapulmonary hemorrhage, or intracranial hemorrhage occur most often in acute promyelocytic leukemia (APL). Bleeding associated with coagulopathy may also occur in monocytic AML and with extreme degrees of leukocytosis or thrombocytopenia in other morphologic subtypes. Retinal hemorrhages are detected in 15% of patients. Infiltration of the gingivae, skin, soft tissues, or the meninges with leukemic blasts at diagnosis is characteristic of the monocytic subtypes (FAB M4 and M5).

Hematologic Findings Anemia is usually present at diagnosis and can be severe. The degree varies considerably irrespective of other hematologic findings, splenomegaly, or the duration of symptoms. The anemia is usually normochromic normocytic. Decreased erythropoiesis often results in a reduced reticulocyte count, and erythrocyte survival is decreased by accelerated destruction. Active blood loss also contributes to the anemia.

The median presenting leukocyte count is about 15,000/μl. Between 25 and 40% of patients have counts <5000/μl, and 20% have counts >100,000/μl. Fewer than 5% have no detectable leukemic cells in the blood. Poor neutrophil function may be noted functionally by impaired phagocytosis and migration and morphologically by abnormal lobulation and deficient granulation.

Platelet counts <100,000/μl are found at diagnosis in ~75% of patients, and about 25% have counts <25,000/μl. Both morphologic and functional platelet abnormalities can be observed, including large and bizarre shapes with abnormal granulation and inability of platelets to aggregate or adhere normally to one another.

Pretreatment Evaluation Once the diagnosis of AML is suspected, a rapid evaluation and initiation of appropriate therapy should follow (Table 96-2). In addition to clarifying the subtype of leukemia, initial studies should evaluate the overall functional integrity of the major organ systems, including the cardiovascular, pulmonary, hepatic, and renal systems. Factors that have prognostic significance, either for achieving complete remission (CR) or for predicting the duration of CR, should also be assessed before initiating treatment. Leukemic cells

TABLE 96-2 Initial Diagnostic Evaluation and Management of Adult Patients with AML

- History
  - Increasing fatigue or decreased exercise tolerance (anemia)
  - Excess bleeding or bleeding from unusual sites (DIC, thrombocytopenia)
  - Fevers or recurrent infections (granulocytopenia)
  - Headache, vision changes, nonfocal neurologic abnormalities (CNS leukemia or bleed)
  - Early satiety (splenomegaly)
  - Family history of AML (Fanconi, Bloom, or Kostmann syndromes or ataxia telangiectasia)
  - History of cancer (exposure to alkylating agents, radiation, topoisomerase II inhibitors)
  - Occupational exposures (radiation, benzene, petroleum products, paint, smoking, pesticides)
- Physical Examination
  - Performance status (prognostic factor)
  - Ecchymosis and oozing from IV sites (DIC, possible acute promyelocytic leukemia)
  - Fever and tachycardia (signs of infection)
  - Papilledema, retinal infiltrates, cranial nerve abnormalities (CNS leukemia)
  - Poor dentition, dental abscesses
  - Gum hypertrophy (leukemic infiltration, most common in monocytic leukemia)
  - Skin infiltration or nodules (leukemia infiltration, most common in monocytic leukemia)
  - Lymphadenopathy, splenomegaly, hepatomegaly
  - Back pain, lower extremity weakness [spinal granulocytic sarcoma, most likely in t(8;21) patients]
- Laboratory and radiologic studies
  - CBC with manual differential cell count
  - Chemistry tests (electrolytes, creatinine, BUN, calcium, phosphorus, uric acid, hepatic enzymes, bilirubin, LDH, amylase, lipase)
  - Clotting studies (prothrombin time, partial thromboplastin time, fibrinogen, D-dimer)
  - Viral serologies (CMV, HSV-1, varicella zoster)
  - RBC type and screen
  - HLA-typing of patient, siblings, and parents for potential allogeneic SCT
  - Bone marrow aspirate and biopsy (morphology, cytochemistry, cytogenetics, flow cytometry, molecular studies)
  - Cryopreservation of viable leukemia cells
  - Echocardiogram
  - PA and lateral chest radiograph
  - Placement of central venous access device
- Interventions for specific patients
  - Dental evaluation (for those with poor dentition)
  - Lumbar puncture (for those with symptoms of CNS involvement)
  - Screening spine MRI (for patients with back pain, lower extremity weakness, paresthesias)
  - Social work referral for patient and family psychosocial support
- Counseling for all patients
  - Provide patient with information regarding their disease, financial counseling, and support group contacts

Abbreviations: BUN, blood urea nitrogen; CBC, complete blood count; CMV, cytomegalovirus; CNS, central nervous system; DIC, disseminated intravascular coagulation; HSV, herpes simplex virus; LDH, lactate dehydrogenase; MRI, magnetic resonance imaging; PA, posteroanterior; RBC, red blood (cell) count; SCT, stem cell transplant.

should be obtained from all patients and cryopreserved for future use as new tests and therapeutics become available. All patients should be evaluated for infection.

Most patients are anemic and thrombocytopenic at presentation. Replacement of the appropriate blood components, if necessary, should begin promptly. Because qualitative platelet dysfunction or the presence of an infection may increase the likelihood of bleeding, evidence of hemorrhage justifies the immediate use of platelet transfusion, even if the platelet count is only moderately decreased.

About 50% of patients have a mild to moderate elevation of serum uric acid at presentation. Only 10% have marked elevations, but renal precipitation of uric acid and the nephropathy that may result is a serious but uncommon complication. The initiation of chemotherapy may aggravate hyperuricemia, and patients are usually started immediately on allopurinol or rasburicase (recombinant uric oxidase) and hydration at diagnosis. Finally, the presence in high concentrations of lysozyme, a marker for monocytic differentiation, may be etiologic in renal tubular dysfunction, which could worsen other renal problems that arise during the initial phases of therapy.

PROGNOSTIC FACTORS Many factors influence the likelihood of entering CR, the length of CR, and the curability of AML. CR is defined after examination of both blood and bone marrow. The blood neutrophil count must be $\geq 1500/\mu l$ and the platelet count $\geq 100{,}000/\mu l$. Hemoglobin concentration or hematocrit are not considered in determining CR. Circulating blasts should be absent. While rare blasts may be detected in the blood during marrow regeneration, they should disappear on successive studies. Bone marrow cellularity should be >20% with trilineage maturation. The bone marrow should contain <5% blasts, and Auer rods should be absent. Extramedullary leukemia should not be present. For patients in CR, reverse transcriptase polymerase chain reaction (RT-PCR) to detect AML-associated molecular abnormalities and fluorescence in situ hybridization (FISH) to detect AML-associated cytogenetic aberrations are currently used to detect residual disease. Such detection of minimal residual disease may become a reliable discriminator between patients in CR who do or do not require additional and/or alternative therapies. Prognostic factors are influenced by the treatment used.

Age at diagnosis remains among the most important pretreatment risk factors, with advancing age being associated with a poorer prognosis primarily because of its influence on the patient's ability to survive induction therapy and thus achieve CR. Age may also influence outcome because AML in older patients differs biologically. The leukemic cells in elderly patients more commonly express CD34 and the multidrug resistance 1 (Mdr1) efflux pump that conveys resistance to natural product–derived agents such as the anthracyclines (see below). With each successive decade of age, a greater proportion of patients have more resistant disease. Chronic and intercurrent diseases impair tolerance to rigorous therapy; acute medical problems at diagnosis reduce the likelihood of survival. Performance status, independent of age, also influences ability to survive induction therapy and thus respond to treatment.

Chromosome findings at diagnosis are an independent prognostic factor. Patients with t(8;21), inv(16), or t(15;17) have good prognoses, while those with no cytogenetic abnormality have a moderately favorable outcome when treated with high-dose cytarabine. Patients with a complex karyotype, inv(3), or −7 have a very poor prognosis. Molecular markers such as the presence of a PTD of *MLL* or the ITD of *FLT3* may also predict poor outcome of AML patients who otherwise have an intermediate prognosis.

A prolonged symptomatic interval with cytopenias preceding diagnosis or a history of an antecedent hematologic disorder are other pretreatment clinical features that are associated with a lower CR rate and shorter survival time. The CR rate is lower in patients who have had anemia, leukopenia, and/or thrombocytopenia for >1 month before the diagnosis of AML when compared to those without such a history. Responsiveness to chemotherapy declines as the duration of the antecedent disorder(s) increases. Secondary AML developing after treatment with cytotoxic agents for other malignancies is extremely difficult to treat successfully.

A high presenting leukocyte count is an independent prognostic factor; duration of CR is inversely related to the presenting leukocyte count or absolute circulating myeloblast count. Among patients with hyperleukocytosis ($>100{,}000/\mu l$), early central nervous system bleeding and pulmonary leukostasis and relapse contribute to poor outcome.

The FAB classification diagnosis has been found to be an independent prognostic factor in some series. Other characteristics of leukemic cells have been reported to have prognostic significance, including Auer rods, ultrastructural features, in vitro and in vivo growth characteristics and chemotherapeutic sensitivity, and immunophenotype. Expression of the *MDR1* gene adversely influences outcome.

In addition to pretreatment variables, several treatment factors correlate with prognosis in AML, including, most importantly, achievement of CR. Another is the rapidity with which the blast cells disappear from the blood after the institution of therapy. In addition, patients who achieve CR after one induction cycle have longer CR durations than those requiring multiple cycles.

TREATMENT

Treatment of the newly diagnosed patient with AML is usually divided into two phases, induction and postremission management (Fig. 96-1). The initial goal is to quickly induce CR. Once CR is obtained, further therapy must be used to prolong survival and achieve cure. The initial induction treatment and subsequent consolidation therapy are often chosen based upon the patient's age.The influence of intensifying therapy with traditional chemotherapy agents such as cytarabine and

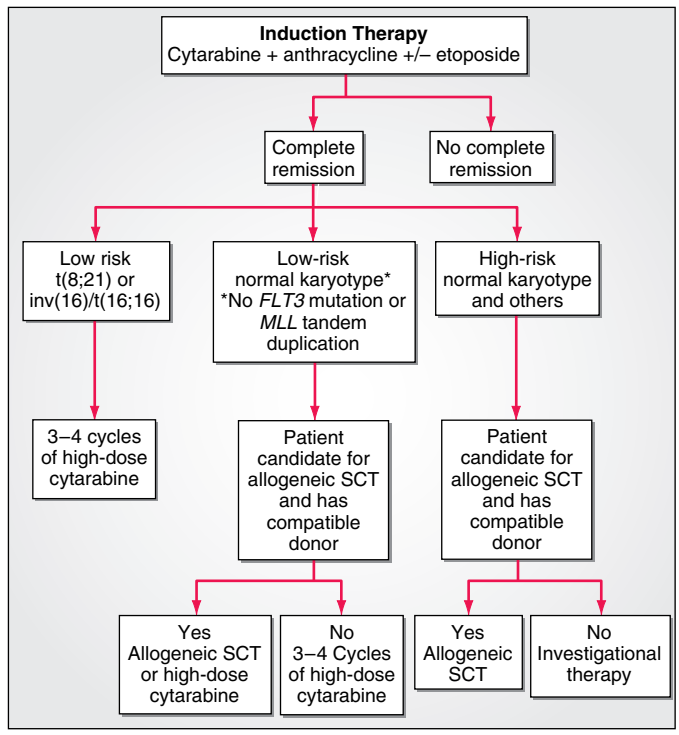

FIGURE 96-1 Flow chart for the therapy of newly diagnosed AML. For all forms of AML except APL, standard therapy includes a 7-day continuous infusion of cytarabine (100–200 mg/m² per day) and a 3-day course of daunorubicin (45–60 mg/m² per day) or idarubicin (12–13 mg/m² per day) with or without 3 days of etoposide. Patients who achieve complete remission undergo some form of consolidation therapy, including sequential courses of high-dose cytarabine, high-dose combination chemotherapy with allogeneic stem cell transplant (SCT), or novel therapies, based on their predicted risk of relapse (i.e., risk-stratified therapy). Patients with APL usually receive tretinoin together with anthracycline chemotherapy for remission induction and then receive consolidation chemotherapy (daunorubicin and cytarabine) followed by maintenance tretinoin, with or without chemotherapy.

anthracyclines in younger patients (<60 years) appears to increase the cure rate of AML. In older patients, the benefit of intensive therapy has been more difficult to document and therefore pursuit of novel therapies as consolidation for these patients has recently been actively pursued.

Induction Chemotherapy The most commonly used CR induction regimens (for patients other than those with APL) consist of combination chemotherapy with cytarabine (cytosine arabinoside) and an anthracycline. Cytarabine is a cell cycle S-phase-specific antimetabolite that becomes phosphorylated intracellularly to an active triphosphate form that interferes with DNA synthesis. Anthracyclines are DNA intercalaters. Their primary mode of action is thought to be inhibition of topoisomerase II, leading to DNA breaks. Cytarabine is usually administered as a continuous intravenous infusion at 100 to 200 mg/m^2 per day for 7 days. Anthracycline therapy generally consists of daunorubicin, 45 to 60 mg/m^2, intravenously on days 1, 2, and 3 (the 7 and 3 regimen). Treatment with idarubicin at 12 or 13 mg/m^2 per day for 3 days in conjunction with cytarabine by 7-day continuous infusion is at least as effective and may be superior to daunorubicin in younger patients. The addition of etoposide does not increase the CR rate but may improve the CR duration.

After induction chemotherapy, the bone marrow is examined to determine if the leukemia has been eliminated. If >5% blasts exist with ≥20% cellularity, the patient has traditionally been retreated with cytarabine and an anthracycline in doses similar to those given initially, but for 5 and 2 days, respectively. Our recommendation, however, is to change therapy in this setting. Patients who fail to attain CR after two induction courses should immediately proceed to an allogeneic stem cell transplant (SCT) if an appropriate donor exists. This approach is only applied to patients under the age of 65 to 70 with acceptable end-organ function.

With the 7 and 3 cytarabine/daunorubicin regimen outlined above, 65 to 75% of adults with de novo AML achieve CR. Two-thirds achieve CR after a single course of therapy, and one-third require two courses. About 50% of patients who do not achieve CR have a drug-resistant leukemia, and 50% do not achieve CR because of fatal complications of bone marrow aplasia or impaired recovery of normal stem cells. A higher induction treatment–related mortality and frequency of resistant disease has been observed as age increases in virtually all studies.

High-dose cytarabine-based regimens have very high CR rates after a single cycle of therapy. When given in high doses, more cytarabine may enter the cells, saturate the cytarabine-inactivating enzymes, and increase the intracellular levels of 1-β-D-arabinofuranylcytosine-triphosphate, the active metabolite incorporated into DNA. Thus, higher doses of cytarabine may increase the inhibition of DNA synthesis and thereby overcome resistance to standard-dose cytarabine. In two randomized studies, high-dose cytarabine with an anthracycline produced CR rates similar to those achieved with standard 7 and 3 regimens. However, the CR duration was longer after high-dose cytarabine than after standard-dose cytarabine.

The hematologic toxicity of high-dose cytarabine-based induction regimens has typically been greater than that associated with 7 and 3 regimens. Toxicity with high-dose cytarabine includes myelosuppression, pulmonary toxicity, and significant and occasionally irreversible cerebellar toxicity. All patients treated with high-dose cytarabine must be closely monitored for cerebellar toxicity. Full cerebellar testing should be performed before each dose, and further high-dose cytarabine should be withheld if evidence of cerebellar toxicity develops. This toxicity occurs more commonly in patients with renal impairment and in those over the age of 60. Indeed, it is the increased toxicity observed with high-dose cytarabine, as opposed to the lack of benefit of this therapy, that has limited the use of this more intensive therapy in elderly AML patients. Clinical trials in the elderly patients have therefore focused upon new agents and attenuated doses of high-dose cytarabine therapy.

Supportive Care Measures geared to supporting patients through several weeks of granulocytopenia and thrombocytopenia are critical to the success of AML therapy. Patients with AML should be treated in centers expert in providing supportive measures for their management.

Recombinant hematopoietic growth factors have been incorporated into clinical trials in AML. These trials have been designed to lower the infection rate after chemotherapy. Both granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF) have reduced the median time to neutrophil recovery by an average of 5 to 7 days. This accelerated rate of neutrophil recovery, however, has not always translated into significant reductions in infection rates. In most randomized studies, both G-CSF and GM-CSF have failed to improve the CR rate, disease-free survival, or overall survival. Although receptors for both G-CSF and GM-CSF are present on AML blasts, therapeutic efficacy is neither enhanced nor inhibited by these agents. The use of growth factors as supportive care for AML patients is controversial. We favor their use in elderly patients, those receiving intensive regimens, patients with uncontrolled infections, or those participating in clinical trials.

Multilumen right atrial catheters should be inserted through a subcutaneous tunnel as soon as patients with newly diagnosed AML have been stabilized. They should be used thereafter for administration of intravenous medications and transfusions, as well as for blood drawing. Antibiotic-impregnated catheters should be considered if the risk or subsequent consequence of line-related infection is high. The separation between the vascular access site and the exit site and the presence of a Dacron cuff in the subcutaneous channel reduce the risk of infection. With meticulous attention to sterile technique in catheter placement and maintenance, catheters may often be left in place for months.

Adequate and prompt blood bank support is critical to therapy of AML. Platelet transfusions should be given as needed to maintain a platelet count >10,000 to 20,000/μl. We believe that the platelet count should be kept at higher levels in febrile patients and during episodes of active bleeding or DIC. Patients with poor posttransfusion platelet count increments may benefit from administration of platelets from human leukocyte antigen (HLA)-matched donors. Red blood cell transfusions should be administered to keep the hemoglobin level >80 g/L (8 g/dL) in the absence of active bleeding, DIC, or congestive heart failure. Blood products leukodepleted by filtration should be used to avert or delay alloimmunization as well as febrile reactions. Blood products should also be irradiated to prevent graft-versus-host disease (GVHD). Cytomegalovirus (CMV)-negative blood products should be used for CMV-seronegative patients who are potential candidates for allogeneic SCT. Leukodepleted products are also effective for these patients if CMV-negative products are not available.

Infectious complications remain the major cause of morbidity and death during induction and postremission chemotherapy for AML. Prophylactic administration of antibiotics in the absence of fever is controversial. Oral nystatin or clotrimazole is recommended to prevent localized candidiasis. For patients who are herpes simplex virus antibody titer–positive, acyclovir prophylaxis is effective in preventing reactivation of latent oral herpes infections.

Fever develops in most patients with AML, but infections are documented in only half of febrile patients. Early initiation of empirical broad-spectrum antibacterial and antifungal antibiotics has significantly reduced the number of patients dying of infectious complications (Chap. 72). An antibiotic regimen adequate to treat gram-negative and gram-positive organisms should be instituted at the onset of fever in a granulocytopenic patient after clinical evaluation, including a detailed physical examination with inspection of the indwelling catheter exit site and a perirectal examination, as well as procurement of cultures and radiographs aimed at documenting the source of fever. Specific antibiotic regimens should be based on antibiotic sensitivity data obtained from the institution at which the patient is being treated. Acceptable regimens include imipenem-cilastin; an antipseudomonal semisynthetic penicillin (e.g., piperacillin) combined with an aminoglycoside; a third-generation cephalosporin with

antipseudomonal activity (i.e., ceftazidime or cefepime); or double β-lactam combinations (ceftazidime and piperacillin). Aminoglycosides should be avoided if possible in patients with renal insufficiency. For patients with known immediate-type hypersensitivity reactions to penicillin, aztreonam may be substituted for β-lactams. Aztreonam should be combined with an aminoglycoside or a quinolone antibiotic rather than used alone.

Empirical vancomycin is not given initially in the absence of suspected gram-positive infection or mucositis but should be initiated in neutropenic patients who remain febrile for 3 days; emperical systemic antifungal therapy is added at 7 days if fever persists. While amphotericin B has been used in the past for this, itraconazole and voriconazole have been shown to be equivalent in efficacy and less toxic. Our approach is therefore to use either itraconozole or voriconazole. Liposomal amphotericin, which has also been demonstrated to be equivalent to regular amphotericin and to have less renal toxicity, is utilized when this treatment approach fails. Antibacterial and antifungal antibiotics should be continued until patients are no longer neutropenic, regardless of whether a specific source has been found for the fever.

Treatment of Promyelocytic Leukemia Tretinoin is an oral drug that induces the differentiation of leukemic cells bearing the t(15;17); it is not effective in other forms of AML. APL is responsive to cytarabine and daunorubicin, but about 10% of patients treated with these drugs die from DIC induced by the release of granule components by dying tumor cells. Tretinoin does not produce DIC but produces another complication called the *retinoic acid syndrome*. Occurring within the first 3 weeks of treatment, it is characterized by fever, dyspnea, chest pain, pulmonary infiltrates, pleural and pericardial effusions, and hypoxia. The syndrome is related to adhesion of differentiated neoplastic cells to the pulmonary vasculature endothelium. Glucocorticoids, chemotherapy, and/or supportive measures can be effective. The mortality of this syndrome is about 10%.

Tretinoin (45 mg/m^2 per day orally until remission is documented) plus concurrent anthracycline chemotherapy appears to be the safest and most effective treatment for APL. Unlike patients with other types of AML, patients with this subtype benefit from maintenance therapy with either tretinoin or chemotherapy. The optimal regimen is being sought in clinical studies.

Arsenic trioxide produces meaningful responses in up to 85% of patients refractory to tretinoin. The use of arsenic trioxide is being explored as part of initial treatment in clinical trials of APL.

The detection of minimal residual disease by RT-PCR amplification of the t(l5;17) chimeric gene product appears to predict relapse. Disappearance of the signal is associated with long-term disease-free survival; its persistence predicts relapse. With increases in the sensitivity of the assay, some patients with persistent abnormal gene product have been found who do not suffer a relapse. Studies are underway to determine whether there is a critical threshold level of transcripts that predicts for leukemia relapse.

Postremission Therapy Induction of a durable first CR is critical to long-term disease-free survival in AML. However, without further therapy virtually all patients experience relapse. Once relapse has occurred, AML is generally curable only by SCT.

Postremission therapy is designed to eradicate any residual leukemic cells; therefore, it should prevent relapse and prolong survival. Approaches to postremission therapy in AML are often based upon age (<55 to 65 and >55 to 65). For younger patients, most studies include intensive chemotherapy and allogeneic or autologous SCT. High-dose cytarabine is more effective than standard-dose cytarabine. The Cancer and Leukemia Group B (CALGB), for example, compared the duration of CR in patients randomly assigned postremission to four cycles of high (3 g/m^2, every 12 h on days 1, 3, and 5), intermediate (400 mg/m^2 for 5 days by continuous infusion), or standard (100 mg/m^2 per day for 5 days by continuous infusion) doses of cytarabine. A dose-response effect for cytarabine in patients with AML who were ≤60 years was demonstrated. High-dose cytarabine significantly prolonged CR and increased the fraction cured in patients with favorable [t(8;21) and inv(16)] and normal cytogenetics, but it had no significant effect on patients with other abnormal karyotypes. For older patients, exploration of attenuated intensive therapy that includes either chemotherapy or nonmyeloablative allogeneic SCT has been pursued. In addition, early introduction of new agents (Table 96-3) is often pursued.

Allogeneic and autologous SCT in first CR have been studied extensively in younger patients with no major organ dysfunction. Allogeneic SCT is used in patients <65 to 70 years with an HLA-compatible donor. Relapse with this therapy occurs in only a small fraction of patients, but toxicity is relatively high from treatment; complications include venoocclusive disease, GVHD, and infections. Autologous transplantation can be administered in young and older patients and uses the same preparative regimens. Patients subsequently receive their own stem cells collected while in remission. The toxicity is lower with autologous SCT (5% mortality rate), but the relapse rate is higher than with allogeneic SCT. The increased relapse rate is due to the absence of the graft-vs-leukemia (GVL) effect seen with allogeneic SCT and possible contamination of the autologous stem cells with tumor cells. Purging the autologous stem cells does not lower the relapse rate with autologous SCT.

Randomized trials comparing intensive therapy and autologous and allogeneic SCT have shown improved duration of remission with allogeneic SCT compared to autologous SCT or chemotherapy alone. However, overall survival is generally not different; the improved disease control with allogeneic SCT is erased by the increase in fatal toxicity. While stem cells were previously harvested from the bone marrow, virtually all efforts currently collect these from the peripheral blood following mobilization regimens including growth factors with or without chemotherapy. Prognostic factors may help select patients in first CR for whom transplant is most effective.

Our approach includes strong consideration for allogeneic SCT in first CR for patients with high-risk karyotypes. Patients with normal karyotypes who have other poor risk factors (antecedent hematologic disorder, failure to attain remission with a single induction course, hyperleukocytosis, PTD of the *MLL* gene, and *FLT3* abnormalities) are also potential candidates. If a suitable HLA donor does not exist, autologous SCT or novel therapeutic approaches are considered. Other novel transplant strategies including nonmyeloblative SCT are being actively explored for consolidation of high-risk AML patients. Patients with t(8;21) and inv(16) are treated with repetitive doses of high-dose

TABLE 96-3 *Selected New Agents Under Study for Treatment of Adults with AML*

Class of Drugs	*Example Agent(s)*
MDR1 modulator	Cyclosporine analogues, PSC-833
Demethylating agent	Decitabine, 5-azacytidine
Histone deacetylase inhibitor	Depsipeptide, suberoylanilide hydroxamic acid (SAHA), MS275, Valproic Acid
Heavy metals	Arsenic trioxide, antimony
Farnesyl transferase inhibitors	R115777, SCH66336
FLT3 inhibitors	SU11248, PKC412, MLN518
HSP-90 antagonists	17-Allylaminogeldanamycin (17-AAG)
BCR/ABL PDGFR/c-*kit* inhibitor	Imatinib (ST1571, Gleevec)
Protein kinase C inhibitor	Bryostatin, UCN-01, CGP41251
Cell cycle inhibitor	Flavopiridol
Humanized antibodies	Anti-CD33 (HuM195), Hu1D10 (β-chain, HLA-DR)
Toxin-conjugated antibodies	Gemtuzumab ozogamicin (Mylotarg)
Radiolabeled antibodies	Yttrium-90-labeled human M195
Cytokines	Recombinant human interleukin (IL) 2 and IL-12
Anticytokines	Antivascular endothelial growth factor (Avastin)

cytarabine, which offers a high frequency of cure without the morbidity of transplant.

Relapse Once relapse occurs after the standard induction and postremission chemotherapy approach described above and outlined in Fig. 96-1, patients are rarely cured with further standard-dose chemotherapy. Patients eligible for allogeneic SCT should receive transplants expeditiously at the first sign of relapse. Long-term disease-free survival is approximately the same (30 to 50%) with allogeneic SCT in first relapse or in second remission. Chemotherapy is administered prior to allogeneic transplant if the AML is rapidly progressing. Autologous SCT rescues about 20% of relapsed patients with AML who have chemosensitive disease. The most important factors predicting response at relapse are the length of the previous CR, whether initial CR was achieved with one or two courses of chemotherapy, and the type of postremission therapy. Because of the poor outcome of patients in early (<12 months) first relapse, it is justified (for patients without HLA-compatible donors) to explore innovative approaches, such as new drugs or immunotherapies (Table 96-3). Patients with longer (>12 months) first CR generally relapse with drug-sensitive disease and have a higher chance of attaining a CR. However, cure for these patients is uncommon, and treatment with novel approaches should be considered if SCT is not possible. New agents (Table 96-3) that may have clinical activity in AML are needed.

For elderly patients (age >60) for whom clinical trials are not available, gemtuzumab ozogamicin (Mylotarg) is another alternative. This therapy is an antibody-targeted chemotherapy consisting of the humanized anti-CD33 antibody linked to calicheamicin, a potent antitumor antibiotic. The CR rate in response to this therapy is ~30%. The effectiveness of this agent in early relapsing (<6 months) or refractory AML patients is limited, possibly due to calicheamicin being a potent Mdr1 substrate. Toxicity, including myelosuppression, infusion toxicity, and venoocclusive disease, can be observed with gemtuzumab ozogamicin. Currently, studies are examining the efficacy of this treatment in combination with chemotherapy for both young and older patients with previously untreated AML.

CHRONIC MYELOGENOUS LEUKEMIA

INCIDENCE The incidence of chronic myelogenous leukemia (CML) is 1.5 per 100,000 people per year, and the age-adjusted incidence is higher in men than in women (2.0 versus 1.2). The incidence of CML increases slowly with age until the middle forties, when it starts to rise rapidly. CML incidence decreased slightly between 1973 and 1999 (1.9 versus 1.5).

DEFINITION The diagnosis of CML is established by identifying a clonal expansion of a hematopoietic stem cell possessing a reciprocal translocation between chromosomes 9 and 22. This translocation results in the head-to-tail fusion of the breakpoint cluster region (*BCR*) gene on chromosome 22q11 with the *ABL* (named after the abelson murine leukemia virus) gene located on chromosome 9q34. Untreated, the disease is characterized by the inevitable transition from a chronic phase to an accelerated phase and on to blast crisis.

ETIOLOGY No clear correlation with exposure to cytotoxic drugs, such as alkylating agents, has been found, and there is no direct evidence of a viral etiology. Cigarette smoking has been shown to accelerate the progression to blast crisis and therefore has an adverse effect on survival in CML. The effect of radiation was demonstrated in a study of the atomic bomb survivors, where it has been estimated that the development of a CML cell mass of 10,000/μl takes 6.3 years. No increase in CML incidence was found in the survivors of the Chernobyl accident, suggesting that only large doses of radiation can induce CML.

PATHOPHYSIOLOGY The product of the fusion gene resulting from the t(9;22) plays a central role in the development of CML. This chimeric gene is transcribed into a hybrid *BCR/ABL* mRNA in which exon 1 of *ABL* is replaced by variable numbers of 5′ *BCR* exons. Bcr/Abl fusion proteins, $p210^{BCR/ABL}$, are produced that contain NH_2-terminal domains of Bcr and the COOH-terminal domains of Abl. A rare breakpoint, occurring within the 3′ region of the *BCR* gene, yields a fusion protein of 230 kDa, $p230^{BCR/ABL}$. Bcr/Abl fusion proteins can transform hematopoietic progenitor cells *in vitro*. Furthermore, reconstituting lethally irradiated mice with bone marrow cells infected with retrovirus carrying the gene encoding the $p210^{BCR/ABL}$ leads to the development of a myeloproliferative syndrome resembling CML in 50% of the mice. Specific antisense oligomers to the *BCR/ABL* junction inhibit the growth of t(9;22)-positive leukemic cells without affecting normal colony formation.

The mechanism(s) by which $p210^{BCR/ABL}$ promotes the transition from the benign state to the fully malignant one is still unclear. Messenger RNA for *BCR/ABL* can occasionally be detected in normal individuals. However, attachment of the *BCR* sequences to *ABL* results in three critical functional changes: (1) the Abl protein becomes constitutively active as a tyrosine kinase enzyme, subsequently activating downstream kinases that prevent apoptosis; (2) the DNA-protein-binding activity of Abl is attenuated; and (3) the binding of Abl to cytoskeletal actin microfilaments is enhanced.

Disease Progression The events associated with transition to the acute phase are poorly understood. Chromosomal instability of the malignant clone, resulting, for example, in the acquisition of an additional t(9;22), trisomy 8, or 17p- (p53 loss), is a fundamental characteristic of CML. Acquisition of these additional genetic and/or molecular abnormalities is critical to the phenotypic transformation. Large deletions adjacent to the translocation breakpoint on the derivative 9 chromosome, detected by microsatellite polymerase chain reaction (PCR) or FISH, are associated with shorter survival time. Heterogeneous structural alterations of the p53 gene, as well as structural alterations and lack of protein production of the retinoblastoma gene, have been associated with disease progression in a subset of patients. Rare patients show alterations in *RAS*. Sporadic reports also document the presence of an altered *MYC* (named after the myelocytomatosis virus) gene. Progressive de novo DNA methylation at the *BCR/ABL* locus has also been shown to herald blastic transformation. Finally, interleukin (IL)-1β may be involved in the progression of CML to the blastic phase. Multiple pathways to disease transformation exist, but the exact timing and relevance of each remain unclear.

CLINICAL PRESENTATION ■ Symptoms The clinical onset of the chronic phase is generally insidious. Accordingly, some patients are diagnosed while still asymptomatic, during health screening tests; other patients present with fatigue, malaise, and weight loss or have symptoms resulting from splenic enlargement, such as early satiety and left upper quadrant pain or mass. Less common are features related to granulocyte or platelet dysfunction, such as infections, thrombosis, or bleeding. Occasionally, patients present with leukostatic manifestations due to severe leukocytosis or thrombosis such as vasoocclusive disease, cerebrovascular accidents, myocardial infarction, venous thrombosis, priapism, visual disturbances, and pulmonary insufficiency. Patients with $p230^{BCR/ABL}$-positive CML have a more indolent course.

Progression of CML is associated with worsening symptoms. Unexplained fever, significant weight loss, increasing dose requirement of the drugs controlling the disease, bone and joint pain, bleeding, thrombosis, and infections suggest transformation into accelerated or blastic phases. Fewer than 10 to 15% of newly diagnosed patients present with accelerated disease or with de novo blastic phase CML.

Physical Findings In most patients the abnormal finding on physical examination at diagnosis is minimal to moderate splenomegaly; mild hepatomegaly is found occasionally. Persistent splenomegaly despite continued therapy is a sign of disease acceleration. Lymphadenopathy and myeloid sarcomas are unusual except late in the course of the disease; when they are present, the prognosis is poor.

Hematologic Findings Elevated white blood cell counts, with various degrees of immaturity of the granulocytic series, are present at diag-

nosis. Usually <5% circulating blasts and <10% blasts and promyelocytes are noted. Cycling of the counts may be observed in patients followed without treatment. Platelet counts are almost always elevated at diagnosis, and a mild degree of normochromic normocytic anemia is present. Leukocyte alkaline phosphatase is characteristically low in CML cells. Serum levels of vitamin B_{12} and vitamin B_{12}–binding proteins are generally elevated. Phagocytic functions are usually normal at diagnosis and remain normal during the chronic phase. Histamine production secondary to basophilia is increased in later stages, causing pruritus, diarrhea, and flushing.

At diagnosis, bone marrow cellularity, primarily of the myeloid and megakaryocytic lineages, with a greatly altered myeloid to erythroid ratio, is increased in almost all patients with CML. The marrow blast percentage is generally normal or slightly elevated. Marrow or blood basophilia, eosinophilia, and monocytosis may be present. While collagen fibrosis in the marrow is unusual at presentation, significant degrees of reticulin stain–measured fibrosis are noted in about half of the patients.

Disease acceleration is defined by the development of increasing degrees of anemia unaccounted for by bleeding or chemotherapy; cytogenetic clonal evolution; or blood or marrow blasts between 10 and 20%, blood or marrow basophils ≥20%, or platelet count <100,000/μl. *Blast crisis* is defined as acute leukemia, with blood or marrow blasts ≥ 20%. Hyposegmented neutrophils may appear (Pelger-Huet anomaly). Blast cells can be classified as myeloid, lymphoid, erythroid, or undifferentiated, based on morphologic, cytochemical, and immunologic features. About half the cases are myeloid, one-third lymphoid, 10% erythroid, and the rest are undifferentiated.

Chromosomal Findings The cytogenetic hallmark of CML, found in 90 to 95% of patients, is the t(9;22)(q34;q11.2). Originally, this was recognized by the presence of a shortened chromosome 22 (22q-), designated as the *Philadelphia chromosome*, that arises from the reciprocal 9;22 translocation. Some patients may have complex translocations (designated as *variant translocations*) involving three, four, or five chromosomes (usually including chromosomes 9 and 22). However, the molecular consequences of these changes appear similar to those resulting from the typical t(9;22). All patients should have evidence of the translocation either by cytogenetics, FISH, or molecularly to make a diagnosis of CML.

PROGNOSTIC FACTORS The clinical outcome of patients with CML is variable. Before imatinib mesylate, death was expected in 10% of patients within 2 years and in about 20% yearly thereafter and the median survival time was ~4 years. Therefore, several prognostic models that identify different risk groups in CML have been developed. The most commonly used staging systems have been derived from multivariate analyses of prognostic factors. The *Sokal index* identified percentage of circulating blasts, spleen size, platelet count, cytogenetic clonal evolution, and age as the most important prognostic indicators. This system was based on chemotherapy-treated patients. The *Hasford system* was developed on interferon α-treated patients. It identified age, spleen size, percentage of circulating blasts, platelet count, and percentage of eosinophils and basophils as the most important prognostic indicators. This system differs from the Sokal index by ignoring clonal evolution and incorporating percentage of eosinophils and basophils. When applied to a data set of 272 patients treated with interferon α (IFN-α), the Hasford system was more potent than the Sokal score for predicting survival time; it identified more low-risk patients but left only a small number of cases in the high-risk group. The Hasford system has not yet been validated in patients undergoing transplantation. However, preliminary results suggest that it is applicable to imatinib-treated patients.

TREATMENT

The therapy of CML is rapidly undergoing evolution because we have a curative treatment (allogeneic transplantation) that has significant toxicity and a new targeted treatment (imatinib) without long-term follow-up data. Therefore, physician experience and patient preference must be factored into the treatment selection process. Discussion of both treatment options with a patient is indicated. The decision should focus on the outcomes, risks, and toxicities of the various approaches. Some centers would employ allogeneic SCT in patients <30 years, as the risk of transplant-related toxicity is minimal in that population.

TABLE 96-4 Response Criteria in CML

Hematologic	
Complete response[a]	White blood cell count <10,000/μl, normal morphology Normal hemoglobin and platelet counts
Incomplete response	White blood cell count ≥ 10,000/μl
Cytogenetic	Percentage of bone marrow metaphases with t(9;22)
Complete response	0
Partial response	≤35
Minor response	36–85[b]
No response	85–100
Molecular	Presence of *BCR/ABL* transcript by RT-PCR
Complete response	None
Incomplete response	Any

[a] Complete hematologic response requires the disappearance of splenomegaly.
[b] Up to 15% normal metaphases are occasionally seen at diagnosis (when 30 metaphases are analyzed).
Note: RT-PCR, reverse transcriptase polymerase chain reaction.

At present, the goal of therapy in CML is to achieve prolonged, durable, nonneoplastic, nonclonal hematopoiesis, which entails the eradication of any residual cells containing the *BCR/ABL* transcript. Hence the goal is complete molecular remission and cure (Table 96-4). A proposed treatment plan for the newly diagnosed patient with CML is presented in Fig. 96-2.

Allogeneic SCT Allogeneic SCT is currently the only curative therapy for CML and, when feasible, is the treatment of choice. However, it is complicated by a high early-mortality rate owing to the transplant procedure. Outcome of SCT depends on multiple factors including: (1) the patient (e.g., age and phase of disease); (2) the type of donor [e.g., syngeneic (monozygotic twins) or HLA-compatible allogeneic, related or unrelated]; (3) the preparative regimen; (4) GVHD; and (5) posttransplantation treatment.

THE PATIENT As experience has been gained and safety and efficacy have been established, it has become clear that patients should have acceptable end-organ function, be <65 to 70 years, and have a healthy

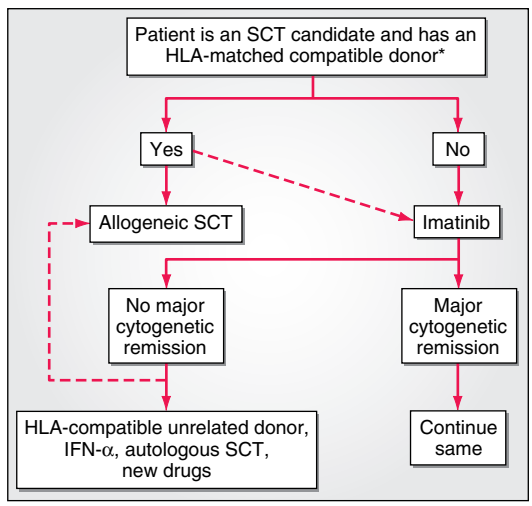

FIGURE 96-2 Flow chart for the therapy of newly diagnosed CML. Patients with an HLA-compatible donor have the possibility to undergo allogeneic stem cell transplant (SCT) as initial therapy or treatment with imatinib. The asterisk denotes that some centers employ allogeneic SCT only if imatinib fails to induce a response. Broken lines denote lack of long-term survival data. IFN, interferon.

and histocompatible donor. Furthermore, survival after SCT in the accelerated and blastic phases of the disease is significantly diminished and is associated with a very high rate of relapse. The Seattle pre-imatinib data demonstrate that bone marrow transplantation (BMT) early in the chronic phase (1 to 2 years from diagnosis) is superior to later BMT.

THE DONOR Transplantation from a family donor, who is either fully matched or mismatched at only one HLA locus, should be considered the only curative therapy for any patient with CML who is a candidate for an HLA-related sibling transplant. Syngeneic BMT in patients with chronic phase CML has been reported from the Seattle group to result in 7-year disease-free survival in 55% of the patients, with a 30% relapse rate. With HLA-identical sibling BMT in the chronic phase, many groups have reported 5-year disease-free survival in 40 to 70% of patients, with a 25% relapse rate. BMT from an HLA-matched unrelated donor in chronic phase <1 year from diagnosis and <30 years resulted in similar 5-year disease-free survival as matched sibling donor transplantation. For all other groups, patients receiving transplants from unrelated individuals have higher rates of graft failure and acute and chronic GVHD and prolonged convalescence after treatment, compared to those who receive allogeneic transplants from related individuals. Peripheral blood is now being studied as a source of hematopoietic progenitor cells; it may offer rapid engraftment and less risk for the donor. With unrelated donors, some studies demonstrated no difference in GVHD and improved disease-free survival when comparing peripheral blood to bone marrow stem cells. No such data are available using matched sibling donors to date. At the current time, some centers collect bone marrow and some peripheral blood from sibling donors for newly diagnosed CML patients. Umbilical-cord blood may permit mismatched SCT with notably less GVHD; GVL effects do not appear to be impaired. A problem with cord blood is obtaining a sufficient number of progenitor cells to reconstitute hematopoiesis in an adult.

PREPARATIVE REGIMENS These regimens have been studied by several groups. A randomized study by the Seattle group compared cyclophosphamide and total-body irradiation with busulphan and cyclophosphamide. They found no significant differences in the 3-year probabilities of survival, relapse, event-free survival, speed of engraftment, or incidence of venoocclusive disease of the liver. Significantly more patients in the total-body irradiation arm experienced major elevations of creatinine, acute GVHD, longer periods of fever, positive blood cultures, hospital admissions, and longer inpatient hospital stays. However, increased chronic GVHD, obstructive bronchiolitis, and alopecia were noted with busulphan. Measurement of busulphan levels revealed no significant association between busulphan levels and regimen-related toxicity, but low levels were associated with an increased risk of relapse. Intravenous busulphan allows better control of serum levels. We tend to favor the use of busulphan and cyclophosphamide. Nonmyeloblative transplants in which the preparative regimen is aimed at eliminating host lymphocytes rather than bone marrow are being tested. Reduced toxicity with preserved antitumor efficacy is the goal.

DEVELOPMENT AND TYPE OF GVHD Development of grade I GVHD, as compared to no GVHD, decreases the risk of relapse. A lower relapse rate was observed also in patients with grade II GVHD but was accompanied by a substantially higher transplant-related mortality rate. The decreased relapse rate may be caused by a GVL effect. Depletion of T lymphocytes from donor marrow can prevent GVHD but results in an increased risk of relapse, which exceeds the relapse rate after syngeneic SCT. Thus, T lymphocytes from the donor marrow mediate a significant antileukemic, or GVL, effect, and even syngeneic marrow may exhibit limited GVL activity in CML.

POSTTRANSPLANTATION TREATMENT Further support for the existence of an immunologically mediated GVL effect came from the observation that donor leukocyte infusions (without any preparative chemotherapy or GVHD prophylaxis) can induce hematologic and cytogenetic remissions in patients with CML who have relapsed after allogeneic SCT.

Imatinib's effect in the chronic phase of the disease prompted its study in patients who relapse after allogeneic SCT. Studies with small numbers of patients have proved that imatinib can control CML that has recurred after allogeneic SCT but is associated with myelosuppression and recurrence of severe GVHD. Imatinib studies after allogeneic SCT to prevent relapse in patients with advanced disease at the time of transplantation (patients at high risk for relapse) or patients undergoing non-myeloblative transplants are under way.

The activity of IFN-α in patients with early chronic-phase CML was the basis for the use of IFN-α after SCT, either to induce cytogenetic remissions in relapsed patients or to prevent relapse after SCT for high-risk patients. The main concern about IFN-α use after allogeneic SCT has been the development or worsening of GVHD, because IFN-α acts as an immunomodulator. IFN-α has also been combined with mononuclear cells obtained from donor blood to induce cytogenetic remissions in relapsed patients. Cytogenetic remissions have been achieved, but the exact role of IFN-α as opposed to the mononuclear cells is unclear.

Imatinib Mesylate Imatinib mesylate (Gleevec, STI571) functions through competitive inhibition at the adenosine triphosphate (ATP) binding site of the Abl kinase, which leads to inhibition of tyrosine phosphorylation of proteins involved in Bcr/Abl signal transduction. It shows a high degree of specificity for Bcr/Abl, the receptor for platelet-derived growth factor, and c-*kit* tyrosine kinases. Imatinib induces apoptosis in cells expressing Bcr/Abl. Based on its antileukemic activity in vitro it was tested in clinical trials.

Most patients with CML in chronic phase have a rapid hematologic response to imatinib therapy. In the initial studies with imatinib in patients with chronic-phase CML who were intolerant to IFN-α, 95% of patients achieved complete hematologic remission, and 60% achieved major cytogenetic remission, with a complete cytogenetic remission rate of 41%. Those who did not achieve at least a major cytogenetic remission following 3 months of therapy had a higher risk of disease progression to the accelerated/blastic phases of the disease. Patients in the accelerated/blastic phases of the disease are less sensitive to imatinib, and the treatment outcome is less favorable. In newly diagnosed CML, a recent randomized phase III study of imatinib (400 mg/d) versus IFN-α and cytarabine revealed the complete hematologic remission rate, at 18 months, of patients treated with imatinib to be 97% as compared to 69% in patients treated with IFN-α and cytarabine. Similarly, the complete cytogenetic remission rate was 76% in patients treated with imatinib as compared to 14% in patients treated with IFN-α and cytarabine. Progression to accelerated/blastic phases of the disease was noted in 3% of patients treated with imatinib as compared to 8.5% of patients treated with IFN-α and cytarabine. These results led to rapid Food and Drug Administration approval of imatinib for all stages of CML.

Imatinib is administered orally and has an acceptable toxicity profile. The main side effects are fluid retention, nausea, muscle cramps, diarrhea, and skin rashes. The management of these side effects is usually supportive. Myelosuppression is the most common hematologic side effect, and patients who received busulphan are at a greater risk than patients who were treated with IFN-α. It seems to result from the eradication of the malignant clone and delayed recovery of the normal nonclonal progenitor cells. Blood and platelet support should be provided, and therefore dose reduction is rarely recommended in the absence of infection. Doses <300 mg/d seem ineffective and may lead to development of resistance.

Four mechanisms of resistance to imatinib have been described to date. These are (1) gene amplification, (2) mutations at the kinase site, (3) enhanced expression of multidrug exporter proteins, and (4) alternative signaling pathways functionally compensating for the imatinib-sensitive mechanisms. The unfavorable prognosis associated with

imatinib-resistance was shown in the accelerated and blast crisis phases of the disease. Specifically, patients who do not achieve major cytogenetic remission within 3 months of initiation of imatinib have shorter survival than patients who achieve that level of remission. Therefore, all four mechanisms are being targeted in clinical trials.

The encouraging results with imatinib have led many clinicians to offer it as a first-line therapy for newly diagnosed CML patients, including those who otherwise would have benefited from transplant (e.g., young patients with a sibling matched donor). This may be unwise since the clinical studies so far have very short follow-up, thus limiting knowledge regarding the curative potential of imatinib. Delaying transplantation until after development of imatinib resistance may worsen outcome.

Interferons When allogeneic SCT is not feasible, IFN-α therapy used to be the treatment of choice before imatinib became available. Only longer follow-up of patients treated with imatinib will prove whether IFN-α will still have a role in the treatment of CML. The interferons are a complex group of naturally occurring proteins produced by eukaryotic cells in response to viruses, antigens, and mitogens. Three distinct groups of IFN species have been identified: IFN-α, -β and -γ. Although various interferons have become available for clinical investigation, most data have been generated with IFN-α preparations.

Interferons have potent, pleiotropic biologic effects, spanning a spectrum of antiviral, microbicidal, immunomodulatory, and antiproliferative properties. While interferons downregulate the expression of several oncogenes and cytokines, they also upregulate the expression of IFN regulatory factor-1 (a transcriptional activator with antioncogenic activity), adhesion molecules, and the histocompatibility genes. Interferons also inhibit angiogenesis and induce a cellular immune response. However, the mode(s) of action in CML is still unknown.

In randomized studies comparing IFN-α and chemotherapy, patients treated with IFN-α survived longer than patients treated with hydroxyurea or busulphan. The 5-year survival rate was 51% with IFN-α and 42% with chemotherapy. Of note, achieving complete cytogenetic or molecular response after IFN-α therapy is associated with a 10-year survival rate as high as 78%.

Patients develop both acute and chronic side effects from IFN-α therapy. Acute side effects (flulike symptoms) appear early in the course of the treatment. Most flulike symptoms respond to acetaminophen, and tachyphylaxis develops within 1 to 2 weeks. Chronic reactions, such as fatigue and lethargy, depression, weight loss, myalgias, and arthralgias, occur in about half of the patients and often require dose reduction. Patients also report cough, postnasal drip, and dryness of the skin. Infrequently, immune-mediated thrombocytopenia and anemia develop. In addition, long-term therapy has been associated with late autoimmune side effects, such as hypothyroidism and occasionally generalized autoimmune phenomena.

The most important persistent side effects in patients with CML who are treated with IFN-α are neurologic. All patients treated with IFN-α are subject to some neurologic toxicity, the most common symptom being lethargy. Up to 20% of patients have neurologic side effects that are associated with compromised quality of life and reduced ability to carry out their regular activity, such as full-time work. In addition, at the required doses, impotence in men is not infrequent. The combination of IFN-α with cytarabine has produced better results in one study but not in another.

Chemotherapy Innovative approaches are still important in CML; the exact role of imatinib in the armamentarium of CML remains undefined. Initial management of patients with chemotherapy is currently reserved for rapid lowering of white blood cell counts, reduction of symptoms, and reversal of symptomatic splenomegaly. Hydroxyurea, a ribonucleotide reductase inhibitor, induces rapid disease control. The initial dose is 1 to 4 g/d; the dose should be halved with each 50% reduction of the leukocyte count. Unfortunately, cytogenetic remissions with hydroxyurea are uncommon. Busulphan, an alkylating agent that acts on early progenitor cells, has a more prolonged effect. However, we do not recommend its use because of its serious side effects, which include unexpected, and occasionally fatal, myelosuppression in 5 to 10% of patients; pulmonary, endocardial, and marrow fibrosis; and an Addison-like wasting syndrome.

Homoharringtonine (HHT) is a plant alkaloid derived from a tree, *Cephalotaxus fortuneii* sp. *harringtonii*. HHT blocks peptide bond formation after binding of the aminoacyl-transfer RNA to the ribosome. In patients whose disease progressed during treatment with IFN-α or who were in later chronic phase (>1 year from diagnosis), HHT induced 72% complete hematologic responses and 15% major cytogenetic responses. The use of HHT before IFN-α in early chronic phase resulted in a 92% complete hematologic response rate and a 27% major cytogenetic response rate. Toxicity is mainly related to myelosuppression. In vitro synergism between HHT and imatinib have led to the development of combination trials.

Arsenic trioxide gained recognition as a therapeutic agent following reports from China of a high incidence of favorable hematologic responses in patients with APL. The mechanism(s) of action of arsenic trioxide in non-APL leukemias is unknown. Initial studies of arsenic trioxide in Bcr/Abl-expressing cell lines demonstrated downregulation of Bcr/Abl expression as well as activation of apoptosis. More recent studies have demonstrated an initial effect of arsenic trioxide on Bcr/Abl expression prior to activation of the apoptotic pathway. In vitro synergism between arsenic trioxide and imatinib have led to the clinical investigation of this combination.

Intensive combination chemotherapy has also been used in chronic-phase CML, with 30 to 50% of patients achieving complete cytogenetic responses. However, these cytogenetic remissions have been short-lived. Consequently, intensive combination chemotherapy regimens are being used today only to mobilize normal progenitors in the blood in order to collect circulating stem cells for autologous transplantation.

Autologous SCT Autologous SCT could potentially cure CML if a means to select the residual normal progenitors, which coexist with their malignant counterparts, could be developed. As a source of autologous hematopoietic stem cells for transplantation, blood offers certain advantages over marrow (e.g., faster engraftment for the patient and no general anesthesia for the donor). Normal hematopoietic stem cells appear with increased frequency in the blood of patients with CML during the recovery phase after chemotherapy and G-CSF. A role for imatinib before stem cell collection to achieve minimal residual disease and following transplantation to maintain this status is currently being investigated. However, only a few cases have been reported to successfully engraft following imatinib therapy. Therefore such approaches should be performed only in clinical trials.

Leukapheresis and Splenectomy Intensive leukapheresis may control the blood counts in chronic-phase CML; however, it is expensive and cumbersome. It is useful in emergencies where leukostasis-related complications such as pulmonary failure or cerebrovascular accidents are likely. It may also have a role in the treatment of pregnant women in whom it is important to avoid potentially teratogenic drugs.

Splenectomy was used in CML in the past because of the suggestion that evolution to the acute phase might occur in the spleen. However, this does not appear to be the case, and splenectomy is now reserved for symptomatic relief of painful splenomegaly unresponsive to chemotherapy or for significant anemia or thrombocytopenia associated with hypersplenism. Splenic radiation is used rarely to reduce the size of the spleen.

Minimal Residual Disease After allogeneic SCT, RT-PCR analysis may be positive for residual disease during the first 6 months in patients who subsequently achieve a long-lasting remission. However, late persistence of RT-PCR positivity appears to indicate a reduced probability of cure. RT-PCR positivity at any single time point is not predictive of imminent relapse. After allogeneic SCT, patients are often divided according to RT-PCR results into one of three groups: (1) persistently positive, (2) intermittently negative, and (3) persistently negative.

These three groups have low, intermediate, and high probability of maintaining remission and disease free-survival, respectively. Although these data suggest that patients who are persistently RT-PCR positive >6 months after allogeneic SCT need additional therapeutic interventions, this conclusion has not been rigorously established. The studies have used an assortment of techniques for measuring minimal residual disease, the level of sensitivity has been variable, and the follow-up durations of patients are short. Quantitative PCR may provide a more sensitive tool to predict relapse in CML. In patients who do not have any evidence for GVHD and are intermittently RT-PCR negative, GVL may be induced by alloreactive donor cells (without the side effects of GVHD) to suppress the proliferation of the leukemic cells. Another approach may be the use of imatinib to eradicate minimal residual disease.

Following imatinib therapy, only a minority (5 to 10%) of the patients develop molecular remission. Extrapolating from the SCT data, most patients without molecular remission are at risk of relapse. However, patients with AML with t(8;21) who are in long-term remission have persistent multipotent progenitor cells expressing *AML1/ETO* transcripts. Therefore it is unclear whether indeed achieving durable molecular remission should still be the goal of treatment in this disease. Until this issue is sorted out, approaches have been developed to try and improve the current results. Based on improved outcome with higher doses of imatinib in patients with the advanced stages of the disease, trials have been initiated that compare 400 mg to 800 mg of imatinib in newly diagnosed patients. Similarly, combination regimens have been developed; based on the effect of IFN-α in the chronic phase of the disease, imatinib with IFN-α or with its long-acting (pegylated) member are being studied. Likewise, based on the combined effect of cytarabine and IFN-α, a regimen of imatinib and cytarabine is being evaluated. The results from these trials are premature at this point. However, they will most probably lead to a randomized trial of imatinib versus imatinib with IFN-α versus imatinib with cytarabine.

After IFN-α therapy, residual disease was found in all samples tested from patients with complete cytogenetic remissions. More recent studies have demonstrated the eventual elimination of the *BCR/ABL* mRNA transcript after more prolonged IFN-α treatment in some cases.

Future Directions Abrogation of DNA methylation with 5-aza-2′deoxycytidine (decitabine) has shown clinical activity in the advanced stages of the disease. Inhibition of *Ras* with a farnesyl transferase inhibitor that blocks its insertion into the membrane may have antitumor activity in CML on the basis of early clinical trials. Preclinical efforts to use Bcr/Abl peptides as a tumor vaccine appear promising. The use of *BCR/ABL* antisense oligonucleotides to purge residual leukemic cells from autologous hematopoietic progenitors before reinfusion, as well as new approaches to induce GVL in the setting of minimal residual disease without inducing GVHD, are under way. All these agents and others are being or will be studied in combination with imatinib. Further, treatment with the histone deacetylase inhibitor suberoylanilide hydroxamic acid (SAHA) was shown to enhance imatinib-induced apoptosis of Bcr/Abl-positive cell lines, and the heat-shock protein 90 antagonist 17-allylaminogeldanamycin (17-AAG) inhibited cell growth of cell lines containing mutations at the kinase site.

Treatment of Blast Crisis The treatment for all forms of blast crisis is generally ineffective, including imatinib. Only 52% of patients treated with imatinib achieved hematologic remission (21% complete hematologic remission), and the median overall survival was 6.6 months. Patients who achieve complete hematologic remission or whose disease returns to a second chronic phase should be considered for allogeneic SCT. Other approaches include induction chemotherapy tailored to the phenotype of the blast cell followed by imatinib, with or without additional chemotherapy and SCT. Blast crisis following initial therapy with imatinib carries a dismal prognosis.

97 MALIGNANCIES OF LYMPHOID CELLS

James O. Armitage, Dan L. Longo

Malignancies of lymphoid cells range from the most indolent to the most aggressive human malignancies. These cancers arise from cells of the immune system at different stages of differentiation, resulting in a wide range of morphologic, immunologic, and clinical findings. Insights on the normal immune system have allowed a better understanding of these sometimes confusing disorders.

Some malignancies of lymphoid cells almost always present as leukemia (i.e., primary involvement of bone marrow and blood), while others almost always present as lymphomas (i.e., solid tumors of the immune system). However, other malignancies of lymphoid cells can present as either leukemia or lymphoma. In addition, the clinical pattern can change over the course of the illness. This change is more often seen in a patient who seems to have a lymphoma and then develops the manifestations of leukemia over the course of the illness.

TABLE 97-1 Lymphoid Disorders That Can Present as "Chronic Leukemia" and Be Confused with Typical B Cell Chronic Lymphoid Leukemia

Follicular lymphoma	Prolymphocytic leukemia (B cell or T cell)
Splenic marginal zone lymphoma	Lymphoplasmacytic lymphoma
Nodal marginal zone lymphoma	Sézary syndrome
Mantle cell lymphoma	Smoldering adult T cell leukemia/lymphoma
Hairy cell leukemia	

BIOLOGY OF LYMPHOID MALIGNANCIES: CONCEPTS OF THE WHO CLASSIFICATION OF LYMPHOID MALIGNANCIES

The classification of lymphoid cancers evolved steadily throughout the twentieth century. The distinction between leukemia and lymphoma was made early, and separate classification systems were developed for each. Leukemias were first divided into acute and chronic subtypes based on average survival. Chronic leukemias were easily subdivided into those of lymphoid or myeloid origin based on morphologic characteristics. However, in recent years, a spectrum of diseases that were formerly all called chronic lymphoid leukemia has become apparent (Table 97-1). The acute leukemias were usually malignancies of blast cells with few identifying characteristics. When cytochemical stains became available, it was possible to divide these objectively into myeloid malignancies and acute leukemias of lymphoid cells. Acute leu-

TABLE 97-2 *Classification of Acute Lymphoid Leukemia (ALL)*

Immunologic Subtype	% of Cases	FAB Subtype	Cytogenetic Abnormalities
Pre-B ALL	75	L1, L2	t(9;22), t(4;11), t(1;19)
T cell ALL	20	L1, L2	14q11 or 7q34
B cell ALL	5	L3	t(8;14), t(8;22), t(2;8)

Note: FAB, French-American-British classification.

kemias of lymphoid cells have been subdivided based on morphologic characteristics by the French-American-British (FAB) group (Table 97-2). Using this system, lymphoid malignancies of small uniform blasts (e.g., typical childhood acute lymphoblastic leukemia) were called L1, lymphoid malignancies with larger and more variable size cells were called L2, and lymphoid malignancies of uniform cells with basophilic and sometimes vacuolated cytoplasm were called L3 (e.g., typical Burkitt's lymphoma cells). Acute leukemias of lymphoid cells have also been subdivided based on immunologic (i.e., T cell vs. B cell) and cytogenetic abnormalities (Table 97-2). Major cytogenetic subgroups include the t(9;22) (e.g., Philadelphia chromosome–positive acute lymphoblastic leukemia) and the t(8;14) found in the L3 or Burkitt's leukemia.

Non-Hodgkin's lymphomas were separated from Hodgkin's disease by recognition of the Sternberg-Reed cells early in the twentieth century. The histologic classification for non-Hodgkin's lymphomas was has been one of the most contentious issues in oncology. Imperfect morphologic systems were supplanted by imperfect immunologic systems, and poor reproducibility of diagnosis has hampered progress. In 1999, the World Health Organization (WHO) classification of lymphoid malignancies was devised through a process of consensus development among international leaders in hematopathology and clinical oncology. The WHO classification takes into account morphologic, clinical, immunologic, and genetic information and attempts to divide non-Hodgkin's lymphomas and other lymphoid malignancies into clinical/pathologic entities that have clinical and therapeutic relevance. This system is presented in Table 97-3. Clinical studies have shown that this new system is clinically relevant and has a higher degree of diagnostic accuracy than those used previously. The possibilities for subdividing lymphoid malignancies are extensive. However, Table 97-3 presents in bold those malignancies that occur in at least 1% of patients. Specific lymphoma subtypes will be dealt with in more detail below.

TABLE 97-3 *WHO Classification of Lymphoid Malignancies*

B Cell	T Cell	Hodgkin's Disease
Precursor B cell neoplasm	Precursor T cell neoplasm	Nodular lymphocyte-predominant Hodgkin's disease
Precursor B lymphoblastic leukemia/lymphoma (precursor B cell acute lymphoblastic leukemia)	**Precursor T lymphoblastic lymphoma/leukemia (precursor T cell acute lymphoblastic leukemia)**	
Mature (peripheral) B cell neoplasms	Mature (peripheral) T cell neoplasms	Classic Hodgkin's disease
B cell chronic lymphocytic leukemia/small lymphocytic lymphoma	T cell prolymphocytic leukemia	Nodular sclerosis Hodgkin's disease
B cell prolymphocytic leukemia	T cell granular lymphocytic leukemia	Lymphocyte-rich classic Hodgkin's disease
Lymphoplasmacytic lymphoma	Aggressive NK cell leukemia	Mixed-cellularity Hodgkin's disease
Splenic marginal zone B cell lymphoma (± villous lymphocytes)	Adult T cell lymphoma/leukemia (HTLV-I+)	Lymphocyte-depletion Hodgkin's disease
Hairy cell leukemia	Extranodal NK/T cell lymphoma, nasal type	
Plasma cell myeloma/plasmacytoma	Enteropathy-type T cell lymphoma	
Extranodal marginal zone B cell lymphoma of MALT type	Hepatosplenic $\gamma\delta$ T cell lymphoma	
Mantle cell lymphoma	Subcutaneous panniculitis-like T cell lymphoma	
Follicular lymphoma	**Mycosis fungoides/Sézary syndrome**	
Nodal marginal zone B cell lymphoma (± monocytoid B cells)	Anaplastic large cell lymphoma, primary cutaneous type	
Diffuse large B cell lymphoma	**Peripheral T cell lymphoma, not otherwise specified (NOS)**	
Burkitt's lymphoma/Burkitt cell leukemia	**Angioimmunoblastic T cell lymphoma**	
	Anaplastic large cell lymphoma, primary systemic type	

Note: HTLV, human T cell lymphotropic virus; MALT, mucosa-associated lymphoid tissue; NK, natural killer; WHO, World Health Organization.

GENERAL ASPECTS OF LYMPHOID MALIGNANCIES

ETIOLOGY AND EPIDEMIOLOGY Chronic lymphoid leukemia (CLL) is the most prevalent form of leukemia in western countries. It occurs most frequently in older adults and is exceedingly rare in children. In 2004, 8190 new cases were diagnosed in the United States, but because of the prolonged survival associated with this disorder, the total prevalence is many times higher. CLL is more common in men than in women and more common in whites than in blacks. This is an uncommon malignancy in Asia. The etiologic factors for typical CLL are unknown.

In contrast to CLL, acute lymphoid leukemias (ALLs) are predominantly cancers of children and young adults. The L3 or Burkitt's leukemia occurring in children in developing countries seems to be associated with infection by the Epstein-Barr virus (EBV) in infancy. However, the explanation for the etiology of more common subtypes of ALL is much less certain. Childhood ALL occurs more often in higher socioeconomic subgroups. Children with trisomy 21 (Down's syndrome) have an increased risk for childhood acute lymphoblastic leukemia as well as acute myeloid leukemia. Exposure to high-energy radiation in early childhood increases the risk of developing T cell acute lymphoblastic leukemia.

The etiology of ALL in adults is also uncertain. ALL is unusual in middle-aged adults but increases in incidence in the elderly. However, acute myeloid leukemia is still much more common in older patients. Environmental exposures including certain industrial exposures, exposure to agricultural chemicals, and smoking might increase the risk of developing ALL as an adult.

The preponderance of evidence suggests that Hodgkin's disease is of B cell origin. The incidence of Hodgkin's disease appears fairly stable, with ~7800 new cases diagnosed in 2004 in the United States. Hodgkin's disease is more common in whites than in blacks and more common in males than in females. A bimodal distribution of age at diagnosis has been observed, with one peak incidence occurring in patients in their 20s and the other in those in their 80s.

Some of the late age peak may be attributed to confusion among entities with similar appearance such as anaplastic large cell lymphoma and T cell–rich B cell lymphoma. Patients in the younger age groups diagnosed in the United States largely have the nodular sclerosing subtype of Hodgkin's disease. Elderly patients, patients infected with HIV, and patients in third world countries more commonly have mixed-cellularity Hodgkin's disease or lymphocyte-depleted Hodgkin's disease. Infection by HIV is a risk factor for developing Hodgkin's disease. In addition, an association between infection by EBV and Hodgkin's disease has been demonstrated. A monoclonal or oligoclonal proliferation of EBV-infected cells in 20 to 40% of the patients with Hodgkin's disease has led to proposals for this virus having an etiologic role in Hodgkin's disease. However, the matter is not settled definitively.

For unknown reasons, non-Hodgkin's lymphomas increased in frequency in the United States at the rate of 4% per year between 1950 and the late 1990s. For uncertain reasons, the rate of increase in the past few years seems to be decreasing. About 54,000 new cases of non-Hodgkin's lymphoma were diagnosed in the United States in the year 2004. Non-Hodgkin's lymphomas are more frequent in the elderly and more frequent in men. Patients with both primary and secondary immunodeficiency states are predisposed to developing non-Hodgkin's lymphomas. These include patients with HIV infection; patients who have undergone organ transplantation; and patients with inherited immune deficiencies, the sicca syndrome, and rheumatoid arthritis.

The incidence of non-Hodgkin's lymphomas and the patterns of expression of the various subtypes differ geographically. T cell lymphomas are more common in Asia than in western countries, while certain subtypes of B cell lymphomas such as follicular lymphoma are more common in western countries. A specific subtype of non-Hodgkin's lymphoma known as the angiocentric nasal T/natural killer (NK) cell lymphoma has a striking geographic occurrence, being most frequent in Southern Asia and parts of Latin America. Another subtype of non-Hodgkin's lymphoma associated with infection by human T cell lymphotropic virus (HTLV) I is seen particularly in southern Japan and the Caribbean (Chap. 172).

A number of environmental factors have been implicated in the occurrence of non-Hodgkin's lymphoma, including infectious agents, chemical exposures, and medical treatments. Several studies have demonstrated an association between exposure to agricultural chemicals and an increased incidence in non-Hodgkin's lymphoma. Patients treated for Hodgkin's disease can develop non-Hodgkin's lymphoma; it is unclear whether this is a consequence of the Hodgkin's disease or its treatment. However, the infectious etiology of non-Hodgkin's lymphoma is the area where evidence has been expanding most rapidly in recent years. Table 97-4 illustrates those infectious agents associated with the development of non-Hodgkin's lymphoma. HTLV-I infects T cells and leads directly to the development of adult T cell lymphoma (ATL) in a small percentage of infected patients. The cumulative lifetime risk of developing lymphoma in an infected patient is 2.5%. The virus is transmitted by infected lymphocytes ingested by nursing babies of infected mothers, blood-borne transmission, or sexually. The median age of patients with ATL is about 56 years, emphasizing the long latency. HTLV-I is also the cause of tropical spastic paraparasis—a neurologic disorder that occurs somewhat more frequently than lymphoma and with shorter latency.

EBV is associated with the development of Burkitt's lymphoma in Central Africa and the occurrence of aggressive non-Hodgkin's lymphomas in immunosuppressed patients in western countries. The majority of primary central nervous system (CNS) lymphomas are associated with EBV. EBV infection is strongly associated with the occurrence of extranodal nasal T/NK cell lymphomas in Asia and South America. Infection with HIV predisposes to the development of aggressive, B cell non-Hodgkin's lymphoma. This may be through overexpression of interleukin 6 by infected macrophages. Infection of the stomach by the bacterium *Helicobacter pylori* induces the development of gastric MALT (mucosa-associated lymphoid tissue) lymphomas. This association is supported by evidence that patients treated with antibiotics to eradicate *H. pylori* have regression of their MALT lymphoma. The bacterium does not transform lymphocytes to produce the lymphoma; instead, a vigorous immune response is made to the bacterium and the chronic antigenic stimulation leads to the neoplasia. MALT lymphomas of the skin may be related to *Borrelia* sp. infections.

Chronic hepatitis C virus infection has been associated with the development of lymphoplasmacytic lymphoma. Human herpesvirus 8 is associated with primary effusion lymphoma in HIV-infected persons and multicentric Castleman's disease, a diffuse lymphadenopathy associated with systemic symptoms of fever, malaise, and weight loss.

In addition to infectious agents, a number of other diseases or exposures may predispose to developing lymphoma (Table 97-5).

IMMUNOLOGY All lymphoid cells are derived from a common hematopoietic progenitor that gives rise to lymphoid, myeloid, erythroid, monocyte, and megakaryocyte lineages. Through the ordered and sequential activation of a series of transcription factors, the cell first becomes committed to the lymphoid lineage and then gives rise to B and T cells. About 75% of all lymphoid leukemias and 90% of all lymphomas are of B cell origin. A cell becomes committed to B cell development when it begins to rearrange its immunoglobulin genes. The sequence of cellular changes, including changes in cell-surface phenotype, that characterizes normal B cell development is shown in Fig. 97-1. A cell becomes committed to T cell differentiation upon migration to the thymus and rearrangement of T cell antigen receptor genes. The sequence of the events that characterize T cell development is depicted in Fig. 97-2.

Although lymphoid malignancies often retain the cell-surface phenotype of lymphoid cells at particular stages of differentiation, this information is of little consequence. The so-called stage of differentiation of a malignant lymphoma does not predict its natural history. For example, the clinically most aggressive lymphoid leukemia is

TABLE 97-4 *Infectious Agents Associated with the Development of Lymphoid Malignancies*

Infectious Agent	*Lymphoid Malignancy*
Epstein-Barr virus	Burkitt's lymphoma
	Post–organ transplant lymphoma
	Primary CNS diffuse large B cell lymphoma
	Hodgkin's disease
	Extranodal NK/T cell lymphoma, nasal type
HTLV-I	Adult T cell leukemia/lymphoma
HIV	Diffuse large B cell lymphoma
	Burkitt's lymphoma
Hepatitis C virus	Lymphoplasmacytic lymphoma
Helicobacter pylori	Gastric MALT lymphoma
Human herpesvirus 8	Primary effusion lymphoma
	Multicentric Castleman's disease

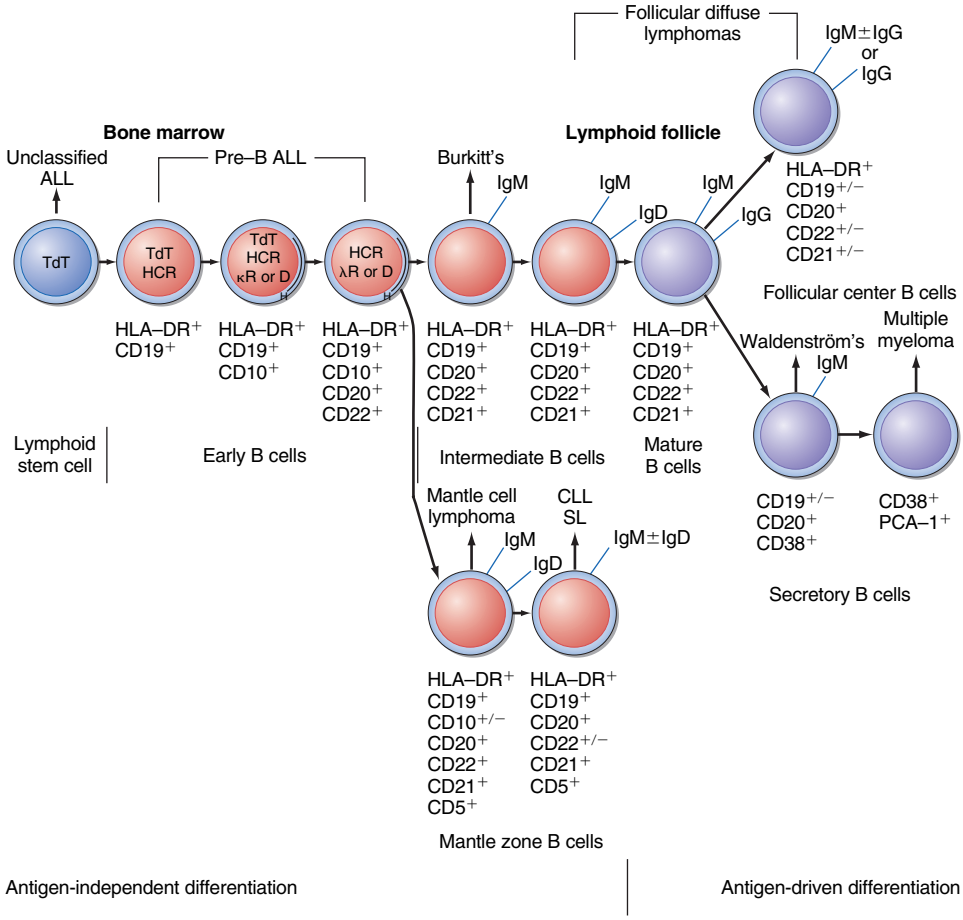

FIGURE 97-1 Pathway of normal B cell differentiation and relationship to B cell lymphomas. HLA-DR, CD10, CD19, CD20, CD21, CD22, CD5, and CD38 are cell markers used to distinguish stages of development. Terminal transferase (TdT) is a cellular enzyme. Immunoglobulin heavy chain gene rearrangement (HCR) and light chain gene rearrangement or deletion (κ R or D, λ R or D) occur early in B cell development. The approximate normal stage of differentiation associated with particular lymphomas is shown. ALL, acute lymphoid leukemia; CLL, chronic lymphoid leukemia; SL, small lymphocytic lymphoma.

Burkitt's leukemia, which has the phenotype of a mature follicle center IgM-bearing B cell. Leukemias bearing the immunologic cell-surface phenotype of more primitive cells (e.g., pre-B ALL, CD10+) are less aggressive and more amenable to curative therapy than the "more mature" appearing Burkitt's leukemia cells. Furthermore, the apparent stage of differentiation of the malignant cell does not reflect the stage at which the genetic lesions that gave rise to the malignancy developed. For example, follicular lymphoma has the cell-surface phenotype of a follicle center cell, but its characteristic chromosomal translocation, the t(14;18), which involves juxtaposition of the anti-apoptotic *bcl-2* gene next to the immunoglobulin heavy chain gene (see below), had to develop early in ontogeny as an error in the process of immunoglobulin gene rearrangement. Why the subsequent steps that led to transformation became manifest in a cell of follicle center differentiation is not clear.

The major value of cell-surface phenotyping is to aid in the differential diagnosis of lymphoid tumors that appear similar by light microscopy. For example, benign follicular hyperplasia may resemble follicular lymphoma; however, the demonstration that all the cells bear the same immunoglobulin light chain isotype strongly suggests the mass is a clonal proliferation rather than a polyclonal response to an exogenous stimulus.

GENETIC CONSIDERATIONS Malignancies of lymphoid cells are associated with recurring genetic abnormalities. While specific genetic abnormalities have not been identified for all subtypes of lymphoid malignancies, it is presumed that they exist. Genetic abnormalities can be identified at a variety of levels including gross chromosomal changes (i.e., translocations, additions, or deletions); rearrangement of specific genes that may or may not be apparent from cytogenetic studies; and overexpression, underexpression, or mutation of specific oncogenes. Altered expression or mutation of specific proteins is particularly important. Many lymphomas contain balanced chromosomal translocations involving the antigen receptor genes; immunoglobulin genes on chromosomes 2, 14, and 22 in B cells; and T cell antigen receptor genes on chromosomes 7 and 14 in T cells. The rearrangement of chromosome segments to generate mature antigen receptors must create a site of vulnerability to aberrant recombination. B cells are even more susceptible to acquiring mutations during their maturation in germinal centers; the generation of antibody of higher affinity requires the introduction of mutations into the variable region genes in the germinal centers. Other nonimmunoglobulin genes, for example *bcl-6*, may acquire mutations as well.

In the case of diffuse large B cell lymphoma, the translocation t(14;18) occurs in ~30% of patients and leads to overexpression of the *bcl-2* gene found on chromosome 18. Some other patients without the translocation also overexpress the BCL-2 protein. This protein is involved in suppressing apoptosis—i.e., the mechanism of cell death most often induced by cytotoxic chemotherapeutic agents. A higher relapse rate has been observed in patients whose tumors overexpress the BCL-2 protein, but not in those patients whose lymphoma cells show only the translocation. Thus, particular genetic mechanisms have clinical ramifications.

Table 97-6 presents the best documented translocations and associated oncogenes for various subtypes of lymphoid malignancies. In some cases, such as the association of the t(14;18) in follicular lymphoma, the t(2;5) in anaplastic large T/null-cell lymphoma, the t(8;14) in Burkitt's lymphoma, and the t(11;14) in mantle cell lymphoma, the great majority of tumors in patients with these diagnoses display these abnormalities. In other types of lymphoma where a minority of the patients have tumors expressing specific genetic abnormalities, the defects may have prognostic significance. No specific genetic abnormalities have been identified in Hodgkin's disease other than aneuploidy.

In typical B cell CLL, trisomy 12 conveys a poorer prognosis. In ALL in both adults and children, genetic abnormalities have important prognostic significance. Patients whose tumor cells display the t(9;22) have a much poorer outlook than patients who do not have this translocation. Other genetic abnormalities that occur frequently in adults with ALL include the t(4;11) and the t(8;14). The t(4;11) is associated with younger age, female predominance, high white cell counts, and L1 morphology. The t(8;14) is associated with older age, male predominance, frequent CNS involvement, and L3 morphology. Both are associated with a poor prognosis. In childhood ALL, hyperdiploidy has been shown to have a favorable prognosis.

Gene profiling using array technology allows the simultaneous assessment of the expression of thousands of genes. This technology provides the possibility to identify new genes with pathologic importance in lymphomas, the identification of patterns of gene expression with diagnostic and/or prognostic significance, and the identification

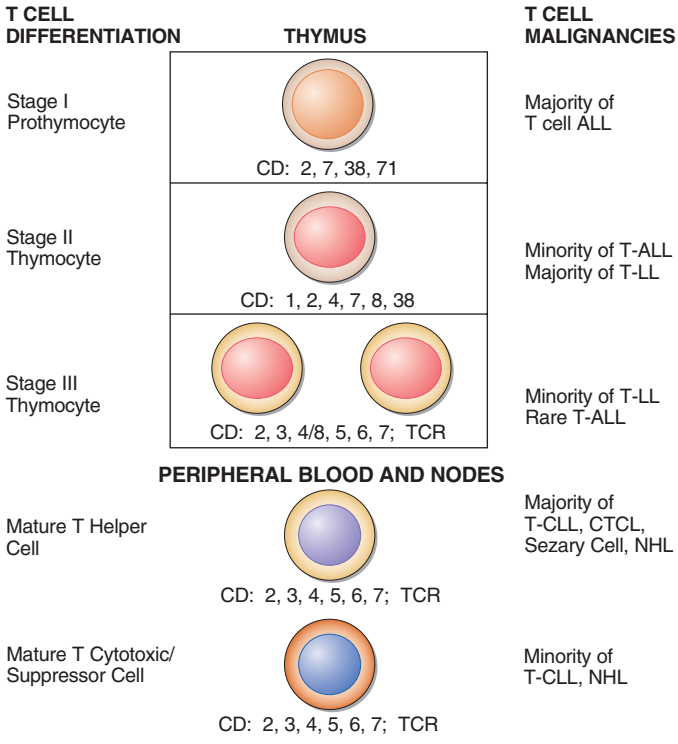

FIGURE 97-2 Pathway of normal T cell differentiation and relationship to T cell lymphomas. CD1, CD2, CD3, CD4, CD5, CD6, CD7, CD8, CD38, and CD71 are cell markers used to distinguish stages of development. T cell antigen receptors (TCR) rearrange in the thymus, and mature T cells emigrate to nodes and peripheral blood. ALL, acute lymphoid leukemia; T-ALL, T cell ALL; T-LL, T cell lymphoblastic lymphoma; T-CLL, T cell chronic lymphoid leukemia; CTCL, cutaneous T cell lymphoma; NHL, non-Hodgkin's lymphoma.

of new therapeutic targets. Recognition of patterns of gene expression is complicated and requires sophisticated mathematical techniques. Early successes using this technology in lymphoma include the identification of previously unrecognized subtypes of diffuse large B cell lymphoma whose gene expression patterns resemble either those of follicular center B cells or activated peripheral blood B cells (Fig. 97-3). Patients whose lymphomas have a germinal center B cell pattern of gene expression have a considerably better prognosis than those whose lymphomas have a pattern resembling that seen in activated peripheral blood B cells. This improved prognosis is independent of other known prognostic factors and provides the opportunity to identify better treatments for these subgroups of patients. Similar information is being generated in follicular lymphoma and mantle cell lymphoma. The challenge remains to provide information from such techniques in a clinically useful time frame.

TABLE 97-6 *Cytogenetic Translocation and Associated Oncogenes Often Seen in Lymphoid Malignancies*

Disease	*Cytogenetic Abnormality*	*Oncogene*
CLL/small lymphocytic lymphoma	t(14;15)(q32;q13)	—

[a] Numerous sites of translocation may be involved with these genes.
Note: CLL, chronic lymphoid leukemia; MALT, mucosa-associated lymphoid tissue; IgH, immunoglobulin heavy chain.

APPROACH TO THE PATIENT

Regardless of the type of lymphoid malignancy, the initial evaluation of the patient should include performance of a careful history and physical examination. These will help confirm the diagnosis, identify those manifestations of the disease that might require prompt attention, and aid in the selection of further studies to optimally characterize the patient's status to allow the best choice of therapy. It is difficult to overemphasize the importance of a carefully done history and physical examination. They might provide observations that lead to reconsidering the diagnosis, provide hints at etiology, clarify the stage, and allow the physician to establish rapport with the patient that will make it possible to develop and carry out a therapeutic plan.

For patients with ALL, evaluation is usually completed after a complete blood count, chemistry studies reflecting major organ function, a bone marrow biopsy with genetic and immunologic studies, and a lumbar puncture. The latter is necessary to rule out occult CNS involvement. At this point, most patients would be ready to begin therapy. In ALL, prognosis is dependent upon the genetic characteristics of the tumor, the patient's age, the white cell count, and the patient's overall clinical status and major organ function.

In CLL, the patient evaluation should include a complete blood count, chemistry tests to measure major organ function, serum protein electrophoresis, and a bone marrow biopsy. However, some physicians believe that the diagnosis would not always require a bone marrow biopsy. Patients often have imaging studies of the chest and abdomen looking for pathologic lymphadenopathy. Patients with typical B cell CLL can be subdivided into three major prognostic groups. Those patients with only blood and bone marrow involvement by leukemia but no lymphadenopathy, organomegaly, or signs of bone marrow failure have the best prognosis. Those with lymphadenopathy and organomegaly have an intermediate prognosis, and patients with bone marrow failure, defined as hemoglobin $<$100 g/L (10 g/dL) or platelet count $<$100,000/μL, have the worst prognosis. The pathogenesis of the anemia or thrombocytopenia is important to discern. The prognosis is adversely affected when either or both of these abnormalities are due to progressive marrow infiltration and loss of productive marrow. However, either or both may be due to autoimmune phenomena or to hypersplenism that can develop during the course of the disease. These destructive mechanisms are usually completely reversible (glucocorticoids for autoimmune disease; splenectomy for hypersplenism) and do not influence disease prognosis.

Two popular staging systems have been developed to reflect these prognostic groupings (Table 97-7). Patients with typical B cell CLL can have their course complicated by immunologic abnormalities including autoimmune hemolytic anemia, autoimmune thrombocytopenia, and hypogammaglobulinemia. Patients with hypogammaglobulinemia benefit from regular (monthly) γ globulin administration. Because of expense, γ globulin is often withheld until the patient experiences a significant infection. These abnormalities do not have a clear prognostic significance and should not be used to assign a higher stage.

The initial evaluation of a patient with Hodgkin's disease or non-Hodgkin's lymphoma is similar. In both situations, the determination of an accurate anatomic stage is an important part of the evaluation. The staging system is the Ann Arbor staging system originally developed for Hodgkin's disease (Table 97-8).

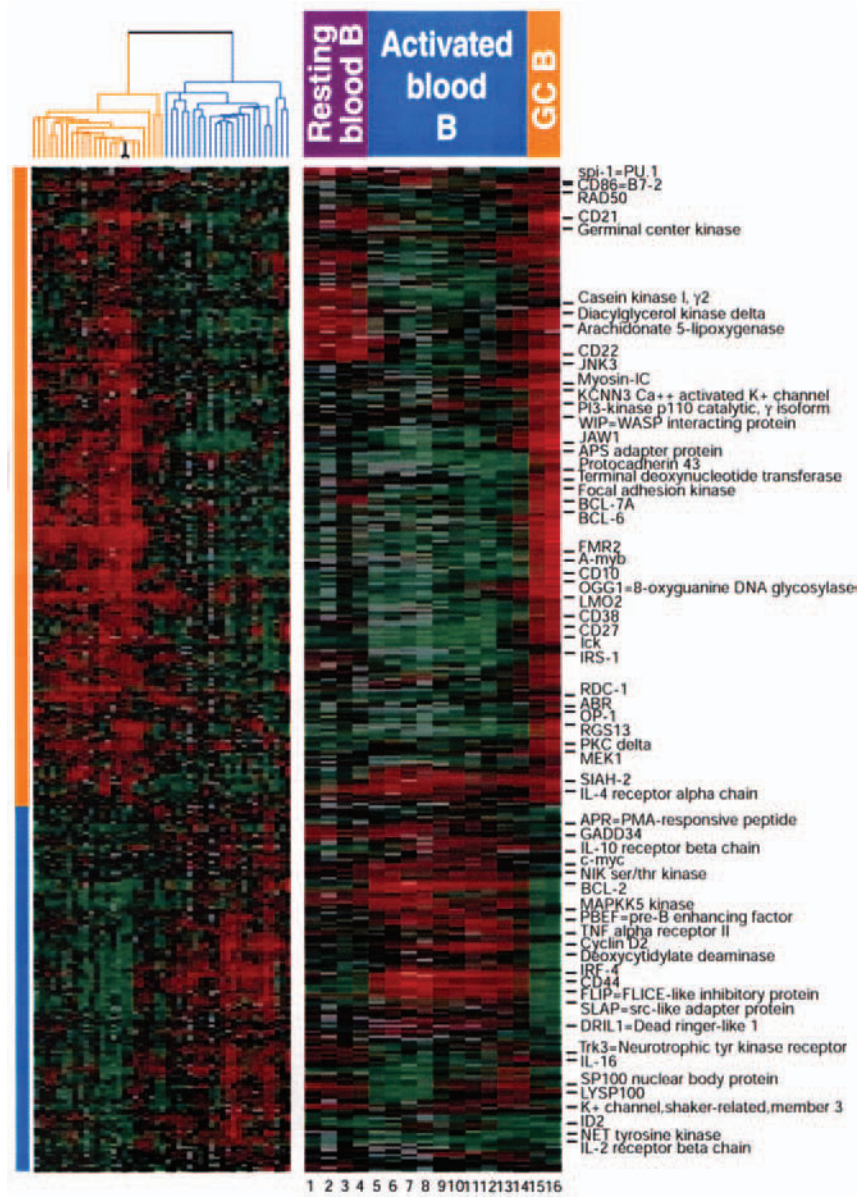

FIGURE 97-3 Relationship of different gene expression patterns to outcome of treatment for diffuse large B cell lymphoma. The top panel reveals the pattern of expression of a large number of lymphocyte-expressed genes in tumors from patients with diffuse large B cell lymphoma, a lymphoma recognized as morphologically heterogeneous but before now not classifiable reproducibly. Two dominant patterns are seen, one mimicking germinal center B cells and one mimicking activated peripheral blood B cells. The bottom panels show the relationship between gene expression pattern and clinical outcome. *A*. Kaplan-Meier survival plots of all patients according to gene profile showing significant differences between follicular center and activated B cell types. *B*. Kaplan-Meier survival of patients based upon the IPI scores. *C*. Kaplan-Meier survival plots showing that among patients with IPI low risk, the gene expression profile has prognostic significance. (IPI, International Prognostic Index.)

TABLE 97-7 *Staging of Typical B Cell Lymphoid Leukemia*

Stage	Clinical Features	Median Survival, Years
RAI SYSTEM		
0: Low risk	Lymphocytosis only in blood and marrow	>10
I: Intermediate risk	Lymphocytosis + lymphadenopathy + splenomegaly ± hepatomegaly	7
II		
III: High risk	Lymphocytosis + anemia	1.5
IV	Lymphocytosis + thrombocytopenia	
BINET SYSTEM		
A	Fewer than three areas of clinical lymphadenopathy; no anemia or thrombocytopenia	>10
B	Three or more involved node areas; no anemia or thrombocytopenia	7
C	Hemoglobin ≤10 g/dL and/or platelets <100,000/μl	2

Evaluation of patients with Hodgkin's disease will typically include a complete blood count; erythrocyte sedimentation rate; chemistry studies reflecting major organ function; computed tomography (CT) scans of the chest, abdomen, and pelvis; and a bone marrow biopsy. Neither a positron emission tomography (PET) scan nor a gallium scan is absolutely necessary for primary staging, but one performed at the completion of therapy allows evaluation of persisting radiographic abnormalities, particularly the mediastinum. Knowing that the PET scan or gallium scan is abnormal before treatment is initiated can help in this assessment. In most cases, these studies will allow assignment of anatomic stage and the development of a therapeutic plan.

In patients with non-Hodgkin's lymphoma, the same evaluation described for patients with Hodgkin's disease is usually carried out. In addition, serum levels of lactate dehydrogenase (LDH) and β_2-microglobulin and serum protein electrophoresis are often included in the evaluation. Anatomic stage is assigned in the same manner as used for Hodgkin's disease. However, the prognosis of patients with non-Hodgkin's lymphoma is best assigned using the International Prognostic Index (IPI) (Table 97-9). This is a powerful predictor of outcome in all subtypes of non-Hodgkin's lymphoma. Patients are assigned an IPI score based on the presence or absence of five adverse prognostic factors and may have none or all five of these adverse prognostic factors. Figure 97-4 shows the prognostic significance of this score in 1300 patients with all types of non-Hodgkin's lymphoma. CT scans are routinely used in the evaluation of patients with all subtypes of non-Hodgkin's lymphoma but PET and gallium scans are much more useful in aggressive subtypes such as diffuse large B cell lymphoma than in more indolent subtypes such a follicular lymphoma or small lymphocytic lymphoma.

TABLE 97-8 *The Ann Arbor Staging System for Hodgkin's Disease*

Stage	Definition
I	Involvement of a single lymph node region or lymphoid structure (e.g., spleen, thymus, Waldeyer's ring)
II	Involvement of two or more lymph node regions on the same side of the diaphragm (the mediastinum is a single site; hilar lymph nodes should be considered "lateralized" and, when involved on both sides, constitute stage II disease)
III	Involvement of lymph node regions or lymphoid structures on both sides of the diaphragm
III_1	Subdiaphragmatic involvement limited to spleen, splenic hilar nodes, celiac nodes, or portal nodes
III_2	Subdiaphragmatic involvement includes paraaortic, iliac, or mesenteric nodes plus structures in III_1
IV	Involvement of extranodal site(s) beyond that designated as "E"
	More than one extranodal deposit at any location
	Any involvement of liver or bone marrow
A	No symptoms
B	Unexplained weight loss of >10% of the body weight during the 6 months before staging investigation
	Unexplained, persistent, or recurrent fever with temperatures >38°C during the previous month
	Recurrent drenching night sweats during the previous month
E	Localized, solitary involvement of extralymphatic tissue, excluding liver and bone marrow

TABLE 97-9 *International Prognostic Index for NHL*

Five clinical risk factors:
- Age ≥ 60 years
- Serum lactate dehydrogenase levels elevated
- Performance status ≥ 2 (ECOG) or ≤ 70 (Karnofsky)
- Ann Arbor stage III or IV
- >1 site of extranodal involvement

Patients are assigned a number for each risk factor they have
Patients are grouped differently based upon the type of lymphoma
For diffuse large B cell lymphoma:

0,1 factor = low risk	35% of cases; 5-year survival, 73%
2 factors = low-intermediate risk	27% of cases; 5-year survival, 51%
3 factors = high-intermediate risk	22% of cases; 5-year survival, 43%
4,5 factors = high risk	16% of cases; 5-year survival, 26%

CLINICAL FEATURES, TREATMENT, AND PROGNOSIS OF SPECIFIC LYMPHOID MALIGNANCIES

PRECURSOR CELL B CELL NEOPLASMS ■ Precursor B Cell Lymphoblastic Leukemia/Lymphoma The most common cancer in childhood is B cell ALL. Although this disorder can also present as a lymphoma in either adults or children, presentation as lymphoma is quite rare.

The malignant cells in patients with precursor B cell lymphoblastic leukemia are most commonly of pre-B cell origin. Patients typically present with signs of bone marrow failure such as pallor, fatigue, bleeding, fever, and infection related to peripheral blood cytopenias. Peripheral blood counts regularly show anemia and thrombocytopenia but might show leukopenia, a normal leukocyte count, or leukocytosis based largely on the number of circulating malignant cells (Fig. 97-5). Extranodal sites of disease are frequently involved in patients who

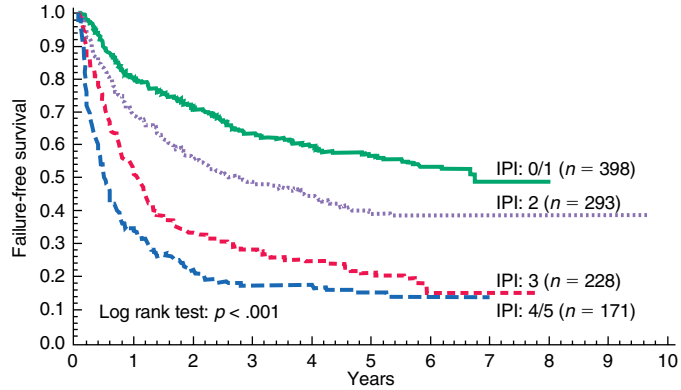

FIGURE 97-4 Relationship of International Prognostic Index (IPI) to survival. Kaplan-Meier survival curves for 1300 patients with various kinds of lymphoma stratified according to the IPI.

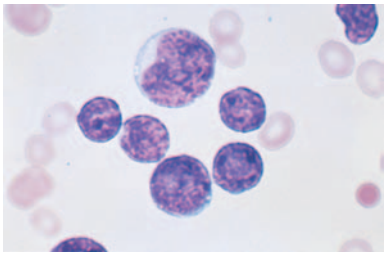

FIGURE 97-5 Acute lymphoblastic leukemia. The cells are heterogeneous in size, have round or convoluted nuclei, high nuclear/cytoplasmic ratio, and absence of cytoplasmic granules.

present with leukemia, which might be manifested by lymphadenopathy, hepato- or splenomegaly, CNS disease, testicular enlargement, and/or cutaneous infiltration.

The diagnosis is usually made by bone marrow biopsy, which shows infiltration by malignant lymphoblasts. Demonstration of a pre-B cell immunophenotype (Fig. 97-1) and, often, characteristic cytogenetic abnormalities (Table 97-6) confirm the diagnosis. An adverse prognosis in patients with precursor B cell ALL is predicted by a very high white cell count, the presence of symptomatic CNS disease, and unfavorable cytogenetic abnormalities. For example, t(9;22) is frequently found in adults with B cell lymphoblastic leukemia and is associated with a very poor outlook.

TREATMENT

The treatment of patients with precursor B cell lymphoblastic leukemia involves remission induction with combination chemotherapy, a consolidation phase that includes administration of high-dose systemic therapy and treatment to eliminate disease in the CNS, and a period of continuing therapy to prevent relapse and effect cure. The overall cure rate in children is 85%, while about 50% of adults are long-term disease-free survivors. This reflects the high proportion of adverse cytogenetic abnormalities seen in adults with precursor B cell lymphoblastic leukemia.

Precursor B cell lymphoblastic lymphoma is a rare presentation of precursor B cell lymphoblastic malignancy. These patients often have a rapid transformation to leukemia, and similar treatment approaches as are used in patients presenting with leukemia are appropriate. In the few patients who present with the disease confined to lymph nodes, a high cure rate has been reported.

MATURE (PERIPHERAL) B CELL NEOPLASMS ■ B Cell Chronic Lymphoid Leukemia/Small Lymphocytic Lymphoma B cell CLL/small lymphocytic lymphoma represents by far the most common lymphoid leukemia, and when presenting as a lymphoma, it accounts for ~7% of non-Hodgkin's lymphomas. As the name implies, presentation can be as either leukemia or lymphoma. The major clinical characteristics of B cell CLL/small lymphocytic lymphoma are presented in Table 97-10.

The diagnosis of typical B cell CLL is made when an increased number of circulating lymphocytes (i.e., $>4 \times 10^9$/L and usually $>10 \times 10^9$/L) is found (Fig. 97-6) that are monoclonal B cells and display the CD5 antigen. Finding bone marrow infiltration by the same cells confirms the diagnosis. The peripheral blood smear in such patients typically shows many "smudge" or "basket" cells, nuclear remnants of cells damaged by the physical shear stress of making the blood smear. If cytogenetic studies are performed, trisomy 12 is found in ~25 to 30% of patients. Abnormalities in chromosome 13 are also seen.

If the primary presentation is lymphadenopathy and a lymph node biopsy is performed, pathologists usually have little difficulty in making the diagnosis of small lymphocytic lymphoma based on morphologic findings and immunophenotype. However, even in these patients, ~70 to 75% will be found to have bone marrow involvement and the search for circulating monoclonal B lymphocytes is often positive.

The differential diagnosis of typical B cell CLL is extensive and presented in Table 97-1. Immunophenotyping will eliminate the T cell disorders and can often help sort out other B cell malignancies. For example, only mantle cell lymphoma and typical B cell CLL are usually CD5 positive. Typical B cell small lymphocytic lymphoma can be confused with other B cell disorders including lymphoplasmacytic lymphoma (i.e., the tissue manifestation of Waldenström's macroglobulinemia), nodal marginal zone B cell lymphoma, and mantle cell lymphoma. In addition, some small lymphocytic lymphomas have areas of large cells that can lead to confusion with diffuse large B cell lymphoma. An expert hematopathologist is vital for making this distinction.

Typical B cell CLL is often found incidentally when a complete blood count is done for another reason. However, complaints that might lead to the diagnosis include fatigue, frequent infections, and new lymphadenopathy. The diagnosis of typical B cell CLL should be considered in a patient presenting with an autoimmune hemolytic anemia or autoimmune thrombocytopenia. B cell CLL has also been associated with red cell aplasia. When this disorder presents as lymphoma, the most common abnormality is asymptomatic new lymphadenopathy, with or without splenomegaly. The staging systems used to predict prognosis in patients with typical B cell CLL are presented in Table 97-7. The IPI for non-Hodgkin's lymphomas, which also predicts prognosis in these patients, is presented in Table 97-9. The evaluation of a new patient with typical B cell CLL/small lym-

TABLE 97-10 *Clinical Characteristics of Patients with Common Types of Non-Hodgkin's Lymphomas (NHL)*

Disease	Median Age, years	Frequency in Children	% Male	Stage I/II vs III/IV, %	B Symptoms, %	Bone Marrow Involvement, %	Gastrointestinal Tract Involvement, %	% Surviving 5 years
B cell chronic lymphocytic leukemia/small lymphocytic lymphoma	65	Rare	53	9 vs 91	33	72	3	51
Mantle cell lymphoma	63	Rare	74	20 vs 80	28	64	9	27

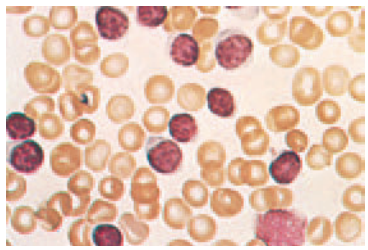

FIGURE 97-6 Chronic lymphocytic leukemia. The peripheral white blood cell count is high due to increased numbers of small, well-differentiated, normal-appearing lymphocytes. The leukemia lymphocytes are fragile, and substantial numbers of broken, smudged cells are usually also present on the blood smear.

phocytic lymphoma will include many of the studies included in Table 97-11, which describes the initial evaluation of a new patient with non-Hodgkin's lymphoma. In addition, particular attention needs to be given to detecting immune abnormalities such as autoimmune hemolytic anemia, autoimmune thrombocytopenia, hypogammaglobulinemia, and red cell aplasia. Molecular analysis of immunoglobulin gene sequences in CLL has demonstrated that about half the patients have tumors expressing mutated immunoglobulin genes and half have tumors expressing unmutated or germ-line immunoglobulin sequences. Patients with unmutated immunoglobulins tend to have a more aggressive clinical course and are less responsive to therapy. Unfortunately, immunoglobulin gene sequencing is not routinely available. CD38 expression is said to be low in the better-prognosis patients expressing mutated immunoglobulin and high in poorer-prognosis patients expressing unmutated immunoglobulin, but this test has not been confirmed as a reliable means of distinguishing the two groups.

TREATMENT

Patients whose presentation is typical B cell CLL with no manifestations of the disease other than bone marrow involvement and lymphocytosis (i.e., Rai stage O and Binet stage A; Table 97-7) can be followed without specific therapy for their malignancy. These patients have a median survival >10 years, and some will never require therapy for this disorder. If the patient has an adequate number of circulating normal blood cells and is asymptomatic, many physicians would not initiate therapy for patients in the intermediate stage of the disease manifested by lymphadenopathy and/or hepatosplenomegaly. However, the median survival for these patients is ~7 years, and most will require treatment in the first few years of follow-up. Patients who present with bone marrow failure (i.e., Rai stage III or IV or Binet stage C) will require initial therapy in almost all cases. These patients have a serious disorder with a median survival of only 1.5 years. It must be remembered that immune manifestations of typical B cell CLL should be managed independently of specific antileukemia therapy. For example, glucocorticoid therapy for autoimmune cytopenias and γ globulin replacement for patients with hypogammaglobulinanemia should be used whether or not antileukemia therapy is given.

Patients who present primarily with lymphoma and have a low IPI score have a 5-year survival of ~75%, but those with a high IPI score have a 5-year survival of <40% and are more likely to require early therapy.

The most common treatments for patients with typical B cell CLL/small lymphocytic lymphoma have been single-agent chlorambucil or fludarabine alone or in combination. Chlorambucil can be administered orally with few immediate side effects, while fludarabine is administered intravenously and is associated with significant immune suppression. However, fludarabine is by far the more active agent and is the only drug associated with a significant incidence of complete remission. The combination of rituximab (375 to 500 mg/m^2 day 1), fludarabine (25 mg/m^2 days 2 to 4 on cycle 1 and 1 to 3 in subsequent cycles), and cyclophosphamide (250 mg/m^2 with fludarabine) achieves complete responses in 69% of patients and those responses are associated with molecular remissions in half of the cases. Half the patients experience grade III or IV neutropenia. For young patients presenting with leukemia requiring therapy, regimens containing fludarabine are today the treatment of choice. Because fludarabine is an effective second-line agent in patients with tumors unresponsive to chlorambucil, the latter agent is often chosen in elderly patients who require therapy. Many patients who present with lymphoma will receive a combination chemotherapy regimen used in other lymphomas such as CVP (cyclophosphamide, vincristine, and prednisone), or CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone) although fludarabine-containing regimens may be preferrable. Alemtuzimab (anti-CD52) is another antibody with activity in the disease, but it kills both B and T cells and is associated with more immune compromise that rituximab. Young patients with this disease can be candidates for bone marrow transplantation. Allogeneic bone marrow transplantation can be curative but is associated with a significant treatment-related mortality. The use of autologous transplantation in patients with this disorder has been discouraging.

Gallium scan (SPECT) or PET scan in large-cell lymphoma

Note: CT, computed tomography; SPECT, single photon emission CT; PET, position emission tomography.

Extranodal Marginal Zone B Cell Lymphoma of MALT Type Extranodal marginal zone B cell lymphoma of MALT type makes up ~8% of non-Hodgkin's lymphomas. This small-cell lymphoma presents in extranodal sites. It was previously considered a small lymphocytic lymphoma or sometimes a pseudolymphoma. The recognition that the gastric presentation of this lymphoma was associated with *H. pylori* infection was an important step in recognizing it as a separate entity. The clinical characteristics of extranodal marginal zone B cell lymphoma of MALT type are presented in Table 97-10.

The diagnosis of extranodal marginal zone B cell lymphoma of MALT type can be made accurately by an expert hematopathologist based on a characteristic pattern of infiltration of small lymphocytes that are monoclonal B cells and CD5 negative. In some cases, transformation to diffuse large B cell lymphoma occurs, and both diagnoses may be made in the same biopsy. The differential diagnosis includes benign lymphocytic infiltration of extranodal organs and other small-cell B cell lymphomas.

Extranodal marginal zone B cell lymphoma of MALT type may occur in the stomach, orbit, intestine, lung, thyroid, salivary gland, skin, soft tissues, bladder, kidney, and CNS. It may present as a new mass, be found on routine imaging studies, or be associated with local symptoms such as upper abdominal discomfort in gastric lymphoma. Most MALT lymphomas are gastric in origin. At least two genetic forms of gastric MALT exist: one (accounting for ~50% of cases) characterized by t(11;18)(q21;q21) that juxtaposes the amino terminal of the *API2* gene with the carboxy terminal of the *MALT1* gene creating an API2/MALT1 fusion product, and the other characterized by multiple sites of genetic instability including trisomies of chromosomes 3, 7, 12, and 18. Ninety-five percent of gastric MALT lymphomas are associated with *H. pylori* infection, and those that are not usually express t(11;18). The t(11;18) usually results in activation of NF-κB, which acts a survival factor for the cells. Lymphomas with t(11;18) translocations are genetically stable and do not evolve to diffuse large B cell lymphoma. By contrast, t(11;18)-negative MALT

lymphomas often acquire *BCL6* mutations and progress to aggressive histology lymphoma. MALT lymphomas are localized to the organ of origin in ~40% of cases and to the organ and regional lymph nodes in ~30% of patients. However, distant metastasis can occur—particularly with transformation to diffuse large B cell lymphoma. Many patients who develop this lymphoma will have an autoimmune or inflammatory process such as Sjögren's syndrome (salivary gland MALT), Hashimoto's thyroiditis (thyroid MALT), or *Helicobacter* gastritis (gastric MALT).

Evaluation of patients with extranodal marginal zone B cell lymphoma of MALT type follows the pattern set forth in Table 97-11 for staging a patient with non-Hodgkin's lymphoma. In particular, patients with gastric lymphoma need to have studies performed to document the presence or absence of *H. pylori* infection. Endoscopic studies including ultrasound can help define the extent of gastric involvement. Most patients with extranodal marginal zone B cell lymphoma of MALT type have a good prognosis, with a 5-year survival of ~75%. In patients with a low IPI score, the 5-year survival is ~90%, while it drops to ~40% in patients with a high IPI score.

TREATMENT

Extranodal marginal zone B cell lymphoma of MALT type is curable when localized. Local therapy such as radiation or surgery can effect cure, and this is one of the few times where surgery might be a reasonable primary therapy for a patient with non-Hodgkin's lymphoma. Patients with gastric MALT lymphomas who are infected with *H. pylori* can achieve remission in the majority of cases with eradication of the infection. These remissions can be durable, but molecular evidence of persisting neoplasia is frequent and the long-term outcome is uncertain. Patients who present with more extensive disease are most often treated with single-agent chemotherapy such as chlorambucil. Coexistent diffuse large B cell lymphoma must be treated with combination chemotherapy. The additional acquired mutations that mediate the histologic progression also convey *Helicobacter* independence to the growth.

Mantle Cell Lymphoma Mantle cell lymphoma makes up ~6% of all non-Hodgkin's lymphomas. Recognized as a separate entity only in the past decade, this lymphoma was previously placed in a number of other subtypes. Its existence was confirmed by the recognition that these lymphomas have a characteristic chromosomal translocation, t(11;14), between the immunoglobulin heavy chain gene on chromosome 14 and the *bcl-1* gene on chromosome 11, and regularly overexpress the BCL-1 protein. The clinical characteristics of mantle cell lymphoma are presented in Table 97-10.

The diagnosis of mantle cell lymphoma can be made accurately by an expert hematopathologist based on morphologic findings and proof that the tumor is a B cell lymphoma. As with all subtypes of lymphoma, an adequate biopsy is important. The differential diagnosis of mantle cell lymphoma includes other small-cell B cell lymphomas. In particular, mantle cell lymphoma and small lymphocytic lymphoma share a characteristic expression of CD5. Mantle cell lymphoma usually has a slightly indented nucleus.

The most common presentation of mantle cell lymphoma is with palpable lymphadenopathy, frequently accompanied by systemic symptoms. Approximately 70% of patients will be stage IV at the time of diagnosis, with frequent bone marrow and peripheral blood involvement. Of the extranodal organs that can be involved, gastrointestinal involvement is particularly important to recognize. Patients who present with lymphomatosis polyposis in the large intestine usually have mantle cell lymphoma. The evaluation of patients with mantle cell lymphoma involves the studies presented in Table 97-11 for staging of patients with non-Hodgkin's lymphoma. Patients who present with gastrointestinal tract involvement often have Waldeyer's ring involvement, and vice versa. The 5-year survival for all patients with mantle cell lymphoma is ~25%, with only occasional patients who present with a high IPI score surviving 5 years and ~50% of patients with a low IPI score surviving 5 years.

TREATMENT

Current therapies for mantle cell lymphoma are unsatisfactory. Patients with localized disease might be treated with combination chemotherapy followed by radiotherapy; however, these patients are exceedingly rare. For the usual presentation with disseminated disease, treatments have been unsatisfactory, with the minority of patients achieving complete remission. Aggressive combination chemotherapy regimens followed by autologous or allogeneic bone marrow transplantation are frequently offered to younger patients. For the occasional elderly, asymptomatic patient, observation followed by single-agent chemotherapy might be the most practical approach. An intensive combination chemotherapy regimen originally used in the treatment of acute leukemia, HyperC-VAD (cyclophosphamide, vincristine, doxorubicin, dexamethasone, cytarabine, and methotrexate) in combination with rituximab seems to be associated with better response rates—particularly in younger patients. CHOP plus rituximab has shown better response rates than CHOP alone, but long-term follow-up is lacking.

Follicular Lymphoma Follicular lymphomas make up 22% of non-Hodgkin's lymphomas worldwide and at least 30% of non-Hodgkin's lymphomas diagnosed in the United States. This type of lymphoma can be diagnosed accurately on morphologic findings alone and has been the diagnosis in the majority of patients in therapeutic trials for "low-grade" lymphoma in the past. The clinical characteristics of follicular lymphoma are presented in Table 97-10.

Evaluation of an adequate biopsy by an expert hematopathologist is sufficient to make a diagnosis of follicular lymphoma. The tumor is composed of small cleaved and large cells in varying proportions organized in a follicular pattern of growth (Fig. 97-7). Confirmation of B cell immunophenotype and the existence of the t(14;18) and abnormal expression of BCL-2 protein are confirmatory. The major differential diagnosis is between lymphoma and reactive follicular hyperplasia. The coexistence of diffuse large B cell lymphoma must be considered. Patients with follicular lymphoma are often subclassified into those with predominantly small cells, those with a mixture of small and large cells, and those with predominantly large cells. While this distinction cannot be made simply or very accurately, these subdivisions do have prognostic significance. Patients with follicular lymphoma with predominantly large cells have a higher proliferative fraction, progress more rapidly, and have a shorter overall survival with simple chemotherapy regimens.

The most common presentation for follicular lymphoma is with new, painless lymphadenopathy. Multiple sites of lymphoid involvement are typical, and unusual sites such as epitrochlear nodes are sometimes seen. However, essentially any organ can be involved, and extranodal presentations do occur. Most patients do not have fevers, sweats, or weight loss, and an IPI score of 0 or 1 is found in ~50% of patients. Fewer than 10% of patients have a high (i.e., 4 or 5) IPI score. The staging evaluation for patients with follicular lymphoma should include the studies included in Table 97-11 for the staging of patients with non-Hodgkin's lymphoma.

TREATMENT

Follicular lymphoma is one of the malignancies most responsive to chemotherapy and radiotherapy. In addition, as many as 25% of the patients undergo spontaneous regression—usually transient—when followed without therapy. In an asymptomatic patient, no initial treatment and watchful waiting can be an appropriate management strategy and is particularly likely to be adopted for older patients. For patients who do require treatment, single-agent chlorambucil or cyclophosphamide or combination chemotherapy with CVP or CHOP are most frequently used. With adequate treatment, 50 to 75% of patients will achieve a complete remission. While most patients relapse (median response duration is ~2 years), at least 20% of complete responders

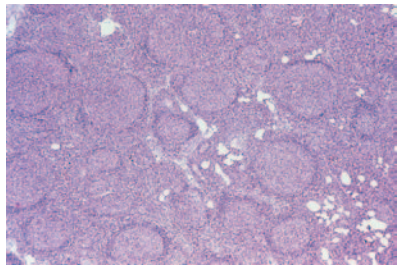

FIGURE 97-7 Follicular lymphoma. The normal nodal architecture is effaced by nodular expansions of tumor cells. Nodules vary in size and contain predominantly small lymphocytes with cleaved nuclei along with variable numbers of larger cells with vesicular chromatin and prominent nucleoli.

will remain in remission for >10 years. For the rare patient with localized follicular lymphoma, involved field radiotherapy produces an excellent treatment result.

A number of new therapies have been shown to be active in the treatment of patients with follicular lymphoma. These include new cytotoxic agents such as fludarabine, and biologic agents such as interferon α, monoclonal antibodies with or without radionuclides, and lymphoma vaccines. In patients treated with a doxorubicin-containing combination chemotherapy regimen, interferon α given to patients in complete remission seems to prolong survival. The monoclonal antibody rituximab can cause objective responses in 35 to 50% of patients with relapsed follicular lymphoma, and radiolabeled antibodies appear to have response rates well in excess of 50%. Trials with tumor vaccines have been encouraging. Both autologous and allogeneic hematopoietic stem cell transplantation yield high complete response rates in patients with relapsed follicular lymphoma, and long-term remissions can occur.

Patients with follicular lymphoma with a predominance of large cells have a shorter survival when treated with single-agent chemotherapy but seem to benefit from receiving an anthracycline-containing combination chemotherapy regimen. When their disease is treated aggressively, the overall survival for such patients is no lower than for patients with other follicular lymphomas, and the failure-free survival is superior.

Patients with follicular lymphoma have a high rate of histologic transformation to diffuse large B cell lymphoma (~7% per year). This is recognized ~40% of the time during the course of the illness by repeat biopsy and is present in almost all patients at autopsy. This transformation is usually heralded by rapid growth of lymph nodes—often localized—and the development of systemic symptoms such as fevers, sweats, and weight loss. Although these patients have a poor prognosis, aggressive combination chemotherapy regimens can sometimes cause a complete remission in the diffuse large B cell lymphoma, often leaving the patient with persisting follicular lymphoma.

Diffuse Large B Cell Lymphoma Diffuse large B cell lymphoma is the most common type of non-Hodgkin's lymphoma, representing approximately one-third of all cases. This lymphoma makes up the majority of cases in previous clinical trials of "aggressive" or "intermediate-grade" lymphoma. The clinical characteristics of diffuse large B cell lymphoma are presented in Table 97-10.

The diagnosis of diffuse large B cell lymphoma can be made accurately by an expert hematopathologist when review of an adequate biopsy and proof of B cell immunophenotype are available (Fig. 97-8). Cytogenetic and molecular genetic studies are not necessary for diagnosis, but some evidence has accumulated that patients who overexpress the BCL-2 protein might be more likely to relapse than others. Patients with prominent mediastinal involvement are sometimes diagnosed as a separate subgroup having primary mediastinal diffuse large B cell lymphoma. This latter group of patients has a younger median age (i.e., 37 years) and a female predominance (66%). Subtypes of diffuse large B cell lymphoma, including those with an immunoblastic subtype and tumors with extensive fibrosis, are recognized by pathologists but do not appear to have important, independent prognostic significance.

Diffuse large B cell lymphoma can present as either primary lymph node disease or at extranodal sites. More than 50% of patients will

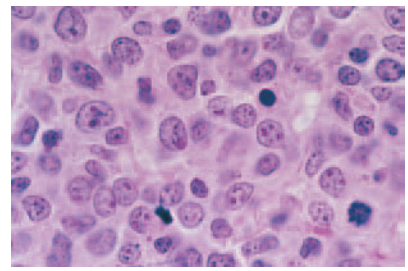

FIGURE 97-8 Diffuse large B cell lymphoma. The neoplastic cells are heterogeneous but predominantly large cells with vesicular chromatin and prominent nucleoli.

have some site of extranodal involvement at diagnosis, with the most common sites being the gastrointestinal tract and bone marrow, each being involved in 15 to 20% of patients. Essentially any organ can be involved, making a diagnostic biopsy imperative. For example, diffuse large B cell lymphoma of the pancreas has a much better prognosis than pancreatic carcinoma but would be missed without biopsy. Primary diffuse large B cell lymphoma of the brain is being diagnosed with increasing frequency. Other unusual subtypes of diffuse large B cell lymphoma such as pleural effusion lymphoma and intravascular lymphoma have been difficult to diagnose and associated with a very poor prognosis.

The initial evaluation of patients with diffuse large B cell lymphoma involves the studies presented in Table 97-11 for staging of patients with non-Hodgkin's lymphoma. After a careful staging evaluation, ~50% of patients will be found to have stage I or II disease and ~50% will have widely disseminated lymphoma. Bone marrow biopsy shows involvement by lymphoma in about 15% of cases, with marrow involvement by small cells more frequent than with large cells.

TREATMENT

The initial treatment of all patients with diffuse large B cell lymphoma should be with a combination chemotherapy regimen. The most popular regimen in the United States is CHOP, sometimes in combination with rituximab, although a variety of other anthracycline-containing combination chemotherapy regimens appear to be equally efficacious. Patients with stage I or nonbulky stage II can be effectively treated with three to four cycles of combination chemotherapy followed by involved field radiotherapy. The results are at least equal and probably superior to six to eight cycles of combination therapy, and cure rates of 60 to 70% in stage II disease and 80 to 90% in stage I disease can be expected.

For patients with bulky stage II, stage III, or stage IV, six to eight cycles of a combination chemotherapy regimen such as CHOP, often in combination with rituximab, are usually administered. A large randomized trial showed the superiority of CHOP combined with rituximab over CHOP alone in elderly patients. A frequent approach would be to administer four cycles of therapy and then reevaluate. If the patient has achieved a complete remission after four cycles, two more cycles of treatment might be given and then therapy discontinued. Using this approach, 70% of patients can be expected to achieve a complete remission, and 50 to 70% of complete responders will be cured. The chances for a favorable response to treatment are predicted by the IPI. In fact, the IPI was developed specifically to predict outcome in patients with diffuse large B cell lymphoma. For the 35% of patients with a low IPI score of 0 to 1, the 5-year survival is >70%, while for the 20% of patients with a high IPI score of 4 to 5, the 5-year survival is ~20%. A number of other factors, including molecular features of the tumor, levels of circulating cytokines and soluble receptors, and other surrogate markers, have been shown to influence prognosis. However, they have not been validated as rigorously as the IPI and have not been uniformly applied clinically.

Because a large number of patients with diffuse large B cell lymphoma are either initially refractory to therapy or relapse after apparently effective chemotherapy, nearly half of patients will be candidates for salvage treatment at some point. Alternative combination chemo-

therapy regimens can induce complete remission in as many as 50% of these patients, but long-term disease-free survival is seen in ≤10%. Autologous bone marrow transplantation has been shown to be superior to salvage chemotherapy at usual doses and leads to long-term disease-free survival in ~40% of patients whose lymphomas remain chemotherapy-sensitive after relapse.

Burkitt's Lymphoma/Leukemia Burkitt's lymphoma/leukemia is a rare disease in adults in the United States, making up <1% of non-Hodgkin's lymphomas, but it makes up ~30% of childhood non-Hodgkin's lymphoma. Burkitt's leukemia, or L3 ALL, makes up a small proportion of childhood and adult acute leukemias. The clinical features of Burkitt's lymphoma occurring in adults are presented in Table 97-10.

Burkitt's lymphoma can be diagnosed morphologically by an expert hematopathologist with a high degree of accuracy. The cells are homogeneous in size and shape (Fig. 97-9). Demonstration of a very high proliferative fraction and the presence of the t(8;14) or one of its variants, t(2;8) (*c-myc* and the λ light chain gene) or t(8;22) (*c-myc* and the κ light chain gene), can be confirmatory. Burkitt's cell leukemia is recognized by the typical monotonous mass of medium-sized cells with round nuclei, multiple nucleoli, and basophilic cytoplasm with cytoplasmic vacuoles. Demonstration of a B cell immunophenotype and one of the above-noted cytogenetic abnormalities is confirmatory.

The three distinct clinical forms of Burkitt's lymphoma that are recognized are endemic, sporadic, and immunodeficiency-associated. Endemic and sporadic Burkitt's lymphomas occur frequently in children in Africa, and the sporadic form in western countries. Immunodeficiency-associated Burkitt's lymphoma is seen in patients with HIV infection.

Pathologists sometimes have difficulty distinguishing between Burkitt's lymphoma and diffuse large B cell lymphoma. In the past, a separate subgroup of non-Hodgkin's lymphoma intermediate between the two was recognized. When tested, this subgroup could not be diagnosed accurately. Distinction between the two major types of B cell aggressive non-Hodgkin's lymphoma can sometimes be made based on the extremely high proliferative fraction seen in patients with Burkitt's lymphoma (i.e., essentially 100% of tumor cells are in cycle) caused by *c-myc* deregulation.

Most patients in the United States with Burkitt's lymphoma present with peripheral lymphadenopathy or an intraabdominal mass. The disease is typically rapidly progressive and has a propensity to metastasize to the CNS. Initial evaluation should always include an examination of cerebral spinal fluid to rule out metastasis in addition to the other staging evaluations noted in Table 97-11. Once the diagnosis of Burkitt's lymphoma is suspected, a diagnosis must be made promptly and staging evaluation must be accomplished expeditiously. This is the most rapidly progressive human tumor, and any delay in initiating therapy can adversely affect the patient's prognosis.

TREATMENT

Treatment of Burkitt's lymphoma in both children and adults should begin within 48 h of diagnosis and involves the use of intensive combination chemotherapy regimens incorporating high doses of cyclophosphamide. Prophylactic therapy to the CNS is mandatory. Burkitt's lymphoma was one of the first cancers shown to be curable by chemotherapy. Today, cure can be expected in 70 to 80% of both children and young adults when effective therapy is administered precisely. Salvage therapy has been generally ineffective in patients failing the initial treatment, emphasizing the importance of the initial treatment approach.

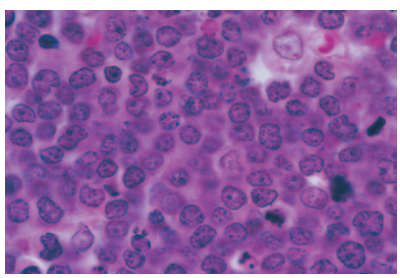

FIGURE 97-9 Burkitt's lymphoma. The neoplastic cells are homogenous, medium-sized B cells with frequent mitotic figures, a morphologic correlate of high growth fraction. Reactive macrophages are scattered through the tumor and their pale cytoplasm in a background of blue-staining tumor cells give the tumor a so-called starry sky appearance.

Other B Cell Lymphoid Malignancies *B-cell prolymphocytic leukemia* involves blood and marrow infiltration by large lymphocytes with prominent nucleoli. Patients typically have a high white cell count, splenomegaly, and minimal lymphadenopathy. The chances for a complete response to therapy are poor.

Hairy cell leukemia is a rare disease that presents predominantly in older males. Typical presentation involves pancytopenia, although occasional patients will have a leukemic presentation. Splenomegaly is usual. The malignant cells appear to have "hairy" projections on light and electron microscopy and show a characteristic staining pattern with tartrate-resistant acid phosphatase. Bone marrow is typically not able to be aspirated, and biopsy shows a pattern of fibrosis with diffuse infiltration by the malignant cells. Patients with this disorder are prone to unusual infections including infection by *Mycobacterium avium intracellulare*, and vasculitic syndromes have been described. Hairy cell leukemia is responsive to chemotherapy with interferon α, pentostatin, or cladribine, with the latter being the usually preferred treatment. Clinical complete remissions with cladribine occur in the majority of patients, and long-term disease-free survival is frequent.

Splenic marginal zone lymphoma involves infiltration of the splenic white pulp by small, monoclonal B cells. This is a rare disorder that can present as leukemia as well as lymphoma. Definitive diagnosis is often made at splenectomy, which is also an effective therapy. This is an extremely indolent disorder, but when chemotherapy is required, the most usual treatment has been chlorambucil.

Lymphoplasmacytic lymphoma is the tissue manifestation of Waldenström's macroglobulinemia (Chap. 98). This type of lymphoma has been associated with chronic hepatitis C virus infection, and an etiologic association has been proposed. Patients typically present with lymphadenopathy, splenomegaly, bone marrow involvement, and occasionally peripheral blood involvement. The tumor cells do not express CD5. Patients often have a monoclonal IgM protein, high levels of which can dominate the clinical picture with the symptoms of hyperviscosity. Treatment of lymphoplasmacytic lymphoma can be aimed primarily at reducing the abnormal protein, if present, but will usually also involve chemotherapy. Chlorambucil, fludarabine, and cladribine have been utilized. The median 5-year survival for patients with this disorder is ~60%.

Nodal marginal zone lymphoma, also known as *monocytoid B cell lymphoma*, represents ~1% of non-Hodgkin's lymphomas. This lymphoma has a slight female predominance and presents with disseminated disease (i.e., stage III or IV) in 75% of patients. Approximately one-third of patients have bone marrow involvement, and a leukemic presentation occasionally occurs. The staging evaluation and therapy should use the same approach as used for patients with follicular lymphoma. Approximately 60% of the patients with nodal marginal zone lymphoma will survive 5 years after diagnosis.

PRECURSOR CELL T CELL MALIGNANCIES ■ Precursor T Cell Lymphoblastic Leukemia/Lymphoma Precursor T cell malignancies can present either as ALL or as an aggressive lymphoma. These malignancies are more common in children and young adults, with males more frequently affected than females.

Precursor T cell ALL can present with bone marrow failure, although the severity of anemia, neutropenia, and thrombocytopenia is often less than in precursor B cell ALL. These patients sometimes have very high white cell counts, a mediastinal mass, lymphadenopathy, and hepatosplenomegaly. Precursor T cell lymphoblastic lymphoma is most often found in young men presenting with a large mediastinal mass and pleural effusions. Both presentations have a propensity to metastasize to the CNS, and CNS involvement is often present at diagnosis.

TREATMENT

Children with precursor T cell ALL seem to benefit from very intensive remission induction and consolidation regimens. The majority of patients treated in this manner can be cured. Older children and young adults with precursor T cell lymphoblastic lymphoma are also often treated with "leukemia-like" regimens. Patients who present with localized disease have an excellent prognosis. However, advanced age is an adverse prognostic factor. Adults with precursor T cell lymphoblastic lymphoma who present with high LDH levels or bone marrow or CNS involvement are often offered bone marrow transplantation as part of their primary therapy.

MATURE (PERIPHERAL) T CELL DISORDERS ■ Mycosis Fungoides Mycosis fungoides is also known as *cutaneous T cell lymphoma*. This lymphoma is more often seen by dermatologists than internists. The median age of onset is in the mid-fifties, and the disease is more common in males and in blacks.

Mycosis fungoides is an indolent lymphoma with patients often having several years of eczematous or dermatitic skin lesions before the diagnosis is finally established. The skin lesions progress from patch stage to plaque stage to cutaneous tumors. Early in the disease, biopsies are often difficult to interpret, and the diagnosis may only become apparent by observing the patient over time. In advanced stages, the lymphoma can metastasize to lymph nodes and visceral organs. A particular syndrome in patients with this lymphoma involves erythroderma and circulating tumor cells. This is known as *Sézary's syndrome*.

Rare patients with localized early stage mycosis fungoides can be cured with radiotherapy, often total-skin electron beam irradiation. More advanced disease has been treated with topical glucocorticoids, topical nitrogen mustard, phototherapy, psoralen with ultraviolet A (PUVA), electron beam radiation, interferon, antibodies, fusion toxins, and systemic cytotoxic therapy. Unfortunately, these treatments are palliative.

Adult T Cell Lymphoma/Leukemia Adult T cell lymphoma/leukemia is one manifestation of infection by the HTLV-I retrovirus. Patients can be infected through transplacental transmission, blood transfusion, and by sexual transmission of the virus. Patients who acquire the virus from their mother through breast milk are most likely to develop lymphoma, but the risk is still only 2.5% and the latency averages 55 years. Nationwide testing for HTLV-I antibodies and the aggressive implementation of public health measures could theoretically lead to the disappearance of adult T cell lymphoma/leukemia. Tropical spastic paraparesis, another manifestation of HTLV-I infection (Chap. 172), occurs after a shorter latency (1 to 3 years) and is most common in people who acquire the virus during adulthood from transfusion or sex.

The diagnosis of adult T cell lymphoma/leukemia is made when an expert hematopathologist recognizes the typical morphologic picture, a T cell immunophenotype (i.e., CD4 positive) of malignant cells has been demonstrated, and the existence of antibodies to HTLV-I is proven. Examination of the peripheral blood will usually reveal characteristic, pleomorphic abnormal CD4-positive cells with indented nuclei, which have been called "flower" cells (Fig. 97-10).

A subset of patients have a smoldering clinical course and long survival, but most patients present with an aggressive disease manifested by lymphadenopathy, hepatosplenomegaly, skin infiltration, hypercalcemia, lytic bone lesions, and elevated LDH levels. The skin lesions can be papules, plaques, tumors, and ulcerations. Bone marrow involvement is not usually extensive, and anemia and thrombocytopenia are not usually prominent. Although treatment by combination chemotherapy regimens can result in objective responses, true complete remissions are unusual, and the median survival of patients is about 7 months.

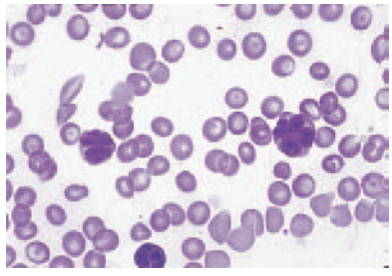

FIGURE 97-10 Adult T cell leukemia/lymphoma. Peripheral blood smear showing leukemia cells with typical "flower-shaped" nucleus.

Anaplastic Large T/Null Cell Lymphoma Anaplastic large T/null cell lymphoma was previously usually diagnosed as undifferentiated carcinoma or malignant histiocytosis. Discovery of the CD30, or Ki-1, antigen and the recognition that some patients with previously unclassified malignancies displayed this antigen led to the identification of a new type of lymphoma. Subsequently, discovery of the t(2;5) and the resultant frequent overexpression of the anaplastic lymphoma kinase (ALK) protein confirmed the existence of this entity. This lymphoma accounts for ~2% of all non-Hodgkin's lymphomas. The clinical characteristics of patients with anaplastic large T/null cell lymphoma are presented in Table 97-10.

The diagnosis of anaplastic large T/null cell lymphoma is made when an expert hematopathologist recognizes the typical morphologic picture and a T cell or null cell immunophenotype is demonstrated along with CD30 positivity. Documentation of the t(2;5) and/or overexpression of ALK protein confirm the diagnosis. Some diffuse large B cell lymphomas can also have an anaplastic appearance but have the same clinical course or response to therapy as other diffuse large B cell lymphomas.

Patients with anaplastic large T/cell null cell lymphoma are typically young (median age, 33 years) and male (~70%). Some 50% of patients present in stage I/II, and the remainder with more extensive disease. Systemic symptoms and elevated LDH levels are seen in about one-half of patients. Bone marrow and the gastrointestinal tract are rarely involved, but skin involvement is frequent. Some patients with disease confined to the skin have a different and more indolent disorder that has been termed *cutaneous anaplastic large T/null cell lymphoma* and might be related to lymphomatoid papulosis.

TREATMENT

Treatment regimens appropriate for other aggressive lymphomas, such as diffuse large B cell lymphoma, should be utilized in patients with anaplastic large T/null cell lymphoma. Surprisingly, given the anaplastic appearance, this disorder has the best survival rate of any aggressive lymphoma. The 5-year survival is >75%. While traditional prognostic factors such as the IPI predict treatment outcome, overexpression of the ALK protein is an important prognostic factor, with patients overexpressing this protein having a superior treatment outcome.

Peripheral T Cell Lymphoma The peripheral T cell lymphomas make up a heterogenous morphologic group of aggressive neoplasms that share a mature T cell immunophenotype. They represent ~7% of all cases of non-Hodgkin's lymphoma. A number of distinct clinical syndromes are included in this group of disorders. The clinical characteristics of patients with peripheral T cell lymphoma are presented in Table 97-10.

The diagnosis of peripheral T cell lymphoma, or any of its specific subtypes, requires an expert hematopathologist, an adequate biopsy, and immunophenotyping. Most peripheral T cell lymphomas are CD4+, but a few will be CD8+, both CD4+ and CD8+, or have an NK cell immunophenotype. No characteristic genetic abnormalities have yet been identified, but translocations involving the T cell antigen receptor genes on chromosomes 7 or 14 may be detected. The differential diagnosis of patients suspected of having peripheral T cell lymphoma includes reactive T cell infiltrative processes. In some cases,

demonstration of a monoclonal T cell population using T cell receptor gene rearrangement studies will be required to make a diagnosis.

The initial evaluation of a patient with a peripheral T cell lymphoma should include the studies in Table 97-11 for staging patients with non-Hodgkin's lymphoma. Unfortunately, patients with peripheral T cell lymphoma usually present with adverse prognostic factors, with >80% of patients having an IPI score ≥2 and >30% having an IPI score ≥4. As this would predict, peripheral T cell lymphomas are associated with a poor outcome, and only 25% of the patients survive 5 years after diagnosis. Treatment regimens are the same as those used for diffuse large B cell lymphoma, but patients with peripheral T cell lymphoma have a poorer response to treatment. Because of this poor treatment outcome, hematopoietic stem cell transplantation is often considered early in the care of young patients.

A number of specific clinical syndromes are seen in the peripheral T cell lymphomas. *Angioimmunoblastic T cell lymphoma* is one of the more common subtypes, making up ~20% of T cell lymphomas. These patients typically present with generalized lymphadenopathy, fever, weight loss, skin rash, and polyclonal hypergammaglobulinemia. In some cases, it is difficult to separate patients with a reactive disorder from those with true lymphoma.

Extranodal T/NK cell lymphoma of nasal type has also been called *angiocentric lymphoma* and was previously termed *lethal midline granuloma*. This disorder is more frequent in Asia and South America than in the United States and Europe. Although most frequent in the upper airway, it can involve other organs. The course is aggressive, and patients frequently have the hemophagocytic syndrome. When marrow and blood involvement occur, distinction between this disease and leukemia might be difficult. Some patients will respond to aggressive combination chemotherapy regimens, but the overall outlook is poor.

Enteropathy-type intestinal T cell lymphoma is a rare disorder that occurs in patients with untreated gluten-sensitive enteropathy. Patients are frequently wasted and sometimes present with intestinal perforation. The prognosis is poor. *Hepatosplenic γδ T cell lymphoma* is a systemic illness that presents with sinusoidal infiltration of the liver, spleen, and bone marrow by malignant T cells. Tumor masses generally do not occur. The disease is associated with systemic symptoms and is often difficult to diagnosis. Treatment outcome is poor. *Subcutaneous panniculitis-like T cell lymphoma* is a rare disorder that is often confused with panniculitis. Patients present with multiple subcutaneous nodules, which progress and can ulcerate. Hemophagocytic syndrome is common. Response to therapy is poor. The development of the hemophagocytic syndrome (profound anemia, ingestion of erythrocytes by monocytes and macrophages) in the course of any peripheral T cell lymphoma is generally associated with a fatal outcome.

HODGKIN'S DISEASE ■ Classic Hodgkin's Disease Hodgkin's disease occurs in 7600 patients in the United States each year, and the disease does not appear to be increasing in frequency. Most patients present with palpable lymphadenopathy that is nontender; in most patients, these lymph nodes are in the neck, supraclavicular area, and axilla. More than half the patients will have mediastinal adenopathy at diagnosis, and this is sometimes the initial manifestation. Subdiaphragmatic presentation of Hodgkin's disease is unusual and more common in older males. Approximately one-third of patients present with fevers, night sweats, and/or weight loss—B symptoms in the Ann Arbor staging classification (Table 97-8). Occasionally, Hodgkin's disease can present as a fever of unknown origin. This is more common in older patients who are found to have mixed-cellularity Hodgkin's disease in an abdominal site. Rarely, the fevers persist for days to weeks, followed by afebrile intervals and then recurrence of the fever. This pattern is known as *Pel-Epstein fever*. Hodgkin's disease can occasionally present with unusual manifestations. These include severe and unexplained itching, cutaneous disorders such as erythema nodosum and ichthyosiform atrophy, paraneoplastic cerebellar degeneration and other distant effects on the CNS, nephrotic syndrome, immune hemolytic anemia and thrombocytopenia, hypercalcemia, and pain in lymph nodes on alcohol ingestion.

The diagnosis of Hodgkin's disease is established by review of an adequate biopsy specimen by an expert hematopathologist. In the United States, most patients would be classified as having nodular sclerosing Hodgkin's disease, with a minority of patients having mixed-cellularity Hodgkin's disease. Lymphocyte-predominant and lymphocyte-depleted Hodgkin's disease are rare. Mixed-cellularity Hodgkin's disease or lymphocyte-depletion Hodgkin's disease are seen more frequently in patients infected by HIV (Fig. 97-11). The differential diagnosis of a lymph node biopsy suspicious for Hodgkin's disease includes inflammatory processes, mononucleosis, non-Hodgkin's lymphoma, phenytoin-induced lymphadenopathy, and nonlymphomatous malignancies.

The staging evaluation for a patient with Hodgkin's disease would typically include a careful history and physical examination; complete blood count; erythrocyte sedimentation rate; serum chemistry studies including LDH; chest radiograph; CT scan of the chest, abdomen, and pelvis; and bone marrow biopsy. Many patients would also have a PET scan or a gallium scan. Although rarely utilized, a bipedal lymphangiogram can be helpful. PET and gallium scans are most useful at the completion of therapy to document remission. Staging laparotomies were once popular for most patients with Hodgkin's disease but are now done rarely because of an increased reliance on systemic rather than local therapy.

TREATMENT

Patients with localized Hodgkin's disease are cured >90% of the time. In patients with good prognostic factors, extended field radiotherapy has a high cure rate. Increasingly, patients with all stages of Hodgkin's disease are treated initially with chemotherapy. Patients with localized or good-prognosis disease receive a brief course of chemotherapy followed by radiotherapy to sites of node involvement. Patients with more extensive disease or those with B symptoms receive a complete course of chemotherapy. The most popular chemotherapy regimens used in the treatment of Hodgkin's disease include doxorubicin, bleomycin, vinblastine, and dacarbazine (ABVD) and mechlorethamine, vincristine, procarbazine, and prednisone (MOPP), or combinations of the drugs in these two regimens. Today, most patients in the United States receive ABVD, but a weekly chemotherapy regimen administered for 12 weeks called *Stanford V* is becoming increasingly popular, but includes radiation therapy, which has been associated with life-threatening late toxicities such as premature coronary artery disease and second solid tumors. In Europe a high-dose regimen called *BEACOPP* incorporating alkylating agents has become popular and might have a better response rate in very high risk patients. Long-term disease-free survival in patients with advanced disease can be achieved in >75% of patients who lack systemic symptoms and in 50 to 70% of patients with systemic symptoms.

Patients who relapse after primary therapy of Hodgkin's disease can frequently still be cured. Patients who relapse after initial treatment only with radiotherapy have an excellent outcome when treated with chemotherapy. Patients who relapse after an effective chemotherapy regimen are usually not curable with subsequent chemotherapy administered at standard doses. However, patients with a long initial

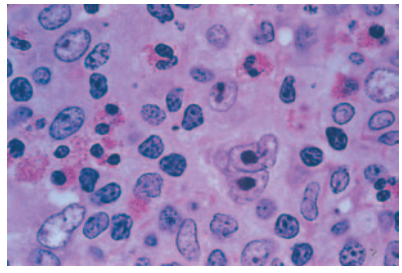

FIGURE 97-11 Mixed cellularity Hodgkin's disease. A Reed-Sternberg cell is present near the center of the field; a large cell with a bilobed nucleus and prominent nucleoli giving an "owl's eyes" appearance. The majority of the cells are normal lymphocytes, neutrophils, and eosinophils that form a pleiomorphic cellular infiltrate.

remission can be an exception to this rule. Autologous bone marrow transplantation can cure half of patients who fail effective chemotherapy regimens.

Because of the very high cure rate in patients with Hodgkin's disease, long-term complications have become a major focus for clinical research. In fact, in some series of patients with early-stage disease, more patients died from late complications of therapy than from Hodgkin's disease itself. This is particularly true in patients with localized disease. The most serious late side effects include second malignancies and cardiac injury. Patients are at risk for the development of acute leukemia in the first 10 years after treatment with combination chemotherapy regimens that contain alkylating agents plus radiation therapy. The risk for development of acute leukemia appears to be greater after MOPP-like regimens than with ABVD. The risk of development of acute leukemia after treatment for Hodgkin's disease is also related to the number of exposures to potentially leukemogenic agents (i.e., multiple treatments after relapse) and the age of the patient being treated, with those >60 years at particularly high risk. The development of carcinomas as a complication of treatment for Hodgkin's disease has become a major problem. These tumors usually occur ≥10 years after treatment and are associated with use of radiotherapy. For this reason, young women treated with thoracic radiotherapy for Hodgkin's disease should institute screening mammograms 5 to 10 years after treatment, and all patients who receive thoracic radiotherapy for Hodgkin's disease should be discouraged from smoking. Thoracic radiation also accelerates coronary artery disease, and patients should be encouraged to minimize risk factors for coronary artery disease such as smoking and elevated cholesterol levels.

A number of other late side effects from the treatment of Hodgkin's disease are well known. Patients who receive thoracic radiotherapy are at very high risk for the eventual development of hypothyroidism and should be observed for this complication; intermittent measurement of thyrotropin should be made to identify the condition before it becomes symptomatic. Lhermitte's syndrome occurs in ~15% of patients who receive thoracic radiotherapy. This syndrome is manifested by an "electric shock" sensation into the lower extremities on flexion of the neck. Infertility is a concern for all patients undergoing treatment for Hodgkin's disease. In both women and men, the risk of permanent infertility is age-related, with younger patients more likely to recover fertility. In addition, treatment with ABVD rather than MOPP increases the chances to retain fertility.

Nodular Lymphocyte-Predominant Hodgkin's Disease Nodular lymphocyte-predominant Hodgkin's disease is now recognized as an entity distinct from classic Hodgkin's disease. Previous classification systems recognized that biopsies from a subset of patients diagnosed as having Hodgkin's disease contained a predominance of small lymphocytes and rare Reed-Sternberg cells. A subset of these patients have tumors with nodular growth pattern and a clinical course that varied from that of patients with classic Hodgkin's disease. This is an unusual clinical entity and represents <5% of cases of Hodgkin's disease.

Nodular lymphocyte-predominant Hodgkin's disease has a number of characteristics that suggest its relationship to non-Hodgkin's lymphoma. These include a clonal proliferation of B cells and a distinctive immunophenotype; tumor cells express J chain and display CD45 and epithelial membrane antigen (ema) and do not express two markers normally found on Sternberg-Reed cells, CD30 and CD15. This lymphoma tends to have a chronic, relapsing course and sometimes transforms to diffuse large B cell lymphoma.

The treatment of patients with nodular lymphocyte-predominant Hodgkin's disease is controversial. Some clinicians favor no treatment and merely close follow-up. In the United States, most physicians will treat localized disease with radiotherapy and disseminated disease with regimens utilized for patients with classic Hodgkin's disease. Regardless of the therapy utilized, most series report a long-term survival of >80%.

LYMPHOMA-LIKE DISORDERS

The most common condition that pathologists and clinicians might confuse with lymphoma is reactive, atypical lymphoid hyperplasia. Patients might have localized or disseminated lymphadenopathy and might have the systemic symptoms characteristic of lymphoma. Underlying causes include a drug reaction to phenytoin or carbamezepine. Immune disorders such as rheumatoid arthritis and lupus erythematosus, viral infections such as cytomegalovirus and EBV, and bacterial infections such as cat-scratch disease may cause adenopathy (Chap. 54). In the absence of a definitive diagnosis after initial biopsy, continued follow-up, further testing, and repeated biopsies, if necessary, are the appropriate approach rather than instituting therapy.

Specific conditions that can be confused with lymphoma include *Castleman's disease*, which can present with localized or disseminated lymphadenopathy; some patients have systemic symptoms. The disseminated form is often accompanied by anemia and polyclonal hypergammaglobulinemia, and the condition has been associated with overproduction of interleukin 6, possibly produced by human herpesvirus 8. Patients with localized disease can be treated effectively with local therapy, while the initial treatment for patients with disseminated disease is usually with systemic glucocorticoids.

Sinus histiocytosis with massive lymphadenopathy (*Rosai-Dorfman's disease*) usually presents with bulky lymphadenopathy in children or young adults. The disease is usually nonprogressive and self-limited, but patients can manifest autoimmune hemolytic anemia.

Lymphomatoid papulosis is a cutaneous lymphoproliferative disorder that is often confused with anaplastic large-cell lymphoma involving the skin. The cells of lymphomatoid papulosis are similar to those seen in lymphoma and stain for CD30, and T cell receptor gene rearrangements are sometimes seen. However, the condition is characterized by waxing and waning skin lesions that usually heal, leaving small scars. In the absence of effective communication between the clinician and the pathologist regarding the clinical course in the patient, this disease will be misdiagnosed. Since the clinical picture is usually benign, misdiagnosis is a serious mistake.

98 PLASMA CELL DISORDERS

Dan L. Longo, Kenneth C. Anderson

GENERAL PRINCIPLES The *plasma cell disorders* are monoclonal neoplasms related to each other by virtue of their development from common progenitors in the B lymphocyte lineage. Multiple myeloma, Waldenström's macroglobulinemia, primary amyloidosis (Chap. 310), and the heavy chain diseases comprise this group and may be designated by a variety of synonyms such as *monoclonal gammopathies*, *paraproteinemias*, *plasma cell dyscrasias*, and *dysproteinemias*. Mature B lymphocytes destined to produce IgG bear surface immunoglobulin molecules of both M and G heavy chain isotypes with both isotypes having identical idiotypes (variable regions). Under normal circumstances, maturation to antibody-secreting plasma cells is stimulated by exposure to the antigen for which the surface immunoglobulin is specific; however, in the plasma cell disorders the control over this process is lost. The clinical manifestations of all the plasma cell disorders relate to the expansion of the neoplastic cells, to the secretion of cell products (immunoglobulin molecules or subunits, lymphokines), and to some extent to the host's response to the tumor. →***Normal development of B lymphocytes is discussed in Chap. 295.***

There are three categories of structural variation among immunoglobulin molecules that form antigenic determinants, and these are used to classify immunoglobulins (Chap. 295). *Isotypes* are those determinants that distinguish among the main classes of antibodies of a given species and are the same in all normal individuals of that species. Therefore, isotypic determinants are, by definition, recognized by antibodies from a distinct species (heterologous sera) but not by antibodies from the same species (homologous sera). There are five heavy chain isotypes (M, G, A, D, E) and two light chain isotypes (κ, λ). *Allotypes* are distinct determinants that reflect regular small differences between individuals of the same species in the amino acid sequences of otherwise similar immunoglobulins. These differences are determined by allelic genes; by definition, they are detected by antibodies made in the same species. *Idiotypes* are the third category of antigenic determinants. They are unique to the molecules produced by a given clone of antibody-producing cells. Idiotypes are formed by the unique structure of the antigen-binding portion of the molecule.

Antibody molecules (Fig. 295-9) are composed of two heavy chains (mol wt ~50,000) and two light chains (mol wt ~25,000). Each chain has a constant portion (limited amino acid sequence variability) and a variable region (extensive sequence variability). The light and heavy chains are linked by disulfide bonds and are aligned so that their variable regions are adjacent to one another. This variable region forms the antigen recognition site of the antibody molecule; its unique structural features form a particular set of determinants, or idiotypes, that are reliable markers for a particular clone of cells because each antibody is formed and secreted by a single clone. Each chain is specified by distinct genes, synthesized separately, and assembled into an intact antibody molecule after translation (Fig. 98-1). Because of the mechanics of the gene rearrangements necessary to specify the immunoglobulin variable regions (VDJ joining for the heavy chain, VJ joining for the light chain), a particular clone rearranges only one of the two chromosomes to produce an immunoglobulin molecule of only one light chain isotype and only one allotype (allelic exclusion). After exposure to antigen, the variable region may become associated with a new heavy chain isotype (class switch). Each clone of cells performs these sequential gene arrangements in a unique way. This results in each clone producing a unique immunoglobulin molecule. In most cells, light chains are synthesized in slight excess, are secreted as free light chains by plasma cells, and are cleared by the kidney, but <10 mg of such light chains is excreted per day.

Electrophoretic analysis of components of the serum proteins permits determination of the amount of immunoglobulin in the serum (Fig. 98-2). The variety of immunoglobulins move heterogeneously in an electric field and form a broad peak in the gamma region. The γ globulin region of the electrophoretic pattern is usually increased in the sera of patients and animals with plasma cell tumors. There is a sharp spike in this region called an *M component* (M for monoclonal). Less commonly, the M component may appear in the β_2 or α_2 globulin region. The antibody must be present at a concentration of at least 5 g/L (0.5 g/dL) to be detectable by this method. This corresponds to approximately 10^9 cells producing the antibody. Confirmation that such an M component is truly monoclonal relies on the use of immunoelectrophoresis that shows a single light and heavy chain type. Hence immunoelectrophoresis and electrophoresis provide qualitative and quantitative assessment of the M component, respectively. Once the presence of an M component has been confirmed, electrophoresis provides the more practical information for managing patients with monoclonal gammopathies. In a given patient, the amount of M component in the serum is a reliable measure of the tumor burden. This makes the M component an excellent tumor marker, yet it is not specific enough to be used to screen asymptomatic patients. In addition

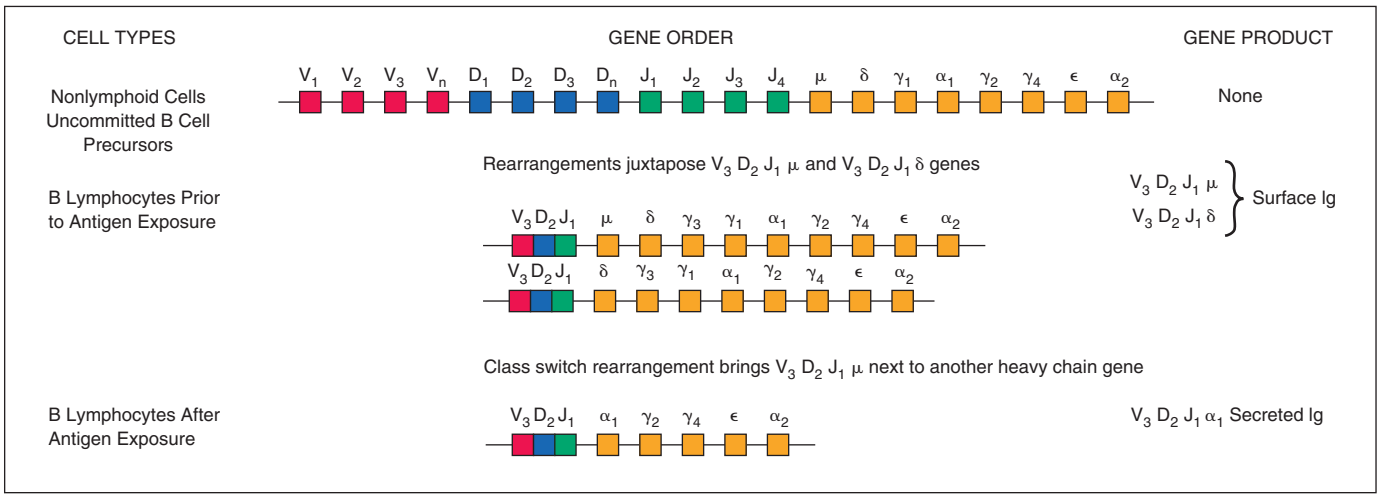

FIGURE 98-1 Immunoglobulin heavy chains are encoded by four distinct genetic elements: variable (Igh-V), diversity (Igh-D), joining (Igh-J), and constant (Igh-C) genes. The variable region of the immunoglobulin heavy chain is encoded by the V, D, and J genes. The same variable region may be associated with any of the 10 heavy chain constant region genes. In the germ-line genome (all cells except B cells) the V, D, and J genes are widely separated and exist in numerous forms. Once a cell becomes committed to B cell differentiation, a single V gene and a single D gene translocate to a single J gene, and the intervening genetic material is excised (VDJ joining). The newly formed VDJ gene is transcribed into a single message along with either an M or D isotype C gene. Upon exposure to antigen, another rearrangement may occur so that the VDJ gene may be associated with a G, A, or E isotype C gene. In light chain genes there appear to be no D genes, and thus light chain variable regions are formed by VJ joining.

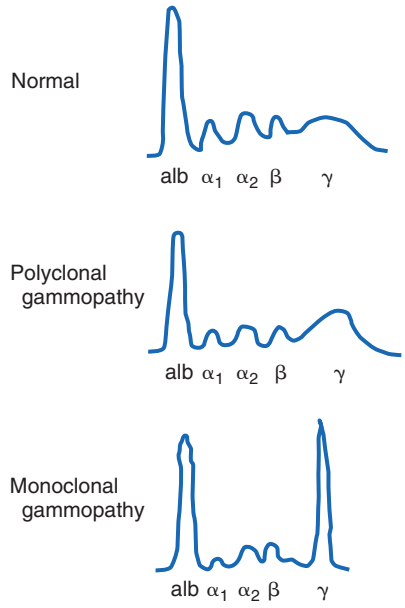

FIGURE 98-2 Representative patterns of serum electrophoresis. The upper panel illustrates the normal pattern of serum protein on electrophoresis. Since there are many different immunoglobulins in the serum, their differing mobilities in an electric field produce a broad peak. In conditions associated with increases in polyclonal immunoglobulin, the broad peak is more prominent (middle panel). In monoclonal gammopathies, the predominance of a product of a single cell produces a "church spire" sharp peak, usually in the γ globulin region (bottom panel).

to the plasma cell disorders, M components may be detected in other lymphoid neoplasms such as chronic lymphocytic leukemia and lymphomas of B or T cell origin; nonlymphoid neoplasms such as chronic myeloid leukemia, breast cancer, and colon cancer; a variety of nonneoplastic conditions such as cirrhosis, sarcoidosis, parasitic diseases, Gaucher disease, and pyoderma gangrenosum; and a number of autoimmune conditions, including rheumatoid arthritis, myasthenia gravis, and cold agglutinin disease. A very rare skin disease known as lichen myxedematosus or papular mucinosis is associated with a monoclonal gammopathy. Highly cationic IgG is deposited in the dermis of patients with this disease. This organ specificity may reflect the specificity of the antibody for some antigenic component of the dermis.

The nature of the M component is variable in plasma cell disorders. It may be an intact antibody molecule of any heavy chain subclass, or it may be an altered antibody or fragment. Isolated light or heavy chains may be produced. In some plasma cell tumors such as extramedullary or solitary bone plasmacytomas, <1/3 of patients will have an M component. In about 20% of myelomas, only light chains are produced and in most cases are secreted in the urine as Bence Jones proteins. The frequency of myelomas of a particular heavy chain class is roughly proportional to the serum concentration, and therefore IgG myelomas are more common than IgA and IgD myelomas.

MULTIPLE MYELOMA

Definition Multiple myeloma represents a malignant proliferation of plasma cells derived from a single clone. The terms *multiple myeloma* and *myeloma* may be used interchangeably. The tumor, its products, and the host response to it result in a number of organ dysfunctions and symptoms of bone pain or fracture, renal failure, susceptibility to infection, anemia, hypercalcemia, and occasionally clotting abnormalities, neurologic symptoms, and vascular manifestations of hyperviscosity.

Etiology The cause of myeloma is not known. Myeloma occurred with increased frequency in those exposed to the radiation of nuclear warheads in World War II after a 20-year latency. A variety of chromosomal alterations have been found in patients with myeloma; 13q14 deletions, 17p13 deletions, and 11q abnormalities predominate. The most common translocation is t(11;14)(q13;q32), and evidence is strong that errors in switch recombination—the genetic mechanism to change antibody heavy chain isotype—participate in the transformation pathway. Overexpression of *myc* or *ras* genes has been noted in some cases. Mutations in p53 and Rb-1 have also been described, but no common molecular pathogenesis has yet emerged.

Myeloma has been seen more commonly than expected among farmers, wood workers, leather workers, and those exposed to petroleum products. The neoplastic event in myeloma may involve cells earlier in B cell differentiation than the plasma cell. Circulating B cells bearing surface immunoglobulin that share the idiotype of the M component are present in myeloma patients. Interleukin (IL) 6 may play a role in driving myeloma cell proliferation; a large fraction of myeloma cells exposed to IL-6 in vitro respond by proliferating. The IL-6 dependency of myeloma is controversial. It remains difficult to distinguish benign from malignant plasma cells on the basis of morphologic criteria in all but a few cases (Fig. 98-3).

Incidence and Prevalence About 15,270 cases of myeloma were diagnosed in 2004, and 11,070 people died from the disease. Myeloma increases in incidence with age. The median age at diagnosis is 68 years; it is rare under age 40. The yearly incidence is around 4 per 100,000 and remarkably similar throughout the world. Males are slightly more commonly affected than females, and blacks have nearly twice the incidence of whites. In the age group over 25 the incidence is 30 per 100,000. Myeloma accounts for about 1% of all malignancies in whites and 2% in blacks; 13% of all hematologic cancers in whites and 33% in blacks.

Pathogenesis and Clinical Manifestations (Table 98-1) Bone pain is the most common symptom in myeloma, affecting nearly 70% of patients. The pain usually involves the back and ribs, and unlike the pain of metastatic carcinoma, which often is worse at night, the pain of myeloma is precipitated by movement. Persistent localized pain in a patient with myeloma usually signifies a pathologic fracture. The bone lesions of myeloma are caused by the proliferation of tumor cells and the activation of osteoclasts that destroy the bone. The osteoclasts respond to osteoclast activating factors (OAF) made by the myeloma cells [OAF activity can be mediated by several cytokines, including IL-1, lymphotoxin, vascular endothelial growth factor (VEGF), receptor activator of NF-κB (RANK) ligand, macrophage inhibitory factor (MIP)-1α, and tumor necrosis factor (TNF)]. However, production of these factors decreases following administration of glucocorticoids or interferon (IFN)-α. The bone lesions are lytic in nature and are rarely associated with osteoblastic new bone formation. Therefore, radioisotopic bone scanning is less useful in diagnosis than is plain radiography. The bony lysis results in substantial mobilization of calcium from bone, and serious acute and chronic complications of hypercalcemia may dominate the clinical picture (see below). Localized bone lesions may expand to the point that mass lesions may be palpated, especially on the skull (Fig. 98-4), clavicles, and sternum, and the collapse of vertebrae may lead to spinal cord compression.

The next most common clinical problem in patients with myeloma is susceptibility to bacterial infections. The most common infections are pneumonias and pyelonephritis, and the most frequent pathogens are *Streptococcus pneumoniae*, *Staphylococcus aureus*, and *Klebsiella pneumoniae* in the lungs and *Escherichia coli* and other gram-negative organisms in the urinary tract. In about 25% of patients, recurrent infections are the presenting features, and over 75% of patients will have a serious infection at some time in their course. The susceptibility to infection has several contributing causes. First, patients with myeloma have diffuse hypogammaglobulinemia if the M component is excluded. The hypogammaglobulinemia is related to both decreased production and increased destruction of normal antibodies. Moreover, some patients generate a population of circulating regulatory cells in response to their myeloma that can suppress normal antibody synthe-

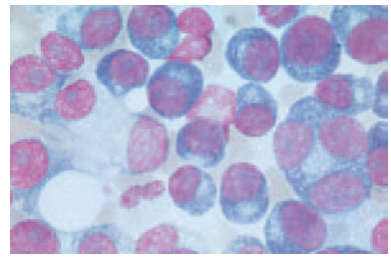

FIGURE 98-3 Multiple myeloma (marrow). The cells bear characteristic morphologic features of plasma cells, round or oval cells with an eccentric nucleus composed of coarsely clumped chromatin, a densely basophilic cytoplasm, and a perinuclear clear zone (hof) containing the Golgi apparatus. Binucleate and multinucleate malignant plasma cells can be seen.

TABLE 98-1 *Pathogenesis and Clinical Manifestations of Multiple Myeloma*

Clinical Finding	Underlying Cause	Pathogenic Mechanism
Hypercalcemia, pathologic fractures, cord compression, lytic bone lesions, osteoporosis, bone pain	Skeletal destruction	Tumor expansion; production of osteoclast activating factors (OAF) by tumor cells
Renal failure	Light chain proteinuria, hypercalcemia, urate nephropathy, amyloid glomerulopathy (rare)	Toxic effects of tumor products, light chains, OAF, DNA breakdown products
	Pyelonephritis	Hypogammaglobulinemia
Anemia	Myelophthisis, decreased production, increased destruction	Tumor expansion; production of inhibitory factors and autoantibodies by tumor cells
Infection	Hypogammaglobulinemia, decreased neutrophil migration	Decreased production due to tumor-induced suppression; increased IgG catabolism
Neurologic symptoms	Hyperviscosity, cryoglobulins, amyloid deposits	Products of tumor; properties of M component; light chains
	Hypercalcemia, cord compression	OAF
Bleeding	Interference with clotting factors, amyloid damage of endothelium, platelet dysfunction	Products of tumor; antibodies to clotting factors; light chains; antibody coating of platelets
Mass lesions		Tumor expansion

sis. In the case of IgG myeloma, normal IgG antibodies are broken down more rapidly than normal because the catabolic rate for IgG antibodies varies directly with the serum concentration. The large M component results in fractional catabolic rates of 8 to 16% instead of the normal 2%. These patients have very poor antibody responses, especially to polysaccharide antigens such as those on bacterial cell walls. Most measures of T cell function in myeloma are normal, but a subset of CD4+ cells may be decreased. Granulocyte lysozyme content is low, and granulocyte migration is not as rapid as normal in patients with myeloma, probably the result of a tumor product. There are also a variety of abnormalities in complement functions in myeloma patients. All these factors contribute to the immune deficiency of these patients.

FIGURE 98-4 Bony lesions in multiple myeloma. The skull demonstrates the typical "punched out" lesions characteristic of multiple myeloma. The lesion represents a purely osteolytic lesion with little or no osteoblastic activity. *(Courtesy of Dr. Geraldine Schechter.)*

Renal failure occurs in nearly 25% of myeloma patients, and some renal pathology is noted in over half. Many factors contribute to this. Hypercalcemia is the most common cause of renal failure. Glomerular deposits of amyloid, hyperuricemia, recurrent infections, and occasional infiltration of the kidney by myeloma cells all may contribute to renal dysfunction. However, tubular damage associated with the excretion of light chains is almost always present. Normally, light chains are filtered, reabsorbed in the tubules, and catabolized. With the increase in the amount of light chains presented to the tubule, the tubular cells become overloaded with these proteins, and tubular damage results either directly from light chain toxic effects or indirectly from the release of intracellular lysosomal enzymes. The earliest manifestation of this tubular damage is the adult Fanconi syndrome (a type 2 proximal renal tubular acidosis), with loss of glucose and amino acids, as well as defects in the ability of the kidney to acidify and concentrate the urine. The proteinuria is not accompanied by hypertension, and the protein is nearly all light chains. Generally, very little albumin is in the urine because glomerular function is usually normal. When the glomeruli are involved, the proteinuria is nonselective. Patients with myeloma also have a decreased anion gap [i.e., $Na^+ - (Cl^- + HCO_3^-)$ because the M component is cationic, resulting in retention of chloride. This is often accompanied by hyponatremia that is felt to be artificial (pseudohyponatremia) because each volume of serum has less water as a result of the increased protein. Myeloma patients are susceptible to developing acute renal failure if they become dehydrated.

Anemia occurs in about 80% of myeloma patients. It is usually normocytic and normochromic and related both to the replacement of normal marrow by expanding tumor cells and to the inhibition of hematopoiesis by factors made by the tumor. In addition, mild hemolysis may contribute to the anemia. A larger than expected fraction of patients may have megaloblastic anemia due to either folate or vitamin B_{12} deficiency. Granulocytopenia and thrombocytopenia are very rare. Clotting abnormalities may be seen due to the failure of antibody-coated platelets to function properly or to the interaction of the M component with clotting factors I, II, V, VII, or VIII. Raynaud's phenomenon and impaired circulation may result if the M component forms cryoglobulins, and hyperviscosity syndromes may develop depending on the physical properties of the M component (most common with IgM, IgG3, and IgA paraproteins). Hyperviscosity is defined on the basis of the relative viscosity of serum as compared with water. Normal relative serum viscosity is 1.8 (i.e., serum is normally almost twice as viscous as water). Symptoms of hyperviscosity occur at a level of 5 to 6, a level usually reached at paraprotein concentrations of around 40 g/L (4 g/dL) for IgM, 50 g/L (5 g/dL) for IgG3, and 70 g/L (7 g/dL) for IgA.

Although neurologic symptoms occur in a minority of patients, they may have many causes. Hypercalcemia may produce lethargy, weakness, depression, and confusion. Hyperviscosity may lead to headache, fatigue, visual disturbances, and retinopathy. Bony damage and collapse may lead to cord compression, radicular pain, and loss of bowel and bladder control. Infiltration of peripheral nerves by amyloid can be a cause of carpal tunnel syndrome and other sensorimotor mono- and polyneuropathies.

Many of the clinical features of myeloma, e.g., cord compression, pathologic fractures, hyperviscosity, sepsis, and hypercalcemia, can present as medical emergencies. Despite the widespread distribution of plasma cells in the body, tumor expansion is dominantly within bone and bone marrow and, for reasons unknown, rarely causes enlargement of spleen, lymph nodes, or gut-associated lymphatic tissue.

Diagnosis and Staging The classic triad of myeloma is marrow plasmacytosis (>10%), lytic bone lesions, and a serum and/or urine M

component. The diagnosis may be made in the absence of bone lesions if the plasmacytosis is associated with a progressive increase in the M component over time or if extramedullary mass lesions develop. There are two important variants of myeloma, solitary bone plasmacytoma and extramedullary plasmacytoma. These lesions are associated with an M component in fewer than 30% of the cases, they may affect younger individuals, and both are associated with median survivals of 10 or more years. Solitary bone plasmacytoma is a single lytic bone lesion without marrow plasmacytosis. Extramedullary plasmacytomas usually involve the submucosal lymphoid tissue of the nasopharynx or paranasal sinuses without marrow plasmacytosis. Both tumors are highly responsive to local radiation therapy. If an M component is present, it should disappear after treatment. Solitary bone plasmacytomas may recur in other bony sites or evolve into myeloma. Extramedullary plasmacytomas rarely recur or progress.

The most difficult differential diagnosis in patients with myeloma involves their separation from individuals with benign monoclonal gammopathies or monoclonal gammopathies of uncertain significance (MGUS). MGUS are vastly more common than myeloma, occurring in 1% of the population over age 50 and in up to 10% over age 75. Patients with MGUS usually have <10% bone marrow plasma cells; <30 g/L (3 g/dL) of M components; no urinary Bence Jones protein; and no anemia, renal failure, lytic bone lesions, or hypercalcemia. When bone marrow cells are exposed to radioactive thymidine in order to quantitate dividing cells, patients with MGUS always have a labeling index <1%; patients with myeloma always have a labeling index >1%. With long-term follow-up, about 1% per year of patients with MGUS go on to develop myeloma. Typically, patients with MGUS require no therapy. Their survival is about 2 years shorter than age-matched controls without MGUS.

The clinical evaluation of patients with myeloma includes a careful physical examination searching for tender bones and masses. Only a small minority of patients has an enlargement of the spleen and lymph nodes, the physiologic sites of antibody production. Chest and bone radiographs may reveal lytic lesions or diffuse osteopenia. MRI offers a sensitive means to document cord or root compression in patients with pain syndromes. A complete blood count with differential may reveal anemia. Erythrocyte sedimentation rate is elevated. Rare patients (~2%) may have plasma cell leukemia with more than 2000 plasma cells/μL. This may be seen in disproportionate frequency in IgD (12%) and IgE (25%) myelomas. Serum calcium, urea nitrogen, creatinine, and uric acid levels may be elevated. Protein electrophoresis and measurement of serum immunoglobulins are useful for detecting and characterizing M spikes, supplemented by immunoelectrophoresis, which is especially sensitive for identifying low concentrations of M components not detectable by protein electrophoresis. A 24-h urine specimen is necessary to quantitate protein excretion, and a concentrated aliquot is used for electrophoresis and immunologic typing of any M component. Serum alkaline phosphatase is usually normal even with extensive bone involvement because of the absence of osteoblastic activity. It is also important to quantitate serum β_2-microglobulin (see below). Serum soluble IL-6 receptor levels and C-reactive protein may reflect physiologic IL-6 levels in the patient.

The serum M component will be IgG in 53% of patients, IgA in 25%, and IgD in 1%; 20% of patients will have only light chains in serum and urine. Dipsticks for detecting proteinuria are not reliable at identifying light chains, and the heat test for detecting Bence Jones protein is falsely negative in about 50% of patients with light chain myeloma. Fewer than 1% of patients have no identifiable M component; these patients usually have light chain myelomas in which renal catabolism has made the light chains undetectable in the urine. IgD myeloma may also present as light chain myeloma. About two-thirds of patients with serum M components also have urinary light chains. The light chain isotype may have an impact on survival. Patients secreting lambda light chains have a significantly shorter overall survival than those secreting kappa light chains. It is not clear whether this is due to some genetically important determinant of cell proliferation or because lambda light chains are more likely to cause renal damage and form amyloid than are kappa light chains. The heavy chain isotype may have an impact on patient management as well. About half of patients with IgM paraproteins develop hyperviscosity compared with only 2 to 4% of patients with IgA and IgG M components. Among IgG myelomas, it is the IgG3 subclass that has the highest tendency to form both concentration- and temperature-dependent aggregates, leading to hyperviscosity and cold agglutination at lower serum concentrations.

The staging system for patients with myeloma is a functional system for predicting survival and is based on a variety of clinical and laboratory tests, unlike the anatomic staging systems for solid tumors. Details of the staging system are given in Table 98-2. Based on the hemoglobin, calcium, M component, and degree of skeletal involvement, the total-body tumor burden is estimated to be low (stage I, $<0.6 \times 10^{12}$ cells/m^2), intermediate (stage II, 0.6 to 1.2×10^{12} cells/m^2), or high (stage III, $>1.2 \times 10^{12}$ cells/m^2), and the stages are further subdivided on the basis of renal function [A if serum creatinine <177 mol/L (<2 mg/dL), B if >177 (>2). Patients in stage IA have a median survival of more than 5 years and those in stage IIIB about 15 months. β_2-Microglobulin is a protein of 11,000 mol wt with homologies with the constant region of immunoglobulins that is the light chain of the class I major histocompatibility antigens (HLA-A, -B, -C) on the surface of every cell. Serum β_2-microglobulin is the single most powerful predictor of survival and can substitute for staging. Patients with β_2-microglobulin levels <0.004 g/L have a median survival of 43 months and those with levels >0.004 g/L only 12 months. It is also felt that once the diagnosis of myeloma is firm, histologic features of atypia may also exert an influence on prognosis. IL-6 may be an autocrine and/or paracrine growth factor for myeloma cells; el-

TABLE 98-2 *Myeloma Staging System*

Stage	Criteria	Estimated Tumor Burden, $\times 10^{12}$ cells/m^2
I	All of the following: 1. Hemoglobin >100 g/L (>10 g/dL) 2. Serum calcium <3 mmol/L (<12 mg/dL) 3. Normal bone x-ray or solitary lesion 4. Low M-component production a. IgG level <50 g/L (<5 g/dL) b. IgA level <30 g/L (<3 g/dL) c. Urine light chain <4 g/24 h	<0.6 (low)
II	Fitting neither I nor III	0.6–1.20 (intermediate)
III	One or more of the following: 1. Hemoglobin <85 g/L (<8.5 g/dL) 2. Serum calcium >3 mmol/L (>12 mg/dL) 3. Advanced lytic bone lesions 4. High M-component production a. IgG level >70 g/L (>7 g/dL) b. IgA level >50 g/L (>5 g/dL) c. Urine light chains >12 g/24 h	>1.20 (high)

Level	Stage	Median Survival, Months
SUBCLASSIFICATION BASED ON SERUM CREATININE LEVELS		
A < 177 μmol/L (<2 mg/dL)	IA	61
B > 177 μmol/L (>2 mg/dL)	IIA,B	55
	IIIA	30
	IIIB	15
STAGING BASED ON SERUM β_2-MICROGLOBULIN LEVELS		
<0.004 g/L (<4 μg/mL)	I	43
>0.004 g/L (>4 μg/mL)	II	12

evated levels are associated with more aggressive disease. High labeling index and high levels of lactate dehydrogenase and thymidine kinase are also associated with poor prognosis.

Other factors that may influence prognosis are the number of cytogenetic abnormalities, chromosome 13q deletion, % plasma cells in the marrow, circulating plasma cells, performance status, and serum levels of IL-6, soluble IL-6 receptors, C-reactive protein, hepatocyte growth factor, C-terminal cross-linked telopeptide of collagen I, TGF-β, and syndecan-1.

TREATMENT

About 10% of patients with myeloma will have an indolent course demonstrating only very slow progression of disease over many years. Such patients only require antitumor therapy when the serum myeloma protein level rises above 50 g/L (5 g/dL) or progressive bone lesions develop. Patients with solitary bone plasmacytomas and extramedullary plasmacytomas may be expected to enjoy prolonged disease-free survival after local radiation therapy to a dose of around 40 Gy. There is a low incidence of occult marrow involvement in patients with solitary bone plasmacytoma. Such patients are usually detected because their serum M component falls slowly or disappears initially only to return after a few months. These patients respond well to systemic chemotherapy.

The vast majority of patients with myeloma require therapeutic intervention. In general such therapy is of two sorts: systemic chemotherapy to control the progression of myeloma, and symptomatic supportive care to prevent serious morbidity from the complications of the disease. All patients with stage II or III disease and stage I patients exhibiting Bence Jones proteinuria, progressive lytic bone lesions, vertebral compression fractures, recurrent infections, or rising serum M component should be treated with systemic combination chemotherapy. Therapy can prolong and improve the quality of life for myeloma patients.

The standard treatment has consisted of intermittent pulses of an alkylating agent [L-phenylalanine mustard (L-PAM, melphalan), cyclophosphamide, or chlorambucil] and prednisone administered for 4 to 7 days every 4 to 6 weeks. The alkylating agents appear to be roughly equally active, but resistance to one agent is often accompanied by resistance to the others. The usual doses are as follows: melphalan, 8 mg/m^2 per day; cyclophosphamide, 200 mg/m^2 per day; chlorambucil, 8 mg/m^2 per day; prednisone, 25 to 60 mg/m^2 per day. Melphalan is used most commonly, but because of their near equivalence in antitumor efficacy, we favor cyclophosphamide as the alkylating agent because it is less toxic to the marrow stem cell compartment and results in a lower incidence of myelodysplastic syndromes than do the other alkylating agents. Doses may need adjustment based on marrow tolerance. However, there are few constraints on the dose of the steroid pulse, and it appears that more is better. Patients responding to therapy generally have a prompt and gratifying reduction in bone pain, hypercalcemia, and anemia, and often have fewer infections. The serum M component lags substantially behind the symptomatic improvement, often taking 4 to 6 weeks to fall. This fall depends on the rate of tumor kill and the fractional catabolic rate of immunoglobulin, which in turn depends on the serum concentration (for IgG). Light chain excretion, with a functional half-life of approximately 6 h, may fall within the first week of treatment. However, since urine light chain levels may relate to renal tubular function, they are not a reliable measure of tumor cell kill. Calculations of tumor cell kill are made by extrapolation of the serum M component level and rely heavily on the assumption that every tumor cell produces immunoglobulin at a constant rate. About 60% of patients will achieve at least a 75% reduction in serum M component level and tumor cell mass in response to an alkylating agent and prednisone. Although this is a tumor reduction of less than 1 log, clinical responses may last many months. The important feature of the level of the M protein is not how far or how fast it falls, but the rate of its increase after therapy. Efforts to improve the fraction of patients responding and the degree of response have involved adding other active chemotherapeutic agents to the treatment program. Patients with more advanced disease may benefit most from such an approach. High-dose therapy with hematopoietic stem cell support can modestly extend progression-free and overall survival but few, if any, patients are cured. Sequential treatment with combination chemotherapy regimens followed by two successive high-dose melphalan treatments, each supported with peripheral blood stem cell transplants, have achieved complete responses in 50% of patients treated within a year of diagnosis. Complete responses are rare (<10%) with standard therapy. Long-term follow-up is not yet available. Allogeneic transplants may also produce high response rates, but treatment-related mortality may be as high as 40%. Nonmyeloablative allogeneic transplantation is now under evaluation to reduce toxicity while permitting an immune graft-vs-tumor effect.

The ideal duration of therapy has not been determined. Most physicians treat every 4 to 6 weeks for 1 or 2 years. Cessation of therapy is followed by relapse, usually within a year. Retreatment may be associated with a second response in up to 80% of patients. Maintenance therapy (e.g., with IFN-α) may prolong the duration of response, but this therapy is toxic and has generally not prolonged survival. Oral prednisone maintenance therapy appears to improve response duration and survival. The regrowth rate of the tumor during relapse accelerates with each relapse. This observation suggests that kinetic resistance to therapy (i.e., increase in cycling cells) is perhaps more important than drug resistance controlled by mdr-1 expression. Patients often respond to treatment, but the length of the response progressively shortens. Patients primarily resistant to initial therapy have a median survival of less than a year. High-dose pulsed glucocorticoids used alone (200 mg prednisone every other day or 1 g/m^2 per day methylprednisolone for 5 days) or VAD combination chemotherapy (vincristine, 0.4 mg/d in a 4-day continuous infusion; doxorubicin, 9 mg/m^2 per day in a 4-day continuous infusion; dexamethasone, 40 mg/d for 4 days per week for 3 weeks) may offer useful palliation in patients resistant to primary therapy. High-dose melphalan has activity in patients with refractory disease. Thalidomide, which inhibits angiogenesis, also produces responses in refractory cases, but at doses that may cause somnolence. Novel agents, including immunomodulatory derivatives of thalidomide (IMIDs) and the proteasome inhibitor, PS-341, target not only the tumor cell but also the tumor cell-bone marrow interaction and production of myeloma growth, survival, drug resistance, and migration factors. These agents can achieve responses in relapsed refractory disease and are under evaluation for efficacy earlier in the disease course.

About 15% of patients die within the first 3 months after diagnosis; subsequently, the death rate is about 15% per year. The disease usually follows a chronic course for 2 to 5 years before developing an acute terminal phase, usually marked by the development of pancytopenia with a cellular marrow that is refractory to treatment. Widespread organ infiltration by myeloma cells occurs, and survival is less than 6 months. About 46% of patients die in the chronic phase of disease from progressive myeloma (16%) and renal failure (10%), sepsis (14%), or both (6%). Death in the acute terminal phase (26%) is chiefly from progressive myeloma (13%) and sepsis (9%). Five percent of patients die of acute leukemia, myeloblastic or monocytic. Although it has been debated that this is related to the primary disease, it appears more likely to be the result of chronic therapy with alkylating agents. Nearly 23% of patients die of myocardial infarction, chronic lung disease, diabetes, or stroke, all intercurrent illnesses related more to the age of the patient group than to the tumor.

Supportive care directed at the anticipated complications of the disease may be as important as primary antitumor therapy. The hypercalcemia generally responds well to bisphosphonates, glucocorticoid therapy, hydration, and natriuresis. Calcitonin may add to the inhibitory effects of steroids on bone resorption. Bisphosphonates (e.g., pamidronate 90 mg or zoledronate 4 mg once a month) reduce osteoclastic bone resorption and preserve performance status and qual-

ity of life; antitumor effects are also possible. Treatments aimed at strengthening the skeleton, such as fluorides, calcium, and vitamin D, with or without androgens, have been suggested but are not of proven efficacy. Iatrogenic worsening of renal function may be prevented by the use of allopurinol during chemotherapy to avoid urate nephropathy and by maintaining a high fluid intake to prevent dehydration and to help excrete light chains and calcium. In the event of acute renal failure, plasmapheresis is approximately 10 times more effective at clearing light chains than peritoneal dialysis, and acutely reducing the protein load may result in functional improvement. Urinary tract infections should be watched for and treated early. Chronic dialysis probably should not be initiated in patients who have failed to respond to antitumor therapy. Plasmapheresis may be the treatment of choice for hyperviscosity syndromes. Although the pneumococcus is a dreaded pathogen in myeloma patients, pneumococcal polysaccharide vaccines may not elicit an antibody response. Prophylactic administration of intravenous γ globulin preparations is used in the setting of recurrent serious infections. Chronic oral antibiotic prophylaxis is probably not warranted. Patients developing neurologic symptoms in the lower extremities, severe localized back pain, or problems with bowel and bladder control may need emergency myelography and radiation therapy for palliation. Most bone lesions respond to analgesics and chemotherapy, but certain painful lesions may respond most promptly to localized radiation. The chronic anemia may respond to hematinics (iron, folate, cobalamin), and some have responded to androgens. The pathogenesis of the anemia should be established and specific therapy instituted, where possible. In the setting of renal disease and low serum erythropoietin levels, erythropoietin is useful to increase red cell mass.

WALDENSTRÖM'S MACROGLOBULINEMIA In 1948, Waldenström described a malignancy of lymphoplasmacytoid cells that secreted IgM. In contrast to myeloma, the disease was associated with lymphadenopathy and hepatosplenomegaly, but the major clinical manifestation was the hyperviscosity syndrome. The disease resembles the related diseases chronic lymphocytic leukemia, myeloma, and lymphocytic lymphoma. Waldenström's macroglobulinemia and IgM myeloma both follow a similar clinical course. The diagnosis of IgM myeloma is usually reserved for patients with lytic bone lesions and is important only because of the hazard of pathologic fractures.

The cause of macroglobulinemia is unknown. The disease is similar to myeloma in being slightly more common in men and occurring with increased incidence with age (median 64 years). There have been reports that the IgM in some patients with macroglobulinemia may have specificity for myelin-associated glycoprotein (MAG), a protein that has been associated with demyelinating disease of the peripheral nervous system and may be lost earlier and to a greater extent than the better known myelin basic protein in patients with multiple sclerosis. Sometimes patients with macroglobulinemia develop a peripheral neuropathy before the appearance of the neoplasm. There is speculation that the whole process begins with a viral infection that may elicit an antibody response that cross-reacts with a normal tissue component.

Like myeloma, the disease involves the bone marrow, but unlike myeloma, it does not cause bone lesions or hypercalcemia. Like myeloma, a serum M component is present in the serum in excess of 30 g/L (3 g/dL), but unlike myeloma, the size of the IgM paraprotein results in little renal excretion and only around 20% of patients excrete light chains. Therefore, renal disease is not common. The light chain isotype is kappa in 80% of the cases. Patients present with weakness, fatigue, and recurrent infections, similar to myeloma patients, but epistaxis, visual disturbances, and neurologic symptoms such as peripheral neuropathy, dizziness, headache, and transient paresis are much more common in macroglobulinemia. Physical examination reveals adenopathy and hepatosplenomegaly, and ophthalmoscopic examination may reveal vascular segmentation and dilatation of the retinal veins characteristic of hyperviscosity states. Patients may have a normocytic, normochromic anemia, but rouleaux formation and a positive Coombs' test are much more common than in myeloma. Malignant lymphocytes are usually present in the peripheral blood. About 10% of macroglobulins are cryoglobulins. These are pure M components and are not the mixed cryoglobulins seen in rheumatoid arthritis and other autoimmune diseases. Mixed cryoglobulins are composed of IgM or IgA complexed with IgG, for which they are specific. In both cases, Raynaud's phenomenon and serious vascular symptoms precipitated by the cold may occur, but mixed cryoglobulins are not commonly associated with malignancy. Patients suspected of having a cryoglobulin based on history and physical examination should have their blood drawn into a warm syringe and delivered to the laboratory in a container of warm water to avoid errors in quantitating the cryoglobulin.

℞ TREATMENT

Control of serious hyperviscosity symptoms such as an altered state of consciousness or paresis can be achieved acutely by plasmapheresis because 80% of the IgM paraprotein is intravascular. Fludarabine (25 mg/m^2 per day for 5 days every 4 weeks) or cladribine (0.1 mg/kg per day for 7 days every 4 weeks) are highly effective single agents. About 80% of patients respond to chemotherapy, and their median survival is over 3 years. Rituximab (anti-CD20) can produce responses alone or combined with chemotherapy. The absence of other serious organ toxicities results in a longer life span of patients with macroglobulinemia compared with those with myeloma.

POEMS SYNDROME The features of this syndrome are *p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy, *m*ultiple myeloma, and *s*kin changes (POEMS). Patients usually have a severe, progressive sensorimotor polyneuropathy associated with sclerotic bone lesions from myeloma. Polyneuropathy occurs in about 1.4% of myelomas, but the POEMS syndrome is only a rare subset of that group. Unlike typical myeloma, hepatomegaly and lymphadenopathy occur in about two-thirds of patients, and splenomegaly is seen in one-third. The lymphadenopathy frequently resembles Castleman's disease histologically, a condition that has been linked to IL-6 overproduction. The endocrine manifestations include amenorrhea in women and impotence and gynecomastia in men. Hyperprolactinemia due to loss of normal inhibitory control by the hypothalamus may be associated with other central nervous system manifestations such as papilledema and elevated cerebrospinal fluid pressure and protein. Type 2 diabetes mellitus occurs in about one-third of patients. Hypothyroidism and adrenal insufficiency are occasionally noted. Skin changes are diverse: hyperpigmentation, hypertrichosis, skin thickening, and digital clubbing. Other manifestations include peripheral edema, ascites, pleural effusions, fever, and thrombocytosis.

The pathogenesis of the disease is unclear, but high circulating levels of the proinflammatory cytokines IL-1, IL-6, VEGF, and TNF have been documented and levels of the inhibitory cytokine transforming growth factor (TGF-β) are lower than expected. Treatment of the myeloma may result in an improvement in the other disease manifestations.

HEAVY CHAIN DISEASES The heavy chain diseases are rare lymphoplasmacytic malignancies. Their clinical manifestations vary with the heavy chain isotype. Patients secrete a defective heavy chain that usually has an intact Fc fragment and a deletion in the Fd region. Gamma, alpha, and mu heavy chain diseases have been described, but no reports of delta or epsilon heavy chain diseases have appeared. Molecular biologic analysis of these tumors has revealed structural genetic defects that may account for the aberrant chain secreted.

Gamma Heavy Chain Disease (Franklin's Disease) This disease affects people of widely different age groups and countries of origin. It is characterized by lymphadenopathy, fever, anemia, malaise, hepatosplenomegaly, and weakness. Its most distinctive symptom is palatal edema, resulting from node involvement of Waldeyer's ring, and this may progress to produce respiratory compromise. The diagnosis depends on the demonstration of an anomalous serum M component [often $<$20 g/L ($<$2 g/dL) that reacts with anti-IgG but not anti-light chain rea-

gents. *The M component is typically present in both serum and urine*. Most of the paraproteins have been of the $gamma_1$ subclass, but other subclasses have been seen. The patients may have thrombocytopenia, eosinophilia, and nondiagnostic bone marrow. Patients usually have a rapid downhill course and die of infection; however, some patients have survived 5 years with chemotherapy.

Alpha Heavy Chain Disease (Seligmann's Disease) This is the most common of the heavy chain diseases. It is closely related to a malignancy known as *Mediterranean lymphoma*, a disease that affects young people in parts of the world where intestinal parasites are common, such as the Mediterranean, Asia, and South America. The disease is characterized by an infiltration of the lamina propria of the small intestine with lymphoplasmacytoid cells that secrete truncated alpha chains. Demonstrating alpha heavy chains is difficult because the alpha chains tend to polymerize and appear as a smear instead of a sharp peak on electrophoretic profiles. Despite the polymerization, hyperviscosity is not a common problem in alpha heavy chain disease. Without J chain–facilitated dimerization, viscosity does not increase dramatically. Light chains are absent from serum and urine. The patients present with chronic diarrhea, weight loss, and malabsorption and have extensive mesenteric and para-aortic adenopathy. Respiratory tract involvement occurs rarely. Patients may vary widely in their clinical course. Some may develop diffuse aggressive histologies of malignant lymphoma. Chemotherapy may produce long-term remissions. Rare patients appear to have responded to antibiotic therapy, raising the question of the etiologic role of antigenic stimulation, perhaps by some chronic intestinal infection. Chemotherapy plus antibiotics may be more effective than chemotherapy alone.

Mu Heavy Chain Disease The secretion of isolated mu heavy chains into the serum appears to occur in a very rare subset of patients with chronic lymphocytic leukemia. The only features that may distinguish patients with mu heavy chain disease are the presence of vacuoles in the malignant lymphocytes and the excretion of kappa light chains in the urine. The diagnosis requires ultracentrifugation or gel filtration to confirm the nonreactivity of the paraprotein with the light chain reagents, because some intact macroglobulins fail to interact with these serums. The tumor cells seem to have a defect in the assembly of light and heavy chains, because they appear to contain both in their cytoplasm. There is no evidence that such patients should be treated differently from other patients with chronic lymphocytic leukemia (Chap. 97).

99 TRANSFUSION BIOLOGY AND THERAPY

Jeffery S. Dzieczkowski, Kenneth C. Anderson

BLOOD GROUP ANTIGENS AND ANTIBODIES

The study of red blood cell (RBC) antigens and antibodies forms the foundation of transfusion medicine. Serologic studies initially characterized these antigens, but now the molecular composition and structure of many are known. Antigens, either carbohydrate or protein, are assigned to a blood group system based upon the structure and similarity of the determinant epitopes. Other cellular blood elements and plasma proteins are also antigenic and can result in *alloimmunization*, the production of antibodies directed against the blood group antigens of another individual. These antibodies are called *alloantibodies*.

Antibodies directed against RBC antigens may result from "natural" exposure, particularly to carbohydrates that mimic some blood group antigens. Those antibodies that occur via natural stimuli are usually produced by a T cell–independent response (thus, generating no memory) and are IgM isotype. *Autoantibodies* (antibodies against autologous blood group antigens) arise spontaneously or as the result of infectious sequelae (e.g., from *Mycoplasma pneumoniae*) and are also often IgM. These antibodies are often clinically insignificant due to their low affinity for antigen at body temperature. However, IgM antibodies can activate the complement cascade and result in hemolysis. Antibodies that result from allogeneic exposure, such as transfusion or pregnancy, are usually IgG. IgG antibodies commonly bind to antigen at warmer temperatures and may hemolyze RBCs. Unlike IgM antibodies, IgG antibodies can cross the placenta and bind fetal erythrocytes bearing the corresponding antigen, resulting in hemolytic disease of the newborn, or *hydrops fetalis*.

Alloimmunization to leukocytes, platelets, and plasma proteins may also result in transfusion complications such as fevers and urticaria but generally does not cause hemolysis. Assay for these other alloantibodies is not routinely performed; however, they may be detected using special assays.

ABO ANTIGENS AND ANTIBODIES The first blood group antigen system, recognized in 1900, was ABO, the most important in transfusion medicine. The major blood groups of this system are A, B, AB, and O. O type RBCs lack A or B antigens. These antigens are carbohydrates attached to a precursor backbone, may be found on the cellular membrane either as glycosphingolipids or glycoproteins, and are secreted into plasma and body fluids as glycoproteins. H substance is the immediate precursor upon which the A and B antigens are added. This H substance is formed by the addition of fucose to the glycolipid or glycoprotein backbone. The subsequent addition of *N*-acetylgalactosamine creates the A antigen, while the addition of galactose produces the B antigen.

The genes that determine the A and B phenotypes are found on chromosome 9p and are expressed in a Mendelian codominant manner. The gene products are glycosyl transferases, which confer the enzymatic capability of attaching the specific antigenic carbohydrate. Individuals who lack the "A" and "B" transferases are phenotypically type "O," while those who inherit both transferases are type "AB." Rare individuals lack the H gene, which codes for fucose transferase, and cannot form H substance. These individuals are homozygous for the silent h allele (hh) and have Bombay phenotype (O_h).

The ABO blood group system is important because essentially all individuals produce antibodies to the ABH carbohydrate antigen that they lack. The naturally occurring anti-A and anti-B antibodies are termed *isoagglutinins*. Thus, type A individuals produce anti-B, while type B individuals make anti-A. Neither isoagglutinin is found in type AB individuals, while type O individuals produce both anti-A and anti-B. Thus, persons with type AB are "universal recipients" because they do not have antibodies against any ABO phenotype, while persons

with type O blood can donate to essentially all recipients because their cells are not recognized by any ABO isoagglutinins. The rare individuals with Bombay phenotype produce antibodies to H substance (which is present on all red cells except those of hh phenotype) as well as to both A and B antigens and are therefore compatible only with other hh donors.

In most people, A and B antigens are secreted by the cells and are present in the circulation. Nonsecretors are susceptible to a variety of infections (e.g., *Candida albicans*, *Neisseria meningitidis*, *Streptococcus pneumoniae*, *Haemophilus influenzae*) as many organisms may bind to polysaccharides on cells. Soluble blood group antigens may block this binding.

Rh SYSTEM The Rh system is the second most important blood group system in pretransfusion testing. The Rh antigens are found on a 30- to 32-kDa RBC membrane protein that has no defined function. Although >40 different antigens in the Rh system have been described, five determinants account for the vast majority of phenotypes. The presence of the D antigen confers Rh "positivity," while persons who lack the D antigen are Rh negative. Two allelic antigen pairs, E/e and C/c, are also found on the Rh protein. The three Rh genes, E/e, D, and C/c, are arranged in tandem on chromosome 1 and inherited as a haplotype, i.e., cDE or Cde. Two haplotypes can result in the phenotypic expression of two to five Rh antigens.

The D antigen is a potent alloantigen. About 15% of individuals lack this antigen. Exposure of these Rh-negative people to even small amounts of Rh-positive cells, by either transfusion or pregnancy, can result in the production of anti-D alloantibody.

OTHER BLOOD GROUP SYSTEMS AND ALLOANTIBODIES More than 100 blood group systems are recognized, composed of more than 500 antigens. The presence or absence of certain antigens has been associated with various diseases and anomalies; antigens also act as receptors for infectious agents. Alloantibodies of importance in routine clinical practice are listed in Table 99-1.

Antibodies to *Lewis system* carbohydrate antigens are the most common cause of incompatibility during pretransfusion screening. The Lewis gene product is a fucosyl transferase and maps to chromosome 19. The antigen is not an integral membrane structure but is adsorbed to the RBC membrane from the plasma. Antibodies to Lewis antigens are usually IgM and cannot cross the placenta. Lewis antigens may be adsorbed onto tumor cells and may be targets of therapy.

I system antigens are also oligosaccharides related to H, A, B, and Le. I and i are not allelic pairs but are carbohydrate antigens that differ only in the extent of branching. The i antigen is an unbranched chain that is converted by the I gene product, a glycosyltransferase, into a branched chain. The branching process affects all the ABH antigens, which become progressively more branched in the first 2 years of life. Some patients with cold agglutinin disease or lymphomas can produce anti-I autoantibodies that cause RBC destruction. Occasional patients with mononucleosis or *Mycoplasma* pneumonia may develop cold agglutinins of either anti-I or anti-i specificity. Most adults lack i expression; thus, finding a donor for patients with anti-i is not difficult.

TABLE 99-1 *RBC Blood Group Systems and Alloantigens*

Blood Group System	Antigen	Alloantibody	Clinical Significance
Rh (D, C/c, E/e)	RBC protein	IgG	HTR, HDN
Lewis (Le^a, Le^b)	Oligosaccharide	IgM/IgG	Rare HTR
Kell (K/k)	RBC protein	IgG	HTR, HDN
Duffy (Fy^a/Fy^b)	RBC protein	IgG	HTR, HDN
Kidd (Jk^a/Jk^b)	RBC protein	IgG	HTR (often delayed), HDN (mild)
I/i	Carbohydrate	IgM	None
MNSsU	RBC protein	IgM/IgG	Anti-M rare HDN, anti-S, -s, and -U HDN, HTR

Note: RBC, red blood cell; HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction.

Even though most adults express I antigen, binding is generally low at body temperature. Thus, administration of warm blood prevents isoagglutination.

The *P system* is another group of carbohydrate antigens controlled by specific glycosyltransferases. Its clinical significance is in rare cases of syphilis and viral infection that lead to paroxysmal cold hemoglobinuria. In these cases, an unusual autoantibody to P is produced that binds to RBCs in the cold and fixes complement upon warming. Antibodies with these biphasic properties are called *Donath-Landsteiner antibodies*. The P antigen is the cellular receptor of parvovirus B19 and also may be a receptor for *Escherichia coli* binding to urothelial cells.

The *MNSsU system* is regulated by genes on chromosome 4. M and N are determinants on glycophorin A, an RBC membrane protein, and S and s are determinants on glycophorin B. Anti-S and anti-s IgG antibodies may develop after pregnancy or transfusion and lead to hemolysis. Anti-U antibodies are rare but problematic; virtually every donor is incompatible because nearly all persons express U.

The *Kell* protein is very large (720 amino acids) and its secondary structure contains many different antigenic epitopes. The immunogenicity of Kell is third behind the ABO and Rh systems. The absence of the Kell precursor protein (controlled by a gene on X) is associated with acanthocytosis, shortened RBC survival, and a progressive form of muscular dystrophy that includes cardiac defects. This rare condition is called the *McLeod phenotype*. The K_x gene is linked to the 91-kDa component of the NADPH-oxidase on the X chromosome, deletion or mutation of which accounts for about 60% of cases of chronic granulomatous disease.

The *Duffy* antigens are codominant alleles, Fy^a and Fy^b, that also serve as receptors for *Plasmodium vivax*. More than 70% of persons in malaria-endemic areas lack these antigens, probably from selective influences of the infection on the population.

The *Kidd* antigens, Jk^a and Jk^b, may elicit antibodies transiently. A delayed hemolytic transfusion reaction that occurs with blood tested as compatible is often related to delayed appearance of anti-Jk^a.

PRETRANSFUSION TESTING

Pretransfusion testing of a potential recipient consists of the "type and screen." The "forward type" determines the ABO and Rh phenotype of the recipient's RBC by using antisera directed against the A, B, and D antigens. The "reverse type" detects isoagglutinins in the patient's serum and should correlate with the ABO phenotype, or forward type.

The alloantibody screen identifies antibodies directed against other RBC antigens. The alloantibody screen is performed by mixing patient serum with type O RBCs that contain the major antigens of most blood group systems and whose extended phenotype is known. The specificity of the alloantibody is identified by correlating the presence or absence of antigen with the results of the agglutination.

Cross-matching is ordered when there is a high probability that the patient will require a packed RBC (PRBC) transfusion. Blood selected for cross-matching must be ABO compatible and lack antigens for which the patient has alloantibodies. Nonreactive cross-matching confirms the absence of any major incompatibility and reserves that unit for the patient.

In the case of Rh-negative patients, every attempt must be made to provide Rh-negative blood components to prevent alloimmunization to the D antigen. In an emergency, Rh-positive blood can be safely transfused to a Rh-negative patient who lacks anti-D; however, the recipient is likely to become alloimmunized and produce anti-D. Rh-negative women of childbearing age who are transfused with products containing Rh-positive RBCs should receive passive immunization with anti-D (RhoGam or WinRho) to reduce or prevent sensitization.

BLOOD COMPONENTS

Blood products intended for transfusion are routinely collected as whole blood (450 mL) in various anticoagulants. Most donated blood is processed into components: PRBCs, platelets, and fresh-frozen

TABLE 99-2 *Characteristics of Selected Blood Components*

Component	Volume, mL	Content	Clinical Response
PRBC	180–200	RBCs with variable leukocyte content and small amount of plasma	Increase hemoglobin 10 g/L and hematocrit 3%
Platelets	50–70	5.5×10^{10}/RD unit	Increase platelet count 5000–10,000/μL
	200–400	$\geq 3.0 \times 10^{11}$/SDAP product	CCI $\geq 10 \times 10^9$/L within 1 h and $\geq 7.5 \times 10^9$/L within 24 h posttransfusion
FFP	200–250	Plasma proteins—coagulation factors, proteins C and S, antithrombin	Increases coagulation factors about 2%
Cryoprecipitate	10–15	Cold-insoluble plasma proteins, fibrinogen, factor VIII, vWF	Topical fibrin glue, also 80 IU factor VIII

Note: PRBC, packed red blood cells; RBC, red blood cell; RD, random donor; SDAP, single-donor apheresis platelets; CCI, corrected count increment; FFP, fresh frozen plasma; vWF, von Willebrand factor.

plasma (FFP) or cryoprecipitate (Table 99-2). Whole blood is first separated into PRBCs and platelet-rich plasma by slow centrifugation. The platelet-rich plasma is then centrifuged at high speed to yield one unit of random donor (RD) platelets and one unit of FFP. Cryoprecipitate is produced by thawing FFP to precipitate the plasma proteins, then separated by centrifugation.

Apheresis technology is used for the collection of multiple units of platelets from a single donor. These single-donor apheresis platelets (SDAP) contain the equivalent of at least six units of RD platelets and have fewer contaminating leukocytes than pooled RD platelets.

Plasma may also be collected by apheresis. Plasma derivatives such as albumin, intravenous immunoglobulin, antithrombin, and coagulation factor concentrates are prepared from pooled plasma from many donors and are treated to eliminate infectious agents.

WHOLE BLOOD Whole blood provides both oxygen-carrying capacity and volume expansion. It is the ideal component for patients who have sustained acute hemorrhage of ≥25% total blood volume loss. Whole blood is stored at 4°C to maintain erythrocyte viability, but platelet dysfunction and degradation of some coagulation factors occurs. In addition, 2,3-bisphosphoglycerate levels fall over time, leading to an increase in the oxygen affinity of the hemoglobin and a decreased capacity to deliver oxygen to the tissues, a problem with all red cell storage. Whole blood is not readily available since it is routinely processed into components.

PACKED RED BLOOD CELLS This product increases oxygen-carrying capacity in the anemic patient. Adequate oxygenation can be maintained with a hemoglobin content of 70 g/L in the normovolemic patient without cardiac disease; however, comorbid factors often necessitate transfusion at a higher threshold. The decision to transfuse should be guided by the clinical situation and not by an arbitrary laboratory value. In the critical care setting, liberal use of transfusions to maintain near normal levels of hemoglobin may have unexpected negative effects on survival. In most patients requiring transfusion, levels of hemoglobin of 100 g/L are sufficient to keep oxygen supply from being critically low.

PRBCs may be modified to prevent certain adverse reactions. Leukocyte reduction of cellular blood products is increasingly common, and universal prestorage leukocyte reduction has been recommended. Prestorage filtration appears superior to bedside filtration as smaller amounts of cytokines are generated in the stored product. These PRBC units contain $<5 \times 10^6$ donor white blood cells (WBCs), and their use lowers the incidence of posttransfusion fever, cytomegalovirus (CMV) infections, and alloimmunization. Other theoretical benefits include less immunosuppression in the recipient and lower risk of infections. Plasma, which may cause allergic reactions, can be removed from cellular blood components by washing.

PLATELETS Thrombocytopenia is a risk factor for hemorrhage, and platelet transfusion reduces the incidence of bleeding. The threshold for prophylactic platelet transfusion is 10,000/μL. In patients without fever or infections, a threshold of 5000/μL may be sufficient to prevent spontaneous hemorrhage. For invasive procedures, 50,000/μL platelets is the usual target level.

Platelets are given either as pools prepared from five to eight RDs or as SDAPs from a single donor. In an unsensitized patient without increased platelet consumption [splenomegaly, fever, disseminated intravascular coagulation (DIC)], six to eight units of RD platelets (about 1 unit per 10 kg body weight) are transfused, and each unit is anticipated to increase the platelet count 5000 to 10,000/μL. Patients who have received multiple transfusions may be alloimmunized to many HLA- and platelet-specific antigens and have little or no increase in their posttransfusion platelet counts. Patients who may require multiple transfusions are best served by receiving SDAP and leukocyte-reduced components to lower the risk of alloimmunization.

Refractoriness to platelet transfusion may be evaluated using the corrected count increment (CCI):

$$\text{CCI} = \frac{\text{posttransfusion count} - \text{pretransfusion count}}{\text{number of platelets transfused} \times 10^{11}} \times \text{BSA}$$

where BSA is body surface area measured in square meters. The platelet count performed 1 h after the transfusion is acceptable if the CCI is 10×10^9/mL, and after 18 to 24 h an increment of 7.5×10^9/mL is expected. Patients who have suboptimal responses are likely to have received multiple transfusions and have antibodies directed against class I HLA antigens. Refractoriness can be investigated by detecting anti-HLA antibodies in the recipient's serum. Patients who are sensitized will often react with 100% of the lymphocytes used for the HLA-antibody screen, and HLA-matched SDAPs should be considered for those patients who require transfusion. Although ABO-identical HLA-matched SDAPs provide the best chance for increasing the platelet count, locating these products is difficult. Platelet cross-matching is available in some centers. Additional clinical causes for a low platelet CCI include fever, bleeding, splenomegaly, DIC, or medications in the recipient.

FRESH-FROZEN PLASMA FFP contains stable coagulation factors and plasma proteins: fibrinogen, antithrombin, albumin, as well as proteins C and S. Indications for FFP include correction of coagulopathies, including the rapid reversal of warfarin; supplying deficient plasma proteins; and treatment of thrombotic thrombocytopenic purpura. FFP should not be routinely used to expand blood volume. FFP is an acellular component and does not transmit intracellular infections, e.g., CMV. Patients who are IgA-deficient and require plasma support should receive FFP from IgA-deficient donors to prevent anaphylaxis (see below).

CRYOPRECIPITATE Cryoprecipitate is a source of fibrinogen, factor VIII, and von Willebrand factor (vWF). It is ideal for supplying fibrinogen to the volume-sensitive patient. When factor VIII concentrates are not available, cryoprecipitate may be used since each unit contains approximately 80 units of factor VIII. Cryoprecipitate may also supply vWF to patients with dysfunctional (type II) or absent (type III) von Willebrand disease.

PLASMA DERIVATIVES Plasma from thousands of donors may be pooled to derive specific protein concentrates, including albumin, intravenous immunoglobulin, antithrombin, and coagulation factors. In addition, donors who have high-titer antibodies to specific agents or antigens provide hyperimmune globulins, such as anti-D (RhoGam, WinRho),

and antisera to hepatitis B virus (HBV), varicella-zoster virus, CMV, and other infectious agents.

ADVERSE REACTIONS TO BLOOD TRANSFUSION

Adverse reactions to transfused blood components occur despite multiple tests, inspections, and checks. Fortunately, the most common reactions are not life-threatening, although serious reactions can present with mild symptoms and signs. Some reactions can be reduced or prevented by modified (filtered, washed, or irradiated) blood components. When an adverse reaction is suspected, the transfusion should be stopped and reported to the blood bank for investigation.

Transfusion reactions may result from immune and nonimmune mechanisms. Immune-mediated reactions are often due to preformed donor or recipient antibody; however, cellular elements may also cause adverse effects. Nonimmune causes of reactions are due to the chemical and physical properties of the stored blood component and its additives.

Transfusion-transmitted viral infections are increasingly rare due to improved screening and testing. As the risk of viral infection is reduced, the relative risk of other reactions increases, such as hemolytic transfusion reactions and sepsis from bacterially contaminated components. More effort is being directed at improving pretransfusion quality assurance to further increase the safety of transfusion therapy. Infections, like any adverse transfusion reaction, must be brought to the attention of the blood bank for appropriate studies (Table 99-3).

IMMUNE-MEDIATED REACTIONS ■ Acute Hemolytic Transfusion Reactions

Immune-mediated hemolysis occurs when the recipient has preformed antibodies that lyse donor erythrocytes. The ABO isoagglutinins are responsible for the majority of these reactions, although alloantibodies directed against other RBC antigens, i.e., Rh, Kell, and Duffy, may result in hemolysis.

Acute hemolytic reactions may present with hypotension, tachypnea, tachycardia, fever, chills, hemoglobinemia, hemoglobinuria, chest and/or flank pain, and discomfort at the infusion site. Monitoring the patient's vital signs before and during the transfusion is important to identify reactions promptly. When acute hemolysis is suspected, the transfusion must be stopped immediately, intravenous access maintained, and the reaction reported to the blood bank. A correctly labeled posttransfusion blood sample and any untransfused blood should be sent to the blood bank for analysis. The laboratory evaluation for hemolysis includes the measurement of serum haptoglobin, lactate dehydrogenase (LDH), and indirect bilirubin levels.

TABLE 99-3 *Risks of Transfusion Complications*

	Frequency, Episodes:Unit
Reactions	
Febrile (FNHTR)	1–4:100
Allergic	1–4:100
Delayed hemolytic	1:1,000
TRALI	1:5,000
Acute hemolytic	1:12,000
Fatal hemolytic	1:100,000
Anaphylactic	1:150,000
Infections[a]	
Hepatitis B	1:63,000
Hepatitis C	1:1,600,000
HIV-1	1:1,960,000
HIV-2	None reported
HTLV-I and -II	1:641,000
Malaria	1:4,000,000
Other complications	
RBC allosensitization	1:100
HLA allosensitization	1:10
Graft-versus-host disease	Rare

[a] Infectious agents rarely associated with transfusion, theoretically possible or of unknown risk include: Hepatitis A virus, parvovirus B-19, *Babesia microti* (babesiosis), *Borrelia burgdorferi* (Lyme disease), *Trypanosoma cruzi* (Chagas disease), and *Treponema pallidum*, human herpesvirus-8 and hepatitis G virus.

Note: FNHTR, febrile nonhemolytic transfusion reaction; TRALI, transfusion-related acute lung injury; HTLV, human T lymphotropic virus; RBC, red blood cell

The immune complexes that result in RBC lysis can cause renal dysfunction and failure. Diuresis should be induced with intravenous fluids and furosemide or mannitol. Tissue factor released from the lysed erythrocytes may initiate DIC. Coagulation studies including prothrombin time (PT), activated partial thromboplastin time (aPTT), fibrinogen, and platelet count should be monitored in patients with hemolytic reactions.

Errors at the patient's bedside, such as mislabeling the sample or transfusing the wrong patient, are responsible for the majority of these reactions. The blood bank investigation of these reactions includes examination of the pre- and posttransfusion samples for hemolysis and repeat typing of the patient samples; direct antiglobulin test (DAT), sometimes called the direct Coombs test, of the posttransfusion sample; repeating the cross-matching of the blood component; and checking all clerical records for errors. DAT detects the presence of antibody or complement bound to RBCs in vivo.

Delayed Hemolytic and Serologic Transfusion Reactions Delayed hemolytic transfusion reactions (DHTRs) are not completely preventable. These reactions occur in patients previously sensitized to RBC alloantigens who have a negative alloantibody screen due to low antibody levels. When the patient is transfused with antigen-positive blood, an anamnestic response results in the early production of alloantibody that binds donor RBCs. The alloantibody is detectable 1 to 2 weeks following the transfusion, and the posttransfusion DAT may become positive due to circulating donor RBCs coated with antibody or complement. The transfused, alloantibody-coated erythrocytes are cleared by the reticuloendothelial system. These reactions are detected most commonly in the blood bank when a subsequent patient sample reveals a positive alloantibody screen or a new alloantibody in a recently transfused recipient.

No specific therapy is usually required, although additional RBC transfusions may be necessary. Delayed serologic transfusion reactions are similar to DHTR, as the DAT is positive and alloantibody is detected; however, RBC clearance is not increased.

Febrile Nonhemolytic Transfusion Reaction The most frequent reaction associated with the transfusion of cellular blood components is a febrile nonhemolytic transfusion reaction (FNHTR). These reactions are characterized by chills and rigors and a $\geq 1°C$ rise in temperature. FNHTR is diagnosed when other causes of fever in the transfused patient are ruled out. Antibodies directed against donor leukocyte and HLA antigens may mediate these reactions; thus, multiply transfused patients and multiparous women are felt to be at increased risk. Although antibodies may be demonstrated in the recipient's serum, investigation is not routinely done because of the mild nature of most FNHTR. The use of leukocyte-reduced blood products may prevent or delay sensitization to leukocyte antigens and thereby reduce the incidence of these febrile episodes. Cytokines released from cells within stored blood components may mediate FNHTR; thus, leukoreduction before storage may prevent these reactions. The incidence and severity of these reactions can be decreased in patients with recurrent reactions by premedicating with acetaminophen or other antipyretic agents.

Allergic Reactions Urticarial reactions are related to plasma proteins found in transfused components. Mild reactions may be treated symptomatically by temporarily stopping the transfusion and administering antihistamines (diphenhydramine, 50 mg orally or intramuscularly). The transfusion may be completed after the signs and/or symptoms resolve. Patients with a history of allergic transfusion reaction should be premedicated with an antihistamine. Cellular components can be washed to remove residual plasma for the extremely sensitized patient.

Anaphylactic Reaction This severe reaction presents after transfusion of only a few milliliters of the blood component. Symptoms and signs include difficulty breathing, coughing, nausea and vomiting, hypotension, bronchospasm, loss of consciousness, respiratory arrest, and shock. Treatment includes stopping the transfusion, maintaining vas-

cular access, and administering epinephrine (0.5 to 1.0 mL of 1:1000 dilution subcutaneously). Glucocorticoids may be required in severe cases.

Patients who are IgA-deficient may be sensitized to this Ig class and are at risk for anaphylactic reactions associated with plasma transfusion. Individuals with severe IgA deficiency should therefore receive only IgA-deficient plasma and washed cellular blood components. Patients who have anaphylactic or repeated allergic reactions to blood components should be tested for IgA deficiency.

Graft-versus-Host Disease Graft-versus-host disease (GVHD) is a frequent complication of allogeneic stem cell transplantation, in which lymphocytes from the donor attack and cannot be eliminated by an immunodeficient host. Transfusion-related GVHD is mediated by donor T lymphocytes that recognize host HLA antigens as foreign and mount an immune response, which is manifested clinically by the development of fever, a characteristic cutaneous eruption, diarrhea, and liver function abnormalities. GVHD can also occur when blood components that contain viable T lymphocytes are transfused to immunodeficient recipients or to immunocompetent recipients who share HLA antigens with the donor (e.g., a family donor). In addition to the aforementioned clinical features of GVHD, transfusion-associated GVHD (TA-GVHD) is characterized by marrow aplasia and pancytopenia. TA-GVHD is highly resistant to treatment with immunosuppressive therapies, including glucocorticoids, cyclosporine, antithymocyte globulin, and ablative therapy followed by allogeneic bone marrow transplantation. Clinical manifestations appear at 8 to 10 days, and death occurs at 3 to 4 weeks posttransfusion.

TA-GVHD can be prevented by irradiation of cellular components (minimum of 2500 cGy) before transfusion to patients at risk. Patients at risk for TA-GVHD include fetuses receiving intrauterine transfusions, selected immunocompetent (e.g., lymphoma patients) or immunocompromised recipients, recipients of donor units known to be from a blood relative, and recipients who have undergone marrow transplantation. Directed donations by family members should be discouraged (they are not less likely to transmit infection); lacking other options, the blood products from family members should always be irradiated.

Transfusion-Related Acute Lung Injury This uncommon reaction results from the transfusion of donor plasma that contains high-titer anti-HLA antibodies that bind recipient leukocytes. The leukocytes aggregate in the pulmonary vasculature and release mediators that increase capillary permeability. The recipient develops symptoms of respiratory compromise and signs of noncardiogenic pulmonary edema, including bilateral interstitial infiltrates on chest x-ray. Treatment is supportive, and patients usually recover without sequelae. Testing the donor's plasma for anti-HLA antibodies can support this diagnosis. The implicated donors are frequently multiparous women, and transfusion of their plasma component should be avoided.

Posttransfusion Purpura This reaction presents as thrombocytopenia 7 to 10 days after platelet transfusion and occurs predominantly in women. Platelet-specific antibodies are found in the recipient's serum, and the most frequently recognized antigen is HPA-1a found on the platelet glycoprotein IIIa receptor. The delayed thrombocytopenia is due to the production of antibodies that react to both donor and recipient platelets. Additional platelet transfusions can worsen the thrombocytopenia and should be avoided. Treatment with intravenous immunoglobulin may neutralize the effector antibodies, or plasmapheresis can be used to remove the antibodies.

Alloimmunization A recipient may become alloimmunized to a number of antigens on cellular blood elements and plasma proteins. Alloantibodies to RBC antigens are detected during pretransfusion testing, and their presence may delay finding antigen-negative cross-match-compatible products for transfusion. Women of childbearing age who are sensitized to certain RBC antigens (i.e., D, c, E, Kell, or Duffy) are at risk for bearing a fetus with hemolytic disease of the newborn. Matching for D antigen is the only pretransfusion selection test to prevent RBC alloimmunization.

Alloimmunization to antigens on leukocytes and platelets can result in refractoriness to platelet transfusions. Once alloimmunization has developed, HLA-compatible platelets from donors who share similar antigens with the recipient may be difficult to find. Hence, prudent transfusion practice is directed at preventing sensitization through the use of leukocyte-reduced cellular components, as well as limiting antigenic exposure by the judicious use of transfusions and use of SDAPs.

NONIMMUNOLOGIC REACTIONS ■ Fluid Overload Blood components are excellent volume expanders, and transfusion may quickly lead to volume overload. Monitoring the rate and volume of the transfusion, along with the use of a diuretic, can minimize this problem.

Hypothermia Refrigerated (4°C) or frozen (−18°C or below) blood components can result in hypothermia when rapidly infused. Cardiac dysrhythmias can result from exposing the sinoatrial node to cold fluid. Use of an in-line warmer will prevent this complication.

Electrolyte Toxicity RBC leakage during storage increases the concentration of potassium in the unit. Neonates and patients in renal failure are at risk for hyperkalemia. Preventive measures, such as using fresh or washed RBCs, are warranted for neonatal transfusions because this complication can be fatal.

Citrate, commonly used to anticoagulate blood components, chelates calcium and thereby inhibits the coagulation cascade. Hypocalcemia, manifested by circumoral numbness and/or tingling sensation of the fingers and toes, may result from multiple rapid transfusions. Because citrate is quickly metabolized to bicarbonate, calcium infusion is seldom required in this setting. If calcium or any other intravenous infusion is necessary, it must be given through a separate intravenous line.

Iron Overload Each unit of RBCs contains 200 to 250 mg of iron. Symptoms and signs of iron overload affecting endocrine, hepatic, and cardiac function are common after 100 units of RBCs have been transfused (total body iron load of 20 g). Preventing this complication by using alternative therapies (e.g., erythropoietin) and judicious transfusion is preferable and cost effective. Deferoxamine and other chelating agents are available, but the response is often suboptimal.

Hypotensive Reactions Transient hypotension may be noted among transfused patients who take angiotensin-converting enzyme (ACE) inhibitors. Since blood products contain bradykinin that is normally degraded by ACE, patients on ACE inhibitors may have increased bradykinin levels that cause hypotension. The blood pressure typically returns to normal without intervention.

Immunomodulation Transfusion of allogeneic blood is immunosuppressive. Multiply transfused renal transplant recipients are less likely to reject the graft, and transfusion may result in poorer outcomes in cancer patients and increase the risk of infections. Transfused leukocytes are thought to mediate the immunosuppression. Leukocyte-depleted cellular products may cause less immunosuppression, though controlled data have not been obtained and are unlikely to be obtained as the blood supply becomes universally leukocyte-depleted.

INFECTIOUS COMPLICATIONS Nucleic acid amplification testing (NAT) has been used since 1999 to screen donated blood for the presence of HIV and hepatitis C virus RNA.

Viral Infections ■ *HEPATITIS C VIRUS (HCV)* Fewer than 150 donors have been found to be HCV RNA positive in the absence of HCV antibodies, and the risk of acquiring HCV through transfusion is now 1 in 1,600,000 units. Infection with HCV may be asymptomatic or lead to chronic active hepatitis, cirrhosis, and liver failure.

HUMAN IMMUNODEFICIENCY VIRUS TYPE 1 Improved donor screening and testing (NAT) have dramatically reduced the risk of HIV-1 infection by blood transfusion. Donated blood is tested for HIV-1 p24 antigen.

Only eight seronegative donors have been shown to harbor HIV RNA. The risk of HIV-1 infection per transfusion episode is 1 in 1.9 million. Antibodies to HIV-2 are also measured in donated blood. No cases of HIV-2 infection have been reported in the United States since 1992.

HEPATITIS B VIRUS Donated blood is screened for HBV using assays for hepatitis B surface antigen (HbsAg). NAT testing is not practical because of slow viral replication and lower levels of viremia. The risk of transfusion-associated HBV infection is 1 in 63,000 units, twenty-fold greater than for HCV. Vaccination of individuals who require long-term transfusion therapy can prevent this complication.

OTHER HEPATITIS VIRUSES Hepatitis A virus is rarely transmitted by transfusion, and the disease is typically asymptomatic and does not lead to chronic infection. Hepatitis G virus, now called GBV-C, along with two other transfusion-transmitted viruses, TTV and SEN-V, do not cause chronic hepatitis or other disease states. Routine testing does not appear to be warranted.

CYTOMEGALOVIRUS This ubiquitous virus infects ≥50% of the general population and is transmitted by the infected "passenger" WBCs found in transfused PRBCs or platelet components. Cellular components that are leukocyte-reduced have a decreased risk of transmitting CMV, regardless of the serologic status of the donor. Groups at risk for CMV infections include immunosuppressed patients, CMV-seronegative transplant recipients, and neonates; these patients should receive leukocyte-depleted components or CMV seronegative products.

HUMAN T LYMPHOTROPIC VIRUS (HTLV) TYPE I Assays to detect HTLV-I and -II are used to screen all donated blood. HTLV-1 is associated with adult T cell leukemia/lymphoma and tropical spastic paraparesis in a small percentage of infected persons (Chap. 172). The risk of HTLV-I infection via transfusion is 1 in 641,000 transfusion episodes. HTLV-II is not clearly associated with any disease.

PARVOVIRUS B-19 Blood components and products derived from pooled plasma can transmit this virus, the etiologic agent of erythema infectiosum, or fifth disease, in children. Parvovirus B-19 shows tropism for erythroid precursors and inhibits both erythrocyte production and maturation. Pure red cell aplasia, presenting either as acute aplastic crisis or chronic anemia with shortened RBC survival, may occur in individuals with an underlying hematologic disease, such as sickle cell disease or thalassemia (Chap. 94). The fetus of a seronegative woman is at risk for developing hydrops from this virus. NAT testing has reduced the risk of transfusion transmission.

Bacterial Contamination Most bacteria do not grow well at cold temperatures; thus, PRBCs and FFP are not common sources of bacterial contamination. However, some gram-negative bacteria, notably *Yersinia* and *Pseudomonas* species, can grow at 1° to 6°C. Platelet concentrates, which are stored at room temperature, are more likely to contain skin contaminants such as gram-positive organisms, including coagulase-negative staphylococci.

Recipients of transfusions contaminated with bacteria may develop fever and chills, which can progress to septic shock and DIC. These reactions may occur abruptly, within minutes of initiating the transfusion, or after several hours. The onset of symptoms and signs is often sudden and fulminant, which distinguishes bacterial contamination from a FNHTR. The reactions, particularly those related to gram-negative contaminants, are the result of infused endotoxins formed within the contaminated stored component.

When contaminated transfusions are suspected (i.e., when there is sudden development of shock), the transfusion must be stopped immediately. Therapy is directed at supporting the recipient's blood pressure, cardiac output, oxygenation, and renal function. The laboratory investigation should include cultures of any untransfused component, along with the routine blood bank clerical checks and serologic studies. Broad-spectrum antibiotic coverage should be started immediately and may be adjusted based on culture and sensitivity.

Other Infectious Agents Various parasites including those causing malaria, babesiosis, and Chagas disease can be transmitted by blood transfusion rarely. Geographic migration and travel of donors can shift the incidence of these rare infections. West Nile virus may be transmitted by transfusion. Other agents implicated in transfusion transmission include Lyme disease and varian Creutzfeld-Jakob disease. Because these infections can prove fatal, they should be considered in the transfused patient in the appropriate clinical setting.

ALTERNATIVES TO TRANSFUSION

Alternatives to allogeneic blood transfusions that avoid homologous donor exposures with attendant immunologic and infectious risks remain attractive. Autologous blood is the best option when transfusion is anticipated. However, the cost:benefit ratio of autologous transfusion remains high. No transfusion is a zero-risk event; clerical errors and bacterial contamination remain potential complications even with autologous transfusions. Additional methods of autologous transfusion in the surgical patient include preoperative hemodilution, recovery of shed blood from sterile surgical sites, and postoperative drainage collection. Directed or designated donation from friends and family of the potential recipient has not been safer than volunteer donor component transfusions. Such directed donations may in fact place the recipient at higher risk for complications such as GVHD and alloimmunization.

Oxygen-carrying blood substitutes, such as perfluorocarbons and aggregated hemoglobin solution, are presently in various stages of clinical trials. Granulocyte and granulocyte-macrophage colony-stimulating factor are clinically useful to hasten leukocyte recovery in patients with leukopenia related to high-dose chemotherapy. Erythropoietin stimulates erythrocyte production in patients with anemia of chronic renal failure and other conditions, thus avoiding or reducing the need for transfusion. This hormone can also stimulate erythropoiesis in the autologous donor to enable additional donation. Thrombopoietin, a cytokine that promotes megakaryocyte proliferation and maturation, is being tested for its ability to reduce the need for platelet transfusion.

100 HEMATOPOIETIC CELL TRANSPLANTATION

Frederick R. Appelbaum

Bone marrow transplantation was the original term used to describe the collection and transplantation of hematopoietic stem cells, but with the recent demonstration that the peripheral blood and umbilical cord blood are also useful sources of stem cells, *hematopoietic cell transplantation* has become the preferred generic term for this process. The procedure is usually carried out for one of two purposes: (1) to replace an abnormal but nonmalignant lymphohematopoietic system with one from a normal donor, or (2) to treat malignancy by allowing the administration of higher doses of myelosuppressive therapy than would otherwise be possible. The use of bone marrow transplantation has been steadily increasing, both because of its demonstrated effectiveness in selected diseases and because of increasing availability of donors. The International Bone Marrow Transplant Registry (*http://www.ibmtr.org*) estimates that about 50,000 transplants are performed each year.

THE HEMATOPOIETIC STEM CELL

Several features of the hematopoietic stem cell make transplantation clinically feasible, including its remarkable regenerative capacity, its ability to home to the marrow space following intravenous injection, and the ability of the stem cell to be cryopreserved. Transplantation of a single stem cell can replace the entire lymphohematopoietic system of an adult mouse. In humans, transplantation of a few percent of a donor's bone marrow volume regularly results in complete and sustained replacement of the recipient's entire lymphohematopoietic system, including all red cells, granulocytes, B and T lymphocytes, and platelets, as well as cells comprising the fixed macrophage population, including Kupffer cells of the liver, pulmonary alveolar macrophages, osteoclasts, Langerhans cells of the skin, and brain microglial cells. The ability of the hematopoietic stem cell to home to the marrow following intravenous injection is mediated, at least in part, by the interaction of specific cell molecules, termed *selectins*, on bone marrow endothelial cells with their unique ligands, termed *integrins*, on early hematopoietic cells. Human hematopoietic stem cells can survive freezing and thawing with little, if any, damage, making it possible to remove and store a portion of the patient's own bone marrow for later reinfusion following treatment of the patient with high-dose myelotoxic therapy.

CATEGORIES OF HEMATOPOIETIC CELL TRANSPLANTATION

Hematopoietic cell transplantation can be described according to the relationship between the patient and the donor and by the anatomic source of stem cells. In ~1% of cases, patients have identical twins who can serve as donors. Syngeneic donors represent the best source of stem cells; unlike the use of allogeneic donors, there is no risk of graft-versus-host disease (GVHD) and, unlike the use of autologous marrow, there is no risk that the stem cells are contaminated with tumor cells.

Allogeneic transplantation involves a donor and recipient who are not immunologically identical. Following allogeneic transplantation immune cells transplanted with the marrow or developing from it can react against the patient, causing GVHD. Alternatively, if the immunosuppressive preparative regimen used to treat the patient before transplant is inadequate, immunocompetent cells of the patient can cause graft rejection. The risks of these complications are greatly influenced by the degree of matching between donor and recipient for antigens encoded by genes of the major histocompatibility complex.

The human leukocyte antigen (HLA) molecules are responsible for binding antigenic proteins and presenting them to T cells. The antigens presented by HLA molecules may derive from exogenous sources (e.g., during active infections) or may be endogenous proteins produced by the cell. If individuals are not matched for HLA, T cells from one individual will react strongly to the mismatched HLA, or "major antigens," of the second. Even if the individuals are HLA-matched, the T cells of the donor may react to differing endogenous, or "minor antigens," presented by the HLA of the recipient. Reactions to minor antigens tend to be less vigorous. The genes of major relevance to transplantation include HLA-A, -B, -C, and -D; they are closely linked and therefore tend to be inherited as haplotypes, with only rare crossovers between them. Thus, the odds that any one full sibling will match a patient are one in four, and the probability that the patient has an HLA-identical sibling is $1 - (0.75)^n$, where n equals the number of siblings.

With current techniques, the risk of graft rejection is 1 to 3%, and the risk of severe, life-threatening acute GVHD is ~15% following transplantation between HLA-identical siblings. The incidence of graft rejection and GVHD increases progressively with the use of family member donors mismatched for one, two, or three antigens. While survival following a one-antigen mismatched transplant is not markedly altered, survival following two- or three-antigen mismatched transplants is significantly impaired, and such transplants should be performed only as part of clinical trials.

The formation of the National Marrow Donor Program has allowed for the identification of HLA-matched unrelated donors for many patients. The genes encoding HLA antigens are highly polymorphic, and thus the odds of any two unrelated individuals being HLA-identical are extremely low, somewhat less than 1 in 10,000. However, by identifying and typing >7 million volunteer donors, HLA-matched donors can now be found for ~50% of patients for whom a search is initiated. It takes, on average, 3 to 4 months to complete a search and schedule and initiate an unrelated donor transplant. Results so far suggest that GVHD is somewhat increased and survival somewhat poorer with such donors than with HLA-matched siblings.

Autologous transplantation involves the removal and storage of the patient's own stem cells with subsequent reinfusion after the patient receives high-dose myeloablative therapy. Unlike allogeneic transplantation, there is no risk of GVHD or graft rejection with autologous transplantation. On the other hand, autologous transplantation lacks a graft-versus-tumor (GVT) effect, and the autologous stem cell product can be contaminated with tumor cells that could lead to relapse. A variety of techniques have been developed to "purge" autologous products of tumor cells. Some use antibodies directed at tumor-associated antigens plus complement, antibodies linked to toxins, or antibodies conjugated to immunomagnetic beads. In vitro incubation with certain chemotherapeutic agents such as 4-hydroperoxycyclophosphamide and long-term culture of bone marrow have also been shown to diminish tumor cell numbers in stem cell products. Another technique is positive selection of stem cells using antibodies to CD34, with subsequent column adherence or flow techniques to select normal stem cells while leaving tumor cells behind. All these approaches can reduce the number of tumor cells from 1000- to 10,000-fold and are clinically feasible; however, no prospective randomized trials have yet shown that any of these approaches results in a decrease in relapse rates or improvements in disease-free or overall survival.

Bone marrow aspirated from the posterior and anterior iliac crests has traditionally been the source of hematopoietic stem cells for transplantation. Typically, anywhere from 1.5 to 5×10^8 nucleated marrow cells per kilogram are collected for allogeneic transplantation. Several recent studies have found improved survival in the settings of both matched sibling and unrelated transplantation by transplanting higher numbers of bone marrow cells.

Hematopoietic stem cells circulate in the peripheral blood but in very low concentrations. Following the administration of certain hematopoietic growth factors, including granulocyte colony-stimulating factor (G-CSF) or granulocyte-macrophage colony-stimulating factor (GM-CSF), and during recovery from intensive chemotherapy, the

concentration of hematopoietic progenitor cells in blood, as measured either by colony-forming units or expression of the CD34 antigen, increases markedly. This has made it possible to harvest adequate numbers of stem cells from the peripheral blood for transplantation. Donors are typically treated with 4 or 5 days of hematopoietic growth factor, following which stem cells are collected in one or two 4-h pheresis sessions. In the autologous setting, transplantation of $>2.5 \times 10^6$ CD34 cells per kilogram, a number easily collected in most circumstances, leads to rapid and sustained engraftment in virtually all cases. Compared to the use of autologous marrow, use of peripheral blood stem cells results in more rapid hematopoietic recovery, with granulocytes recovering to 500/μL by day 12 and platelets recovering to 20,000/μL by day 14. While this more rapid recovery diminishes the morbidity of transplantation, no studies show an improvement in survival.

Hesitation in studying the use of peripheral blood stem cells for allogeneic transplantation was because peripheral blood stem cell products contain as much as one log more T cells than are contained in the typical marrow harvest; in animal models, the incidence of GVHD is related to the number of T cells transplanted. Nonetheless, phase II and randomized phase III trials have shown that the use of growth factor–mobilized peripheral blood stem cells from HLA-matched family members leads to faster engraftment without an increase in acute GVHD. Chronic GVHD may be increased with peripheral blood stem cells, but in trials conducted so far, this has been more than balanced by reductions in relapse rates and nonrelapse mortality, with the use of peripheral blood stem cells resulting in improved overall survival.

Umbilical cord blood contains a high concentration of hematopoietic progenitor cells, allowing for its use as a source of stem cells for transplantation. Cord blood transplantation from family members has been explored in the setting where the immediate need for transplantation precludes waiting the 9 or so months generally required for the baby to mature to the point of donating marrow. Use of cord blood in such settings results in somewhat slower engraftment than seen with marrow but a low incidence of GVHD, perhaps reflecting the low number of T cells in cord blood. Several banks have been developed to harvest and store cord blood for possible transplantation to unrelated patients from material that would otherwise be discarded. A summary of the first 562 unrelated cord blood transplants, facilitated by the New York Blood Center, reported engraftment in ~85% of patients but at a slower pace than seen with marrow. Severe GVHD was seen in 23% of patients. The risk of graft failure was related to the dose of cord blood cells per kilogram infused. The low cell content of most cord blood collections has limited the use of this approach as a source of stem cells for adult patients.

THE TRANSPLANT PREPARATIVE REGIMEN

The treatment regimen administered to patients immediately preceding transplantation is designed to eradicate the patient's underlying disease and, in the setting of allogeneic transplantation, immunosuppress the patient adequately to prevent rejection of the transplanted marrow. The appropriate regimen, therefore, depends on the disease setting and source of marrow. For example, when transplantation is performed to treat severe combined immunodeficiency and the donor is a histocompatible sibling, no treatment is required because no host cells require eradication and the patient is already too immunoincompetent to reject the transplanted marrow. For aplastic anemia, there is no large population of cells to eradicate and high-dose cyclophosphamide plus antithymocyte globulin are sufficient to immunosuppress the patient adequately to accept the marrow graft. In the setting of thalassemia and sickle cell anemia, high-dose busulfan is frequently added to cyclophosphamide in order to eradicate the hyperplastic host hematopoiesis. A variety of different regimens have been developed to treat malignant diseases. Most of these regimens include agents that have high activity against the tumor in question at conventional doses and have myelosuppression as their predominant dose-limiting toxicity. Therefore, these regimens commonly include busulfan, cyclophosphamide, melphalan, thiotepa, carmustine, etoposide, and total-body irradiation in various combinations.

Although high-dose treatment regimens have typically been used in transplantation, the understanding that much of the antitumor effect of transplantation derives from an immunologically mediated GVT response has led investigators to ask if less intensive "nonmyeloablative" regimens might be effective and more tolerable. Evidence for a GVT effect comes from studies showing posttransplant relapse rates are lowest in patients who develop acute and chronic GVHD, higher in those without GVHD, and higher still in recipients of T cell–depleted allogeneic or syngeneic marrow. The demonstration that complete remissions can be obtained in many patients who have relapsed posttransplant by simply administering viable lymphocytes from the original donor further strengthens the argument for a potent GVT effect. Accordingly, a variety of less intensive nonmyeloablative regimens have been studied, ranging in intensity from the very minimum required to achieve engraftment (e.g., fludarabine plus 200 cGy total-body irradiation) to regimens of more immediate intensity (e.g., fludarabine plus melphalan). Studies to date document that engraftment can be readily achieved with less toxicity than seen with conventional transplantation. Complete sustained responses have been documented in many patients, particularly those with more indolent hematologic malignancies. The precise role of nonmyeloablative transplants in any one disease category, however, has not yet been fully defined.

THE TRANSPLANT PROCEDURE

Marrow is usually collected from the donor's posterior and sometimes anterior iliac crests with the donor under general or spinal anesthesia. Typically, 10 to 15 mL/kg of marrow is aspirated, placed in heparinized media, and filtered through 0.3- and 0.2-mm screens to remove fat and bony spicules. The collected marrow may undergo further processing depending on the clinical situation, such as the removal of red cells to prevent hemolysis in ABO-incompatible transplants, the removal of donor T cells to prevent GVHD, or attempts to remove possible contaminating tumor cells in autologous transplantation. Marrow donation is safe, with only very rare complications reported.

Peripheral blood stem cells are collected by leukopheresis after the donor has been treated with hematopoietic growth factors or, in the setting of autologous transplantation, sometimes after treatment with a combination of chemotherapy and growth factors. Stem cells for transplantation are generally infused through a large-bore central venous catheter. Such infusions are usually well tolerated, although occasionally patients develop fever, cough, or shortness of breath. These symptoms usually resolve with slowing of the infusion. When the stem cell product has been cryopreserved using dimethyl sulfoxide, patients more often experience short-lived nausea or vomiting due to the odor and taste of the cryoprotectant.

ENGRAFTMENT

Peripheral blood counts usually reach their nadir several days to a week posttransplant as a consequence of the preparative regimen, then cells produced by the transplanted stem cells begin to appear in the peripheral blood. The rate of recovery depends on the source of stem cells, the use of posttransplant growth factors, and the form of GVHD prophylaxis employed. If marrow is the source of stem cells, recovery to 100 granulocytes/μL occurs by day 16 and 500/μL by day 22. Use of G-CSF-mobilized peripheral blood stem cells speeds the rate of recovery by ~1 week when compared to marrow. Use of myeloid growth factor (G-CSF or GM-CSF) posttransplant can further accelerate recovery by 3 to 5 days, while use of methotrexate to prevent GVHD delays engraftment by a similar period. Following allogeneic transplantation, engraftment can be documented using fluorescence in situ hybridization of sex chromosomes if donor and recipient are sex-mismatched, HLA-typing if HLA-mismatched, or restriction fragment length polymorphism analysis if sex- and HLA-matched.

COMPLICATIONS FOLLOWING HEMATOPOIETIC CELL TRANSPLANT

EARLY DIRECT CHEMORADIOTOXICITIES The transplant preparative regimens commonly used cause a spectrum of acute toxicities that vary according to the specific regimen but frequently result in nausea, vomiting, and mild skin erythema (Fig. 100-1). Regimens that include high-dose cyclophosphamide can result in hemorrhagic cystitis, which can usually be prevented by bladder irrigation or with the sulfhydryl compound, mercaptoethanesulfonate (MESNA); rarely, acute hemorrhagic carditis is seen. Most preparative regimens will result in oral mucositis, which typically develops 5 to 7 days posttransplant and often requires narcotic analgesia. Use of a patient-controlled analgesic pump provides the greatest patient satisfaction and results in a lower cumulative dose of narcotic. Patients begin losing their hair 5 to 6 days posttransplant and by 1 week are usually profoundly pancytopenic.

Approximately 10% of patients will develop venoocclusive disease of the liver, a syndrome resulting from direct cytotoxic injury to hepatic-venular and sinusoidal endothelium, with subsequent deposition of fibrin and the development of a local hypercoagulable state. This chain of events results in the clinical symptoms of tender hepatomegaly, ascites, jaundice, and fluid retention. These symptoms can develop any time during the first month posttransplant, with the peak incidence at day 16. The mortality of venoocclusive disease is ~30%, with progressive hepatic failure culminating in a terminal hepatorenal syndrome. Both thrombolytic and antithrombotic agents, such as tissue plasminogen activator, heparin, and prostaglandin E, have been studied as therapy, but none has proven of consistent major benefit in controlled trials and all have significant toxicity. Early studies with defibrotide, a polydeoxyribonucleotide, seem encouraging.

Although most pneumonias developing posttransplant are caused by infectious agents, in ~5% of patients a diffuse interstitial pneumonia will develop that is thought to be the result of direct toxicity of the preparative regimen. Bronchoalveolar lavage typically shows alveolar hemorrhage, and biopsies are typically characterized by diffuse alveolar damage, although some cases may have a more clearly interstitial pattern. High-dose glucocorticoids are often used as treatment, although randomized trials testing their utility have not been reported.

LATE DIRECT CHEMORADIOTOXICITIES Late complications of the preparative regimen include decreased growth velocity in children and delayed development of secondary sex characteristics. These complications can be partly ameliorated with the use of appropriate growth and sex hormone replacement. Most men become azoospermic, and most postpubertal women will develop ovarian failure, which should be treated. Thyroid dysfunction, usually well compensated, is sometimes seen. Cataracts develop in 10 to 20% of patients and are most common in patients treated with total-body irradiation and those who receive glucocorticoid therapy posttransplant for treatment of GVHD. Aseptic necrosis of the femoral head is seen in 10% of patients and is particularly frequent in those receiving chronic glucocorticoid therapy.

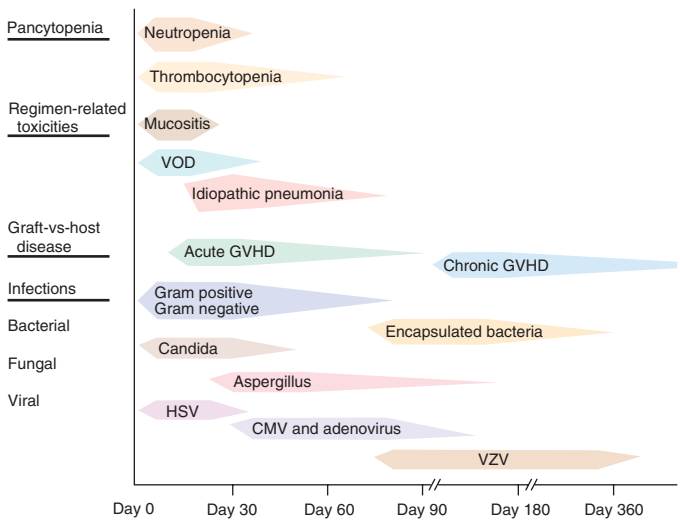

FIGURE 100-1 Major syndromes complicating marrow transplantation. VOD, venoocclusive disease; GVHD, graft-versus-host disease; HSV, herpes simplex virus; CMV, cytomegalovirus; VZV, varicella-zoster virus. The size of the shaded area roughly reflects the risk of the complication.

GRAFT-VERSUS-HOST DISEASE GVHD is the result of allogeneic T cells that were either transferred with the donor's stem cell inoculum or develop from it, reacting with antigenic targets on host cells. GVHD developing within the first 3 months posttransplant is termed *acute GVHD*, while GVHD developing or persisting beyond 3 months posttransplant is termed *chronic GVHD*. Acute GVHD most often first becomes apparent 2 to 4 weeks posttransplant and is characterized by an erythematous maculopapular rash; persistent anorexia or diarrhea, or both; and by liver disease with increased serum levels of bilirubin, alanine and aspartate aminotransferase, and alkaline phosphatase. Since many conditions can mimic acute GVHD, diagnosis usually requires skin, liver, or endoscopic biopsy for confirmation. In all these organs, endothelial damage and lymphocytic infiltrates are seen. In skin, the epidermis and hair follicles are damaged; in liver, the small bile ducts show segmental disruption; and in intestines, destruction of the crypts and mucosal ulceration may be noted. A commonly used rating system for acute GVHD is shown in Table 100-1. Grade I acute GVHD is of little clinical significance, does not affect the likelihood of survival, and does not require treatment. In contrast, grades II to IV GVHD are associated with significant symptoms and a poorer probability of survival and require aggressive therapy. The incidence of acute GVHD is higher in recipients of stem cells from mismatched or unrelated donors, in older patients, and in patients unable to receive full doses of drugs used to prevent the disease.

One general approach to the prevention of GVHD is the administration of immunosuppressive drugs early after transplant. Combinations of methotrexate and either cyclosporine or tacrolimus are among the most effective and widely used regimens. Prednisone, anti–T cell antibodies, mycophenolate mofetil, and other immunosuppressive agents have also been or are being studied in various combinations. A second general approach to GVHD prevention is removal of T cells from the stem cell inoculum. While effective in preventing GVHD, T cell depletion is associated with an increased incidence of graft failure and of tumor recurrence posttransplant; as yet, little evidence suggests that this approach improves cure rates in any specific setting.

Despite prophylaxis, significant acute GVHD will develop in ~30% of recipients of stem cells from matched siblings and in as many as 60% of those receiving stem cells from unrelated donors. The disease is usually treated with glucocorticoids, antithymocyte globulin, or monoclonal antibodies targeted against T cells or T cell subsets.

Between 20 and 50% of patients surviving >6 months after allogeneic transplantation will develop chronic GVHD. The disease is more common in older patients, in recipients of mismatched or unrelated stem cells, and in those with a preceding episode of acute GVHD. The disease resembles an autoimmune disorder with malar rash, sicca syndrome, arthritis, obliterative bronchiolitis, and bile duct degeneration and cholestasis. Single-agent prednisone or cyclosporine is standard treatment at present, although trials of other agents, including thalidomide, are under way. In most patients, chronic GVHD resolves, but it may require 1 to 3 years of immunosuppressive treatment before these agents can be withdrawn without the disease recurring. Because patients with chronic GVHD are susceptible to significant infection, they should receive prophylactic trimethoprim-sulfamethoxazole, and all suspected infections should be investigated and treated aggressively.

GRAFT FAILURE While complete and sustained engraftment are usually seen posttransplant, occasionally marrow function either does not return or, after a brief period of engraftment, is lost. Graft failure after autologous transplantation can be the result of inadequate numbers of stem cells being transplanted, damage during ex vivo treatment or

storage, or exposure of the patient to myelotoxic agents posttransplant. Infections with cytomegalovirus (CMV) or human herpes virus type 6 have also been associated with loss of marrow function. Graft failure after allogeneic transplantation can also be due to immunologic rejection of the graft by immunocompetent host cells. Immunologically based graft rejection is more common following use of less immunosuppressive preparative regimens, in recipients of T cell–depleted stem cell products, and in patients receiving grafts from HLA-mismatched donors.

Treatment of graft failure usually involves removing all potentially myelotoxic agents from the patient's regimen and attempting a short trial of myeloid growth factor. Persistence of lymphocytes of host origin in allogeneic transplant recipients with graft failure indicates immunologic rejection. Reinfusion of donor stem cells in such patients is usually unsuccessful unless preceded by a second immunosuppressive preparative regimen. Standard preparative regimens are generally tolerated poorly if administered within 100 days of a first transplant because of cumulative toxicities. However, use of regimens combining, for example, anti-CD3 antibodies with high-dose glucocorticoids have been successful in achieving engraftment in >50% of patients.

INFECTION Posttransplant patients, particularly recipients of allogeneic transplantation, require unique approaches to the problem of infection. Early after transplantation, patients are profoundly neutropenic, and because the risk of bacterial infection is so great, most centers initiate antibiotic treatment once the granulocyte count falls to <500/μL. Fluconazole prophylaxis at a dose of 200 to 400 mg/kg per day reduces the risk of candidal infections. Patients seropositive for herpes simplex should receive acyclovir prophylaxis. One approach to infection prophylaxis is shown in Table 100-2. Despite these prophylactic measures, most patients will develop fever and signs of infection posttransplant. The management of patients who become febrile despite bacterial and fungal prophylaxis is a difficult challenge and is guided by individual aspects of the patient and by the institution's experience. →***The general problem of infection in the immunocompromised host is discussed in Chap. 117.***

Once patients engraft, the incidence of bacterial infection diminishes; however, patients, particularly allogeneic transplant recipients, remain at significant risk of infection. During the period from engraftment until about 3 months posttransplant, the most common causes of infection are gram-positive bacteria, fungi (particularly *Aspergillus*) and viruses including CMV. CMV infection, which in the past was frequently seen and often fatal, can be prevented in seronegative patients by the use of seronegative blood products. The use of ganciclovir, either as prophylaxis beginning at the time of engraftment or initiated when CMV first reactivates as evidenced by development of antigenemia, can significantly reduce the risk of CMV disease in seropositive patients. Foscarnet is effective for some patients who develop CMV antigenemia or infection despite the use of ganciclovir or who cannot tolerate the drug.

Pneumocystis carinii pneumonia, once seen in 5 to 10% of patients, can be prevented by treating patients with oral trimethoprim-sulfamethoxazole for 1 week pretransplant and resuming the treatment once patients have engrafted.

The risk of infection diminishes considerably beyond 3 months after transplant unless chronic GVHD develops, requiring continuous immunosuppression. Most transplant centers recommend continuing trimethoprim-sulfamethoxazole prophylaxis while patients are receiving any immunosuppressive drugs and also recommend careful monitoring for late CMV reactivation. In addition, many centers recommend prophylaxis against varicella zoster, using acyclovir for 1 year posttransplant.

TABLE 100-1 *Clinical Staging and Grading of Acute Graft-versus-Host Disease*

Clinical Stage	Skin	Liver—Bilirubin, μmol/L (mg/dL)	Gut
1	Rash <25% body surface	34–51 (2–3)	Diarrhea 500–1000 mL/d
2	Rash 25–50% body surface	51–103 (3–6)	Diarrhea 1000–1500 mL/d
3	Generalized erythroderma	103–257 (6–15)	Diarrhea >1500 mL/d
4	Desquamation and bullae	>257 (> 15)	Ileus

II	1–3	1	1
III	1–3	2–3	2–3
IV	2–4	2–4	2–4

TREATMENT OF SPECIFIC DISEASES USING HEMATOPOIETIC CELL TRANSPLANTATION

NONMALIGNANT DISEASES ■ Immunodeficiency Disorders By replacing abnormal stem cells with cells from a normal donor, hematopoietic cell transplantation can cure patients of a variety of immunodeficiency disorders including severe combined immunodeficiency, Wiskott-Aldrich syndrome, and Chédiak-Higashi syndrome. The widest experience has been with severe combined immunodeficiency disease, where cure rates of 90% can be expected with HLA-identical donors and success rates of 50 to 70% have been reported using haplotype-mismatched parents as donors (Table 100-3).

Aplastic Anemia Transplantation from matched siblings after a preparative regimen of high-dose cyclophosphamide and antithymocyte globulin can cure up to 90% of patients <40 years with severe aplastic anemia. Results in older patients and in recipients of mismatched family member or unrelated marrow are less favorable; therefore, a trial of immunosuppressive therapy is generally recommended for such patients before considering transplantation. Transplantation is effective in all forms of aplastic anemia including, for example, the syndromes associated with paroxysmal nocturnal hemoglobinuria and Fanconi's anemia. Patients with Fanconi's anemia are abnormally sensitive to the toxic effects of alkylating agents and so less intensive preparative regimens must be used in their treatment (Chap. 94).

Hemoglobinopathies Marrow transplantation from an HLA-identical sibling following a preparative regimen of busulfan and cyclophosphamide can cure 70 to 90% of patients with thalassemia major. The best outcomes can be expected if patients are transplanted before they develop hepatomegaly or portal fibrosis and if they have been given adequate iron chelation therapy. Among such patients, the probabilities of 5-year survival and disease-free survival are 95 and 90%, respectively. Although prolonged survival can be achieved with aggressive chelation therapy, transplantation is the only curative treatment for

TABLE 100-2 *Approach to Infection Prophylaxis in Allogeneic Transplant Recipients*

Organism		Approach
Bacterial	Ceftazidime	2 g IV q8h while neutropenic
Fungal	Fluconazole	400 mg PO qd to day 75 posttransplant
Pneumocystis carinii	Trimethoprim-sulfamethoxazole	1 double-strength tablet PO bid 2 days/week until day 180 or off immunosuppression
Viral		
Herpes simplex	Acyclovir	800 mg PO bid to day 30
Varicella zoster	Acyclovir	800 mg PO bid to day 365
Cytomegalovirus	Ganciclovir	5 mg/kg IV bid for 7 days, then 5 (mg/kg)/d 5 days/week to day 100

thalassemia. Transplantation is being studied as a curative approach to patients with sickle cell anemia. Two-year survival and disease-free survival rates of 90 and 80%, respectively, have been reported following matched sibling transplantation. Decisions about patient selection and the timing of transplantation remain difficult, but transplantation seems to represent a reasonable option for younger patients who suffer repeated crises or other significant complications and who have not responded to other interventions (Chap. 91).

Other Nonmalignant Diseases Theoretically, hematopoietic cell transplantation should be able to cure any disease that results from an inborn error of the lymphohematopoietic system. Transplantation has been used successfully to treat congenital disorders of white blood cells such as Kostmann's syndrome, chronic granulomatous disease, and leukocyte adhesion deficiency. Congenital anemias such as Blackfan-Diamond anemia can also be cured with transplantation. Infantile malignant osteopetrosis is due to an inability of the osteoclast to resorb bone, and since osteoclasts derive from the marrow, transplantation can cure this rare inherited disorder.

Hematopoietic cell transplantation has been used as treatment for a number of storage diseases caused by enzymatic deficiencies, such as Gaucher's disease, Hurler's syndrome, Hunter's syndrome, and infantile metachromatic leukodystrophy. Transplantation for these diseases has not been uniformly successful, but treatment early in the course of these diseases, before irreversible damage to extramedullary organs has occurred, increases the chance for success.

Transplantation is being explored as a treatment for severe acquired autoimmune disorders. These trials are based on studies demonstrating that transplantation can reverse autoimmune disorders in animal models and on the observation that occasional patients with coexisting autoimmune disorders and hematologic malignancies have been cured of both with transplantation.

MALIGNANT DISEASES ■ Acute Leukemia Allogeneic hematopoietic cell transplantation cures 15 to 20% of patients who do not achieve complete response from induction chemotherapy for acute myeloid leukemia (AML) and is the only form of therapy that can cure such patients. Cure rates of 30 to 35% are seen when patients are transplanted in second remission or in first relapse. The best results with allogeneic transplantation are achieved when applied during first remission, with disease-free survival rates averaging 55 to 60%. Chemotherapy alone can cure a portion of AML patients, and so the relative merits of transplanting all patients during first remission versus only transplanting very high risk patients and those who relapse continue to be discussed. Autologous transplantation is also able to cure a portion of patients with AML. The rates of disease recurrence with autologous transplantation are higher than seen after allogeneic transplantation, and cure rates are generally somewhat less.

Similar to patients with AML, adults with acute lymphocytic leukemia who do not achieve a complete response to induction chemotherapy can be cured in 15 to 20% of cases with immediate transplantation. Cure rates improve to 30 to 50% in second remission, and therefore transplantation can be recommended for adults who have persistent disease after induction chemotherapy or who have subsequently relapsed. Transplantation in first remission results in cure rates around 55%. While transplantation appears to offer a clear advantage over chemotherapy for patients with high-risk disease, such as those with Philadelphia chromosome–positive disease, debate continues about whether adults with standard-risk disease should be transplanted in first remission or whether transplantation should be reserved until relapse. Autologous transplantation is associated with a higher relapse rate but a somewhat lower risk of nonrelapse mortality when compared to allogeneic transplantation. On balance, most experts recommend use of allogeneic stem cells if an appropriate donor is available.

Chronic Leukemia Allogeneic hematopoietic cell transplantation is the only therapy shown to cure a substantial portion of patients with chronic myeloid leukemia (CML). Five-year disease-free survival rates are 15 to 20% for patients transplanted for blast crisis, 25 to 50% for accelerated-phase patients, and 60 to 70% for chronic phase patients, with cure rates as high as 80% at selected centers. Time from diagnosis to transplantation influences outcome, with best results obtained among patients transplanted within 1 year of diagnosis. Use of unrelated donors results in more GVHD and slightly worse survival than seen with matched siblings, although, at some large centers, 3-year disease-free survival rates of 70% have been reported. Autologous transplantation is being studied; however, few data suggest that this approach has curative potential in this disease. The timing of transplantation in CML has become more complicated with the introduction of imatinib mesylate, a remarkably effective, relatively nontoxic oral agent. Because imatinib does not generally result in complete molecular remissions, many would argue that allogeneic transplantation remains the treatment of choice for younger patients with matched donors. For older patients and those without matched donors, an initial trial of imatinib is appropriate (Chap. 96).

Allogeneic transplantation has been used to only a limited extent for chronic lymphocytic leukemia, in large part because of the chronic nature of the disease and because of the age profile of patients. With allogeneic transplantation, complete remissions have been achieved in the majority of patients so far reported, with disease-free survival rates of ~50% at 3 years. However, treatment-related mortality has been substantial, and further follow-up is needed. There is even less experience with autologous transplantation in this disorder.

Myelodysplasia Between 40 and 50% of patients with myelodysplasia appear to be cured with allogeneic transplantation. Results are better among younger patients and those with less advanced disease. However, some patients with myelodysplasia can live for extended periods without intervention, and so transplantation is generally recommended only for patients with disease categorized as intermediate risk I or greater according to the International Prognostic Scoring System (Chap. 94).

Lymphoma Patients with disseminated intermediate- or high-grade non-Hodgkin's lymphoma who have not been cured by first-line chemotherapy and are transplanted in first relapse or second remission can still be cured in 40 to 50% of cases. This represents a clear advantage over results obtained with salvage chemotherapy. It is unsettled whether patients with high-risk disease benefit from transplantation in first remission. Most experts favor the use of autol-

ogous rather than allogeneic transplantation for patients with non-Hodgkin's lymphoma, because fewer complications occur with this approach and survival appears equivalent. The role of transplantation in patients with indolent non-Hodgkin's lymphoma is less well defined. Long-term remissions can be obtained in many patients with acceptable toxicity and results with transplantation in patients with recurrent disease generally appear better than one would expect with conventional-dose chemotherapy. However, late relapses are seen after transplantation, and no randomized study has confirmed its superiority.

The role of transplantation in Hodgkin's disease is similar to that in non-Hodgkin's lymphoma. With transplantation, 5-year disease-free survival is 20 to 30% in patients who never achieve a first remission with standard chemotherapy and up to 60% for those transplanted in second remission. Transplantation has no defined role in first remission in Hodgkin's disease.

Myeloma Patients with myeloma who have progressed on first-line therapy can sometimes benefit from allogeneic or autologous transplantation. Autologous transplantation has been studied as part of the initial therapy of patients, and in randomized trials, both disease-free survival as well as overall survival were improved with this approach. A strategy of autologous transplantation followed by nonmyeloablative allogeneic transplantation has shown encouraging results.

Solid Tumors Among women with metastatic breast cancer, 15 to 20% disease-free survival rates at 3 years have been reported, with better results seen in younger patients who have responded completely to standard-dose therapy before undergoing transplantation. Randomized trials have not shown superior survival for patients treated for metastatic disease with high-dose chemotherapy plus stem cell support. Randomized trials evaluating transplantation as treatment for primary breast cancer are being conducted, but final results are not yet available.

Patients with testicular cancer who have failed first-line chemotherapy have been treated with autologous transplantation; ~10 to 20% of such patients apparently have been cured with this approach.

The use of high-dose chemotherapy with autologous stem cell support is being studied for several other solid tumors, including ovarian cancer, small cell lung cancer, neuroblastoma, and pediatric sarcomas. As in most other settings, the best results have been obtained in patients with limited amounts of disease and where the remaining tumor retains sensitivity to conventional-dose chemotherapy. Few randomized trials of transplantation in these diseases have been completed.

Partial and complete responses have been reported following nonmyeloablative allogeneic transplantation for several solid tumors, most notably renal cell carcinomas. These results suggest that the GVT effect, well documented in the treatment of hematologic malignancies, may under certain circumstances apply to selected solid tumors.

Posttransplant Relapse Patients who relapse following autologous transplantation sometimes respond to further chemotherapy, particularly if the remission following transplantation was long. More options are available for patients who relapse following allogeneic transplantation. Of particular interest are the response rates seen with infusion of unirradiated donor lymphocytes. Complete responses in as many as 75% of patients with chronic myeloid leukemia, 40% in myelodysplasia, 25% in AML, and 15% in myeloma have been reported. Major complications of donor lymphocyte infusions include transient myelosuppression and the development of GVHD. These complications appear to be dependent on the number of donor lymphocytes given and the schedule of infusions, with less GVHD seen with lower dose, fractionated schedules.

Section 3 Disorders of Hemostasis

101 DISORDERS OF THE PLATELET AND VESSEL WALL

Robert I. Handin

Patients with platelet or vessel wall disorders usually bleed into superficial sites such as the skin, mucous membranes, or genitourinary or gastrointestinal tract. Bleeding begins immediately after trauma and either responds to simple measures, such as pressure and packing, or requires systemic therapy with glucocorticoids, desmopressin, plasma fractions, or platelet concentrates. The most common platelet/vessel wall disorders are (1) various forms of thrombocytopenia, (2) von Willebrand's disease (vWD), and (3) drug-induced platelet dysfunction. This chapter reviews the diagnosis and treatment of quantitative and qualitative platelet disorders as well as vessel wall defects that cause bleeding.→***For further discussion of the physiology of normal hemostasis and the cardinal manifestations of bleeding arising from hemostatic disorders, see Chap. 53.***

PLATELET DISORDERS

Platelets arise from the fragmentation of megakaryocytes, which are very large, polyploid bone marrow cells produced by the process of endomitosis. They undergo from three to five cycles of chromosomal duplication without cytoplasmic division. After leaving the marrow space, about one-third of the platelets are sequestered in the spleen, while the other two-thirds circulate for 7 to 10 days. Normally, only a small fraction of the platelet mass is consumed in the process of hemostasis, so most platelets circulate until they become senescent and are removed by phagocytic cells. The normal blood platelet count is 150,000 to 450,000/μL. A decrease in platelet count stimulates an increase in the number, size, and ploidy of megakaryocytes, releasing additional platelets into the circulation. This process is regulated by thrombopoietin (TPO) binding to its megakaryocyte receptor, a protooncogene c-mpl. TPO (c-mpl ligand) is secreted continuously at a low level and binds tightly to circulating platelets. A reduction in platelet count increases the level of free TPO and thereby stimulates megakaryocyte and platelet production.

The platelet count varies during the menstrual cycle, rising following ovulation and falling at the onset of menses. It is also influenced by the patient's nutritional state and can be decreased in severe iron, folic acid, or vitamin B_{12} deficiency. Platelets are acute-phase reac-

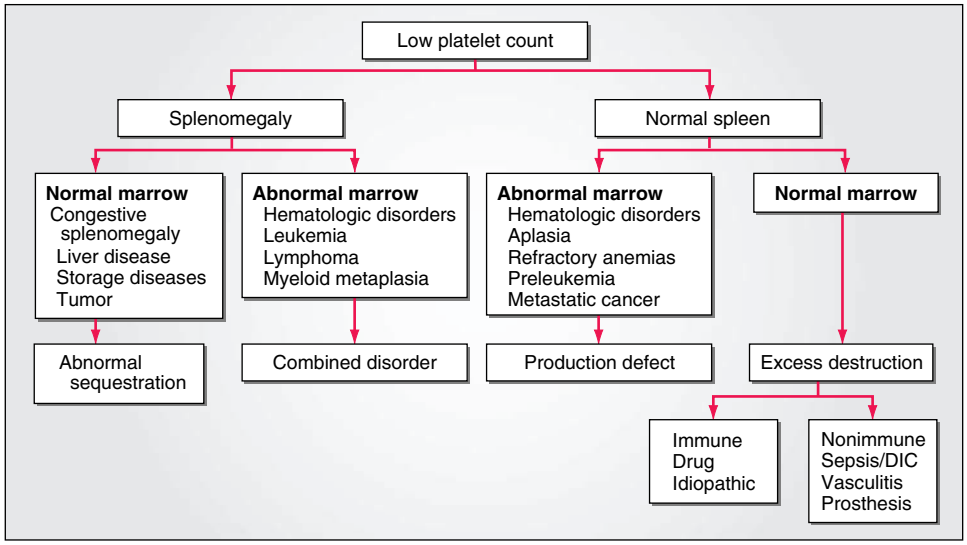

FIGURE 101-1 Clinical evaluation of patients with thrombocytopenia. [*Modified from RI Handin, in W Beck (ed), Hematology, 4th ed. Cambridge, MA, MIT Press, 1985.*]

tants, and patients with systemic inflammation, tumors, bleeding, and mild iron deficiency may have an increased platelet count, a benign condition called *secondary, or reactive, thrombocytosis*. The cytokines interleukin (IL) 3, IL-6, and IL-11 may stimulate platelet production in acute inflammation. In these conditions, the platelet count is usually $<$ 1 million/μL. In contrast, the increase in platelet count that is characteristic of the myeloproliferative disorders such as polycythemia vera, chronic myeloid leukemia, myeloid metaplasia, and essential thrombocytosis can be much higher and cause either severe bleeding or thrombosis. In these patients, unregulated platelet production is secondary to a clonal stem cell abnormality affecting all bone marrow progenitors.

THROMBOCYTOPENIA Thrombocytopenia is caused by one of three mechanisms—decreased bone marrow production, increased splenic sequestration, or accelerated destruction of platelets. In order to determine the etiology of thrombocytopenia, each patient should have a careful examination of the peripheral blood film, an assessment of marrow morphology by examination of an aspirate or biopsy, and an estimate of splenic size by bedside palpation supplemented, if necessary, by ultrasonography or computed tomography (CT). Occasional patients have "pseudothrombocytopenia," a benign condition in which platelets agglutinate or adhere to leukocytes when blood is collected with EDTA as anticoagulant. This is a laboratory artifact, and the actual platelet count in vivo is normal. A scheme for classifying patients with thrombocytopenia based on these clinical observations and laboratory tests is outlined in Fig. 101-1.

Impaired Production Disorders that injure stem cells or prevent their proliferation frequently cause thrombocytopenia. They usually affect multiple hematopoietic cell lines so that thrombocytopenia is accompanied by varying degrees of anemia and leukopenia. Diagnosis of a platelet production defect is readily established by examination of a bone marrow aspirate or biopsy, which should show a reduced number of megakaryocytes. The most common causes of decreased platelet production are marrow aplasia, fibrosis, or infiltration with malignant cells, all of which produce highly characteristic marrow abnormalities. Occasionally, thrombocytopenia is the presenting laboratory abnormality in these disorders. Cytotoxic drugs impair megakaryocyte proliferation and maturation and frequently cause thrombocytopenia. Rare marrow disorders, such as congenital amegakaryocytic hypoplasia and thrombocytopenia with absent radii (TAR syndrome), produce a selective decrease in megakaryocyte production.

Splenic Sequestration Since one-third of the platelet mass is normally sequestered in the spleen, splenectomy will increase the platelet count by 30%. Postsplenectomy thrombocytosis is a benign self-limited condition that does not require specific therapy. In contrast, when the spleen enlarges, the fraction of sequestered platelets increases, lowering the platelet count. The most common causes of splenomegaly are portal hypertension secondary to liver disease and splenic infiltration with tumor cells in myeloproliferative or lymphoproliferative disorders (Chap. 54). Isolated splenomegaly is rare, and in most patients it is accompanied by other clinical manifestations of an underlying disease. Many patients with leukemia, lymphoma, or a myeloproliferative syndrome have both marrow infiltration and splenomegaly and develop thrombocytopenia from a combination of impaired marrow production and splenic sequestration of platelets.

Accelerated Destruction Abnormal vessels, fibrin thrombi, and intravascular prostheses can all shorten platelet survival and cause nonimmunologic thrombocytopenia. Thrombocytopenia is common in patients with vasculitis, the hemolytic uremic syndrome (HUS), thrombotic thrombocytopenic purpura (TTP), or as a manifestation of disseminated intravascular coagulation (DIC). In addition, platelets coated with antibody, immune complexes, or complement are rapidly cleared by mononuclear phagocytes in the spleen or other tissues, inducing immunologic thrombocytopenia. The most common causes of immunologic thrombocytopenia are viral or bacterial infections, drugs (often heparin), and a chronic autoimmune disorder referred to as *idiopathic thrombocytopenic purpura* (ITP). Patients with immunologic thrombocytopenia do not usually have splenomegaly and have an increased number of bone marrow megakaryocytes.

DRUG-INDUCED THROMBOCYTOPENIA Many common drugs can cause thrombocytopenia (Table 101-1). Cancer chemotherapeutic agents may depress megakaryocyte production. Ingestion of large quantities of alcohol has a marrow-depressing effect leading to transient thrombocytopenia, particularly in binge drinkers. Thiazide diuretics, used to treat hypertension or congestive heart failure, impair megakaryocyte production and can produce mild thrombocytopenia (50,000 to 100,000/μL), which may persist for several months after the drug is discontinued.

Most drugs induce thrombocytopenia by eliciting an immune response in which the platelet is an innocent bystander. The platelet is damaged by complement activation following the formation of drug-antibody complexes. Current laboratory tests can identify the causative agent in 10% of patients with clinical evidence of drug-induced thrombocytopenia. The best proof of a drug-induced etiology is a prompt rise in the platelet count when the suspected drug is discontinued. Patients with drug-induced platelet destruction may also have a secondary increase in megakaryocyte number without other marrow abnormalities.

Although most patients recover within 7 to 10 days and do not require therapy, occasional patients with platelet counts $<$10,000 to 20,000/μL have severe hemorrhage and may require temporary support with glucocorticoids, plasmapheresis, or platelet transfusions

TABLE 101-1 *Drugs That May Cause Thrombocytopenia*

1. Chemotherapeutic agents—especially carboplatin, alkylating agents, anthracyclines, antimetabolites
2. Antibiotics—sulfonamides, penicillins, cephalosporins
3. Heparins—highest incidence is with unfractionated products
4. Cardiovascular agents—thiazide diuretics, rarely angiotensin converting enzyme inhibitors

while waiting for the platelet count to rise. A patient who has recovered from drug-induced immunologic thrombocytopenia should be instructed to avoid the offending drug in the future, since only minute amounts of drug are needed to set up subsequent immune reactions. Certain drugs that are cleared from body storage depots quite slowly, such as phenytoin, may induce prolonged thrombocytopenia.

Heparin is a common cause of thrombocytopenia in hospitalized patients. Between 10 and 15% of patients receiving therapeutic doses of unfractionated heparin develop thrombocytopenia (heparin-induced thrombocytopenia, HIT) and, occasionally, may have severe bleeding or intravascular platelet aggregation and paradoxical thrombosis. Heparin-induced thrombosis, sometimes called the "white clot syndrome," can be fatal unless recognized promptly. Heparin can cause mild thrombocytopenia by directly agglutinating platelets (type I HIT). The more serious form (type II HIT) results from an immune reaction. The offending antigen is a complex formed between heparin and the platelet-derived heparin-neutralizing protein, platelet factor 4. Type II HIT is particularly severe because the heparin–PF-4 antibody complexes bind the platelet Fc receptor and induce platelet activation and secretion. Prompt cessation of heparin will reverse the thrombocytopenia and lepirudin can reduce the risk of thrombosis. Low-molecular-weight heparin products have reduced the incidence of HIT. They are effective antithrombotic agents (Chap. 103) and are less immunogenic. Unfortunately, 80 to 90% of the antibodies generated against conventional heparins cross-react with low-molecular-weight heparins, so only a minority of patients with preformed antibody can be treated with these products. Several potent thrombin inhibitors with different structures from heparin can be used to treat patients with HIT (Chap. 103). Argatroban is the current drug of choice, but pentasaccharides that mimic heparin's active site are in development.

IDIOPATHIC THROMBOCYTOPENIC PURPURA The immunologic thrombocytopenias can be classified on the basis of the pathologic mechanism, the inciting agent, or the duration of the illness. The explosive onset of severe thrombocytopenia following recovery from a viral exanthem or upper respiratory illness (*acute ITP*) is common in children and accounts for 90% of the pediatric cases of immunologic thrombocytopenia. Of these patients, 60% recover in 4 to 6 weeks and >90% recover within 3 to 6 months. Transient immunologic thrombocytopenia also complicates some cases of infectious mononucleosis, acute toxoplasmosis, or cytomegalovirus infection and can be part of the prodromal phase of viral hepatitis and initial infection with HIV. Acute ITP is rare in adults and accounts for <10% of postpubertal patients with immune thrombocytopenia. Acute ITP is caused by immune complexes containing viral antigens that bind to platelet Fc receptors or by antibodies produced against viral antigens that cross-react with the platelet. In addition to these viral disorders, the differential diagnosis includes atypical presentations of aplastic anemia, acute leukemias, or metastatic tumor. A bone marrow examination is essential to exclude these disorders, which can occasionally mimic acute ITP.

Most adults present with a more indolent form of thrombocytopenia that may persist for many years and is referred to as *chronic ITP*. Women age 20 to 40 are afflicted most commonly and outnumber men by a ratio of 3:1. They may present with an abrupt fall in platelet count and bleeding similar to patients with acute ITP. More often they have a prior history of easy bruising or menometrorrhagia. These patients have an autoimmune disorder with antibodies directed against target antigens on the glycoprotein (Gp) IIb/IIIa or, less frequently, the Gp Ib/IX complex (Fig. 53-2). Although most antibodies function as opsonins and accelerate platelet clearance by phagocytic cells, occasional antibodies bind to epitopes on critical regions of these glycoproteins and impair platelet function. Platelet-associated IgG can be measured, but specificity is a problem. High "background" level of IgG on normal platelets and elevations in plasma immunoglobulin levels or in circulating immune complexes will nonspecifically increase platelet-associated IgG. Few clinical situations require platelet-associated IgG testing.

A low platelet count may be the initial manifestation of systemic lupus erythematosus (SLE) or the first sign of a primary hematologic disorder. Thus, patients with chronic ITP should have a bone marrow examination and an antinuclear antibody determination. In addition, patients with hepatic or splenic enlargement, lymphadenopathy, or atypical lymphocytes should have serologic studies for hepatitis viruses, cytomegalovirus, Epstein-Barr virus, *Toxoplasma*, and HIV. HIV infection is a common cause of immunologic thrombocytopenia. Thrombocytopenia can be the initial symptom of HIV infection or a complication of fully developed clinical AIDS.

TREATMENT

Treatment of patients with ITP must take into account the age of the patient, the severity of the illness, and the anticipated natural history. Although adults have a higher incidence of intracranial bleeding than children, specific therapy may not be necessary unless the platelet count is <20,000/μL or there is extensive bleeding. Hemorrhage in patients with either acute or chronic ITP can usually be controlled with glucocorticoids but, in rare cases, may require temporary phagocytic blockade with intravenous immunoglobulin (IVIg) or anti-RhD (WinRho). Although antibody preparations are effective, they are expensive and should be reserved for patients with severe thrombocytopenia and clinical bleeding who are refractory to other measures. Emergency splenectomy is usually reserved for patients with acute or chronic ITP who are desperately ill and have not responded to any medical measures. The treatment of symptomatic thrombocytopenia in patients with HIV infection is more complex because the administration of glucocorticoids or splenectomy may increase susceptibility to opportunistic infections. Splenectomy has been effective in the course of HIV before the onset of symptomatic AIDS. Treatment with zidovudine (AZT) and other antiviral agents that reduce viral load can improve the platelet count in patients with HIV-induced thrombocytopenia.

Symptomatic patients with chronic ITP are usually placed on prednisone, 60 mg/d for 4 to 6 weeks. The drug is then decreased slowly over another few weeks. About 50% of patients with chronic ITP will normalize their platelet count on high doses of prednisone. However, the majority will have a fall in platelet count following steroid withdrawal. Patients with chronic ITP who fail to maintain a normal platelet count after a course of prednisone are eligible for elective splenectomy. These glucocorticoid-responsive but glucocorticoid-dependent patients are very likely to respond to splenectomy, and 70% will have a normal platelet count within 1 week after surgery. Splenectomy can now often be performed by minimally invasive laparoscopic techniques that reduce morbidity and shorten hospital stay. Some patients who do not respond to glucocorticoids may still respond to splenectomy. Occasionally, patients may fail to respond to splenectomy because of the failure to remove an accessory spleen. In other patients, a small, inactive accessory spleen may grow or new splenic foci may develop from splenic cells shed at the time of surgery and cause the late onset of thrombocytopenia. In either case, the presence of splenic tissue can be diagnosed by examination of the blood smear for Howell-Jolly bodies that appear in the red cells of asplenic individuals. Persistent splenic tissue can be confirmed by a radionuclide scan.

Patients still thrombocytopenic after splenectomy or who relapse months to years after initial therapy have received a variety of immunosuppressive drugs including azathioprine, cyclophosphamide, vincristine, vinblastine, and cyclosporine. Danazol has also been used with some success. Although each of these drugs may be beneficial, they have serious side effects and should be used judiciously. IVIg and anti-RhD are only transiently effective and expensive. IVIg can cause meningismus and headache, and some lots have carried hepatitis C virus. Anti-RhD can cause hemolysis. These drugs should be used to raise the platelet count temporarily and to support patients before surgery or labor and delivery; they are not substitutes for splenectomy. If a patient is not bleeding and maintains a platelet count >20,000/

μL, consideration should be given to withholding therapy. Patients with severe chronic thrombocytopenia may live with their disease for two or three decades.

Rituximab, an anti-CD20 monoclonal antibody used to treat lymphoma, has also proven an effective approach to ITP and is probably preferable to long-term glucocorticoid therapy. Rituximab eliminates normal B cells, including those producing the antiplatelet antibody. This B cell depletion is transient (lasting 12 to 18 months, normally) and has surprisingly few side effects or toxicities.

FUNCTIONAL PLATELET DISORDERS As described in Chap. 53, normal hemostasis requires three critical platelet reactions—adhesion, aggregation, and granule release. Clinical bleeding can result from a failure of any of these important functions. Table 101-2 lists the major functional platelet disorders. Table 101-3 lists methods to assess platelet function.

von Willebrand's Disease vWD is the most common inherited bleeding disorder, occurring in 1 in 100 to 500 individuals. The von Willebrand factor (vWF) is a heterogeneous multimeric plasma glycoprotein with two major functions: (1) It facilitates platelet adhesion under conditions of high shear stress by linking platelet membrane receptors to vascular subendothelium; and (2) it serves as the plasma carrier for factor VIII, the antihemophilic factor, a critical blood coagulation protein. Discrete domains in each vWF subunit mediate each of these important functions. The normal plasma vWF level is 10 mg/L. The vWF activity is distributed among a series of plasma multimers with estimated molecular weights ranging from 400,000 to >20 million. A single large vWF precursor subunit is synthesized in endothelial cells and megakaryocytes, where it is cleaved and assembled into the disulfide-linked multimers present in plasma, platelets, and vascular subendothelium. A modest reduction in plasma vWF concentration or a selective loss in the high-molecular-weight multimers decreases platelet adhesion and causes clinical bleeding.

Although vWD is heterogeneous, certain clinical features are common to all the syndromes. With one exception (type III disease), all forms are inherited as autosomal dominant traits, and affected patients are heterozygous with one normal and one abnormal vWF allele. In mild cases, bleeding occurs only after surgery or trauma. More severely affected patients have spontaneous epistaxis or oral mucosal, gastrointestinal, or genitourinary bleeding. The laboratory findings are variable. The most diagnostic pattern is the combination of (1) a prolonged bleeding time, (2) a reduction in plasma vWF concentration, (3) a parallel reduction in biologic activity as measured with the ristocetin cofactor assay, and (4) reduced factor VIII activity. The variability in laboratory tests is related to both the heterogeneous nature of the defects in vWD and the fact that plasma levels are influenced by ABO blood group type, central nervous system disorders, systemic inflammation, and pregnancy. Since vWD is an autosomal dominant disorder, some vWF is produced by the remaining normal allele. Thus patients with mild defects may have laboratory values that fluctuate over time and may occasionally be within the normal range.

There are three major types of vWD. Their mode of inheritance and laboratory findings are shown in Fig. 101-2. Patients with type I disease, the most common abnormality, have a mild to moderate decrease in plasma vWF. In the milder cases, although hemostasis is impaired, the vWF level is just below normal (50% activity, or 5 mg/L). In type I disease, vWF antigen, factor VIII activity, and ristocetin cofactor activity are decreased with a normal spectrum of multimers detected by sodium dodecyl sulfate (SDS)–agarose gel electrophoresis.

The variant forms of vWD (type II disease) are much less common and characterized by normal or near-normal levels of a dysfunctional protein. Patients with the type IIa variant of vWD have a deficiency in the high- and medium-molecular-weight forms of vWF multimer detected by SDS-agarose electrophoresis. This is due either to an inability to secrete the high-molecular-weight vWF multimers or to proteolysis of the multimers soon after they leave the endothelial cell and enter the circulation. Mutations in a localized region of the vWF A-2 domain have been identified in families with type IIa vWD (Fig. 101-3). The quantity of vWF antigen and the amount of associated factor VIII are usually normal. In the type IIb variant, high-molecular-weight multimers are also decreased; however, the decrease is due to the inappropriate binding of vWF to platelets. Intravascular platelet aggregates form that are rapidly cleared from the circulation, causing mild, variable thrombocytopenia. Mutations in a disulfide-bonded loop in the A-1 domain that binds to Gp Ib/IX are the cause of the type IIb defect (Fig. 101-3). A few patients have a platelet membrane disorder that mimics type IIb vWD—*platelet-type vWD*. It is due to mutations in the portion of Gp Ib/IX that interacts with vWF. Levels of total vWF antigen and factor VIII are normal.

Approximately 1 in 1 million individuals has a very severe form of vWD that is phenotypically recessive (type III disease). Type III patients are usually the offspring of two parents (usually asymptomatic) with mild type I disease. Type III patients may inherit a different abnormality from each parent (a doubly heterozygous or compound

TABLE 101-2 Classification of Functional Platelet Disorders

I. Disorders of adhesion
  A. Inherited
    1. Bernard-Soulier syndrome
    2. von Willebrand's disease (vWD)
  B. Acquired
    1. Uremia
    2. Acquired vWD
II. Disorders of aggregation
  A. Inherited
    1. Glanzmann's thrombasthenia
    2. Afibrinogenemia
  B. Acquired
    1. Fibrin degradation product inhibition
    2. Dysproteinemias
    3. Drugs—e.g., ticlopidine, Gp IIb/IIIa inhibitors
III. Disorders of granule release
  A. Inherited
    1. Oculocutaneous albinism (Hermansky-Pudlak syndrome)
    2. Chédiak-Higashi syndrome
    3. Isolated dense (δ) granule deficiency
    4. Gray-platelet syndrome—combined α and β granule deficiency
  B. Acquired
    1. Cardiopulmonary bypass
    2. Myeloproliferative disorders
    3. Drugs—aspirin and other nonsteroidal anti-inflammatory agents

TABLE 101-3 Evaluation of Platelet Function

Bleeding time
  Modified Ivy method
  Skin incision—time to stop bleeding
  Global screen of platelet role in hemostasis
von Willebrand factor assays
  vWF Ag—immunoassay of total vWF protein
  vWF: RCof—bioassay of vWF that measures ability of patient plasma to support agglutination of normal platelets in the presence of ristocetin
  Factor VIII—coagulation assay of factor VIII bound and carried by plasma vWF
Platelet aggregometry
  Measures platelet aggregation in response to a panel of agonists, usually ADP, collagen, arachidonic acid, and epinephrine
Membrane glycoproteins
  Presence of glycoproteins Ib/IX and IIb/IIIa can be measured using monoclonal antibodies and flow cytometry
Platelet granule content
  Dense granules—electron microscopy or uptake and retention of radiolabeled serotonin
  Alpha granules—electron microscopy and/or immunoassays for platelet-associated proteins—vWF, fibrinogen, platelet factor 4

Note: vWF, von Willebrand factor; ADP, adenosine diphosphate; Ag, antigen, R:Cof, ristocetin cofactor.

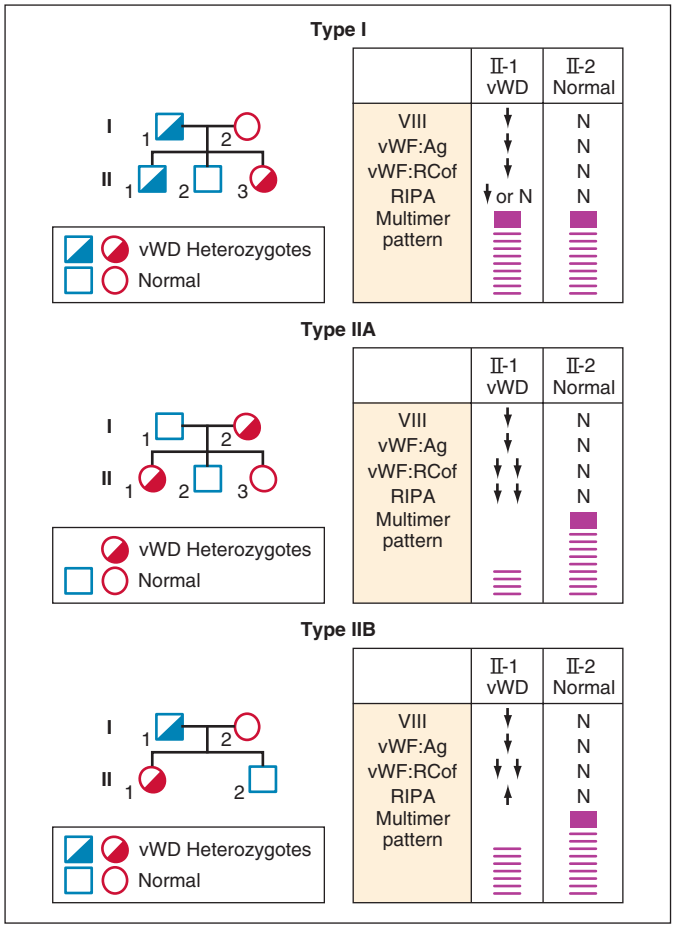

FIGURE 101-2 Pattern of inheritance and laboratory findings in von Willebrand's disease. The assays of platelet function include a coagulation assay of factor VIII bound and carried by von Willebrand factor (vWF), abbreviated as VIII; immunoassay of total vWF protein, abbreviated vWF:Ag; bioassay of the ability of patient plasma to support ristocetin-induced agglutination of normal platelets, abbreviated vWF:RCoF; and ristocetin-induced aggregation of patient platelets, abbreviated RIPA. The multimer pattern illustrates the protein bonds present when plasma is electrophoresed in a polyacrylamide gel. The II-1 and II-2 columns refer to the phenotypes of the second-generation offspring.

heterozygous state) or be homozygous for a single defect. Type III patients have severe mucosal bleeding and no detectable vWF antigen or activity and, like patients with mild hemophilia, may have sufficiently low factor VIII that they have occasional hemarthroses. Major deletions in the vWF gene have been found in some type III families. Families with nonsense mutations and the combination of a deleted and nonsense mutant allele have also been described.

Type IIn disease is due to a defect in the factor VIII binding site of vWF. Patients resemble those with mild hemophilia and have low levels of factor VIII. The presence of disease in both males and females in a family is a clue to the role of vWF in this disease.

TREATMENT

There are two therapeutic options. Factor VIII concentrates retain high-molecular-weight vWF multimers (Humate-P, Alfanate), are highly purified and heat-treated to destroy HIV, and are appropriate treatments for all the inherited forms of vWD. During surgery or after major trauma, patients should receive factor VIII concentrates twice daily for 2 to 3 days to assure optimal hemostasis. Minor bleeding episodes such as prolonged epistaxis or severe menorrhagia may respond to a single infusion. Recurrent menorrhagia, a major problem for women with severe vWD, can be treated effectively with oral contraceptive agents that suppress menses.

A second therapeutic option, which avoids the use of plasma, is the use of desmopressin, a vasopressin analogue that has minimal blood pressure–elevating and fluid-retaining properties and raises the plasma vWF level in both normal individuals and patients with mild vWD. Patients with type I disease are the best candidates for desmopressin therapy. However, they must be tested for an adequate response before anticipated surgery, and vWF levels must be monitored closely during therapy, since the patient may develop tachyphylaxis when therapy is continued for >48 h. Desmopressin should not be given to patients with variant forms of vWD without prior testing, since it may not improve multimer pattern or hemostasis in type IIa patients and may actually worsen the defect by depleting high-molecular-weight multimers, inducing intravascular platelet aggregation, and lowering the platelet count in type IIb patients. It is ineffective therapy for the severe (type III) form of vWD.

ACQUIRED vWD Although most cases of vWD are inherited, acquired vWD may be caused by antibodies that inhibit vWF function or by lymphoid or other tumors that selectively adsorb vWF multimers onto their surfaces. Anti-vWF antibodies have developed in patients with severe vWD following multiple transfusions, as well as in patients with autoimmune and lymphoproliferative disorders. Adsorption of vWF to tumor surfaces has been documented in patients with Waldenström's macroglobulinemia and Wilms' tumor and inferred in other patients with lymphoma. Treatment of acquired vWD should focus on the underlying disease, since plasma derivatives and desmopressin are often not effective and the disorder can be fatal.

Platelet Membrane Defects Receptors that modulate platelet adhesion and aggregation are located on the two major platelet surface glycoproteins. vWF facilitates platelet adhesion by binding to Gp Ib/IX, while fibrinogen links platelets into aggregates via sites on the Gp IIb/IIIa complex. Two rare platelet defects are characterized by a loss of or a defect in these Gp receptors. Patients with the *Bernard-Soulier syndrome* have markedly reduced platelet adhesion and cannot bind vWF to their platelets due to deficiency or dysfunction of the Gp Ib/IX complex. They also have reduced levels of another membrane protein (GpV that associates with Gp Ib/II), mild thrombocytopenia, and extremely large, lymphocytoid platelets. Platelets from patients with *Glanzmann's disease*, or *thrombasthenia*, are deficient or defective in the Gp IIb/IIIa complex. Their platelets do not bind fibrinogen and cannot form aggregates, although the platelets undergo shape change and secretion and are of normal size.

Both these disorders are autosomal recessive traits and markedly

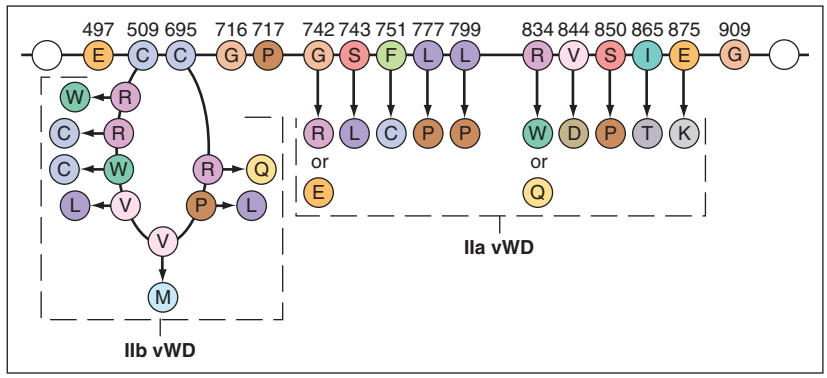

FIGURE 101-3 Location of mutations in types IIa and IIb von Willebrand's disease. Mutations in the region of the protein between amino acids 742 and 875 have been identified in patients with type IIa disease. These result in a deficiency in high- and medium-molecular-weight multimers due either to failure to secrete high-molecular-weight forms of von Willebrand factor (vWF) or to their proteolytic degradation in the circulation. In type IIb disease, there is also a decrease in high-molecular-weight vWF, but the defect is due to the failure of vWF with mutations in the A-1 domain of the protein (amino acids 509–695) to bind properly to platelet glycoprotein Ib/IX.

impair hemostasis, leading to recurrent episodes of severe mucosal hemorrhage. Bernard-Soulier platelets react normally to all stimuli except ristocetin. In contrast, thrombasthenic platelets adhere normally and will agglutinate with ristocetin but will not aggregate with any of the agonists that require fibrinogen binding, such as adenosine diphosphate (ADP), thrombin, or epinephrine.

The only effective therapy for hemorrhagic episodes in these two disorders is transfusion with normal platelets. Alloimmunization will eventually limit the life span of infused platelets. In addition, a few patients have developed inhibitor antibodies with specificity for the missing protein. These antibodies bind to the protein that is expressed on the transfused normal platelets and impair their function.

Platelet Release Defects The most common mild bleeding disorders arise from the ingestion of aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) that inhibit platelet production of thromboxane A_2, an important mediator of platelet secretion and aggregation (Figs. 53-3 and 53-4). These drugs inhibit cyclooxygenase (COX), which converts arachidonic acid to a labile endoperoxide intermediate that is critical for thromboxane formation. Aspirin is the most potent of these agents; it irreversibly acetylates the platelet enzyme so that a single dose impairs hemostasis for 5 to 7 days. The other agents are competitive and reversible inhibitors with more transient effects. Blocking thromboxane A_2 synthesis partially inhibits platelet release and aggregation with weak agonists, such as ADP and epinephrine, and produces a mild hemostatic defect. Cyclooxygenase exists in two isoforms, COX-1, which is constitutively expressed and active in the normal platelet, and COX-2, which is induced, especially in inflamed tissue. The selective COX-2 inhibitors, such as celecoxib, are increasingly being used to control arthritis pain and in other settings where NSAIDs are clinically useful. The COX-2 inhibitors are long-acting reversible inhibitors that have no adverse effects on platelet function. Their chronic use may be associated with high blood pressure and risk of thrombosis. The administration of high doses of certain antibiotics, particularly penicillin, can coat the platelet surface, block platelet release, and impair hemostasis.

Patients with release defects generally have minimal symptoms such as easy bruising, and bleeding is usually confined to the skin. Occasional patients will have prolonged oozing after surgery, particularly with procedures involving mucous membranes such as periodontal, oral, or reconstructive plastic surgery. The antiplatelet effect of drugs such as aspirin is more dramatic when they are administered to patients with underlying defects such as vWD or hemophilia. Patients with drug-induced COX deficiency often have a mildly prolonged bleeding time, and their platelets fail to aggregate when incubated with arachidonic acid, epinephrine, or low doses of ADP. Patients who have taken aspirin should be treated as if they have a mild hemostatic defect for the next 5 to 7 days. Platelet responses to collagen and thrombin are impaired at low doses but normal at higher doses. Symptomatic patients should be encouraged to use drugs such as acetaminophen that do not impair platelet function. Although most cases of COX deficiency are drug-induced, occasional patients have inherited disorders in platelet COX activity that impair thromboxane production or receptor level defects that prevent platelets from responding to thromboxane A_2.

Of the metabolic disorders that can perturb hemostasis, uremic platelet dysfunction is clinically the most important. The mechanism by which uremia impairs platelet function is not well understood, and retention of phenolic and guanidinosuccinic acids, excess prostacyclin production, or impaired vWF-platelet interactions have all been implicated. The degree of uremia correlates with bleeding symptoms and anemia. Bleeding can usually be reversed by dialysis and often improves after red cell transfusion or treatment with erythropoietin. In addition, factor VIII concentrate or desmopressin, both of which raise plasma vWF levels, can also improve hemostasis. Conjugated estrogens improve hemostasis and can be used as long-term therapy.

Storage Pool Defects Platelet granules have considerable amounts of adenine nucleotides, calcium, and adhesive glycoproteins such as thrombospondin, fibronectin, and vWF, all of which promote platelet adhesion and aggregation. Patients with defective platelet granules have a mild bleeding disorder. Platelet storage pool defects may be inherited as an isolated disorder or be part of systemic granule packaging defects such as oculocutaneous albinism or the Hermansky-Pudlak or Chédiak-Higashi syndromes. Clinically, these patients cannot be distinguished from those with other functional platelet disorders, since they all have easy bruising, mucosal bleeding, and a prolonged bleeding time. They can be differentiated from patients with the COX defects because their platelets will usually aggregate in response to arachidonic acid. In addition, their platelets have decreased levels of specific granule constituents such as ADP and serotonin and abnormalities in granule morphology that are best visualized by electron microscopy.

Occasionally, patients with acute or chronic leukemia or one of the myeloproliferative disorders develop an acquired storage pool disorder due to dysplastic megakaryocyte development. In addition, patients with liver disease and some patients with SLE or other immune complex–mediated disorders may have circulating platelets that have degranulated prematurely. Platelet degranulation and a transient storage pool disorder may occur after prolonged cardiopulmonary bypass. Fortunately, most patients with storage pool defects have only mildly impaired hemostasis. They can be treated with platelet transfusions. Occasional patients have responded to desmopressin.

VESSEL WALL DISORDERS

Bleeding from vascular disorders (nonthrombocytopenic purpura) is usually mild and confined to the skin and mucous membranes. The pathogenesis of bleeding is poorly defined in many of the syndromes, and classic tests of hemostasis, including the bleeding time and tests of platelet function, are usually normal. Vascular purpura arises from damage to capillary endothelium, abnormalities in the vascular subendothelial matrix or extravascular connective tissues that support blood vessels, or from the formation of abnormal blood vessels. Several idiopathic disorders involve the vessel wall and can cause more severe bleeding and organ dysfunction.

THROMBOTIC THROMBOCYTOPENIC PURPURA TTP is a fulminant, often lethal disorder that may be initiated by endothelial injury and subsequent release of vWF and other procoagulant materials from the endothelial cell. Causes include pregnancy, metastatic cancer, mitomycin C, high-dose chemotherapy, HIV infection, and certain drugs, such as the antiplatelet agent ticlopidine. Characteristic findings include the microvascular deposition of hyaline fibrin thrombi, thrombocytopenia, microangiopathic hemolytic anemia, fever, renal failure, fluctuating levels of consciousness, and evanescent focal neurologic deficits. The presence of hyaline thrombi in arterioles, capillaries, and venules without any inflammatory changes in the vessel wall is diagnostic. The presence of a severe Coombs-negative hemolytic anemia with schistocytes or fragmented red blood cells in the peripheral blood smear, coupled with thrombocytopenia, and minimal activation of the coagulation system help to confirm the clinical suspicion of TTP. This disorder should be distinguished from vasculitis and SLE, which can predispose patients to TTP. Platelet-associated IgG and complement levels are usually normal in TTP.

Clinical Manifestations The classic pentad of TTP consists of hemolytic anemia with fragmentation of erythrocytes and signs of intravascular hemolysis, thrombocytopenia, diffuse and nonfocal neurologic findings, decreased renal function, and fever. These signs and symptoms occur variably, depending on the number and sites of the arteriolar lesions. The anemia may be very mild to very severe, and the thrombocytopenia often parallels it. The neurologic and renal symptoms are usually seen only when the platelet count is markedly diminished (<20 to $30 \times 10^3/\mu L$). Fever is not reliably present. TTP may be acute in onset, but its course spans days to weeks in most patients and occasionally continues for months. Proteinuria and a moderate elevation of

blood urea nitrogen may be found on initial presentation; the latter continues to rise while urine output falls if the patient develops renal failure. Neurologic symptoms develop in >90% of patients whose disease terminates in death. Initially, changes in mental status such as confusion, delirium, or altered states of consciousness may occur. Focal findings include seizures, hemiparesis, aphasia, and visual field defects. These neurologic symptoms may fluctuate and terminate in coma. Involvement of myocardial blood vessels may be a cause of sudden death. The severity of the disorder can be estimated from the degree of anemia and thrombocytopenia and the serum lactic dehydrogenase level. Prothrombin time, partial thromboplastin time, fibrinogen concentration, and the level of fibrin split products are usually normal or only mildly abnormal. If the coagulation tests indicate a major consumption of clotting factors, the diagnosis of TTP is doubtful. A positive antinuclear antibody (ANA) determination is obtained in ~20% of patients.

Pathogenesis TTP is due to a deficiency in the activity of a specific metalloproteinase called *ADAMTS 13*, a normal plasma constituent that cleaves the ultra-high-molecular-weight (UHMW) forms of vWF secreted by endothelial cells to yield the heterogeneous set of multimers normally present in plasma (Fig. 101-4). A small number of patients have recurrent episodes of a TTP-like illness (*Upshaw-Schulman syndrome*) and are deficient in ADAMTS 13; the syndrome is inherited as an autosomal recessive trait. The more common acquired form of TTP is due to an inhibitory antibody that blocks ADAMTS 13 activity. These findings have led to more reliable diagnostic tests based on ADAMTS 13 enzyme activity and may have implications beyond TTP. Studies are underway to see if asymptomatic carriers with 50% levels of ADAMTS 13 are at increased risk of thromboembolism.

℞ TREATMENT

The treatment of acute TTP has focused on the use of exchange transfusion or intensive plasmapheresis coupled with infusion of fresh-frozen plasma. Therapy may remove abnormal forms of vWF, lower the concentration of ADAMTS 13 inhibitor, and replenish the deficient enzyme. Overall mortality has been markedly reduced, and the majority of patients with TTP recover from this formerly fatal disorder. Most patients surviving the acute illness recover completely, with no residual renal or neurologic disease. Occasional patients with a chronic, relapsing form of TTP require maintenance plasmapheresis and plasma infusion, and a few patients are controlled only with glucocorticoids. They presumably have persistence of the ADAMTS 13 inhibitor. In the future, TTP patients may be treated with some combination of enzyme replacement and immunosuppression to block inhibitor production.

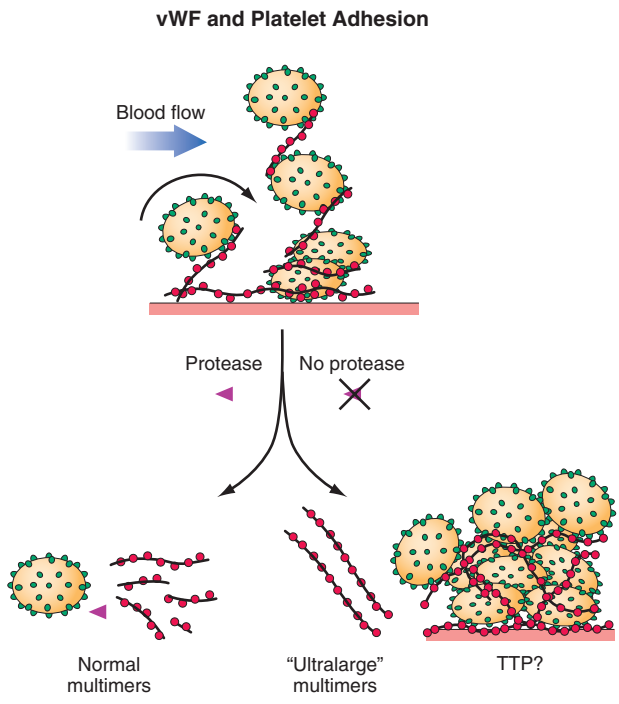

FIGURE 101-4 Pathogenesis of thrombotic thrombocytopenic purpura (TTP). Normally, the ultra-high-molecular-weight multimers of von Willebrand factor (vWF) produced by the endothelial cells are processed into smaller multimers by a plasma metalloproteinase called ADAMTS 13. In TTP, the activity of the protease is inhibited, and the ultra-high-molecular-weight multimers of vWF initiate platelet aggregation and thrombosis. *(From Vesely et al., Copyright American Society of Hematology.)*

HEMOLYTIC-UREMIC SYNDROME HUS is a disease of infancy and early childhood that closely resembles TTP. Patients present with fever, thrombocytopenia, microangiopathic hemolytic anemia, hypertension, and varying degrees of acute renal failure. In many cases, onset is preceded by a minor febrile or viral illness, and an infectious or immune complex–mediated cause has been proposed. Epidemics related to infection with a specific strain of *Escherichia coli* (O157:H7) have been documented. The bacteria contain a *Shigella*-like toxin that damages endothelial cells. As in TTP, DIC is not found. In contrast to TTP, the disorder remains localized to the kidney, where hyaline thrombi are seen in the afferent arterioles and glomerular capillaries. Thrombi are not present in other vessels, and neurologic symptoms, other than those associated with uremia, are uncommon. No therapy is proven effective; however, with dialysis for acute renal failure, the initial mortality is only 5% in children but may be higher in adults. Between 10 and 50% of patients have some chronic renal impairment. ADAMTS 13 levels are normal, and no inhibitors of the enzyme are present in this disorder.

HENOCH-SCHÖNLEIN PURPURA Henoch-Schönlein, or anaphylactoid, purpura is a distinct, self-limited type of vasculitis that occurs in children and young adults. Patients have an acute inflammatory reaction in capillaries, mesangial tissues, and small arterioles that leads to increased vascular permeability, exudation, and hemorrhage. Vessel lesions contain IgA and complement components. The syndrome may be preceded by an upper respiratory infection or streptococcal pharyngitis or be associated with food or drug allergies. Patients develop a purpuric or urticarial rash on the extensor surfaces of the arms and legs and on the buttocks as well as polyarthralgias or arthritis, colicky abdominal pain, and hematuria from focal glomerulonephritis. Despite the hemorrhagic features, all coagulation tests are normal. A small number of patients may develop fatal acute renal failure, and 5 to 10% develop chronic nephritis. Glucocorticoids provide symptomatic relief of the joint and abdominal pains but do not alter the course of the illness.

METABOLIC AND INFLAMMATORY DISORDERS Acute febrile illnesses may cause capillary fragility and skin bleeding. Immune complexes containing viral antigens or the viruses themselves may damage endothelial cells. In addition, certain pathogens such as the rickettsiae that cause Rocky Mountain spotted fever replicate in endothelial cells and damage them. Thrombocytopenia is also a frequent finding in acute infectious disorders and may contribute to skin bleeding. In addition, whenever the platelet count is <10,000/μL, gaps develop between endothelial cells, which allow the diapedesis of red cells into the dermis, forming petechiae. Drugs such as the sulfonamides, penicillin, and allopurinol may cause vascular inflammation, resulting in maculopapular or urticarial rashes. Some of these mechanisms are additive, and drug reactions in thrombocytopenic individuals cause an intensely hemorrhagic rash.

Occasionally, patients with diffuse polyclonal hyperglobulinemia will develop purpuric lesions on the lower limbs—a benign condition referred to as *hyperglobulinemic purpura*. Vascular purpura may occur in patients with various monoclonal gammopathies, including Waldenström's macroglobulinemia, multiple myeloma, and cryoglobuli-

nemia. These proteins markedly increase serum viscosity and may impair blood flow through capillaries and lead to retinal hemorrhage, central nervous system dysfunction, and skin necrosis. In addition, the globulins may impair platelet aggregation and adhesion and interfere with fibrin polymerization. Patients with mixed cryoglobulinemia develop a more extensive maculopapular lesion due to immune complex–mediated damage to the vessel wall. The mixed cryoglobulinemia (usually IgG and anti-IgG) may be associated with arthralgias, diffuse weakness, and unexplained nephritis. Plasmapheresis will temporarily lower the level of globulins, remove immune complexes, and improve symptoms in these patients. However, long-term management must include control of the underlying disease that produces the abnormal globulins or immune complexes.

Patients with *scurvy* (vitamin C deficiency) develop painful episodes of perifollicular skin bleeding as well as bleeding into muscles and, occasionally, into the gastrointestinal and genitourinary tracts. The diagnosis is confirmed by the presence of hyperkeratosis of skin, gum swelling, and low levels of the vitamin in leukocytes. Vitamin C is needed to synthesize hydroxyproline, an essential constituent of collagen. Thus, collagen synthesis is impaired by scurvy. Patients with *Cushing's syndrome*, an excess production of glucocorticoids, or patients on large doses of glucocorticoids develop generalized protein wasting and may show skin bleeding or easy bruising due to atrophy of the supporting connective tissue around blood vessels. Aging causes a similar atrophy of perivascular connective tissue on the extensor surfaces of the hands and arms, leading to *senile purpura*—dark purple, irregularly shaped hemorrhagic areas due to abnormal skin mobility that tears small blood vessels.

Patients with inherited disorders of the connective tissue matrix such as *Marfan's syndrome*, *Ehlers-Danlos syndrome*, and *pseudoxanthoma elasticum* also have easy bruising. In addition to having fragile skin vessels and easy bruising, patients with Ehlers-Danlos syndrome may develop aneurysms in intraabdominal vessels and apoplectic rupture and hemorrhage due to defects in the vascular collagen network. Primary vascular abnormalities can also lead to bleeding. Patients with *Osler-Rendu-Weber disease* [hereditary hemorrhagic telangiectasia (HHT)], an inherited autosomal dominant disorder, have frequent episodes of nasal and gastrointestinal bleeding from abnormal telangiectatic capillaries. They may develop pulmonary arteriovenous fistulas. Two genetic defects have been identified in these patients, both involving proteins that bind to transforming growth factor β (TGF-β); HHT-1 has mutations in endoglin, and HHT-2 has mutations in ALK-1. Patients with *angiodysplasia of the colon* have increased incidence of gastrointestinal bleeding. In the *Kasabach-Merritt syndrome*, patients may have very extensive and progressively enlarging vascular malformation that may involve large portions of their extremities. Bleeding is secondary to DIC triggered by stagnant blood flow through the tortuous vessels.

102 DISORDERS OF COAGULATION AND THROMBOSIS

Robert I. Handin

Patients with congenital plasma coagulation defects characteristically bleed into muscles, joints, and body cavities hours or days after an injury. Most of the *inherited* plasma coagulation disorders are due to defects in single coagulation proteins, with the two X-linked disorders, factors VIII and IX deficiency, accounting for the majority. These patients may have severe bleeding and chronic disability and require specialized medical therapy. With rare exceptions, the known disorders prolong either the prothrombin time (PT), partial thromboplastin time (PTT), or both. If they are abnormal, quantitative assays of specific coagulation proteins are then carried out using the PT or PTT tests with plasma from congenitally deficient individuals as substrate. The corrective effect of varying concentrations of patient plasma is measured and expressed as a percentage of a normal pooled plasma standard. The interval range for most coagulation factors is 50 to 150% of this average value, and the minimal level of most individual factors needed for adequate hemostasis is 25%.

Acquired coagulation disorders are both more frequent and more complex, arising from deficiencies of multiple coagulation proteins and simultaneously affecting both primary and secondary hemostasis. The most common acquired hemorrhagic disorders are (1) disseminated intravascular coagulation (DIC), (2) the hemorrhagic diathesis of liver disease, and (3) vitamin K deficiency and complications of anticoagulant therapy.

Although congenital and acquired bleeding disorders are relatively rare, venous and arterial thrombosis and embolism are common medical disorders that have been recognized for >100 years. Although risk factors such as atherosclerotic vascular disease, congestive heart failure, malignancy, and immobility predispose patients to thrombosis, specific coagulation defects have not yet been identified in most patients with thromboembolism. Several inherited coagulation abnormalities induce a hypercoagulable or prethrombotic state and predispose patients to thrombosis. These disorders affect young people, cause recurrent episodes of thromboembolism, and may involve multiple members of a single family. An understanding of the biochemical basis of thromboembolism is also important because anticoagulant and antithrombotic regimens are based on the premise that modifying critical coagulation reactions will reduce the incidence of thrombosis. →***For further discussion of the physiology of normal hemostasis and the cardinal manifestations of the hemorrhagic and thrombotic disorders, see Chap. 53.***

FACTOR VIII DEFICIENCY—HEMOPHILIA A ■ **Pathogenesis and Clinical Manifestations** The antihemophilic factor (AHF), or factor VIII coagulant protein, is a large (265-kDa), single-chain protein that regulates the activation of factor X by proteases generated in the intrinsic coagulation pathway (Figs. 53-6 and 53-7). It is synthesized in liver and circulates complexed to the von Willebrand factor (vWF) protein. Factor VIII molecule is present in low concentration (10 μg/L) and is susceptible to proteolysis. The gene for factor VIII is on the X chromosome, and carrier detection and prenatal diagnosis are well established.

One in 10,000 males is born with deficiency or dysfunction of the factor VIII molecule. The resulting disorder, *hemophilia A*, is characterized by bleeding into soft tissues, muscles, and weight-bearing joints. Symptomatic patients usually have factor VIII levels <5%, with a close correlation between the clinical severity of hemophilia and plasma AHF level. Patients with <1% factor VIII activity have *severe*

disease; they bleed frequently even without discernible trauma. Patients with levels of 1 to 5% have *moderate* disease with less frequent bleeding episodes. Those with levels >5% have *mild* disease with infrequent bleeding that is usually secondary to trauma. Occasional patients with factor VIII levels as high as 25% are discovered when they bleed after major trauma or surgery. The majority of patients with hemophilia A have factor VIII levels <5%.

Hemophilic bleeding occurs hours or days after injury, can involve any organ, and, if untreated, may continue for days or weeks. This can result in large collections of partially clotted blood putting pressure on adjacent normal tissues and can cause necrosis of muscle (compartment syndromes), venous congestion (pseudophlebitis), or ischemic damage to nerves. Patients with hemophilia often develop femoral neuropathy due to pressure from an unsuspected retroperitoneal hematoma. They can also develop large calcified masses of blood and inflammatory tissue that are mistaken for cancers (pseudotumor syndrome).

Patients with severe hemophilia are usually diagnosed shortly after birth because of an extensive cephalhematoma or profuse bleeding at circumcision. However, young children with moderate disease may not bleed until they begin to walk or crawl, and individuals with mild hemophilia may not be diagnosed until they are adolescents or young adults. Typically, a hemophilia patient presents with pain followed by swelling in a weight-bearing joint, such as the hip, knee, or ankle. The presence of blood in the joint (*hemarthrosis*) causes synovial inflammation, and repetitive bleeding erodes articular cartilage and causes osteoarthritis, articular fibrosis, joint ankylosis, and eventually muscle atrophy. Bleeding may occur into any joint, but after a joint has been damaged, it may become a site for subsequent bleeding episodes.

Hematuria, without any genitourinary pathology, is also common. It is usually self-limited and may not require specific therapy. The most feared complications of hemophilia are oropharyngeal and central nervous system bleeding. Patients with oropharyngeal bleeding may require emergency intubation to maintain an adequate airway. Central nervous system bleeding can occur without antecedent trauma or without evidence of a specific lesion.

Patients suspected of having hemophilia should have a platelet count, bleeding time, PT, and PTT determination. Typically, the patient will have a prolonged PTT with all other tests normal. Because of the clinical similarity of factor VIII deficiency and factor IX deficiency, any male with an appropriate bleeding history and a prolonged PTT should have specific assays for factor VIII and factor IX.

TREATMENT

Tenets regarding the treatment of bleeding in hemophilia patients include the following: (1) Symptoms often precede objective evidence of bleeding. (2) Signs of bleeding may not appear until several days after well-documented trauma. The patients can generally be relied upon to identify early symptoms, usually pain. Early treatment is more effective, less costly, and can be lifesaving. (3) Avoid the use of aspirin or aspirin-containing drugs, which impair platelet function and may cause severe hemorrhage. Cyclooxygenase inhibitors can be used, as they do not impair platelet function.

Plasma products enriched in factor VIII reduce the degree of orthopedic deformity and permit virtually any form of elective and emergency surgery. The widespread use of factor VIII concentrates has also produced serious complications, including viral hepatitis, chronic liver disease, and AIDS. *Cryoprecipitate*, which contains about half the factor VIII activity of fresh-frozen plasma in one-tenth the original volume, is simple to prepare and is produced in hospital or regional blood banks.

Three developments have increased the safety of factor VIII therapy and have changed medical practice. First, heating of lyophilized factor VIII concentrates under carefully controlled conditions can inactivate HIV without destroying factor VIII activity. Second, highly purified factor VIII can be produced by adsorbing and eluting factor VIII from monoclonal antibody columns. Third, recombinant factor VIII is now available. Patients with hemophilia should receive either monoclonal purified or recombinant factor VIII to minimize viral infections and exposure to irrelevant proteins.

Each unit of factor VIII infused, defined as the amount present in 1 mL normal plasma, will raise the plasma level of the recipient by 2%/kg of body weight. Factor VIII has a half-life of 8 to 12 h, making it necessary to infuse it continuously or at least twice daily to sustain a chosen factor VIII level. In patients with mild hemophilia, an alternative treatment is desmopressin (DDAVP), which transiently increases the factor VIII level. Desmopressin will increase the factor level two- to threefold. Although generally safe, it occasionally causes hyponatremia or may precipitate thrombosis in elderly patients.

An uncomplicated episode of soft tissue bleeding or an early hemarthrosis can be treated with one infusion of sufficient factor VIII concentrate to raise the factor VIII level to 15 or 20%. A more extensive hemarthrosis or retroperitoneal bleeding requires twice-daily or continuous infusions in order to keep the factor VIII level at 25 to 50% for at least 72 h. Life-threatening bleeding into the central nervous system or major surgery may require therapy for 2 weeks with levels kept at a minimum of 50% normal. Patients also need skilled orthopedic care, with immobilization of inflamed joints to promote healing and to prevent contractures, and physical therapy to strengthen muscles and maintain joint mobility.

Before surgery, every hemophilia patient should be screened for the presence of an inhibitor to factor VIII. Patients with hemophilia who do not have an inhibitor should receive factor VIII infusions just before surgery and will require daily monitoring so that the factor VIII level is maintained >50% for 10 to 14 days after surgery. When patients undergo joint replacement or other major orthopedic surgery, therapy should be continued for 3 weeks to permit wound healing and the institution of physical therapy.

Hemophilia patients also require treatment before dental procedures. Filling of a carious tooth can be managed by a single infusion of factor VIII concentrate coupled with the administration of 4 to 6 g of ϵ-aminocaproic acid (EACA) four times daily for 3 to 4 days after the dental procedure. EACA is a potent antifibrinolytic agent that inhibits plasminogen activators present in oral secretions and stabilizes clot formation in oral tissue. Alternatives include tranexamic acid, a longer-acting antifibrinolytic. EACA is also effective when used as a mouthwash. For major oral and periodontal surgery and extractions of permanent teeth, patients should probably be hospitalized briefly and also treated with factor VIII concentrates. Therapy should begin just before surgery and continue for at least 2 to 3 days.

Many centers have organized home-care programs so that patients can administer their own factor VIII infusions with the onset of symptoms. Occasional patients with very frequent bleeding receive regularly scheduled infusions. Despite the expense and inconvenience of "prophylactic" infusions, their use in early childhood has reduced or eliminated hemarthroses. Concern about transmission of AIDS has made some patients reluctant to treat themselves, despite the fact that current blood products carry a very low or no risk of transmitting HIV.

The prospects for correcting factor VIII deficiency by gene therapy are promising; some success has been achieved in dogs. Clinical studies in humans are underway. Concerns about the side effects of current viral vectors used to deliver the factor VIII cDNA are slowing clinical trials.

Complications Most hemophilia patients have had multiple episodes of hepatitis, and a majority have elevated hepatocellular enzyme levels and abnormalities on liver biopsy. Donated blood is now being screened for various types of hepatitis, so the risk of this disease is diminishing. Between 10 and 20% of patients also have hepatosplenomegaly, and a small number develop chronic active or persistent hepatitis or cirrhosis. A few patients with hemophilia and end-stage liver disease have received liver transplants with cure of both diseases. Along with homosexuals and intravenous drug abusers, long-time he-

mophilia patients are at high risk for AIDS because they frequently received blood products before the era of testing them for HIV; they can also present with the full range of AIDS-related syndromes, including diffuse lymphadenopathy and immune thrombocytopenia. Although up to 50% of current multiply transfused hemophiliacs are HIV-positive and many have clinical AIDS, the advances in factor VIII concentrate production should prevent future HIV infection.

Despite frequent bleeding, severe iron-deficiency anemia is uncommon because most of the bleeding is internal and iron is effectively recycled. Mild iron deficiency from chronic epistaxis or gastrointestinal bleeding occurs in some patients. In addition, some patients have developed a mild Coombs-positive hemolytic anemia due to small amounts of anti-A and anti-B antibody that are present in intermediate purity factor VIII concentrates.

Following multiple transfusions, 10 to 20% of patients with severe hemophilia develop inhibitors to factor VIII. Inhibitors are usually IgG antibodies that rapidly neutralize factor VIII activity. Two types of inhibitors are found with different biologic characteristics and different clinical presentations. Patients with type I inhibitors have a typical anamnestic response and raise their antibody titer following exposure to factor VIII. Patients with a type II inhibitor have a low antibody titer that is not stimulated by factor VIII infusion. Patients with the type I inhibitor should not receive factor VIII. Control of bleeding may require the infusion of either porcine factor VIII concentrates, which may not be affected by inhibitors, or prothrombin complex concentrates, which contain trace quantities of activated coagulation factors and can bypass the block in coagulation produced by the inhibitor. Patients with low-titer type II antibodies may respond to higher doses of factor VIII. Another alternative is the infusion of recombinant factor VIIa; it activates factor X directly and bypasses the inhibitor-induced block.

Protocols to induce tolerance to human factor VIII use massive doses of the factor coupled with immunosuppression. Tolerance induction is expensive and not always effective; it should be reserved for severely affected patients.

Genetic Counseling and Carrier Detection It is possible to trace the defective allele in some families by examining the inheritance of restriction fragment length polymorphisms (RFLP) linked to the factor VIII gene. In addition, in families in which a specific mutation has been defined in the factor VIII gene, it can be readily detected by gene amplification and allele-specific oligonucleotide hybridization. For example, 45% of patients with severe hemophilia A have a chromosomal inversion arising from homologous recombination between sequences in intron 22 and an upstream gene. The inversion is readily detected by polymerase chain reaction (PCR) or Southern blotting. Precise diagnosis is possible early in pregnancy from either chorionic villus biopsy or amniocentesis.

Female carriers of hemophilia, who are heterozygotes, usually produce sufficient factor VIII from the factor VIII allele on their normal X chromosome for normal hemostasis. However, occasional hemophilia carriers will have factor VIII levels far below 50% due to random inactivation of normal X chromosomes in tissue producing factor VIII. These symptomatic carriers may bleed with major surgery or bleed occasionally with menses. Rarely, true female hemophiliacs arise from consanguinity within families with hemophilia or from concomitant Turner's syndrome or XO mosaicism in a carrier female.

FACTOR IX DEFICIENCY—HEMOPHILIA B Factor IX is a single-chain, 55-kDa proenzyme that is converted to an active protease (IXa) by factor XIa or by the tissue factor–VIIa complex. Factor IXa then activates factor X in conjunction with activated factor VIII. Factor IX is one of six proteins synthesized in the liver that require vitamin K for biologic activity. Vitamin K is a cofactor for a unique posttranslational modification that inserts a second carboxyl group onto certain glutamic acid residues on factor IX (Chap. 53). This modification permits calcium binding and adsorption onto phospholipid surfaces. Factor IX gene is on the X chromosome.

Factor IX deficiency or dysfunction (hemophilia B, Christmas disease) occurs in 1 in 100,000 male births. Accurate laboratory diagnosis is critical, since it is indistinguishable clinically from factor VIII deficiency (hemophilia A) but requires different treatment. Either fresh-frozen plasma or a plasma fraction enriched in the prothrombin complex proteins is used. Monoclonally purified or recombinant factor IX preparations are now available. In addition to the expected complications of hepatitis, chronic liver disease, and AIDS, the therapy of factor IX deficiency has a special hazard. Trace quantities of activated coagulation factors in prothrombin complex concentrates may activate the coagulation system and cause thrombosis and embolism. This is particularly common in immobilized surgical patients and patients with liver disease. As a result, some centers have returned to fresh-frozen plasma for factor IX–deficient surgical patients, while others have recommended the addition of small doses of heparin to the concentrate to activate antithrombin III during the infusion and reduce hypercoagulability. The recombinant or monoclonally purified products are less likely to be thrombogenic.

FACTOR XI DEFICIENCY Factor XI is a 160-kDa dimeric protein activated to an active protease (XIa) by factor XIIa, in conjunction with high-molecular-weight kininogen and kallikrein (Figs. 53-6 and 53-7). Factor XI deficiency is inherited as an autosomal recessive trait and is especially common in Ashkenazi Jews. In contrast to deficiency in factors VIII and IX, the correlation between factor level and propensity to bleed is not as precise, spontaneous bleeding is less, and hemarthroses are rare. Many patients with factor XI deficiency present with posttraumatic bleeding or with bleeding in the perioperative period, and occasional factor XI–deficient women have menorrhagia. Daily infusions of fresh-frozen plasma are sufficient, since the half-life of factor XI is approximately 24 h. The majority of defective factor XI alleles were accounted for by a limited number of mutations.

OTHER FACTOR DEFICIENCIES Deficiencies in factors V, VII, X, and prothrombin (factor II) are exceedingly rare autosomal recessive disorders. Spontaneous or posttraumatic musculoskeletal bleeding or menorrhagia can occur with these deficiencies, but hemarthroses are uncommon. Fresh-frozen plasma is the appropriate therapy, although prothrombin concentrates may be employed for patients with severe prothrombin deficiency or decreases in factors VII and X as long as the risks of hepatitis and thrombosis are recognized.

Defects in the contact activation pathway involving Hageman factor (factor XII), high-molecular-weight kininogen, and prekallikrein cause laboratory abnormalities but no clinical bleeding. Despite dramatic prolongation of the PTT, often to greater than 100 s, deficient individuals have normal hemostasis and can undergo major surgery without plasma replacement therapy. Direct activation of factor IX by the tissue factor–VIIa complex may bypass this defective step in coagulation (Fig. 53-8). Patients with these disorders should neither be treated inappropriately with plasma nor denied indicated surgery on the basis of these laboratory abnormalities.

AFIBRINOGENEMIA AND DYSFIBRINOGENEMIA Fibrinogen is a 340-kDa dimeric molecule made up of two sets of three covalently linked polypeptide chains. Thrombin sequentially cleaves fibrinopeptides A and B from the Aα and Bβ chains of fibrinogen to produce fibrin monomer, which then polymerizes to form a fibrin clot. Although fibrinogen is needed for platelet aggregation and fibrin formation, severe fibrinogen deficiency does not usually cause serious bleeding except after surgery. Patients with afibrinogenemia, who have no detectable fibrinogen in plasma or platelets, may have infrequent, mild bleeding episodes. Genetic analyses do not show any gross deletion or structural changes in the genes encoding the α, β, and γ chains of fibrinogen despite the total absence of plasma fibrinogen.

Fibrinogen is an abundant plasma protein (2.5 g/L). Mutations have been identified that alter the release of fibrinopeptides from the Aα and Bβ chains of fibrinogen, the rate of polymerization of fibrin monomers, and the sites for fibrin cross-linking. These dysfibrinogenemias

are almost always inherited as autosomal dominant traits, so patients have nearly equal concentrations of normal and mutant fibrinogen in their plasma. Patients with dysfibrinogenemia have a slightly prolonged PT and PTT, a prolonged thrombin time, and a disparity in levels of fibrinogen measured with functional and immunologic assays. Despite these abnormalities, most patients have no symptoms or only moderate bleeding. A few dysfibrinogenemias induce a hypercoagulable state and increase the risk of thrombosis, and others have been associated with an increased incidence of abortion (Chap. 103). Some patients with liver disease, hepatomas, AIDS, and lymphoproliferative disorders develop an acquired form of dysfibrinogenemia.

FACTOR XIII DEFICIENCY AND DEFECTIVE FIBRIN CROSS-LINKING Factor XIII is a transglutaminase that stabilizes fibrin clots by forming ϵ-amino–γ-glutamyl cross-links between adjacent α and γ chains of fibrin. Factor XIII deficiency is an extremely rare inherited syndrome. Patients usually bleed in the neonatal period from their umbilical stump or circumcision. In addition to hemorrhage, these patients may have poor wound healing, a high incidence of infertility among males and abortion among affected females, and a high incidence of intracerebral hemorrhage. These observations suggest that the enzyme may be important in other physiologic processes beyond hemostasis, including placental implantation, spermatogenesis, and wound healing. Several drugs, including isoniazid, may bind to cross-linking sites on fibrinogen and mimic factor XIII deficiency by blocking enzyme activity. Normal hemostasis requires only 1% of normal enzyme activity; a single infusion of fresh-frozen plasma or a purified factor XIII–rich product derived from human placenta called Fibrogammin is effective. Factor XIII has a 14-day half-life.

VITAMIN K DEFICIENCY Vitamin K is a fat-soluble vitamin that plays a critical role in hemostasis. Dietary vitamin K is absorbed in the small intestine and stored in the liver. The vitamin is also synthesized by endogenous bacterial flora in the small intestine and colon; however, the quantity of endogenous vitamin K absorbed from the large intestine is debated. Following absorption, vitamin K is converted to an active epoxide in liver microsomes and serves as a cofactor in the enzymatic carboxylation of glutamic acid residues on prothrombin complex proteins (Fig. 102-1).

The three major causes of vitamin K deficiency are inadequate dietary intake, intestinal malabsorption, and loss of storage sites due to hepatocellular disease. Neonatal vitamin K deficiency, which causes hemorrhagic disease of the newborn, has disappeared from western countries with the routine administration of vitamin K to all newborn infants. Although a 30-day supply of vitamin K is stored in the normal liver, acutely ill patients can become deficient within 7 to 10 days. Acute vitamin K deficiency is particularly common in patients recovering from biliary tract surgery who have no dietary intake of vitamin K, have T-tube drainage of bile, and are on broad-spectrum antibiotics. Vitamin K deficiency is also seen in chronic liver disease, particularly primary biliary cirrhosis, and in some malabsorption states (Chaps. 275 and 286). The cephalosporins inhibit the reduction and recycling of vitamin K, much like warfarin.

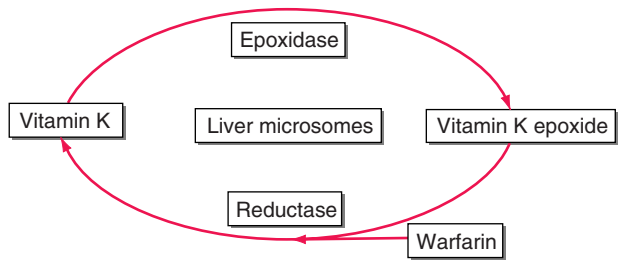

FIGURE 102-1 The mechanism of action of vitamin K, a cofactor in the formation of di-γ-carboxyglutamic acid residues on coagulation proteins, is depicted. Vitamin K is converted to an epoxide in liver microsomes. The epoxide is the active form and is reduced back to vitamin K by a liver membrane reductase. Warfarin blocks the action of the reductase and competitively inhibits the effects of vitamin K.

With vitamin K deficiency, plasma levels of all the prothrombin complex proteins (factors II, VII, IX, X; proteins C and S) decrease. Those with the shortest half-lives, factor VII and protein C, decrease first. Because of the rapid fall in factor VII, patients with mild vitamin K deficiency may have a prolonged PT and a normal PTT. Later, as the levels of the other factors fall, the PTT will also become prolonged. Parenteral administration of 10 mg vitamin K rapidly restores vitamin K levels in the liver and permits normal production of prothrombin complex proteins within 8 to 10 h. Severe hemorrhage can be treated with fresh-frozen plasma, which immediately corrects the hemostatic defect. If the cause of vitamin K deficiency cannot be eliminated, patients may need monthly injections. Purified prothrombin complex concentrates should be avoided because they contain trace quantities of activated forms of the prothrombin complex proteins and can cause thrombosis in patients with liver disease. They also carry an increased risk of hepatitis.

DISSEMINATED INTRAVASCULAR COAGULATION DIC can be either an explosive and life-threatening bleeding disorder or a relatively mild or subclinical disorder. Although a long list of diseases can be complicated by DIC, it is most frequently associated with obstetric catastrophes, metastatic malignancy, massive trauma, and bacterial sepsis (Table 102-1). Tentative triggering mechanisms have been identified. Tumors and traumatized or necrotic tissue release tissue factor into the circulation. Endotoxin from gram-negative bacteria activates several steps in the coagulation cascade. In addition to a direct effect on the activation of Hageman factor (factor XII), endotoxin induces the expression of tissue factor on the surface of monocytes and endothelial cells. These activated cell surfaces then accelerate coagulation reactions. These potent thrombogenic stimuli cause the deposition of small thrombi and emboli throughout the microvasculature. This early thrombotic phase of DIC is then followed by a phase of procoagulant consumption and secondary fibrinolysis. Continued fibrin formation and fibrinolysis lead to hemorrhage from the coagulation factor and platelet depletion and the antihemostatic effects of fibrin degradation products (Fig. 102-2).

The clinical presentation varies with the stage and severity of the

TABLE 102-1 *Etiologic Factors and Disorders Causing Disseminated Intravascular Coagulation*

Liberation of tissue factors	Obstetric syndromes—abruptio placentae, amniotic fluid embolism, retained dead fetus, second trimester abortion
	Hemolysis
	Neoplasms, particularly mucinous adenocarcinomas, acute promyelocytic leukemia
	Intravascular hemolysis
	Fat embolism
	Tissue damage—burns, frostbite, head injury, gunshot wounds
Endothelial damage	Aortic aneurysm
	Hemolytic uremic syndrome
	Acute glomerulonephritis
	Rocky Mountain spotted fever
Vascular malformation, decreased blood flow	Kasabach-Merritt syndrome
Infections	Bacterial: staphylococci, streptococci, pneumococci, meningococci, gram-negative bacilli
	Viral: arboviruses, varicella, variola, rubella
	Parasitic: malaria, kala-azar
	Rickettsial: Rocky Mountain spotted fever
	Mycotic: acute histoplasmosis

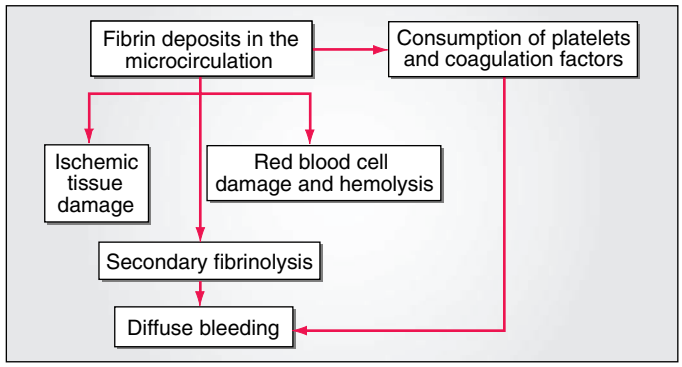

FIGURE 102-2 The pathophysiology of disseminated intravascular coagulation (DIC). Shown are the interactions between coagulation and fibrinolytic pathways that result in bleeding in patients with DIC.

syndrome. Most patients have extensive skin and mucous membrane bleeding and hemorrhage from surgical incisions or venipuncture or catheter sites. Less often, patients present with peripheral acrocyanosis, thrombosis, and pregangrenous changes in digits, genitalia, and nose—areas where blood flow is markedly reduced by vasospasm or microthrombi. Some patients, particularly those with chronic DIC and malignancy, have laboratory abnormalities without any evidence of thrombosis or hemorrhage.

The laboratory manifestations include thrombocytopenia and the presence of schistocytes or fragmented red blood cells that arise from cell trapping and damage within fibrin thrombi; prolonged PT and PTT and thrombin time and a reduced fibrinogen level from depletion of coagulation proteins; and elevated fibrin degradation products (FDP) from intense secondary fibrinolysis. The D dimer immunoassay, which measures cross-linked fibrin derivatives (i.e., those that have been in blood clots), is a more specific FDP assay. Low fibrinogen levels in DIC predict more bleeding.

TREATMENT

DIC, although sometimes indolent, can cause life-threatening hemorrhage and may require emergency treatment including (1) an attempt to correct any reversible cause of DIC; (2) measures to control the major symptom, either bleeding or thrombosis; and (3) a prophylactic regimen to prevent recurrence in cases of chronic DIC. Treatment will vary with the clinical presentation. In patients with an obstetric complication such as abruptio placentae or acute bacterial sepsis, prompt delivery of the fetus and placenta or treatment with appropriate antibiotics will reverse the DIC syndrome. In patients with metastatic tumor causing DIC, control of the primary disease may not be possible, and long-term prophylaxis may be necessary.

Patients with bleeding as a major symptom should receive fresh-frozen plasma to replace depleted clotting factors and platelet concentrates to correct thrombocytopenia. Those with acrocyanosis and incipient gangrene or other thrombotic problems need immediate anticoagulation with intravenous heparin. The use of heparin in the treatment of bleeding is still controversial. Although it is a logical way to reduce thrombin generation and prevent further consumption of clotting proteins, it should be reserved for patients with thrombosis or who continue to bleed despite vigorous treatment with plasma and platelets.

Patients who initially have mild asymptomatic DIC may begin to bleed following surgery or chemotherapy. For example, mild DIC, without clinical bleeding, has been documented during saline- or prostaglandin-induced midtrimester abortions. Prophylactic treatment of patients with heparin may prevent progression of a mild DIC syndrome and has been used in the treatment of patients with acute promyelocytic leukemia and in some patients with a retained dead fetus who require surgical extraction. However, most patients with low-grade DIC can be managed with plasma and platelet replacement and do not require heparin. Chronic DIC does not respond to oral warfarin anticoagulants, but it can be controlled with long-term heparin infusion. Occasional patients with indolent tumors and severe DIC have been maintained on heparin administered by intermittent subcutaneous injection or continuous infusion with portable pumps.

Despite our detailed understanding of the pathophysiology of DIC and a vigorous approach to therapy, treatment does not usually change the natural history of the underlying disorder. Therapy will only stabilize the patient, prevent exsanguination or massive thrombosis, and permit institution of definitive therapy.

COAGULATION DISORDERS IN LIVER DISEASE Liver dysfunction is frequently accompanied by a hemostatic defect. The major causes of hemorrhage in patients with liver disease are shown in Table 102-2. Bleeding is usually due to an anatomic lesion that is exacerbated by a hemostatic defect. Most patients bleed from complications of portal hypertension, esophageal varices, or gastritis and peptic ulcer disease. Portal hypertension also causes splenomegaly, with splenic sequestration of platelets and thrombocytopenia, which contributes to the hemostatic defect.

Patients with hepatocellular liver disease cannot store vitamin K optimally and may have some degree of vitamin K deficiency. Cholestasis, a frequent feature of liver disease, impairs vitamin K absorption and further decreases liver vitamin K stores. Abnormalities in the γ-carboxylation of prothrombin complex proteins independent of vitamin K and the production of abnormal proteins have also been described. Patients may also have decreased production of other coagulation proteins, including fibrinogen and factor V. The liver also produces inhibitors of coagulation such as antithrombin III and proteins C and S and is the clearance site for activated coagulation factors and fibrinolytic enzymes. Thus patients with liver disease are also "hypercoagulable" and predisposed to developing DIC or systemic fibrinolysis. Coagulation defects in advanced liver failure are often difficult to distinguish from those of DIC.

Each patient with hemorrhage and liver disease should have a PT, PTT, platelet count, and fibrinogen determination, although it is not always possible to determine the major hemostatic abnormality from a single set of laboratory values. It is helpful to have previous laboratory data available for patients with chronic liver disease who develop an acute complication. The degree of prolongation of the PT predicts the risk of bleeding. Most patients present with moderate prolongation of the PT and PTT, mild thrombocytopenia, and a normal fibrinogen level. However, they may also present with a more complex defect combining defective synthesis, abnormal clearance, and active consumption of coagulation proteins. Since vitamin K deficiency is so common, a single parenteral dose of vitamin K is given after initial

TABLE 102-2 *Causes of Bleeding in Liver Disease*

Anatomic Factors
Portal hypertension
Varices
Splenomegaly and secondary thrombocytopenia
Peptic ulceration
Gastritis
Hepatic Function Abnormalities
Decreased synthesis of procoagulant proteins: fibrinogen, prothrombin, factors V, VII, IX, X, XI
Decreased synthesis of coagulation inhibitors: protein C, protein S, antithrombin III
Impaired absorption and metabolism of vitamin K
Failure to clear activated coagulation proteins leading to:
Disseminated intravascular coagulation
Systemic fibrinolysis
Complications of Therapy
Dilution of platelets and coagulation proteins from massive transfusions
Infusion of activated coagulation proteins in prothrombin complex concentrates
Bleeding from heparin; thrombosis from ε-aminocaproic acid (EACA)

laboratory studies have been obtained, even though this may only partially correct the laboratory abnormalities. The presence of severe thrombocytopenia or a low fibrinogen level suggests the additional complication of DIC and may require further studies and therapy.

The safest replacement therapy for a patient with liver disease is fresh-frozen plasma, since it supplies all known coagulation factors. However, even this form of therapy has drawbacks, since large quantities of plasma may precipitate hepatic encephalopathy and cause fluid and sodium overload. Prothrombin complex concentrates should be avoided because they replace only the vitamin K–dependent factors, may be contaminated with hepatitis and AIDS virus, and contain trace quantities of activated coagulation proteins. Similarly, fibrinogen concentrates (or cryoprecipitate), rich in factor VIII and fibrinogen, should not be used without additional fresh-frozen plasma. Anticoagulation with heparin has been advocated to control DIC, but this is particularly hazardous and not recommended in cirrhosis because heparin is metabolized erratically and may lead to severe bleeding.

FIBRINOLYTIC DEFECTS Bleeding can also occur from defects in the fibrinolytic system. Patients with α_2 plasmin inhibitor deficiency or plasminogen activator inhibitor (PAI) 1 have rapid fibrinolysis following fibrin deposition after trauma or surgery and may experience recurrent hemorrhage. Similarly, patients with cirrhosis have an impaired clearance of tissue plasminogen activator (tPA) and systemic fibrinolysis that may contribute to their hemorrhagic defect. Rarely, patients with tumors such as metastatic prostatic cancer may develop diffuse bleeding from primary fibrinolysis rather than DIC. Clues to the diagnosis include a disproportionately low fibrinogen level with a relatively normal PT and PTT and the presence of a normal or nearly normal platelet count. With rare exceptions, patients with primary fibrinolysis should have an elevated titer of FDP but a normal D dimer level. However, it is sometimes difficult or impossible to differentiate primary fibrinolysis from the secondary fibrinolysis in DIC. Patients with clearly established primary fibrinolysis should not receive heparin; they require plasma therapy and, occasionally, fibrinolytic inhibitors such as EACA. However, EACA should not be given to patients suspected of having DIC unless they are also receiving heparin, since EACA can cause massive, often fatal, thrombosis in a patient with DIC.

CIRCULATING ANTICOAGULANTS Circulating anticoagulants, or inhibitors, are usually IgG antibodies that interfere with coagulation reactions. Specific inhibitors inactivate individual coagulation proteins and may cause severe hemorrhage. They arise in 15 to 20% of patients with factor VIII or factor IX deficiency who have received plasma infusions. *Specific* inhibitors also occur in previously normal individuals. Although the most common target protein is factor VIII, inhibitors with specificity for each of the coagulation proteins occur. In addition to hemophiliacs, anti-factor VIII antibodies are seen in postpartum females, in patients on various drugs, as part of the spectrum of autoantibodies in systemic lupus erythematosus (SLE) patients, and in normal elderly individuals. Circulating anticoagulants also occur in patients with AIDS.

Nonspecific (lupus-like) inhibitors prolong coagulation tests by binding to phospholipids. They are assayed by their anticoagulant effect [lupus anticoagulant (LA) activity] or their ability to bind to the complex phospholipid cardiolipin [anticardiolipin antibody (ACLA) activity]. While most often encountered in patients with SLE, these nonspecific inhibitors may develop in patients with many other disorders and also in otherwise normal individuals.

The critical laboratory feature that identifies the presence of either type of inhibitor is the failure of normal plasma to correct a prolonged PT, PTT, or both. Plasma from patients with a specific inhibitor will progressively inactivate a coagulation protein and thus prolong whichever of these screening tests requires the participation of that clotting factor. This effect persists after dilution. Nonspecific inhibitors immediately prolong the PT and PTT and, at low dilution, block multiple coagulation reactions. However, these effects can be overcome by altering the quantity or type of phospholipid or by diluting the plasma.

Hemorrhage in patients with specific inhibitors may require treatment with massive plasma or concentrate infusion, the use of activated prothrombin complex concentrates to bypass the antibodies against factors VIII or IX, and plasmapheresis or exchange transfusion to lower antibody titer. Chronic immunosuppressive regimens have been particularly useful in otherwise normal individuals with an acquired factor VIII antibody. Many patients lose their antibody and recover within 6 to 12 months, although the acute mortality rate from bleeding may approach 10%.

Patients with LA activity have normal hemostasis and will not bleed unless they have concomitant thrombocytopenia or prothrombin deficiency. Both thrombocytopenia and hypoprothrombinemia are secondary to autoantibodies that bind either to platelets or the prothrombin molecule. While these antibodies have no effect on function, they accelerate clearance of the coated platelets or the antibody-prothrombin complexes.

The presence of LA activity may predispose patients to venous and arterial thromboembolism and may cause midtrimester abortions. However, the risk of thrombosis is difficult to estimate, and the appropriate therapy for individual patients difficult to choose. Tests for either LA or ACLA activity are not well standardized, and results vary among and within patients. The best predictor is a consistent prolongation of more than one coagulation test coupled with a high titer of ACLA activity. Second, the risk of thrombosis is increased in patients who have SLE compared with those with idiopathic LA or ACLA activity. Prophylactic therapy is not clearly beneficial, and treatments aimed at reducing the titer of antibody are not superior to conventional antithrombotic therapy.

Therapy should be individualized. Patients with SLE and either LA or ACLA activity who have had a thrombotic episode are at high risk for a recurrence and should receive long-term anticoagulant therapy. Women who have had more than one midtrimester abortion, especially those with SLE, should have a trial of anticoagulant therapy. Patients with a single thrombotic episode (stroke or pulmonary embolus) and no other risk factor except LA or ACLA activity should be treated. No consensus has been reached about treatment after an initial minor event [deep venous thrombosis (DVT)]. Asymptomatic patients with only laboratory abnormalities should not be treated. Glucocorticoids should be administered only in conjunction with antithrombotic agents and are not of proven efficacy.

INHERITED PROTHROMBOTIC DISORDERS Coagulation is carefully regulated by a series of inhibitors that limit thrombin generation and fibrin formation and by the fibrinolytic system, which effectively removes fibrin thrombi (Figs. 53-6 and 53-7). Inherited defects in the natural coagulation inhibitors (i.e., antithrombin, proteins C and S), abnormalities in the fibrinolytic system, and certain dysfibrinogenemias predispose patients to thrombosis (Table 53-5). A single point mutation in the factor V gene (factor V Leiden), which converts arginine 506 to glutamine and makes the molecule resistant to degradation by activated protein C, may account for 25% of inherited prethrombotic states. Antithrombin, protein C, and protein S defects are all autosomal dominant traits, so heterozygous individuals, who have a 50% reduction in protein concentration or a mixture of mutant and normal molecules, will have an increased risk of thrombosis. The patients have similar clinical presentations with a strong family history of thrombosis, episodes of recurrent venous thromboembolism, and symptoms by their early twenties. Any patient with this distinctive history should be tested for specific abnormalities.

ANTITHROMBIN DEFICIENCY Antithrombin complexes with activated coagulation proteins and blocks their biologic activity (Fig. 53-6). The rate of this reaction is enhanced by heparin-like molecules within the vessel wall or on endothelial cells. Plasma antithrombin III content is 5 to 15 mg/L (50 to 150%), with values only slightly below normal increasing the risk of thrombosis. For optimal screening, the antithrombin III concentration is measured by immunoassay and the

plasma antithrombin and heparin cofactor activity assessed with functional assays. The most common defect (1 in 2000 indidivuals) is mild (heterozygous) antithrombin deficiency. Dysfunctional antithrombin molecules with mutations affecting either the serine protease or heparin-binding site or activation of inhibitor by heparin have also been described.

Patients with antithrombin deficiency who develop acute thrombosis or embolism can be treated with intravenous heparin, since there is usually sufficient normal antithrombin to act as a heparin cofactor. Following their first episode of thromboembolism, patients should be placed on oral anticoagulants for life to prevent recurrent thrombosis. Family studies should be conducted when an antithrombin-deficient individual is discovered, since up to half the members of a kindred may be affected. Asymptomatic individuals with antithrombin deficiency should receive prophylactic anticoagulation with heparin or plasma infusions to raise their antithrombin level before medical or surgical procedures that may increase their risk of thrombosis. Chronic oral anticoagulation is not recommended until individuals at risk have a thrombotic episode.

DEFICIENCIES OF PROTEINS C AND S Protein C is a vitamin K–dependent hepatic protein that binds to the endothelial cell surface protein thrombomodulin and is converted to an active protease by thrombin (Fig. 53-6). Activated protein C, in conjunction with protein S, proteolyzes factors Va and VIIIa, which shuts off fibrin formation. Activated protein C may also stimulate fibrinolysis and accelerate clot lysis. Deficiencies of proteins C and S are usually autosomal dominant disorders, and deficiencies in the two proteins cause an identical syndrome of recurrent venous thrombosis and pulmonary embolism. Dysfunctional molecules have also been identified in some patients with thrombosis. Rare patients with homozygous protein C deficiency have fulminant neonatal intravascular coagulation and require prompt diagnosis and treatment.

The correlation between levels of proteins C and S and the risk of thrombosis is not as precise as for antithrombin III deficiency. In fact, some asymptomatic individuals with protein C "deficiency" have been discovered. In some well-studied protein C–deficient kindreds, asymptomatic individuals may have protein C levels as low as or lower than relatives with recurrent thrombosis. It is possible that an undiscovered cofactor is present in symptomatic patients. Finally, since a fraction of the available protein S is bound to C4b-binding protein and is unavailable for coagulation reactions, both free and total protein S levels or C4b-binding protein levels should be assessed for maximum accuracy.

Heterozygous patients with protein C or S deficiencies who develop acute thrombosis should be heparinized and then placed on oral anticoagulants. There are, however, two potential problems with the use of warfarin anticoagulants in these patients. First, these vitamin K antagonists (Fig. 102-1), which lower the level of the procoagulant factors II, VII, IX, and X, may also reduce the concentration of proteins C and S sufficiently to nullify the desired antithrombotic effect. In addition, patients who are protein C–deficient may develop warfarin-induced skin necrosis; this defect may predispose patients to a rare but serious complication. Patients with homozygous protein C deficiency require periodic plasma infusions rather than oral anticoagulants to prevent recurrent intravascular coagulation and thrombosis.

RESISTANCE TO ACTIVATED PROTEIN C AND THE FACTOR V LEIDEN MUTATION Some patients with familial or recurrent venous thromboembolism were found not to prolong their PTT when activated protein C was added to their plasma. These patients were found to have an identical mutation in which arginine 506 in factor V is converted to glutamine. This amino acid substitution abolishes a protein C cleavage site in factor V and thus prolongs the thrombogenic effect of factor V activation. About 3% of the population worldwide is heterozygous for this mutation. The mutation is absent in certain populations, e.g., Asians, African Americans, and Native Americans. It may account for 25% of patients with recurrent DVT or pulmonary embolism.

[a] Anticardiolipin antibody—lupus anticoagulant.

Heterozygosity at this allele increases an individual's lifetime risk of venous thromboembolism sevenfold. The risk rises steadily with age. A homozygote has a twentyfold increased risk of thrombosis. Heterozygosity coupled with ingestion of oral contraceptives or pregnancy increases the risk at least fifteenfold. Coinheritance of factor V Leiden and another low-penetrance defect such as protein C or S deficiency is also additive. Many previous studies of risk factors predisposing patients to venous thromboembolism are being reevaluated to take into account this common mutation.

PROTHROMBIN GENE MUTATION A specific point mutation in the prothrombin gene [conversion of G to A at position 20210 (G20210A)] also predisposes to venous thrombosis and embolism. This mutation is in the 3′-untranslated region of the gene and results in a 30% increase in plasma prothrombin levels, either through more efficient translation or greater stability of the message. Heterozygotes account for ~18% of cases with family histories of venous thrombosis and 6% of patients with first episodes of DVT.

The inheritance of multiple mutations increases the risk of thrombosis. The relationship between known mutations and the type of thrombosis is shown in Table 102-3. The fraction of patients with DVT with known mutations is shown in Table 102-4.

TREATMENT

Patients who develop venous thromboembolism without a clear predisposing factor, have a strong family history, present under age 30, or have more than one episode should have assays for antithrombin III, proteins C and S, and factor V Leiden. Patients who present with DVT or pulmonary embolism during pregnancy or while using oral contraceptives have a 30% chance of having factor V Leiden.

Treatment recommendations for patients with the inherited prethrombotic disorders are still evolving. All patients should receive standard initial therapy with heparin, either conventional or low dose (Chap. 103), followed by 3 months of oral warfarin. This regimen should allow for maximal healing and reendothelialization of the thrombosed vessels and minimize recurrence in the damaged vascular beds. It is not clear which patients should go on to receive long-term (perhaps lifelong) anticoagulation, a judgment that depends on assessing the risk/benefit ratio.

Patients with antithrombin III deficiency who become symptomatic have a high likelihood of recurrent events and should be placed on lifelong anticoagulation. Patients with protein C or S deficiency or heterozygous factor V Leiden and prothrombin G20210A patients have a lower likelihood of recurrent disease. Long-term anticoagula-

TABLE 102-4 *Prevalence of Coagulation Defects in Patients with Venous Thrombosis*

Defect	Prevalence, %
Factor V Leiden (Arg506Gln) R506 Q	12–40
Hyperhomocysteinemia	10–20
Prothrombin G20210A	6–18
Deficiencies of antithrombin III, proteins C and S	5–15
Antiphospholipid antibody syndrome	10–20

tion should be reserved until their second or subsequent episode of thromboembolism. Homozygous factor V Leiden patients should be placed on long-term anticoagulation after their initial episode, and all patients should receive replacement therapy or receive heparin prophylaxis during surgery or after trauma; women with these defects should avoid the use of oral contraceptives. The asymptomatic relatives of patients shown to have these disorders should be screened to determine if they have inherited the defective gene. If so, they should receive appropriate prophylaxis but not start anticoagulation until they are symptomatic. In the absence of a congenital defect predisposing a patient to thrombosis, recurring or migratory thrombophlebitis may indicate an underlying malignancy.

DYSFIBRINOGENEMIAS AND FIBRINOLYTIC DEFECTS Recurrent venous thrombosis and embolism may be due to familial defects in fibrinogen or plasminogen or decreased synthesis or release of tPA. While most dysfibrinogenemias cause bleeding, several variants have excessively rapid release of fibrinopeptides and recurrent thromboembolism. Patients with this disorder and those with an abnormal plasminogen that resists activation by streptokinase and urokinase have been treated successfully with heparin and oral anticoagulants. Defects in tPA content or release have not been completely characterized. One group of patients with recurrent venous thrombosis and embolism failed to increase venous blood fibrinolytic activity when challenged with local ischemia or physical exercise. The other group had impaired fibrinolytic activity in extracts prepared from biopsied veins. Young patients with acute myocardial infarction may have impaired fibrinolysis due to increased plasma levels of PAI, a serine protease inhibitor that binds to tPA and is derived from endothelial cells.

Many common illnesses are associated with an increased risk of thrombosis (Table 53-5). These patients are said to have a "hypercoagulable" or "prethrombotic" state. This increased risk is seen in patients with chronic congestive heart failure and metastatic cancer and in patients undergoing major surgery. The generation of tissue factor activity in damaged or ischemic tissue or metastatic tumor, coupled with venous stasis and endothelial injury, induces the formation of venous and, more rarely, arterial thrombi. Several hematologic disorders, paroxysmal nocturnal hemoglobinuria, essential thrombocythemia, and polycythemia vera predispose patients to venous and arterial thrombosis through diverse mechanisms related to increased blood viscosity and abnormal blood cells. Diseases that affect the endothelial cell, such as Behçet's syndrome, Kawasaki's disease, and homocystinuria, or the administration of drugs such as oral contraceptives, which lower antithrombin III levels, or L-asparaginase, which inhibits production of multiple coagulation factors, may also predispose patients to thrombosis. Infusion of granulocyte-macrophage colony-stimulating factor (GM-CSF) has been associated with thrombosis. Tamoxifen, an estrogen receptor antagonist, can cause venous thrombosis. The mechanism is unclear.

Plasma homocysteine levels influence the risk of both venous and arterial thromboembolism. Individuals with the congenital homocystinuria syndrome have, in addition to their Marfanoid habitus, an increased incidence of strokes and coronary artery disease. These patients have well-recognized enzyme defects (Chap. 343), excrete homocysteine in their urine, and have very high plasma levels of the amino acid. Some patients with early-onset cerebral vascular events have mild homocystinuria that can be brought out by a methionine loading test. Epidemiologic studies show a relationship between homocysteine levels that are nearer to the normal range and coronary artery disease. Vitamin B_{12} deficiency occurs in about 30% of people over age 70, produces elevated homocysteine levels, and may be a reversible cause of thrombotic disease.

103 ANTIPLATELET, ANTICOAGULANT, AND FIBRINOLYTIC THERAPY

Steven R. Deitcher

Arterial and venous thrombosis together with complicating embolic phenomena are major causes of mortality in the developed countries of the world. In the United States alone, myocardial infarction (MI) and thromboembolic stroke account for >800,000 deaths annually, and from one-half to 2 million venous thromboembolic events (VTE) including deep venous thrombosis (DVT) and pulmonary embolism (PE) occur annually. A common feature of the management of *all* thromboembolic vascular diseases is the use of antithrombotic agents. Antithrombotic agents, including antiplatelet drugs, anticoagulants, and fibrinolytic agents, are used to prevent thrombotic events, prevent or mitigate the complications of thrombotic events, and restore vascular patency in order to prevent loss of tissue, limb, and organ function as well as life. The pathologic basis of thrombosis in different vascular beds dictates the choice of agents: drugs that inhibit platelet activation and aggregation play a primary role in arterial disease management; drugs that inhibit thrombin and fibrin generation play a primary role in venous disease.

ANTIPLATELET DRUGS

Antiplatelet treatment reduces overall mortality from vascular disease by 15% and nonfatal vascular events by 30%. Multiple targets exist for antiplatelet therapy (Fig. 103-1), including cyclooxygenase (COX), adenosine diphosphate (ADP) receptors, the platelet adhesion glycoprotein (Gp) Ib, and the platelet agonist thrombin. Prostaglandin E_1 and stable analogues of prostacyclin inhibit platelet activation by increasing platelet cyclic AMP levels. Dipyridamole inhibits platelet activation by inhibiting phosphodiesterase to increase cyclic AMP. Because expression of functionally active GpIIb/IIIa on platelet surfaces is the final common pathway of platelet activation regardless of initial stimulus, it is a logical therapeutic target.

ASPIRIN Aspirin (acetylsalicylic acid) irreversibly inactivates by acetylation the activity of platelet prostaglandin H synthase-1 and -2 (COX-1 and -2). COX inhibition leads to the prevention of thromboxane A_2 synthesis and impairment of platelet secretion and aggregation. Non-enteric-coated aspirin is rapidly absorbed from the upper gastrointestinal tract; plasma salicylate concentrations peak within 1 h of ingestion. The effects of aspirin on platelet function occur within 1 h and last for the duration of the affected platelets' life span (1 week). Toxicities including gastrointestinal discomfort, blood loss, and systemic bleeding are dose-related. Aspirin doses as low as 30 mg/d are antithrombotic. Aspirin has been convincingly shown to be effective in treatment of stable and unstable angina, acute MI, transient ischemic

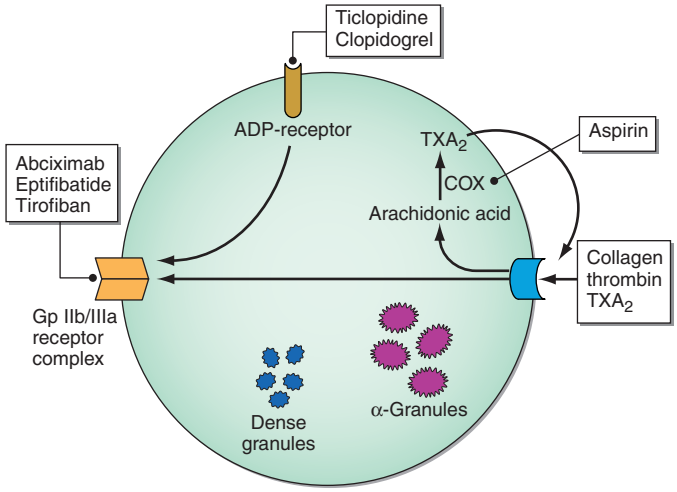

FIGURE 103-1 Antiplatelet drugs and targets for platelet function inhibition. The thienopyridines, ticlopidine and clopidogrel, inhibit the ADP-receptor of platelets. Aspirin targets platelet cyclooxygenase (COX). The disintegrins bind to and inhibit the final common pathway of platelet activation, namely the glycoprotein (Gp) IIb/IIIa complex. (TXA_2, thromboxane A_2.)

attack and incomplete stroke, stroke following carotid artery surgery, and atrial fibrillation. The minimum effective aspirin dose for these indications is 75 to 325 mg/d. Aspirin reduces mortality after coronary artery bypass surgery. In patients with acute MI or stroke, aspirin prevents 35 to 40 cardiovascular events per 1000 patients treated (secondary prevention). For primary prevention in persons >50 years of age with at least one major risk factor for coronary artery disease, aspirin prevents 4 events per 1000 patients treated. Aspirin is advisable following peripheral arterial bypass surgery and carotid endarterectomy and in patients with intermittent claudication. Though beneficial when compared to placebo, aspirin cannot be recommended as first-line VTE prophylaxis in hip fracture patients because the benefit of aspirin is less than with anticoagulants.

THIENOPYRIDINES Ticlopidine and clopidogrel are structurally related compounds that selectively inhibit ADP-induced platelet aggregation and likely ADP-mediated amplification of the platelet response to other agonists. Though more effective than aspirin in reducing vascular events in many settings, enthusiasm for ticlopidine is dampened by hematologic toxicities, including thrombotic thrombocytopenic purpura (TTP). Clopidogrel is rapidly absorbed, extensively metabolized, and inhibits ADP-induced platelet aggregation in a dose-dependent fashion with inhibition detectable 2 h after an oral dose of 400 mg. The plasma half-life of the main metabolite, SR 26334, is ~8 h. On repeated daily dosing of 50 to 100 mg, 25 to 30% inhibition of ADP-induced platelet aggregation is noted on the second day of therapy, with 50 to 60% steady-state inhibition noted after 4 to 7 days. Platelet function returns to normal about 7 days after the last dose of clopidogrel. The CAPRIE trial demonstrated a modest reduction in ischemic events in patients with recent stroke or MI and in those with symptomatic peripheral arterial disease randomly assigned to clopidogrel, 75 mg/d, compared to aspirin (5.32% vs. 5.83%). The majority of the difference in efficacy occurred in the patients who entered because of symptomatic peripheral arterial disease, with a 23.8% relative risk reduction. Another trial (PCI-CURE) demonstrated an advantage of pretreatment clopidogrel plus aspirin followed by long-term therapy over aspirin alone in patients with acute coronary syndromes. Clopidogrel rarely precipitates TTP.

GpIIb/IIIa (αIIbβ3) ANTAGONISTS GpIIb/IIIa is a member of the integrin family of receptors. These receptors recognize the amino acid sequence arginine-glycine-aspartate (Arg-Gly-Asp; RGD), which represents the cell attachment recognition sequence present in adhesive proteins such as fibrinogen. Three potent parenteral GpIIb/IIIa inhibitors (disintegrins) have been extensively studied, primarily in the settings of percutaneous coronary intervention (PCI), unstable angina, and non-Q-wave MI. Abciximab (c7E3 Fab) is a chimeric monoclonal Fab fragment of human and murine protein that binds to GpIIb/IIIa. Eptifibatide is a synthetic cyclic heptapeptide with a KGD sequence more specific for GpIIb/IIIa than RGD. Tirofiban is a synthetic peptidomimetic based on the RGD sequence. Oral, in contrast to intravenous, GpIIb/IIIa inhibitors have been generally disappointing.

ANTICOAGULANT DRUGS

Anticoagulant drugs are used to prevent and treat thrombosis in medical and surgical patients. Narrow-spectrum (single-protein target) anticoagulants (e.g., fondaparinux and ximelagatran) are being developed to supplant more broad-spectrum anticoagulants (e.g., heparin and warfarin). The molecular targets of selected agents are shown in Fig. 103-2. Oral delivery and lack of obligatory therapeutic monitoring are desired anticoagulant characteristics.

HEPARIN Commercial unfractionated heparin (UFH), obtained from bovine lung or porcine intestinal mucosa, consists of a heterogeneous mixture of highly sulfated polysaccharides (glycosaminoglycans) with molecular masses ranging from 4 to 30 kDa, with a mean molecular mass of ~15 kDa (≈45 saccharide units). UFH molecules contain a randomly distributed unique pentasaccharide sequence that binds to antithrombin. Once bound to UFH, the natural anticoagulant effect of antithrombin is potentiated, resulting in accelerated binding and inactivation of serine proteases such as the common pathway coagulation factors, factor Xa and thrombin. Heparin is active when given intravenously or subcutaneously. Delivery systems utilizing synthetic amino acids such as sodium *N*-[8(2-hydroxybenzoyl)amino] caprylate (SNAC) facilitate oral heparin gut absorption. The half-life of heparin increases with increasing dosage. A 100-U/kg intravenous dose is cleared with a half-life of ~1 h. Heparin is cleared by the reticuloendothelial system and metabolized by the liver, and metabolic products are excreted in the urine. "True" heparin resistance, manifesting as inadequate anticoagulant [activated partial thromboplastin time (aPTT) prolongation] and antithrombotic (anti-factor Xa activity) responses from what would otherwise be perceived as an adequate heparin dose, likely results from the nonspecific heparin binding to white blood cells, vascular endothelial cells, and acute-phase proteins. In "apparent" heparin resistance, usually as a result of elevated factor VIII levels, the aPTT may be normal or near normal while the anti-factor Xa activity assay reveals a therapeutic heparin activity level. Simply escalating the dose of heparin to achieve the desired aPTT without checking a heparin assay may result in a pronounced bleeding

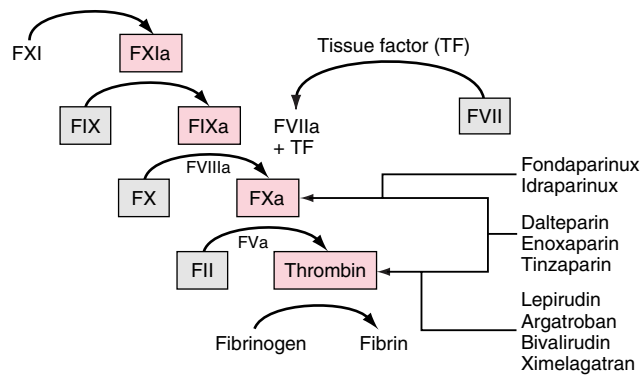

FIGURE 103-2 Anticoagulant drugs and molecular targets of anticoagulation. Unfractionated heparin targets the serine protease coagulation factors (highlighted in pale red); warfarin affects the vitamin K–dependent factors (highlighted in pale gray); pentasaccharide-based agents such as fondaparinux and idraparinux are select factor Xa inhibitors; the low-molecular-weight heparins target both factor Xa and thrombin with preference for factor Xa; and the direct thrombin inhibitors selectively target thrombin.

risk. These variables warrant close laboratory monitoring of heparin therapy.

LOW-MOLECULAR-WEIGHT HEPARINS (LMWHS) LMWHs are derived from the enzymatic or chemical cleavage of UFH into a mixture of glycosaminoglycans with a mean molecular mass of ~5 kDa (≈15 saccharide units). LMWHs bind antithrombin via the same pentasaccharide sequence as UFH. Due to the predominance of molecules <18 saccharide units in length, LMWHs have limited antithrombin activity compared to anti-factor Xa activity, and LMWH therapy is unable to be monitored by aPTT. Whereas UFH has an anti-factor Xa:antithrombin activity ratio of 1:1, LMWHs have reported ratios of 1.9:1 to 4.1:1. LMWHs differ in their degree of tissue factor pathway inhibitor release, degree of sulfation, and degree of stimulated von Willebrand factor (vWF) release. Superior bioavailability, limited nonspecific binding, and non-dose-dependent half-lives facilitate once- or twice-daily subcutaneous dosing based solely on weight and without laboratory monitoring. LMWH is cleared by renal mechanisms; therefore, multiday use in patients with severe renal insufficiency (creatinine clearance <30 mL/min) should be avoided. Reversible elevations of liver transaminases may occur during the administration of LMWH and UFH. LMWHs are associated with less heparin-induced thrombocytopenia (HIT) (Chap. 101) and osteopenia than UFH but are only partially (≈60%) neutralized by protamine sulfate.

HEPARINOIDS The heparinoid dermatan sulfate acts as an anticoagulant by activating heparin cofactor II. Danaparoid is a glycosaminoglycan mixture derived from porcine intestinal mucosa composed of heparan sulfate (84%), dermatan sulfate (12%), and chondroitin sulfate (4%). Danaparoid has an anti-factor Xa:antithrombin activity ratio of >22:1. Danaparoid's potential for heparin cross-reactivity and longer half-life (24 h) make it less desirable than a direct thrombin inhibitor for the treatment of patients with HIT, the main indication for heparinoid use.

PENTASACCHARIDES Fondaparinux is a synthetic pentasaccharide that causes selective indirect inhibition of factor Xa. Fondaparinux is administered subcutaneously and does not require therapeutic monitoring. Fondaparinux elimination is prolonged in patients with renal impairment, in those >75 years, and in those weighing <50 kg. Fondaparinux is primarily used for thromboprophylaxis in patients with hip fracture undergoing surgery and in those undergoing elective knee and hip joint replacement. Fondaparinux does not bind platelet factor 4 and may result in less HIT than UFH and LMWH. A long-acting pentasaccharide, idraparinux, has a half-life of 130 h, which may facilitate once-weekly dosing for primary and/or secondary prevention of thromboembolic events.

DIRECT THROMBIN INHIBITORS (DTI) Despite elimination of all heparin exposure and platelet count recovery, patients with isolated, serologically confirmed HIT have up to a 50% risk of developing a confirmed thrombotic event during the 30-day period following HIT diagnosis. The persistent prothrombotic tendency associated with HIT, the presence of thrombus in HIT with thrombosis, and a patient's original indication for heparin therapy all warrant use of an alternative anticoagulant agent such as DTI following heparin cessation.

Lepirudin Lepirudin is a recombinant hirudin that, unlike native hirudin in medicinal leech saliva, lacks sulfation on tyrosine 63 and has a leucine at position 1. Lepirudin is a potent, irreversible DTI that lacks any structural homology with heparin, does not cross-react with heparin, has a short half-life (1.5 h), inactivates clot-bound thrombin, and can be monitored by the aPTT assay or ecarin clotting time. The rate of death, amputation, and new thromboembolic events is reduced by >50% in HIT patients treated with lepirudin, compared with historic controls. Current lepirudin dosing recommendations for acute HIT management are 0.4 mg/kg as a bolus followed by 0.15 mg/kg per hour (up to 110 kg). The target aPTT is 1.5 to 2.5 times the median value for the normal range. The target plasma lepirudin concentration during heart bypass is 2.0 μg/mL. Outpatient subcutaneous lepirudin has been used to treat patients with HIT and patients refractory to other anticoagulant therapy. The major challenges of lepirudin treatment are the lack of an antidote, the extreme care needed when treating patients with even mild renal insufficiency, and immunogenicity. Marked bolus and infusion rate reductions are necessary in patients with a creatinine clearance of <60 mL/min. Lepirudin should be avoided completely or administered with extreme care in the settings of hemodialysis and acute renal failure. Approximately 40% of HIT patients treated with lepirudin develop IgG anti-hirudin antibodies that decrease renal elimination of the drug rather than exerting any in vivo neutralizing effect. This enhancement of anticoagulant effect often warrants a major reduction of the infusion rate.

Argatroban Argatroban is a synthetic, small-molecule, L-arginine derivative, rapid, and reversible DTI capable of inhibiting both free and fibrin-bound thrombin. Argatroban exerts its antithrombotic effects by inhibiting thrombin-mediated fibrin formation; coagulation factor V, VII, and XIII activation; and platelet activation. Argatroban does not cross-react with heparin. Argatroban is hepatically metabolized with biliary excretion and has a half-life of 40 min. Dose reduction is required in patients with significant hepatic disease. In HIT, the combined incidence of death, amputation, and new thromboembolic events is significantly lower in argatroban recipients compared with controls. The recommended starting intravenous infusion rate is 2 μg/kg per min with a target aPTT of 1.5 to 3 times the baseline value. Prothrombin time (PT) prolongation makes an accurate International Normalized Ratio (INR) determination during conversion to oral warfarin a challenge. Argatroban [350-μg/kg bolus followed by 25 μg/kg per min titrated to achieve an activated clotting time (ACT) of 300 to 450 s] provides adequate anticoagulation with minimal bleeding risk while enabling procedural success in HIT patients undergoing a PCI.

Bivalirudin Bivalirudin is a semisynthetic, bivalent DTI consisting of a dodecapeptide analogue of the carboxyterminus of hirudin. Bivalirudin has four glycine residues that connect the thrombin exocite 1 and thrombin active-site binding moieties. Bivalirudin has a very short half-life (25 min) and is a reversible DTI. Bivalirudin is primarily used during PCI, where it is at least as effective as heparin with an improved safety profile.

Ximelagatran Ximelagatran is an oral prodrug of the DTI melagatran. Ximelagatran is administered in a fixed-dose fashion, does not require therapeutic monitoring, and has no apparent major food or drug interactions. Ximelagatran is rapidly absorbed (peak levels in 15 to 30 min) and rapidly converted to melagatran (peak levels in 1 to 2 h). Melagatran is renally eliminated. Melagatran binds to the thrombin active site resulting in inhibition of thrombin-mediated activation of coagulation factors and platelets. It is active against free and clot-bound thrombin. Ximelagatran is promising as a treatment of acute VTE, chronic management of atrial fibrillation, and prevention of VTE in high-risk settings such as following surgery and HIT. Reversible liver function abnormalities have been reported.

WARFARIN Warfarin inhibits vitamin K epoxide reductase and vitamin K reductase, thus inhibiting γ-carboxylation of select glutamic acid residues in the N-terminus of prothrombin; factors VII, IX, and X; and protein C and protein S. Inhibition of γ-carboxylation leads to synthesis of hypofunctional coagulation proteins that are unable to bind to cellular surfaces to mediate coagulation reactions. Commercially available warfarin is a racemic mixture of levo- and dextrorotatory forms of the drug. The half-life of warfarin in plasma is ~36 h. Because factor X and prothrombin have half-lives >2 days, reduction of all vitamin K–dependent coagulation proteins into the therapeutic range (~20% of normal) requires 4 to 5 days of therapy. Warfarin dosage is influenced by dietary stores of vitamin K, liver function, coexisting medical disorders, concurrent medications, and presence or absence of a common cytochrome P450 2C9 gene mutation. Warfarin metabolism is affected by other drugs metabolized by the cytochrome P450, by drugs that displace albumin-bound warfarin and impair gas-

trointestinal absorption, and by antibiotics that alter the natural flora of the colon (an endogenous source of vitamin K). The PT assay is useful to monitor warfarin therapy because this assay measures three vitamin K–dependent coagulation proteins—factors VII, X, and prothrombin. The PT is particularly sensitive to factor VII deficiency; with a half-life of 4 to 6 h, the factor VII level may drop rapidly after only 1 day of warfarin therapy and prolong the PT value. Large loading doses of warfarin result in a more rapid drop in factor VII levels, delay in attainment of a stable PT, a precipitous fall in protein C levels, and predisposition to warfarin-induced skin necrosis. The INR is a method that standardizes PT assays. Each new PT reagent (thromboplastin) is calibrated against the World Health Organization reference thromboplastin. A relative sensitivity of the unknown preparation compared with the reference called the International Sensitivity Index (ISI) is derived. By adjusting for the ISI of a particular thromboplastin, an INR, defined as the PT ratio (patient PT divided by the mean normal PT) that would have been obtained if the reference thromboplastin had been used, can be determined. The INR is calculated using the following formula: $\text{INR} = (\text{PT ratio})^{\text{ISI}}$. An INR of 2.0 to 3.0 is recommended for all indications except prosthetic mechanical heart valves and prophylaxis of recurrent MI, for which higher-intensity warfarin therapy (INR 2.5 to 3.5) is suggested, and primary prophylaxis where an INR <2.0 is usually desired. In part because many patients with lupus anticoagulants have elevated baseline PTs, the INR may not be an accurate means of monitoring warfarin therapy in this setting. Factors contributing to warfarin-associated bleeding include an INR > 3.0, structural gastrointestinal lesions, concomitant antiplatelet therapy, hypertension, renal disease, and cerebrovascular disease. Visceral bleeding while on warfarin therapy often results in identification of structural lesions. In pregnant women, warfarin can cause an embryopathy consisting of nasal hypoplasia and epiphyseal stippling. The risk may be greatest between weeks 6 and 12 of gestation and may reflect the effect of warfarin on a vitamin K–dependent bone matrix protein, osteocalcin. Most practitioners avoid warfarin during pregnancy. Warfarin-induced skin necrosis is a devastating complication of warfarin therapy, occurring within the first week of therapy and associated in some with protein C deficiency. The skin lesions often begin on fatty body parts (breasts, abdomen, thighs) as erythematous patches and progress to blebs followed by demarcated skin necrosis. Skin biopsy reveals generalized thrombosis of skin vessels. The "purple-toe syndrome" is an uncommon syndrome described in patients with underlying atherosclerotic vascular disease receiving warfarin. These patients present with atheroembolic symptoms including ischemic (purple) toes, livedo reticularis, gangrene, abdominal pain, or symptoms of renal infarction. Skin biopsy reveals cholesterol emboli in the purple-toe syndrome.

FIBRINOLYTIC DRUGS

Most thrombolytic agents are recombinant forms of physiologic plasminogen activators (PAs) that differ in plasma half-life, fibrin specificity, primary clinical usage, primary infusion strategy, and immunogenicity. Therapeutic PAs are fashioned after endogenous tissue-type plasminogen activator (t-PA) or urokinase that converts plasminogen into the active enzyme plasmin. Plasmin degrades fibrinogen and fibrin into fibrin(ogen) degradation products. Major goals of new thrombolytic agent development include increasing fibrin specificity to theoretically reduce bleeding complications, prolonging initial plasma half-life to facilitate bolus administration, and reducing sensitivity to inactivation by plasminogen activator inhibitor (PAI) 1.

STREPTOKINASE Streptokinase is obtained from cultures of β-hemolytic streptococci. By itself, streptokinase has no PA activity, but when complexed with plasminogen, it can convert other plasminogen molecules to plasmin. It is not fibrin-selective in that the so-called lytic state resulting from its therapeutic use is due to lysis of fibrinogen as well as fibrin. Platelet function may be perturbed because plasmin can proteolyze key platelet membrane receptors. The half-life of streptokinase is ~20 min. Because streptokinase is a bacterial protein, it is antigenic; allergic reactions occur in up to 6% of patients, and anaphylaxis occurs in ~0.1% of patients. Patients previously exposed to streptokinase or with previous streptococcal infections may acquire antistreptococcal antibody levels sufficient to neutralize its activity. Streptokinase has been primarily used to treat VTE and MI as well as to treat central venous line–associated thrombosis.

UROKINASE-TYPE PLASMINOGEN ACTIVATOR Native urokinase is obtained from human fetal kidney cell cultures. Recombinant high-molecular-weight urokinase is produced using nonhuman, mammalian tissue cultures. Urokinase is not fibrin-selective and thus produces a lytic state. Its half-life is ~20 min, and it is used to treat DVT, PE, MI, peripheral arterial thrombosis, and occluded catheters.

TISSUE-TYPE PLASMINOGEN ACTIVATOR Recombinant tissue-type plasminogen activator (rt-PA) produced by recombinant technology demonstrates high in vitro affinity for fibrin with which it forms a ternary complex with plasminogen. Despite reported fibrin-specificity, the lytic state is produced with dosages currently used. Bleeding complications with t-PA are similar to those of streptokinase or urokinase. The half-life of t-PA is ~5 min. t-PA is used to treat DVT, PE, acute MI, acute thrombotic stroke, and dysfunctional central venous lines.

TISSUE-TYPE PLASMINOGEN ACTIVATOR VARIANTS Recombinant PA (r-PA; reteplase) is a nonglycosylated deletion mutant of wild-type human t-PA composed of only the kringle 2 and the protease domains of the parent molecule. Lack of the finger domain imparts lower fibrin-binding affinity. Lack of glycosylation, a finger domain, and epidermal growth factor domain imparts an extended half-life (15 min versus 5 min). TNK-t-PA differs from t-PA by three sets of mutations. The $Asn^{117} \rightarrow Gln$ and $Thr^{103} \rightarrow Asn$ mutations promote a lower plasma clearance rate and greater fibrin specificity. The Lys^{296}-His^{297}-Arg^{298}-$Arg^{299} \rightarrow$ Ala-Ala-Ala-Ala mutation imparts an 80-fold increased resistance to PAI-1. The longer half-lives of r-PA and TNK-rt-PA compared with rt-PA facilitate bolus administration primarily for acute coronary thrombosis.

NEWER NON-t-PA FIBRINOLYTICS Recombinant glycosylated pro-urokinase is a rapid acting and safe fibrin-specific PA. Staphylokinase produced by *Staphylococcus aureus* possesses substantial thrombolytic activity but may be immunogenic. Vampire bat (*Desmodus rotundus*) salivary PA, possessing 85% primary structure homology to human t-PA but lacking a kringle 2 domain, holds promise as a potent thrombolytic. Alfimiprase is a novel thrombolytic based on the snake venom–derived protein fibrolase. Alfimiprase is a direct fibrinolytic (not a PA) neutralized by α_2-macroglobulin that holds promise as a rapid and safe catheter-delivered thrombolytic.

THROMBOLYTIC THERAPY–ASSOCIATED BLEEDING Bleeding associated with all PAs stems from plasmin's inability to differentiate between hemostatic and pathologic thrombi. Bleeding complications range from minor bleeding to life-threatening hemorrhage including intracranial hemorrhage. Older age, female sex, black ethnicity, systolic blood pressure $\geq$ 140 mmHg, diastolic blood pressure $\geq$ 100 mmHg, history of stroke, t-PA dose $>$ 1.5 mg/kg, and lower body weight are all associated with increased intracranial hemorrhage risk. The ability of a thrombolytic agent (PA) to distinguish between plasminogen in the general circulation and plasminogen bound to fibrin surfaces dictates its fibrin specificity. Activation of fibrin-bound plasminogen results in the generation of fibrin-bound plasmin that is protected from inactivation by α_2-antiplasmin. Bound plasmin generates soluble fibrin degradation products, whereas circulating plasmin degrades fibrinogen into fibrinogen degradation products. High fibrin specificity is thought to be associated with lower risk for hemorrhagic complications because of the belief that plasmin born on the fibrin surface of a thrombus will restrict its activity only to that surface. This view is not supported by available data from large-scale clinical trials. Unlike in acute MI where intravenous bolus PA dosing is necessary to facilitate rapid lysis of a relatively small thrombus, lysis of larger diameter and longer

peripheral thromboses is best achieved with catheter-directed infusions of PA over several hours to days. Drugs designed for bolus infusion to treat acute coronary thrombosis (e.g., r-PA and TNK-t-PA) may be associated with loss of fibrin specificity, accumulation of fragment X, and increased bleeding rates when given by extended continuous infusion.

MANAGEMENT OF VENOUS THROMBOEMBOLIC DISEASE (Fig. 103-3)

The major clinical consequences of extremity DVT include the postthrombotic syndrome (swelling, stasis dermatitis, ulceration, and venous claudication all due to venous insufficiency), PE, and paradoxical embolism resulting in stroke. The major clinical consequences of PE include chronic dyspnea, pulmonary hypertension, pulmonary infarction, and death. Inadequately treated DVT involving the popliteal or more proximal leg veins is associated with a 20 to 50% risk of clinically relevant recurrence and is strongly associated with both symptomatic and fatal pulmonary embolism. Death from PE occurs most frequently within 2 days of presentation in untreated patients. All-cause mortality rates in treated patients with PE run as high as 11% at 2 weeks and 17% at 3 months.

CALF DEEP VENOUS THROMBOSIS While calf DVT and proximal DVT may be considered separate diseases at their outset, 15 to 25% of calf DVTs propagate and convert into proximal DVT. Symptomatic and asymptomatic calf DVT appear to propagate with equal frequency. Such "proximal conversion" renders what was initially a calf DVT just as dangerous as any proximal DVT. Proximal conversion has been shown to occur within the initial 2 weeks after diagnosis in the majority of cases and warrants treatment accordingly. The most essential goal of calf DVT treatment should be to prevent early proximal conversion. Treatment approaches for isolated calf DVT range from identical therapy as is used for proximal DVT to a complete lack of any pharmacologic therapy. Appropriate management, which falls between these extremes, includes serial duplex ultrasound surveillance (twice-weekly for 2 to 3 weeks) with therapy begun only in the event of proximal conversion and abbreviated courses of standard anticoagulation. Serial surveillance seems especially prudent in situations such as recent gastrointestinal bleeding where the risk of anticoagulation likely exceeds the benefit. Situational calf DVT (DVT with a clear precipitant) can be safely treated with anticoagulation for only 6 weeks, assuming the precipitating illness or event has resolved. Inferior vena cava (IVC) filter placement is not recommended for calf DVT in most circumstances.

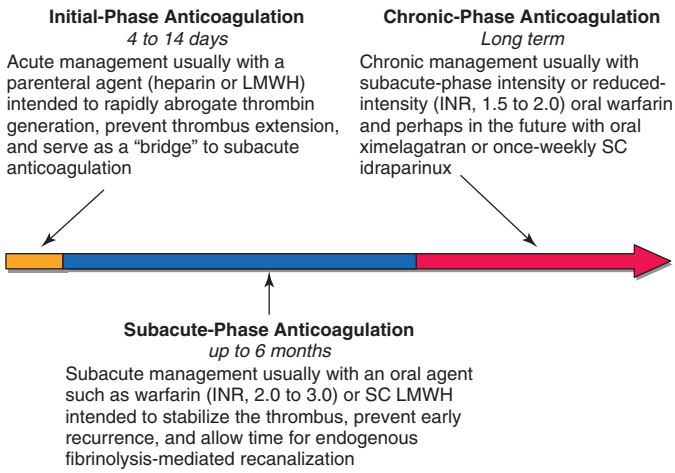

FIGURE 103-3 Phases of anticoagulation for venous thromboembolic events. Anticoagulation for a venous thromboembolic event can be divided into three distinct phases. Acute-phase anticoagulation usually consists of several days of parenteral therapy with intravenous unfractionated heparin or subcutaneous low-molecular-weight heparin (LMWH). Acute-phase therapy is usually continued for at least 4 days and until stable-dose, subacute-phase anticoagulation has been achieved. Subacute anticoagulation traditionally consists of oral warfarin for up to 6 months. Low-molecular-weight heparin therapy may offer superior and more convenient subacute anticoagulation in select populations. Long-term, chronic-phase anticoagulation consists of identical intensity therapy as is employed during subacute-phase therapy in high-risk patients and attenuated-intensity warfarin in others.

PROXIMAL DEEP VENOUS THROMBOSIS The goals of proximal DVT therapy include restoration of venous patency and prevention of embolization, thrombus extension, early and late recurrence, and postthrombotic syndrome. Studies done before the routine use of anticoagulant therapy demonstrated that 20% of patients with untreated DVT died of PE. Intravenous, aPTT-adjusted UFH and weight-based LMWH effectively prevent embolization, extension, and recurrence. LMWHs appear to be slightly but significantly better than standard heparin at restoring venous patency and may reduce the incidence of early postthrombotic syndrome. Placement of an IVC filter prevents PE in the short run but probably at the expense of a greater long-term DVT recurrence rate.

PULMONARY EMBOLISM In general, acute PE should be treated in the same fashion as acute proximal DVT. It is advisable to start anticoagulation at the time of suspected PE even before diagnostic testing has been performed. LMWHs have been shown to be safe and effective in patients with acute PE treated in hospital. Outpatient treatment of PE is investigational. Placement of an IVC filter at the time of PE diagnosis is usually reserved for those with an absolute contraindication to anticoagulation. Filters may be reasonable in select patients with underlying cardiac or pulmonary disease perceived as being at high risk for death in the event of even a small PE. Placement of a filter because of a "free-floating" DVT is probably not indicated.

INITIAL VTE ANTICOAGULATION Initial anticoagulation refers to the therapy begun at the time of VTE diagnosis and continued only until stable, usually oral, more long-term therapy has been achieved. Treatment with heparin or LMWH should be begun as soon as possible unless an absolute contraindication exists. A delay in achieving a therapeutic intensity of initial parenteral therapy may increase a patient's long-term VTE recurrence rate. Weight-based initial dosing of heparin (80 U/kg bolus followed by 18 U/kg per hour) with subsequent dose adjustments based on any published standardized nomogram facilitates achieving a target aPTT. An aPTT that correlates with an anti-FXa activity level of 0.3 to 0.7 IU/mL is considered therapeutic. The aPTT should be checked every 4 to 6 h until the aPTT surpasses the minimum of the target range. Fixed-dose boluses and initial infusions are preferred by some and are not necessarily inferior to weight-based dosing. Active bleeding, HIT or a history of HIT, and known sensitivity to UFH or pork products are absolute contraindications to heparin therapy. Patients with acute DVT and active bleeding require placement of an IVC filter. In patients with filters placed because of bleeding, appropriate anticoagulation should be begun as soon as the bleeding source has been properly and completely treated. Because of the risk of re-bleeding, such a patient may benefit from inpatient anticoagulation initiation. Placement and subsequent removal of a temporary (or retrievable) IVC filter once the contraindication to anticoagulation has passed seems ideal. Patients who are excessively anticoagulated with heparin without serious bleeding can be treated simply by stopping the drug; the short half-life (1 to 2 h) of heparin ensures rapid return of the aPTT to the therapeutic range. In occasional patients with thrombosis, such as those with lupus anticoagulants, the aPTT assay may not be reliable in monitoring heparin therapy. For these patients, one can follow heparin levels determined using the anti-factor Xa method or give a LMWH, with the dosage determined solely by body weight. Excessively anticoagulated and actively bleeding patients should be considered for reversal of anticoagulation with protamine sulfate. Protamine is given by slow IV infusion, with 1 mg of protamine neutralizing ~100 U of heparin. Protamine infusion may be associated with anaphylaxis, and excess protamine may lead to a paradoxical bleeding disorder. Weight-based subcutaneous LMWH is an established standard of care. Whether to use LMWH or UFH for acute anticoagulation should be determined for each patient taking into account the individual patient medical history, bleeding risk, ambu-

latory status, and insurance coverage. LMWHs are at least as safe and effective as UFH for the initial treatment of DVT. The major advantage of subcutaneous LMWH is its ability to be self-administered at home without the need for therapeutic monitoring. This translates into a significant reduction in mean hospital length of stay (6.5 days for UFH versus 1.1 days for LMWH in one study). Patients may be started on LMWH in the hospital and then discharged in an "accelerated" fashion to continue their conversion to oral warfarin or treated exclusively in the outpatient setting. Meta-analyses have shown a survival advantage in patients with acute DVT treated initially with LMWH versus those treated initially with UFH. This survival advantage seems primarily derived from a survival advantage in cancer patients with DVT. Enoxaparin is dosed at 1 mg/kg body weight every 12 h or 1.5 mg/kg once daily. Dalteparin is dosed at 200 IU/kg (up to 18,000 IU) once-daily. Tinzaparin is dosed at 175 IU/kg once daily. Patients at increased risk for bleeding should probably be treated initially in an inpatient setting. Such patients include those with active bleeding (including occult stool blood), a history of recent surgery, past gastrointestinal tract or neuraxial bleeding, recent trauma or stroke, concomitant regular use of nonsteroidal anti-inflammatory drugs (NSAIDs), thrombocytopenia, and renal insufficiency. Severe renal dysfunction (creatinine clearance < 30 mL/min) results in a $\geq 25\%$ reduction in LMWH clearance and thus results in drug accumulation. LMWH therapy may not be suitable for the morbidly obese. Monitored heparin therapy is always a choice for the obese patient with acute DVT or PE. Therapeutic monitoring of LMWH therapy using the anti-factor Xa activity assay is not indicated in most patients. An exact therapeutic range has not been carefully determined, and adjusting the dose of LMWH based on such testing has not been shown to be superior to weight-based dosing. Fondaparinux has been shown to be equivalent to enoxaparin for the initial management of DVT and equivalent to intravenous UFH for the initial management of PE. Ximelagatran holds promise as an oral acute VTE treatment. Warfarin therapy *alone* is contraindicated as initial therapy of acute thrombosis because of the inherent delay in achieving therapeutic anticoagulation and the theoretical transient exacerbation of hypercoagulability caused by a rapid reduction in protein C functional activity. This warfarin-induced paradoxical hypercoagulability may explain warfarin-induced skin necrosis and warfarin-induced limb gangrene in patients with HIT.

SUBACUTE VTE ANTICOAGULATION *Subacute anticoagulation* refers to treatment (usually oral warfarin) that follows acute-phase therapy and continues for up to 6 months (Table 103-1). Warfarin therapy (oral or intravenous) can be started as soon as an aPTT > 1.5 times control has been achieved with heparin or an initial weight-based dose of LMWH has been given. Bolus dosing of warfarin does not help achieve a stable, target INR faster and may actually delay achievement of a stable INR and prolong hospitalization. Initial dosing with 2.5 to 7.5 mg/d (based on patient weight and nutritional status) seems prudent. Heparin and LMWH therapy must overlap oral warfarin therapy for a minimum of 4 days and ideally until a stable, target range (2.0 to 3.0) INR has been achieved. Starting warfarin therapy early after heparin therapy (day 1 or 2) facilitates earlier hospital discharge and potential reduction in the incidence of HIT. Patients with massive DVT or PE may benefit from 7 to 10 days of initial heparin or LMWH therapy. Because of its teratogenic effects, warfarin therapy is contraindicated in pregnancy, so continued heparin or LMWH is prudent. Patients should be encouraged to consume a constant intake of dietary vitamin K and avoid large variations or fluctuations in their diet. Because of the number of pharmacologic interactions that exist between warfarin and other drugs, patients should be instructed to inform their physician of the addition or withdrawal of any medication, vitamin, and herbal preparation (Table 103-2). Recently completed studies (LITE, ONCENOX, and CLOT) provide strong evidence to support the use of LMWH as acute *plus* subacute VTE treatment. Once-daily tinzaparin (175 IU/kg) was as effective and safer than INR-adjusted oral warfarin in a mixed population of acute DVT patients. Once-daily tinzaparin, enoxaparin, and dalteparin were shown to be more effective than oral warfarin at preventing recurrent VTE in cancer patients with thrombosis. Patients with DVT secondary to a transient risk such as surgery, trauma, or pregnancy may be anticoagulated for a duration of 6 weeks to 3 months, as long as the risk factor has passed. Patients with a first idiopathic VTE should be anticoagulated for a minimum of 3 to 6 months.

CHRONIC ANTICOAGULATION FOR VTE Patients with persistent risk factors for thrombosis such as an anti-phospholipid antibody, hyperhomocysteinemia, active malignancy, or a deficiency of a natural anticoagulant (protein C, protein S, and antithrombin), homozygous factor V Leiden, and those with recurrent idiopathic VTE may benefit from long-term therapy (Table 103-1). The risk of VTE recurrence is very low as long as therapeutic anticoagulation is continued. It is the up to 3 to 4% annual risk of major hemorrhage secondary to warfarin (INR 2.0 to 3.0) that prevents physicians from prescribing long-term anticoagulation with abandon. The long-term risks and inconvenience of chronic (>6 months) therapeutic-intensity warfarin anticoagulation have led to the study of alternative approaches to chronic-phase anticoagulation following VTE. Extended secondary prevention with the oral DTI ximelagatran (24 mg bid) for 18 months after 6 months of standard anticoagulation in patients with VTE (THRIVE III) revealed recurrence rates of 2.0% and 11.6% ($p < .0001$) in the ximelagatran and placebo groups, respectively. Reported major and minor bleeding rates on therapy were not different between groups. Another successful approach

TABLE 103-1 *Duration of Anticoagulation for Venous Thromboembolic Events (VTE)*

Event	Duration of Anticoagulation
Situational DVT	6 weeks to 3 months
Idiopathic DVT	3 to 6 months (minimum)
Recurrent idiopathic DVT	12 months (minimum)
VTE with ongoing risk factors[a]	Long-term/indefinite
Pulmonary embolism	6 months (minimum)
Massive pulmonary embolism	Long-term/indefinite

[a] Malignancy, anti-phospholipid antibodies, homozygous factor V Leiden, natural anticoagulant deficiency, etc.

Note: DVT, deep venous thrombosis.

TABLE 103-2 *Effect of Select Drugs and Medical Conditions on Oral Warfarin Anticoagulation*

DRUGS THAT POTENTIATE WARFARIN EFFECT (INCREASE THE PROTHROMBIN TIME)	
Acetaminophen	Phenylbutazone
Anabolic steroids	Phenytoin
Broad-spectrum antibiotics	Propranolol
Cimetidine	Protease inhibitors (except retinovir)
Fluconazole	Quinidine
Lovastatin	Salicylate
Metronidazole	Tamoxifen
Omeprazole	Trimethoprim-sulfamethoxazole
MEDICAL CONDITIONS THAT POTENTIATE WARFARIN EFFECT (INCREASE THE PROTHROMBIN TIME)	
Advanced age	Fever
Hepatobiliary disease	Hyperthyroidism
Malabsorption	Malnutrition
Congestive heart failure	Cancer
DRUGS THAT ANTAGONIZE WARFARIN EFFECT (DECREASE THE PROTHROMBIN TIME)	
Adrenal glucocorticoids	Griseofulvin
Barbiturates	Penicillin
Carbamazapine	Rifampin
Cholestyramine	Sulcrafate
Efavirenz	Trazadone
MEDICAL CONDITIONS THAT ANTAGONIZE WARFARIN EFFECT (DECREASE THE PROTHROMBIN TIME)	
Excess dietary vitamin K	Hypothyroidism
Inherited warfarin resistence	Nephrotic syndrome

to chronic-phase anticoagulation involves long-term, low-intensity oral warfarin therapy with infrequent (every 8 weeks) INR monitoring (PREVENT). In this landmark study, patients with idiopathic VTE who had received standard acute- and subacute-phase anticoagulant therapy were randomly assigned to placebo or low-intensity warfarin (target INR 1.5 to 2.0). Recurrent VTE rates were 7.2 per 100 person-years and 2.6 per 100 person-years in the placebo and warfarin groups, respectively. This 64% risk reduction was accomplished in both those with and without inherited thrombophilia without any increase in major hemorrhage rates. Such safe and effective regimens have the potential to redefine the standard of care for VTE.

THROMBOLYSIS FOR VTE Benefits of DVT thrombolysis include the ability to subsequently diagnosis and treat underlying venous stenosis, venous compression (as in May-Thurner syndrome) or venous webs. Thrombolysis results in improved venous patency and symptom resolution and in a decrease in postthrombolic syndrome symptoms, and it may improve health-related quality of life. Because of the bleeding risk, thrombolysis is best reserved to treat iliofemoral DVT in the young and those with extensive thrombosis resulting in venous limb gangrene (*phlegmasia cerulea dolens*). Intravenous thrombolysis has been demonstrated to improve survival in patients with massive PE plus shock and is probably indicated in these patients. When compared to anticoagulation alone, thrombolytic therapy results in more rapid thrombus lysis, an early improvement in pulmonary blood flow, and improvement of right ventricular function. However, these improvements in cardiopulmonary function alone have not resulted in decreased mortality in stable patients without significant hemodynamic compromise. It remains unclear whether patients with PE and evidence of right ventricular dysfunction and/or elevated cardiac troponin levels are subgroups that benefit more from thrombolysis. Major hemorrhage rates have varied between 4 and 22% when thrombolytic agents are used in studies at the currently recommended doses.

VENOUS THROMBOEMBOLIC DISEASE PREVENTION If physicians focused more on VTE prophylaxis, much less time would need to be dedicated to emphasizing methods for VTE treatment. Fatal PE is the most common preventable cause of hospital death. A key to proper prophylaxis is the recognition of risk factors for thrombosis. Established clinical risk factors include: advanced age; prolonged immobility, stroke, or paralysis; prior VTE; active malignancy and its treatment; major surgery especially involving the abdomen, pelvis, and lower extremities; trauma, especially involving fracture of the pelvis, hip, or leg; obesity; varicose veins; depressed left ventricular ejection fraction; central venous access devices; inflammatory bowel disease; lobar pneumonia; nephrotic syndrome; pregnancy; estrogen use; and inherited and acquired hypercoagulable states. The number of risk factors, risk of DVT, risk of clinical PE, risk of fatal PE, and the required intensity of prophylactic therapy necessary to mitigate the risk all seem to increase in parallel. Medically ill patients (predominantly those immobilized with severe cardiopulmonary disease) have a 14.9% risk of developing DVT within 14 days of admission in the absence of active prophylaxis (MEDENOX). The DVT rate is reduced to 5.5% by the addition of a once-daily dose of LMWH (enoxaparin, 40 mg) without a significant increase in bleeding risk. Other studies have demonstrated equivalency between LMWH and heparin (5000 U tid) in medical patients with acute cardiac or pulmonary disease. Not all patients at risk will develop a thrombosis, and not all thromboses will result in symptoms, morbidity, or death. The benefit of pharmacologic thromboprophylaxis must always be weighed against the bleeding risk. Patients at high risk for bleeding should still receive prophylaxis in the form of intermittent pneumatic compression and/or thromboembolism-deterrence stockings.

104 INTRODUCTION TO INFECTIOUS DISEASES: HOST–PATHOGEN INTERACTIONS

Lawrence C. Madoff, Dennis L. Kasper

Despite decades of dramatic progress in their treatment and prevention, infectious diseases remain a major cause of death and debility and are responsible for worsening the living conditions of many millions of people around the world. Infections frequently challenge the physician's diagnostic skill and must be considered in the differential diagnoses of syndromes affecting every organ system.

CHANGING EPIDEMIOLOGY OF INFECTIOUS DISEASES With the advent of antimicrobial agents, some medical leaders believed that infectious diseases would soon be eliminated and become of historic interest only. Indeed, the hundreds of chemotherapeutic agents developed since World War II, most of which are potent and safe, include drugs effective not only against bacteria but also against viruses, fungi, and parasites. Nevertheless, we now realize that as we developed antimicrobial agents, microbes developed the ability to elude our best weapons and to counterattack with new survival strategies. Antibiotic resistance occurs at an alarming rate among all classes of mammalian pathogens. Pneumococci resistant to penicillin and enterococci resistant to vancomycin have become commonplace. Even *Staphylococcus aureus* that is resistant to vancomycin has appeared. Such pathogens present real clinical problems in managing infections that were easily treatable just a few years ago. Diseases once thought to have been nearly eradicated from the developed world—tuberculosis, cholera, and rheumatic fever, for example—have rebounded with renewed ferocity. Newly discovered and emerging infectious agents appear to have been brought into contact with humans by changes in the environment and by movements of human and animal populations. An example of the propensity for pathogens to escape from their usual niche is the alarming 1999 outbreak in New York of encephalitis due to West Nile virus, which had never previously been isolated in the Americas. In 2003, severe acute respiratory syndrome (SARS) was first recognized. This emerging clinical entity is caused by a novel coronavirus that may have jumped from an animal niche to become a significant human pathogen. In early 2004, avian influenza spread rapidly through poultry farms in Asia and caused deaths in exposed humans, raising the specter of a new influenza pandemic.

Many infectious agents have been discovered only in recent decades (Fig. 104-1). Ebola virus, human metapneumovirus, *Anaplasma phagocytophila* (the agent of human granulocytotropic ehrlichiosis), and retroviruses such as HIV humble us despite our deepening understanding of pathogenesis at the most basic molecular level. Even in developed countries, infectious diseases have made a resurgence. Between 1980 and 1996, mortality from infectious diseases in the United States increased by 64% to levels not seen since the 1940s.

The role of infectious agents in the etiology of diseases once believed to be noninfectious is being increasingly recognized. For example, it is now widely accepted that *Helicobacter pylori* is the causative agent of peptic ulcer disease and perhaps of gastric malignancy. Human papillomavirus is likely to be the most important cause of invasive cervical cancer. Human herpesvirus type 8 is believed to be the cause of most cases of Kaposi's sarcoma. Epstein-Barr virus is a cause of certain lymphomas and may play a role in the genesis of Hodgkin's disease. The possibility certainly exists that other diseases of unknown cause, such as rheumatoid arthritis, sarcoidosis, or inflammatory bowel disease, have infectious etiologies. There is even evidence that atherosclerosis may have an infectious component. In contrast, there are data to suggest that decreased exposures to pathogens in childhood may be contributing to an increase in the observed rate of allergic diseases.

Medical advances over infectious diseases have been hindered by changes in the patient population. Immunocompromised hosts now constitute a significant proportion of the seriously infected population. Physicians immunosuppress their patients to prevent the rejection of

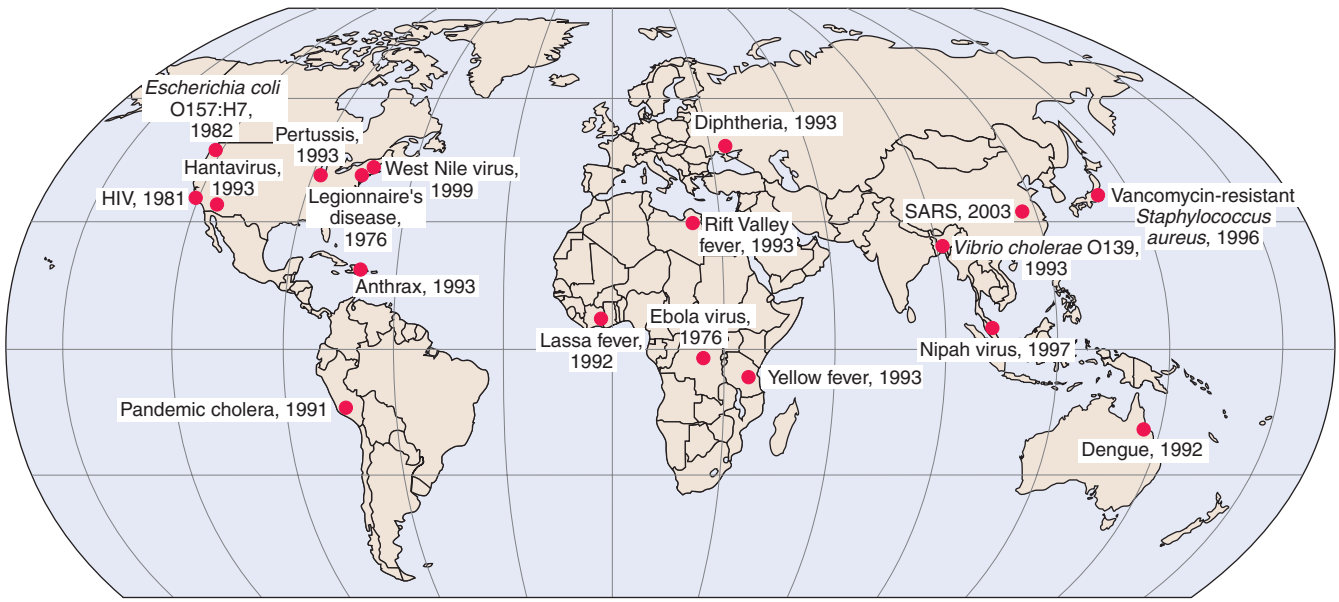

FIGURE 104-1 Map of the world showing examples of geographic locales where infectious diseases were noted to have emerged or resurged. (Adapted from *Addressing Emerging Infectious Disease Threats: A Prevention Strategy for the United States*, Department of Health and Human Services, Centers for Disease Control and Prevention, 1994.)

transplants and to treat neoplastic and inflammatory diseases. Some infections, most notably that caused by HIV, immunocompromise the host in and of themselves. Lesser degrees of immunosuppression are associated with other infections, such as influenza and syphilis. Infectious agents that coexist peacefully with immunocompetent hosts wreak havoc in those who lack a complete immune system. AIDS has brought to prominence once-obscure organisms such as *Pneumocystis*, *Cryptosporidium parvum*, and *Mycobacterium avium*.

HOST FACTORS IN INFECTION For any infectious process to occur, the pathogen and the host must first encounter each other. Factors such as geography, environment, and behavior thus influence the likelihood of infection. Although the initial encounter between a susceptible host and a virulent organism frequently results in disease, some organisms can be harbored in the host for years before disease becomes clinically evident. For a complete view, individual patients must be considered in the context of the population to which they belong. Infectious diseases do not often occur in isolation; rather, they spread through a group exposed from a point source (e.g., a contaminated water supply) or from individual to individual (e.g., via respiratory droplets). Thus, the clinician must be alert to infections prevalent in the community as a whole. A detailed history, including information on travel, behavioral factors, exposures to animals or potentially contaminated environments, and living and occupational conditions, must be elicited. For example, the likelihood of infection by *Plasmodium falciparum* can be significantly affected by altitude, climate, terrain, season, and even time of day. Antibiotic-resistant strains are localized to specific geographic regions, and a seemingly minor alteration in a travel itinerary can dramatically influence the likelihood of acquiring chloroquine-resistant malaria. If such important details in the history are overlooked, inappropriate treatment may result in the death of the patient. Likewise, the chance of acquiring a sexually transmitted disease can be greatly affected by a relatively minor variation in sexual practices, such as the method used for birth control. Knowledge of the relationship between specific risk factors and disease allows the physician to influence a patient's health even before the development of infection by modification of these risk factors and—when a vaccine is available—by immunization.

Many specific host factors influence the likelihood of acquiring an infectious disease. Age, immunization history, prior illnesses, level of nutrition, pregnancy, coexisting illness, and perhaps emotional state all have some impact on the risk of infection after exposure to a potential pathogen. The importance of individual host defense mechanisms, either specific or nonspecific, becomes apparent in their absence, and our understanding of these immune mechanisms is enhanced by studies of clinical syndromes developing in immunodeficient patients (Table 104-1). For example, the higher attack rate of meningococcal disease in people with deficiencies in specific complement proteins of the so-called membrane attack complex (see "Adaptive Immunity," below) than in the general population underscores the importance of an intact complement system in the prevention of meningococcal infection.

Medical care itself increases the patient's risk of acquiring an infection in several ways: (1) through contact with pathogens during hospitalization, (2) through breaching of the skin (with intravenous devices or surgical incisions) or mucosal surfaces (with endotracheal tubes or bladder catheters), (3) through introduction of foreign bodies, (4) through alteration of the natural flora with antibiotics, and (5) through treatment with immunosuppressive drugs.

Infection involves complicated interactions of parasite and host and inevitably affects both. In most cases, a pathogenic process consisting of several steps is required for the development of infections. Since the competent host has a complex series of barricades in place to prevent infection, the successful parasite must use specific strategies at each of these steps. The specific strategies used by bacteria, viruses, and parasites (Chap. 105) have some remarkable conceptual similarities, but the strategic details are unique not only for each class of organism but also for individual species within a class.

THE IMMUNE RESPONSE ■ Innate Immunity As they have co-evolved with microbes, higher organisms have developed mechanisms for recognizing and responding to microorganisms. Many of these mechanisms, referred to together as *innate immunity*, are evolutionarily ancient, having been conserved from insects to humans (Fig. 104-2). In general, innate immune mechanisms exploit molecular patterns found specifically in pathogenic microorganisms. These "pathogen signatures" are recognized by host molecules that either directly interfere with the pathogen or initiate a response that does so. Innate immunity serves to protect the host without prior exposure to an infectious agent—i.e., before specific or adaptive immunity has had a chance to develop. Innate immunity also functions as a warning system that activates components of adaptive immunity early in the course of infection.

Examples of innate immune effectors include defensins, simple peptides found on the skin and mucosal surfaces with activity against bacteria, fungi, and viruses. Macrophages that engulf and kill microbes (and other cells with similar function) are found even in invertebrates, such as *Drosophila*. The complement system (described below and discussed in more detail in Chap. 295) can respond to microbes without prior exposure.

The response to lipopolysaccharide (LPS), a molecule found uniquely in gram-negative bacteria, is instructive in understanding innate immunity. Even minuscule amounts of LPS are detected by LPS-binding protein, CD14, and Toll-like receptor 4 (Fig. 104-2). The interaction of LPS with these components of the innate immune system prompts macrophages, via the transcriptional activator NFκB, to produce cytokines that lead to inflammation and enzymes that enhance the clearance of microbes. These initial responses serve not only to limit infection but also to initiate specific or adaptive immune responses.

Adaptive Immunity Once in the bloodstream or a normally sterile body site, the microorganism faces the host's tightly integrated cellular and humoral immune systems. Cellular immunity (Chap. 295), comprising T lymphocytes, macrophages, and natural killer cells, primarily recognizes and combats pathogens that proliferate intracellularly. Cellular immune mechanisms are important in immunity to all classes of infectious agents, including most viruses and many bacteria (e.g., *Mycoplasma*, *Chlamydia*, *Listeria*, *Salmonella*, and *Mycobacterium*), parasites (e.g., *Trypanosoma*, *Toxoplasma*, and *Leishmania*), and fungi (e.g., *Histoplasma*, *Cryptococcus*, and *Coccidioides*). Usually, T lymphocytes are activated by macrophages and B lymphocytes, which present foreign antigens along with the host's own major histocompatibility complex antigen to the T cell receptor. Activated T cells may then act in several ways to fight infection. *Cytotoxic* T cells may directly attack and lyse host cells that express foreign antigens. *Helper* T cells stimulate the proliferation of B cells and the production of immunoglobulins. B cells and T cells communicate with each other via a variety of signals; often, more than one signal is employed simultaneously. For example, costimulation through the CD40-CD40 ligand increases B cell responses, and costimulation via the B7-CD28 axis is required for activation of the CD4+ helper T cell. T cells elaborate cytokines (e.g., interferon) that directly inhibit the growth of pathogens or stimulate killing by host macrophages and cytotoxic cells. Cytokines also augment the host's immunity by stimulating the inflammatory response (fever, the production of acute-phase serum components, and the proliferation of leukocytes). Cytokine stimulation does not always result in a favorable response in the host; septic shock (Chap. 254) and toxic shock syndrome (Chaps. 120 and 121) are among the conditions that are mediated by these inflammatory substances.

The reticuloendothelial system comprises monocyte-derived phagocytic cells that are located in the liver (Kupffer cells), lung (alveolar macrophages), spleen, kidney (mesangial cells), brain (microglia), and lymph nodes and that clear circulating microorganisms.

TABLE 104-1 *Infections Associated with Selected Defects in Immunity*

Host Defect	Disease or Therapy Associated with Defect	Common Etiologic Agent of Infection
NONSPECIFIC IMMUNITY		
Impaired cough	Rib fracture, neuromuscular dysfunction	Bacteria causing pneumonia, aerobic and anaerobic oral flora
Loss of gastric acidity	Achlorhydria, histamine blockade	*Salmonella* spp., enteric pathogens
Loss of cutaneous integrity	Penetrating trauma, athlete's foot	*Staphylococcus* spp., *Streptococcus* spp.
	Burn	*Pseudomonas aeruginosa*
	Intravenous catheter	*Staphylococcus* spp., *Streptococcus* spp., gram-negative rods, coagulase-negative staphylococci
Implantable device	Heart valve	*Streptococcus* spp., coagulase-negative staphylococci, *Staphylococcus aureus*
	Artificial joint	*Staphylococcus* spp., *Streptococcus* spp., gram-negative rods
Loss of normal bacterial flora	Antibiotic use	*Clostridium difficile*, *Candida* spp.
Impaired clearance		
Poor drainage	Urinary tract infection	*Escherichia coli*
Abnormal secretions	Cystic fibrosis	Chronic pulmonary infection with *P. aeruginosa*
INFLAMMATORY RESPONSE		
Neutropenia	Hematologic malignancy, cytotoxic chemotherapy, aplastic anemia, HIV infection	Gram-negative enteric bacilli, *Pseudomonas* spp., *Staphylococcus* spp., *Candida* spp.
Chemotaxis	Chédiak-Higashi syndrome, Job's syndrome, protein-calorie malnutrition	*S. aureus*, *Streptococcus pyogenes*, *Haemophilus influenzae*, gram-negative bacilli
	Leukocyte adhesion defects 1 and 2	Bacteria causing skin and systemic infections, gingivitis
Phagocytosis (cellular)	Systemic lupus erythematosus (SLE), chronic myelogenous leukemia, megaloblastic anemia	*Streptococcus pneumoniae*, *H. influenzae*
Splenectomy	—	*H. influenzae*, *S. pneumoniae*, other streptococci, *Capnocytophaga* spp., *Babesia microti*, *Salmonella* spp.
Microbicidal defect	Chronic granulomatous disease	Catalase-positive bacteria and fungi: staphylococci, *E. coli*, *Klebsiella* spp., *P. aeruginosa*, *Aspergillus* spp., *Nocardia* spp.
	Chédiak-Higashi syndrome	*S. aureus*, *S. pyogenes*
	Interferon γ receptor defect, interleukin 12 deficiency, interleukin 12 receptor defect	*Mycobacterium* spp., *Salmonella* spp.
INNATE IMMUNITY		
Complement system		
C3	Congenital liver disease, SLE, nephrotic syndrome	*S. aureus*, *S. pneumoniae*, *Pseudomonas* spp., *Proteus* spp.
C5	Congenital	*Neisseria* spp., gram-negative rods
C6, C7, C8	Congenital, SLE	*Neisseria meningitidis*, *N. gonorrhoeae*
Alternative pathway	Sickle cell disease	*S. pneumoniae*, *Salmonella* spp.
Toll-like receptor 4	Congenital	Gram-negative bacilli
Interleukin 1 receptor–associated kinase (IRAK) 4	Congenital	*S. pneumoniae*, *S. aureus*, other bacteria
Mannan-binding lectin	Congenital	*N. meningitidis*, other bacteria
ADAPTIVE IMMUNITY		
T lymphocyte deficiency/ dysfunction	Thymic aplasia, thymic hypoplasia, Hodgkin's disease, sarcoidosis, lepromatous leprosy	*Listeria monocytogenes*, *Mycobacterium* spp., *Candida* spp., *Aspergillus* spp., *Cryptococcus neoformans*, herpes simplex virus, varicella-zoster virus
	AIDS	*Pneumocystis*, cytomegalovirus, herpes simplex virus, *Mycobacterium avium-intracellulare*, *C. neoformans*, *Candida* spp.
	Mucocutaneous candidiasis	*Candida* spp.
	Purine nucleoside phosphorylase deficiency	Fungi, viruses
B cell deficiency/ dysfunction	Bruton's X-linked agammaglobulinemia	*S. pneumoniae*, other streptococci
	Agammaglobulinemia, chronic lymphocytic leukemia, multiple myeloma, dysglobulinemia	*H. influenzae*, *N. meningitidis*, *S. aureus*, *Klebsiella pneumoniae*, *E. coli*, *Giardia lamblia, Pneumocystis*, enteroviruses
	Selective IgM deficiency	*S. pneumoniae*, *H. influenzae*, *E. coli*
	Selective IgA deficiency	*G. lamblia*, hepatitis virus, *S. pneumoniae*, *H. influenzae*
Mixed T and B cell deficiency/ dysfunction	Common variable hypogammaglobulinemia	*Pneumocystis*, cytomegalovirus, *S. pneumoniae*, *H. influenzae*, various other bacteria
	Ataxia-telangiectasia	*S. pneumoniae*, *H. influenzae*, *S. aureus*, rubella virus, *G. lamblia*
	Severe combined immunodeficiency	*S. aureus*, *S. pneumoniae*, *H. influenzae*, *Candida albicans*, *Pneumocystis*, varicella-zoster virus, rubella virus, cytomegalovirus
	Wiskott-Aldrich syndrome	Agents of infections associated with T and B cell abnormalities
	X-linked hyper-IgM syndrome	*Pneumocystis*, cytomegalovirus, *Cryptosporidium parvum*

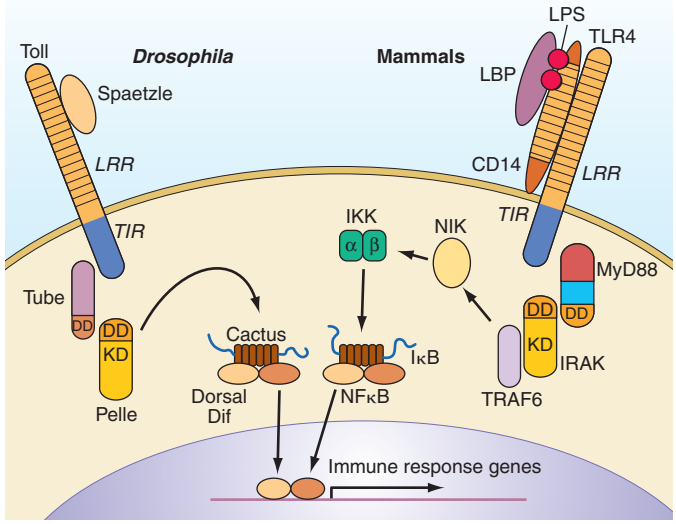

FIGURE 104-2 Conserved pathways in innate immunity in *Drosophila* and mammals. Examples chosen are, left, the induction of the antifungal gene drosomycin by binding of processed Spaetzle protein to the transmembrane receptor Toll and, right, activation of costimulatory protein genes by binding of an LPS-LBP-CD14 complex to a human Toll homologue, TLR4. DD, death domain; IκB, inhibitor of κB; IKK, IκB kinase; IRAK, interleukin 1 receptor–associated kinase; KD, kinase domain; LBP, LPS-binding protein; LPS, lipopolysaccharide; LRR, leucine-rich domain; NFκB, nuclear factor κB; NIK, NFκB-inducing kinase; TIR, Toll/IL-1 receptor homology domain; TRAF6, tumor necrosis factor receptor–associated factor 6. (*Reprinted with permission from JA Hoffman et al: Science 284:1315, 1999. Copyright 1999 American Association for the Advancement of Science.*)

Although these tissue macrophages and polymorphonuclear leukocytes (PMNs) are capable of killing microorganisms without help, they function much more efficiently when pathogens are first *opsonized* (Greek, "to prepare for eating") by components of the complement system such as C3b and/or by antibodies.

Extracellular pathogens, including most encapsulated bacteria (those surrounded by a complex polysaccharide coat), are attacked by the humoral immune system, which includes antibodies, the complement cascade, and phagocytic cells. Antibodies are complex glycoproteins (also called immunoglobulins) that are produced by mature B lymphocytes, circulate in body fluids, and are secreted on mucosal surfaces. Antibodies specifically recognize and bind to foreign antigens. One of the most impressive features of the immune system is the ability to generate an incredible diversity of antibodies capable of recognizing virtually every foreign antigen yet not reacting with self. In addition to being exquisitely specific for antigens, antibodies come in different structural and functional classes: IgG predominates in the circulation and persists for many years after exposure; IgM is the earliest specific antibody to appear in response to infection; secretory IgA is important in immunity at mucosal surfaces, while monomeric IgA appears in the serum; and IgE is important in allergic and parasitic diseases. Antibodies may directly impede the function of an invading organism, neutralize secreted toxins and enzymes, or facilitate the removal of the antigen (invading organism) by phagocytic cells. Immunoglobulins participate in cell-mediated immunity by promoting the antibody-dependent cellular cytotoxicity functions of certain T lymphocytes. Antibodies also promote the deposition of complement components on the surface of the invader.

The complement system (Chap. 295) consists of a group of serum proteins functioning as a cooperative, self-regulating cascade of enzymes that adhere to—and in some cases disrupt—the surface of invading organisms. Some of these surface-adherent proteins (e.g., C3b) can then act as opsonins for destruction of microbes by phagocytes. The later, "terminal" components (C7, C8, and C9) can directly kill some bacterial invaders (notably, many of the neisseriae) by forming a membrane attack complex and disrupting the integrity of the bacterial membrane, thus causing bacteriolysis. Other complement components, such as C5a, act as chemoattractants for PMNs. Complement activation and deposition occur by either or both of two pathways: the classic pathway is activated primarily by immune complexes (i.e., antibody bound to antigen), and the alternative pathway is activated by microbial components, frequently in the absence of antibody. PMNs have receptors for both antibody and C3b, and antibody and complement function together to aid in the clearance of infectious agents.

PMNs, short-lived white blood cells that engulf and kill invading microbes, are first attracted to inflammatory sites by chemoattractants such as C5a, which is a product of complement activation at the site of infection. PMNs localize to the site of infection by adhering to cellular adhesion molecules expressed by endothelial cells. Endothelial cells express these receptors, called *selectins* (CD-62, ELAM-1), in response to inflammatory cytokines such as tumor necrosis factor (TNF) α and interleukin 1. The binding of these selectin molecules to specific receptors on PMNs results in the adherence of the PMNs to the endothelium. Cytokine-mediated upregulation and expression of intercellular adhesion molecule 1 (ICAM 1) on endothelial cells then take place, and this latter receptor binds to β_2 integrins on PMNs, thereby facilitating diapedesis into the extravascular compartment. Once the PMNs are in the extravascular compartment, various molecules such as arachidonic acids further enhance the inflammatory process.

APPROACH TO THE PATIENT

The clinical manifestations of infectious diseases at presentation are myriad, varying from fulminant life-threatening processes to brief and self-limited conditions to indolent chronic maladies. The clinician must use all the skills of medicine to diagnose the infection and prescribe appropriate treatment. First, a careful history is essential and must include details on underlying chronic diseases; medications; occupation; travel; and risk factors for exposure to certain types of pathogens, such as those associated with sexual contacts, family illnesses, illicit drug use, particular animals, blood transfusions, ingestion of contaminated liquids or foods, or bites of insect vectors. Since infectious diseases may involve many organ systems, a careful review of systems may elicit important clues as to the disease process. The physical examination must be thorough, and attention must be paid to seemingly minor details: a soft heart murmur that might indicate bacterial endocarditis; an evanescent skin rash that suggests rheumatic fever; or a retinal lesion that suggests disseminated candidiasis or cytomegalovirus (CMV) infection.

LABORATORY INVESTIGATIONS Laboratory studies must be carefully considered and directed toward establishing an etiologic diagnosis in the shortest possible time, at the lowest possible cost, and with the least possible discomfort to the patient. Cultures must be performed in a manner that minimizes the likelihood of contamination with normal flora while maximizing the yield. A sputum sample is far more likely to be valuable when elicited with careful coaching by the clinician than when collected in a container simply left at the bedside with cursory instructions. Gram's stains of specimens should be interpreted carefully and the quality of the specimen assessed. The findings on Gram's staining should correspond to the results of culture; a discrepancy may suggest diagnostic possibilities such as infection due to fastidious or anaerobic bacteria.

The microbiology laboratory must be an ally in the diagnostic endeavor. Astute laboratory personnel will suggest optimal culture and transport conditions or alternative tests to facilitate diagnosis. If informed about specific potential pathogens, an alert laboratory staff will allow sufficient time for these organisms to become evident in culture, even when present in small numbers or when slow-growing. The parasitology technician who is attuned to the specific diagnostic considerations relevant to a particular case may be able to detect the rare, otherwise-elusive egg or cyst in a stool specimen. In cases where a

diagnosis appears difficult, serum should be stored during the early acute phase of the illness so that a diagnostic rise in titer of antibody to a specific pathogen can be detected later. Bacterial and fungal antigens can sometimes be detected in body fluids, even when cultures are negative or are rendered sterile by antibiotic therapy. Techniques such as the polymerase chain reaction allow the amplification of specific DNA sequences so that minute quantities of foreign nucleic acids can be recognized in host specimens.

TREATMENT

Optimal therapy for infectious diseases requires a broad knowledge of medicine and careful clinical judgment. Life-threatening infections such as bacterial meningitis or sepsis, viral encephalitis, or falciparum malaria must be treated immediately, often before a specific causative organism is identified. Antimicrobial agents must be chosen empirically and must be active against the range of potential infectious agents consistent with the clinical scenario. In contrast, good clinical judgment sometimes dictates withholding of antimicrobials in a self-limited process or until a specific diagnosis is made. The dictum *primum non nocere* should be adhered to, and it should be remembered that all antimicrobials carry a risk (and a cost) to the patient. Direct toxicity may be encountered—e.g., ototoxicity due to aminoglycosides, lipodystrophy due to antiretroviral agents, and hepatotoxicity due to antituberculous agents such as isoniazid and rifampin. Allergic reactions are common and can be serious. Since superinfection sometimes follows the eradication of the normal flora and colonization by a resistant organism, one invariable principle is that infectious disease therapy should be directed toward as narrow a spectrum of infectious agents as possible. Treatment specific for the pathogen should result in as little perturbation as possible of the host's microflora. With few exceptions, abscesses require surgical or percutaneous drainage for cure. Foreign bodies, including medical devices, must generally be removed in order to eliminate an infection of the device or of the adjacent tissue. Other infections, such as necrotizing fasciitis, peritonitis due to a perforated organ, gas gangrene, and chronic osteomyelitis, require surgery as the primary means of cure; in these conditions, antibiotics play only an adjunctive role.

The role of immunomodulators in the management of infectious diseases has received increasing attention. Glucocorticoids have been shown to be of benefit in the treatment of *Haemophilus influenzae* meningitis in children and in therapy for *Pneumocystis* pneumonia in patients with AIDS. The use of these agents in other infectious processes remains less clear and in some cases (in cerebral malaria and septic shock, for example) is detrimental. Activated protein C is the first immunomodulatory agent widely available for the treatment of severe sepsis. Its usefulness demonstrates the interrelatedness of the clotting cascade and systemic immunity. Other agents that modulate the immune response include prostaglandin inhibitors, specific lymphokines, and TNF inhibitors. Specific antibody therapy plays a role in the treatment and prevention of many diseases. Specific immunoglobulins have long been known to prevent the development of symptomatic rabies and tetanus. More recently, CMV immune globulin has been recognized as important not only in preventing the transmission of the virus during organ transplantation but also in treating CMV pneumonia in bone marrow transplant recipients. There is a strong need for well-designed clinical trials to evaluate each new interventional modality.

PERSPECTIVE The genetic simplicity of many infectious agents allows them to undergo rapid evolution and to develop selective advantages that result in constant variation in the clinical manifestations of infection. Moreover, changes in the environment and the host can predispose new populations to a particular infection. The dramatic march of West Nile virus from a single focus in New York City in 1999 to locations across the North American continent by the summer of 2002 caused widespread alarm, illustrating the fear that new plagues induce in the human psyche. The intentional release of deadly spores of *Bacillus anthracis* awakened many from a sense of complacency regarding biological weapons.

"The terror of the unknown is seldom better displayed than by the response of a population to the appearance of an epidemic, particularly when the epidemic strikes without apparent cause." Edward Kass made this statement in 1977 in reference to the newly discovered Legionnaire's disease, but it could apply equally to SARS or to any other new and mysterious disease. The potential for infectious agents to emerge in novel and unexpected ways requires that physicians and public health officials be knowledgeable, vigilant, and open-minded in their approach to unexplained illness. The emergence of antimicrobial-resistant pathogens (e.g., enterococci that are resistant to all known antimicrobial agents and cause infections that are essentially untreatable) has led some to conclude that we are entering the "post-antibiotic era." Others have held to the perception that infectious diseases no longer represent as serious a concern to world health as they once did. The progress that science, medicine, and society as a whole have made in combating these maladies is impressive, and it is ironic that, as we stand on the threshold of an understanding of the most basic biology of the microbe, infectious diseases are posing renewed problems. We are threatened by the appearance of new diseases such as AIDS, SARS, hepatitis C, and Ebola virus infection and by the reemergence of old foes such as tuberculosis, cholera, plague, and *Streptococcus pyogenes* infection. True students of infectious diseases were perhaps less surprised than anyone else by these developments. Those who know pathogens are aware of their incredible adaptability and diversity. As ingenious and successful as therapeutic approaches may be, our ability to develop methods to counter infectious agents so far has not matched the myriad strategies employed by the sea of microbes that surrounds us. Their sheer numbers and the rate at which they can evolve are daunting. Moreover, environmental changes, rapid global travel, population movements, and medicine itself—through its use of antibiotics and immunosuppressive agents—all increase the impact of infectious diseases. Although new vaccines, new antibiotics, improved global communication, and new modalities for treating and preventing infection will be developed, pathogenic microbes will continue to develop new strategies of their own, presenting us with an unending and dynamic challenge.

105 MOLECULAR MECHANISMS OF MICROBIAL PATHOGENESIS

Gerald B. Pier

Over the past three decades, molecular studies of the pathogenesis of microorganisms have yielded an explosion of information about the various microbial and host molecules that contribute to the processes of infection and disease. These processes can be classified into several stages: microbial encounter with and entry into the host; microbial growth after entry; avoidance of innate host defenses; tissue invasion and tropism; tissue damage; and transmission to new hosts. *Virulence* is the measure of an organism's capacity to cause disease and is a function of the pathogenic factors elaborated by microbes. These factors promote *colonization* (the simple presence of potentially pathogenic microbes in or on a host), *infection* (attachment and growth of pathogens and avoidance of host defenses), and *disease* (often, but not always, the result of activities of secreted toxins or toxic metabolites). In addition, the host's inflammatory response to infection greatly contributes to disease and its attendant clinical signs and symptoms.

MICROBIAL ENTRY AND ADHERENCE

ENTRY SITES A microbial pathogen can potentially enter any part of a host organism. In general, the type of disease produced by a particular microbe is often a direct consequence of its route of entry into the body. The most common sites of entry are mucosal surfaces (the respiratory, alimentary, and urogenital tracts) and the skin. Ingestion, inhalation, and sexual contact are typical routes of microbial entry. Other portals of entry include sites of skin injury (cuts, bites, burns, trauma) along with injection via natural (i.e., vector-borne) or artificial (i.e., needle-stick injury) routes. A few pathogens, such as *Schistosoma* spp., can penetrate unbroken skin. The conjunctiva can serve as an entry point for pathogens of the eye.

Microbial entry usually relies on the presence of specific microbial factors needed for persistence and growth in a tissue. Fecal-oral spread via the alimentary tract requires a biology consistent with survival in the varied environments of the gastrointestinal tract (including the low pH of the stomach and the high bile content of the intestine) as well as in contaminated food or water outside the host. Organisms that gain entry via the respiratory tract survive well in small moist droplets produced during sneezing and coughing. Pathogens that enter by venereal routes often survive best on the warm moist environment of the urogenital mucosa and have restricted host ranges (e.g., *Neisseria gonorrhoeae*, *Treponema pallidum*, and HIV).

The biology of microbes entering through the skin is highly varied. Some of these organisms can survive in a broad range of environments, such as the salivary glands or alimentary tracts of arthropod vectors, the mouths of larger animals, soil, and water. A complex biology allows protozoan parasites such as *Plasmodium*, *Leishmania*, and *Trypanosoma* spp. to undergo morphogenic changes that permit transmission of the organism to mammalian hosts during insect feeding for blood meals. Plasmodia are injected as infective sporozoites from the salivary glands during mosquito feeding. *Leishmania* parasites are regurgitated as promastigotes from the alimentary tract of sandflies and injected by bite into a susceptible host. Trypanosomes are first ingested from infected hosts by reduviid bugs; the pathogens then multiply in the gastrointestinal tract of the insects and are released in feces onto the host's skin during subsequent feedings. Most microbes that land directly on intact skin are destined to die, as survival on the skin or in hair follicles requires resistance to fatty acids, low pH, and other antimicrobial factors on skin. Once it is damaged (and particularly if it becomes necrotic), the skin can be a major portal of entry and growth for pathogens or their toxic products. Tetanus and burn wound infections are clear examples. After animal bites, pathogens resident in the animal's saliva gain access to the victim's tissues through the skin. Rabies is the paradigm for this pathogenic process; rabies virus grows in striated muscle cells at the site of inoculation.

TABLE 105-1 *Examples of Microbial Ligand-Receptor Interactions*

Microorganism	Type of Microbial Ligand	Host Receptor
VIRAL PATHOGENS		
Influenza virus	Hemagglutinin	Sialic acid
Measles virus		
Vaccine strain	Hemagglutinin	CD46/moesin
Wild-type strains	Hemagglutinin	Signaling lymphocytic activation molecule (SLAM)
Human herpesvirus type 6	?	CD46
Herpes simplex virus	Glycoprotein C	Heparin sulfate
HIV	Surface glycoprotein	CD4 and chemokine receptors (CCR5 and CXCR4)
Epstein-Barr virus	Envelope protein	CD21 (=CR2)
Adenovirus	Fiber protein	Coxsackie-adenovirus receptor (CAR)
Coxsackievirus	Fiber protein	CAR and major histocompatibility class I antigens
BACTERIAL PATHOGENS		
Neisseria species	Pili	Membrane cofactor protein (CD46)
Pseudomonas aeruginosa	Pili and flagella	Asialo-GM1
	Lipopolysaccharide	Cystic fibrosis transmembrane conductance regulator (CFTR)
Escherichia coli	Pili	Ceramides/mannose and digalactosyl residues
Yersinia spp.	Invasin/accessory invasin locus	β_1 Integrins
Bordetella pertussis	Filamentous hemagglutinin	CR3
Legionella pneumophila	Adsorbed C3bi	CR3
Mycobacterium tuberculosis	Adsorbed C3bi	CR3
FUNGAL PATHOGENS		
Blastomyces dermatitidis	WI-1	Possibly matrix proteins and integrins
Candida albicans	Int1p	Extracellular matrix proteins
PROTOZOAL PATHOGENS		
Plasmodium vivax	Merozoite form	Duffy Fy antigen
Plasmodium falciparum	EBA-175	Glycophorin A
Entamoeba histolytica	Surface lectin	*N*-Acetylglucosamine

MICROBIAL ADHERENCE Once in or on a host, most microbes must anchor themselves to a tissue or tissue factor; the possible exceptions are organisms that directly enter the bloodstream and multiply there. Specific ligands or adhesins for host receptors constitute a major area of study in the field of microbial pathogenesis. Adhesins comprise a wide range of surface structures, not only anchoring the microbe to a tissue and promoting cellular entry where appropriate but also eliciting host responses critical to the pathogenic process (Table 105-1). Most microbes produce multiple adhesins specific for multiple host receptors. These adhesins are often redundant, are serologically variable, and act additively or synergistically with other microbial factors to promote microbial sticking to host tissues. In addition, some microbes adsorb host proteins onto their surface and utilize the natural host protein receptor for microbial binding and entry into target cells.

Viral Adhesins All viral pathogens must bind to host cells, enter them, and replicate within them. Viral coat proteins serve as the ligands for cellular entry, and more than one ligand-receptor interaction may be needed; for example, HIV utilizes its envelope glycoprotein (gp) 120 to enter host cells by binding to both CD4 and one of two receptors for chemokines (designated CCR5 and CXCR4). Similarly, the measles virus H glycoprotein binds to both CD46 and the membrane-organizing protein moesin on host cells. The gC protein on herpes simplex virus binds to heparin sulfate; this step is followed by attachment to mammalian cells mediated by the viral gD (and possibly gH) protein. CD46 has now been shown to be the cellular receptor for human herpesvirus type 6.

Bacterial Adhesins Among the microbial adhesins studied in greatest detail are bacterial pili and flagella (Fig. 105-1). *Pili* or *fimbriae* are commonly used by gram-negative bacteria for attachment to host cells and tissues. In electron micrographs, these hairlike projections (up to several hundred per cell) may be confined to one end of the organism (polar pili) or distributed more evenly over the surface. An individual cell may have pili with a variety of functions. Most pili are made up of a major pilin protein subunit (molecular weight, 17,000 to 30,000) that polymerizes to form the pilus. Many strains of *Escherichia coli* express mannose-binding type 1 pili, whose binding to host tissues is inhibited by D-mannose. Other strains produce the Pap (pyelonephritis-associated) or P pilus adhesin that mediates binding to digalactose (gal-gal) residues on globosides of the human P blood groups. These pili have proteins located at the tips of the main pilus unit that are critical to the binding specificity of the whole pilus unit. Immunization with the mannose-binding FimH tip protein of type 1 pili prevents experimental *E. coli* bladder infections in mice and monkeys. *E. coli* cells causing diarrheal disease express pilus-like receptors for enterocytes on the small bowel, along with other receptors termed *colonization factors*.

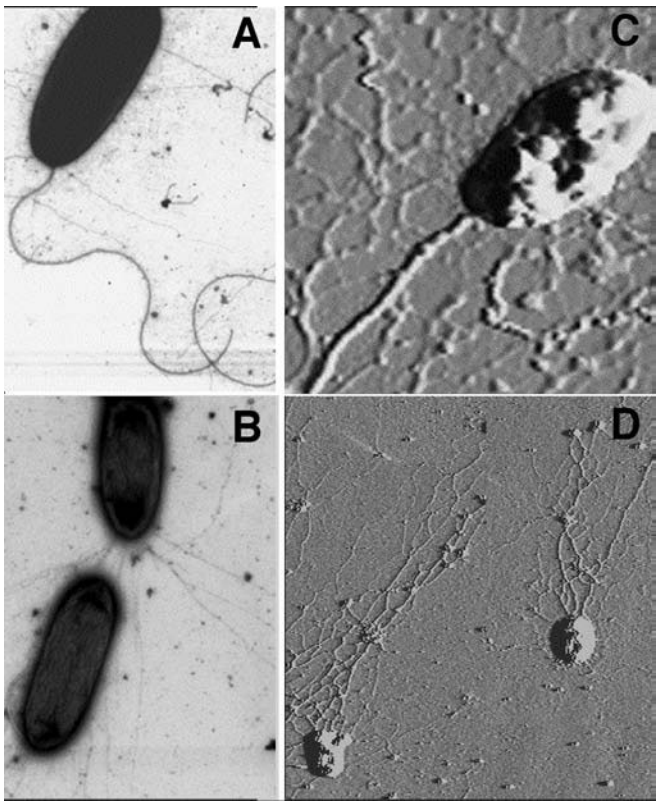

FIGURE 105-1 Bacterial surface structures. *A and B*. Traditional electron micrographic images of fixed cells of *Pseudomonas aeruginosa*. Flagella (*A*) and pili (*B*) projecting out from the bacterial poles can be seen. *C* and *D*. Atomic force microscopic image of live *P. aeruginosa* freshly planted onto a smooth mica surface. This new technology reveals the fine, three-dimensional detail of the bacterial surface structures. *(Images courtesy of Dr. Martin Lee and Mr. Milan Bajmociz, Harvard Medical School.)*

A common type of pilus found in *Neisseria* spp., *Moraxella* spp., *Vibrio cholerae*, and *Pseudomonas aeruginosa* mediates adherence of these organisms to target surfaces. These pili tend to have a relatively conserved amino-terminal region and a more variable carboxyl-terminal region. For some species such as *N. gonorrhoeae* and *Neisseria meningitidis*, the pili are critical for attachment to mucosal epithelial cells. For others, such as *P. aeruginosa*, the pili only partially mediate the cells' adherence to host tissues. *V. cholerae* cells appear to use two different types of pili for intestinal colonization. Whereas interference with this stage of colonization would appear to be an effective antibacterial strategy, attempts to develop pilus-based vaccines for human diseases have not been highly successful to date.

Flagella are long appendages attached at either one or both ends of the bacterial cell (polar flagella) or distributed over the entire cell surface (peritrichous flagella). Flagella, like pili, are composed of a polymerized or aggregated basic protein. In flagella, the protein subunits form a tight helical structure and vary serologically with the species. Spirochetes such as *T. pallidum* and *Borrelia burgdorferi* have axial filaments similar to flagella running down the long axis of the center of the cell, and they "swim" by rotation around these filaments. Some bacteria can glide over a surface in the absence of obvious motility structures.

Other bacterial structures involved in adherence to host tissues include specific staphylococcal and streptococcal proteins that bind to human extracellular matrix proteins such as fibrin, fibronectin, laminin, and collagen. Fibronectin appears to be a commonly used receptor for various pathogens; a particular amino acid sequence in fibronectin, Arg-Gly-Asp or RGD, is critical for bacterial binding. The surface lipopolysaccharide (LPS) of *P. aeruginosa* mediates binding to the cystic fibrosis transmembrane conductance regulator (CFTR) on airway epithelial cells. Coagulase-negative staphylococci and *Staphylococcus aureus* readily colonize prosthetic devices and catheters commonly used in medical care; a surface polysaccharide composed of poly-N-acetyl glucosamine elaborated by these organisms promotes binding to the prosthetic material. High-powered imaging techniques such as atomic force microscopy have revealed that bacterial cells have a nonhomogeneous surface that is likely attributable to different concentrations of cell surface molecules, including microbial adhesins, at specific places on the cell surface (Fig. 105-1*D*).

Fungal Adhesins Several fungal adhesins have been described that mediate colonization of epithelial surfaces, particularly adherence to structures like fibronectin, laminin, and collagen. The product of the *Candida albicans INT1* gene, Int1p, bears similarity to mammalian integrins that bind to extracellular matrix proteins. Transformation of normally nonadherent *Saccharomyces cerevisiae* with this gene allows these yeast cells to adhere to human epithelial cells. Disruption of *INT1* in *C. albicans* diminishes but does not eliminate epithelial cell adhesion; this result indicates that other adhesins participate in binding of *C. albicans* to epithelial cells. Moreover, Int1p is needed for filamentous growth of *C. albicans*—a phenotype linked to virulence, and particularly to the ability to penetrate keratinized epithelium. *INT1*-deficient *C. albicans* exhibits markedly reduced virulence in a mouse model of infection.

For several fungal pathogens that initiate infections after inhalation of infectious material, the inoculum is ingested by alveolar macrophages, in which the fungal cells transform to pathogenic phenotypes. Like *C. albicans*, *Blastomyces dermatitidis* binds to CD11b/CD18 integrins as well as to CD14 on macrophages. *B. dermatitidis* produces a 120-kDa surface protein, designated WI-1, that mediates this adherence. The binding domain of WI-1 is homologous to the invasin protein of *Yersinia* that binds to the same type of host cell receptor. An unidentified factor on *Histoplasma capsulatum* also mediates binding of this fungal pathogen to the integrin surface proteins.

Eukaryotic Pathogen Adhesins Eukaryotic parasites use complicated surface glycoproteins as adhesins, some of which are lectins (proteins that

bind to specific carbohydrates on host cells). For example, *Plasmodium vivax*, one of four *Plasmodium* species causing malaria, binds (via Duffy-binding protein) to the Duffy blood group carbohydrate antigen Fy on erythrocytes. *Entamoeba histolytica*, the third leading cause of death from parasitic diseases, expresses two proteins that bind to the disaccharide galactose/N-acetyl galactosamine. Reports indicate that children with mucosal IgA antibody to one of these lectins are resistant to reinfection with virulent *E. histolytica*. A major surface glycoprotein (gp63) of *Leishmania* promastigotes is needed for these parasites to enter human macrophages—the principal target cell of infection. This glycoprotein promotes complement binding but inhibits complement lytic activity, allowing the parasite to use complement receptors for entry into macrophages; gp63 also binds to fibronectin receptors on macrophages. In addition, the pathogen can express a carbohydrate that mediates binding to host cells. Evidence suggests that, as part of hepatic granuloma formation, *Schistosoma mansoni* expresses a carbohydrate epitope related to the Lewis X blood group antigen that promotes adherence of helminthic eggs to vascular endothelial cells under inflammatory conditions.

HOST RECEPTORS Host receptors are found both on target cells (such as epithelial cells lining mucosal surfaces) and within the mucus layer covering these cells. Microbial pathogens bind to a wide range of host receptors to establish infection (Table 105-1). Selective loss of host receptors for a pathogen may confer natural resistance to an otherwise susceptible population. For example, 70% of individuals in West Africa lack Fy antigens and are resistant to *P. vivax* infection. *Salmonella typhi*, the etiologic agent of typhoid fever, uses CFTR to enter the gastrointestinal submucosa after being ingested. As homozygous mutations in *CFTR* are the cause of the life-shortening disease cystic fibrosis, heterozygote carriers (e.g., 4 to 5% of individuals of European ancestry) may have had a selective advantage due to decreased susceptibility to *S. typhi* infection.

Numerous virus–target cell interactions have been described, and it is now clear that different viruses can use similar host cell receptors for entry. The list of certain and likely host receptors for viral pathogens is long. Among the host membrane components that can serve as receptors for viruses are sialic acids, gangliosides, glycosaminoglycans, integrins and other members of the immunoglobulin superfamily, histocompatibility antigens, and regulators and receptors for complement components.

MICROBIAL GROWTH AFTER ENTRY

Once established on a mucosal or skin site, pathogenic microbes must replicate before causing full-blown infection and disease. Within cells, viral particles release their nucleic acids, which may be directly translated into viral proteins (positive-strand RNA viruses), transcribed from a negative strand of RNA into a complementary mRNA (negative-strand RNA viruses), or transcribed into a complementary strand of DNA (retroviruses); for DNA viruses, mRNA may be transcribed directly from viral DNA, either in the cell nucleus or in the cytoplasm. To grow, bacteria must acquire specific nutrients or synthesize them from precursors in host tissues. Many infectious processes are usually confined to specific epithelial surfaces—influenza to the respiratory mucosa, gonorrhea to the urogenital epithelium, shigellosis to the gastrointestinal epithelium. While there are multiple reasons for this specificity, one important consideration is the ability of these pathogens to obtain from these specific environments the nutrients needed for growth and survival.

Temperature restrictions also play a role in limiting certain pathogens to specific tissues. Rhinoviruses, a cause of the common cold, grow best at 33°C and replicate in cooler nasal tissues but not in the lung. Leprosy lesions due to *Mycobacterium leprae* are found in and on relatively cool body sites. Fungal pathogens that infect the skin, hair follicles, and nails (dermatophyte infections) remain confined to the cooler, exterior, keratinous layer of the epithelium.

A topic of major interest is the ability of many bacterial, fungal, and protozoal species to grow in multicellular masses referred to as *biofilms*. These masses are biochemically and morphologically quite distinct from the free-living individual cells referred to as *planktonic cells*. Growth in biofilms leads to altered microbial metabolism, production of extracellular virulence factors, and decreased susceptibility to biocides, antimicrobial agents, and host defense molecules and cells. *P. aeruginosa* growing on the bronchial mucosa during chronic infection, staphylococci and other pathogens growing on implanted medical devices, and dental pathogens growing on tooth surfaces to form plaques represent several examples of microbial biofilm growth associated with human disease. Many other pathogens can form biofilms during in vitro growth, but the data are insufficient to determine whether this property is related to microbial virulence and induction of disease.

AVOIDANCE OF INNATE HOST DEFENSES

As microbes have probably interacted with mucosal/epithelial surfaces since the emergence of multicellular organisms, it is not surprising that multicellular hosts have a variety of innate surface defense mechanisms that can sense when pathogens are present and contribute to their elimination. The skin is acidic and is bathed with fatty acids toxic to many microbes. Successful skin pathogens such as staphylococci must tolerate these adverse conditions. Mucosal surfaces are covered by a barrier composed of a thick mucus layer that entraps microbes and facilitates their transport out of the body by such processes as mucociliary clearance, coughing, and urination. Mucous secretions, saliva, and tears contain antibacterial factors such as lysozyme and antimicrobial peptides as well as antiviral factors such as interferons. Gastric acidity is inimical to the survival of many ingested pathogens, and many mucosal surfaces—particularly the nasopharynx, the vaginal tract, and the gastrointestinal tract—contain a resident flora of commensal microbes that interfere with the ability of pathogens to colonize and infect a host.

Pathogens that survive these factors must still contend with host endocytic, phagocytic, and inflammatory responses as well as with host genetic factors that determine the degree to which a pathogen can survive and grow. The growth of viral pathogens entering skin or mucosal epithelial cells can be limited by a variety of host genetic factors, including production of interferons, modulation of receptors for viral entry, and age- and hormone-related susceptibility factors; by nutritional status; and even by personal habits such as smoking and exercise.

ENCOUNTERS WITH EPITHELIAL CELLS Over the past decade, many bacterial pathogens have been shown to enter epithelial cells (Fig. 105-2); the bacteria often use specialized surface structures that bind to receptors, with consequent internalization. However, the exact role and the importance of this process in infection and disease are not well defined for most of these pathogens. Bacterial entry into host epithelial cells is seen as a means for dissemination to adjacent or deeper tissues or as a route to sanctuary to avoid ingestion and killing by professional phagocytes. Epithelial cell entry appears, for instance, to be a critical aspect of dysentery induction by *Shigella*.

Curiously, the less virulent strains of many bacterial pathogens are more adept at entering epithelial cells than are more virulent strains; examples include pathogens that lack the surface polysaccharide capsule needed to cause serious disease. Thus, for *Haemophilus influenzae*, *Streptococcus pneumoniae*, *Streptococcus agalactiae* (group B *Streptococcus*), and *Streptococcus pyogenes*, isogenic mutants or variants lacking capsules enter epithelial cells better than the wild-type, encapsulated parental forms that cause disseminated disease. These observations have led to the proposal that epithelial cell entry may be a manifestation of host defense, resulting in bacterial clearance by both shedding of epithelial cells containing internalized bacteria and initiation of a subclinical inflammatory response. However, a consequence of this process would be the opening of a hole in the epithelium, potentially allowing uningested organisms to enter the submucosa.

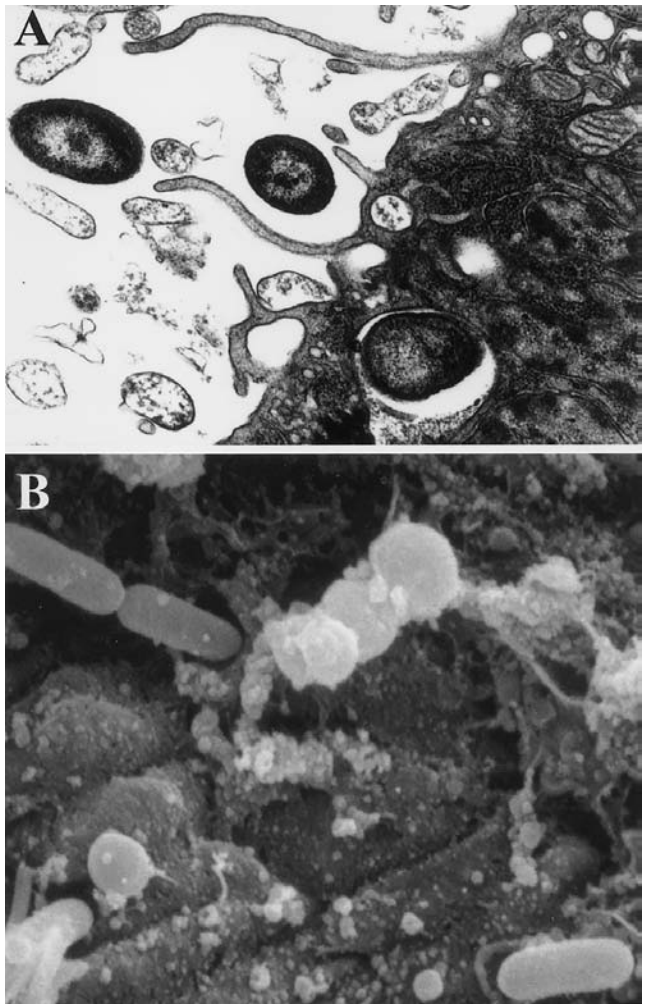

FIGURE 105-2 Entry of bacteria into epithelial cells. *A*. Internalization of *P. aeruginosa* by cultured airway epithelial cells expressing wild-type cystic fibrosis transmembrane conductance regulator (CFTR), the cell receptor for bacterial ingestion. *B*. Entry of *P. aeruginosa* into murine tracheal epithelial cells after murine infection by the intranasal route.

This scenario has been documented in murine *Salmonella typhimurium* infections and in experimental bladder infections with uropathogenic *E. coli*. In the latter system, bacterial pili mediate cell attachment to integral membrane glycoproteins called *uroplakins* that coat the host cells, resulting in exfoliation of the cells with attached bacteria. Subsequently, infection is produced by residual bacterial cells that invade the denuded epithelium. Perhaps at low bacterial inocula epithelial cell ingestion and subclinical inflammation are efficient means to eliminate pathogens, while at higher inocula a proportion of surviving bacterial cells enter the host tissue through the damaged mucosal surface and multiply, producing disease. Alternatively, failure of the appropriate epithelial cell response to a pathogen may allow the organism to survive on a mucosal surface where, if it avoids other host defenses, it can grow and cause a local infection. Along these lines, as noted above, *P. aeruginosa* is taken into epithelial cells by CFTR, a protein missing or nonfunctional in most severe cases of cystic fibrosis. The major clinical consequence of this disease is chronic airway-surface infection with *P. aeruginosa* in 80 to 90% of patients with cystic fibrosis. The failure of airway epithelial cells to ingest and promote the removal of *P. aeruginosa* has been proposed as a key component of the hypersusceptibility of these patients to chronic airway infection.

ENCOUNTERS WITH PHAGOCYTES ■ Phagocytosis and Inflammation Phagocytosis of microbes is a major innate host defense that limits the growth and spread of pathogens. Phagocytes appear rapidly at sites of infection in conjunction with the initiation of inflammation. Ingestion of microbes by both tissue-fixed macrophages and migrating phagocytes probably accounts for the limited ability of most microbial agents to cause disease. A family of related molecules called *collectins*, *soluble defense collagens*, or *pattern-recognition molecules* are found in blood (mannose-binding lectins), in lung (surfactant proteins A and D), and most likely in other tissues as well and bind to carbohydrates on microbial surfaces to promote phagocyte clearance. Bacterial pathogens seem to be ingested principally by polymorphonuclear neutrophils (PMNs), while eosinophils are frequently found at sites of infection by protozoan or multicellular parasites. Successful pathogens, by definition, must avoid being cleared by professional phagocytes. One of several antiphagocytic strategies employed by bacteria and by the fungal pathogen *Cryptococcus neoformans* is to elaborate large-molecular-weight surface polysaccharide antigens, often in the form of a capsule that coats the cell surface. Most pathogenic bacteria produce such antiphagocytic capsules.

As activation of local phagocytes in tissues is a key step in initiating inflammation and migration of additional phagocytes into infected sites, much attention has been paid to microbial factors that initiate inflammation. Encounters with phagocytes are governed largely by the structure of the microbial constituents that elicit inflammation, and detailed knowledge of these structures for bacterial pathogens has contributed greatly to our understanding of molecular mechanisms of microbial pathogenesis (Fig. 105-3). One of the best-studied systems involves the interaction of LPS from gram-negative bacteria and the glycosylphosphatidylinositol (GPI)-anchored membrane protein CD14 found on the surface of professional phagocytes, including migrating and tissue-fixed macrophages and PMNs. A soluble form of CD14 is also found in plasma and on mucosal surfaces. A plasma protein, LPS-binding protein (LBP), transfers LPS to membrane-bound CD14 on myeloid cells and promotes binding of LPS to soluble CD14. Soluble CD14/LPS/LBP complexes bind to many cell types and may be internalized to initiate cellular responses to microbial pathogens. It has been shown that peptidoglycan and lipoteichoic acid from gram-positive bacteria and cell-surface products of mycobacteria and spirochetes can interact with CD14 (Fig. 105-3).

GPI-anchored receptors do not have intracellular signaling domains, and mammalian Toll-like receptors (TLRs) transduce signals for cellular activation due to LPS binding. TLRs initiate cellular activation through a series of signal-transducing molecules (Fig. 105-3) that lead to nuclear translocation of the transcription factor NF-κB, a master-switch for production of important inflammatory cytokines such as tumor necrosis factor α (TNF-α) and interleukin (IL) 1.

The initiation of inflammation can occur not only with LPS and peptidoglycan but also with viral particles and other microbial products such as polysaccharides, enzymes, and toxins. Bacterial flagella activate inflammation by binding to TLR5. Bacteria also produce a high proportion of DNA molecules with unmethylated CpG residues that activate inflammation through TLR9. TLR3 recognizes double-stranded RNA, a pattern-recognition molecule produced by many viruses during their replicative cycle. TLR1 and TLR6 associate with TLR2 to promote recognition of acylated microbial proteins and peptides.

The myeloid differentiation factor 88 (MyD88) molecule is a generalized adaptor protein that binds to the cytoplasmic domains of all known TLRs and also to receptors that are part of the IL-1 receptor (IL-1Rc) family. Numerous studies have shown that MyD88-mediated transduction of signals from TLRs and IL-1Rc is critical for innate resistance to infection. Mice lacking MyD88 are more susceptible than normal mice to infection with group B *Streptococcus*, *Listeria monocytogenes*, and *Mycobacterium tuberculosis*.

Additional Interactions of Microbial Pathogens and Phagocytes Other ways that microbial pathogens avoid destruction by phagocytes include production of factors that are toxic to the phagocytes or that interfere with the chemotactic and ingestion function of phagocytes. Hemolysins,

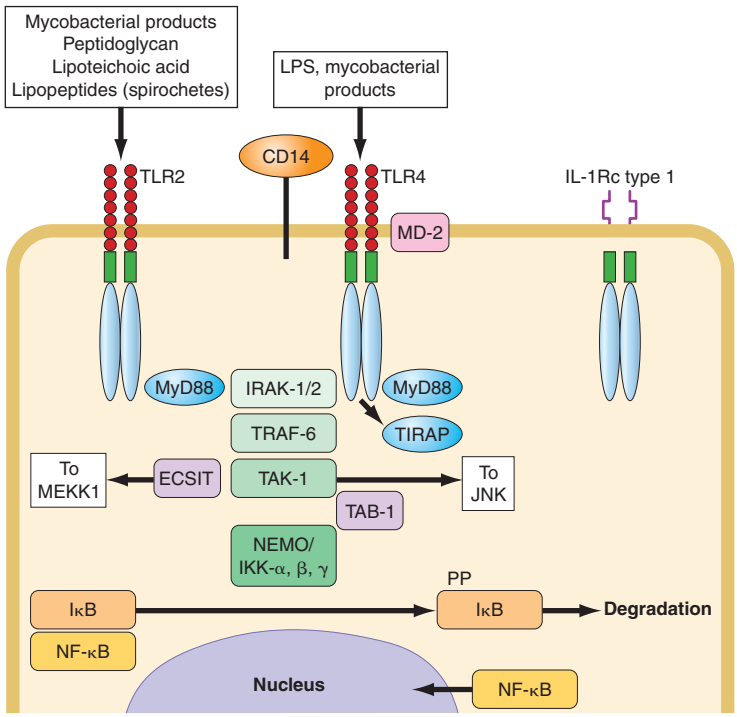

FIGURE 105-3 Cellular signaling pathways for production of inflammatory cytokines in response to microbial products. Various microbial cell-surface constituents interact with CD14, which in turn interacts in a currently unknown fashion with Toll-like receptors (TLRs). Some microbial factors do not need CD14 to interact with TLRs. Associating with TLR4 (and to some extent with TLR2) is MD-2, a cofactor that facilitates the response to lipopolysaccharide (LPS). Both CD14 and TLRs contain extracellular leucine-rich domains. The cytoplasmic domains of TLRs are oligomerized for binding to the general adaptor protein MyD88, which also binds to members of the interleukin-1 receptor (IL-1Rc) transmembrane proteins because of homology in the intracellular domain. TIRAP (TIR domain-containing adaptor protein) participates in the transduction of signals from TLR4. The receptor complex clusters or oligomerizes; oligomerization is followed by activation of signal-transducing molecules such as IRAK-1/2 (IL-1Rc-associated kinase 1 or 2), TRAF-6 (tumor necrosis factor receptor–associated factor 6), TAK-1 (transforming growth factor β–activating kinase 1), and TAB1 (TAK1-binding protein 1)/NIK (Nck-interacting kinase). In addition to activating other signaling pathways leading to cytokine production and stress responses, such as the c-Jun N-terminal kinase (JNK) pathway and MAP kinase kinase kinase (MEKK1) pathway [via evolutionarily conserved signaling intermediate in Toll pathways (ECSIT)], TLR-mediated signaling leads to activation of the inducible kinase complex, IKK-α, -β, and -γ. IKK-γ is also called NEMO [nuclear factor κB (NF-κB) essential modulator]. These are part of a larger complex that phosphorylates the inhibitory portion (I) of NF-κB, resulting in release of IκB from NF-κB. Phosphorylated (PP) IκB is then degraded, and NF-κB translocates to the nucleus, where it binds to transcriptional sites on target genes, many of which encode inflammatory proteins. *(Figure courtesy of Dr. Terry Means and Dr. Douglas Golenbock.)*

leukocidins, and the like are microbial proteins that can kill phagocytes that are attempting to ingest organisms elaborating these substances. For example, staphylococcal hemolysins inhibit macrophage chemotaxis and kill these phagocytes. Streptolysin O made by *S. pyogenes* binds to cholesterol in phagocyte membranes and initiates a process of internal degranulation, with the release of normally granule-sequestered toxic components into the phagocyte's cytoplasm. *Entamoeba histolytica*, an intestinal protozoan that causes amebic dysentery, can disrupt phagocyte membranes after direct contact via the release of protozoal phospholipase A and pore-forming peptides.

Microbial Survival Inside Phagocytes Many important microbial pathogens use a variety of strategies to survive inside phagocytes (particularly macrophages) after ingestion. Inhibition of fusion of the phagocytic vacuole (the phagosome) containing the ingested microbe with the lysosomal granules containing antimicrobial substances (the lysosome) allows *M. tuberculosis*, *S. typhi*, and *Toxoplasma gondii* to survive inside macrophages. Some organisms, such as *L. monocytogenes*, escape into the phagocyte's cytoplasm to grow and eventually spread to other cells. Resistance to killing within the macrophage and subsequent growth are critical to successful infection by herpes-type viruses, measles virus, poxviruses, *Salmonella*, *Yersinia*, *Legionella*, *Mycobacterium*, *Trypanosoma*, *Nocardia*, *Histoplasma*, *Toxoplasma*, and *Rickettsia*. *Salmonella* spp. use a master regulatory system, in which the *PhoP/PhoQ* genes control other genes, to enter and survive within cells, with intracellular survival entailing structural changes in the cell envelope LPS.

TISSUE INVASION AND TISSUE TROPISM

TISSUE INVASION Most viral pathogens cause disease by growth at skin or mucosal entry sites, but some pathogens spread from the initial site to deeper tissues. Virus can spread via the nerves (rabies virus) or plasma (picornaviruses) or within migratory blood cells (poliovirus, Epstein-Barr virus, and many others). Specific viral genes determine where and how individual viral strains can spread.

Bacteria may invade deeper layers of mucosal tissue via intracellular uptake by epithelial cells, traversal of epithelial cell junctions, or penetration through denuded epithelial surfaces. Among virulent *Shigella* strains and invasive *E. coli*, outer-membrane proteins are critical to epithelial cell invasion and bacterial multiplication. *Neisseria* and *Haemophilus* spp. penetrate mucosal cells by poorly understood mechanisms before dissemination into the bloodstream. Staphylococci and streptococci elaborate a variety of extracellular enzymes, such as hyaluronidase, lipases, nucleases, and hemolysins, that are probably important in breaking down cellular and matrix structures and allowing the bacteria access to deeper tissues and blood. Organisms that colonize the gastrointestinal tract can often translocate through the mucosa into the blood and, under circumstances in which host defenses are inadequate, cause bacteremia. *Yersinia enterocolitica* can invade the mucosa through the activity of the invasin protein. Some bacteria (e.g., *Brucella*) can be carried from a mucosal site to a distant site by phagocytic cells (e.g., PMNs) that ingest but fail to kill the bacteria.

Fungal pathogens almost always take advantage of host immunocompromise to spread hematogenously to deeper tissues. The AIDS epidemic has resoundingly illustrated this principle: the immunodeficiency of many HIV-infected patients permits the development of life-threatening fungal infections of the lung, blood, and brain. Other than the capsule of *C. neoformans*, specific fungal antigens involved in tissue invasion are not well characterized. Both fungal pathogens and protozoal pathogens (e.g., *Plasmodium* spp. and *E. histolytica*) undergo morphologic changes to spread within a host. Malarial parasites grow in liver cells as merozoites and are released into the blood to invade erythrocytes and become trophozoites. *E. histolytica* is found as both a cyst and a trophozoite in the intestinal lumen, through which this pathogen enters the host, but only the trophozoite form can spread systemically to cause amebic liver abscesses. Other protozoal pathogens, such as *T. gondii*, *Giardia lamblia*, and *Cryptosporidium*, also undergo extensive morphologic changes after initial infection to spread to other tissues.

TISSUE TROPISM The propensity of certain microbes to cause disease by infecting specific tissues has been known since the early days of bacteriology, yet the molecular basis for this propensity is understood somewhat better for viral pathogens than for other agents of infectious disease. Specific receptor-ligand interactions clearly underlie the ability of certain viruses to enter cells within tissues and disrupt normal tissue function, but the mere presence of a receptor for a virus on a target tissue is not sufficient for tissue tropism. Factors in the cell, route of viral entry, viral capacity to penetrate into cells, viral genetic elements that regulate gene expression, and pathways of viral spread in a tissue all affect tissue tropism. Some viral genes are best transcribed in specific target cells, such as hepatitis B genes in liver cells and Epstein-Barr virus genes in B lymphocytes. The route of inoculation of poliovirus determines its neurotropism, although the molecular basis for this circumstance is not understood.

The lesser understanding of the tissue tropism of bacterial and parasitic infections is exemplified by *Neisseria* spp. There is no well-accepted explanation of why *N. gonorrhoeae* colonizes and infects the human genital tract while the closely related species *N. meningitidis* principally colonizes the human oropharynx. *N. meningitidis* expresses a capsular polysaccharide, while *N. gonorrhoeae* does not; however, there is no indication that this property plays a role in the different tissue tropisms displayed by these two bacterial species. *N. gonorrhoeae* can use cytidine monophosphate *N*-acetylneuraminic acid from host tissues to add *N*-acetylneuraminic acid (sialic acid) to its lipooligosaccharide (LOS) O side chain, and this alteration appears to make the organism resistant to host defenses. Lactate, present at high levels on genital mucosal surfaces, stimulates sialylation of gonococcal LOS. Bacteria with sialic acid sugars in their capsules, such as *N. meningitidis*, *E. coli* K1, and group B streptococci, have a propensity to cause meningitis, but this generalization has many exceptions. For example, all recognized serotypes of group B streptococci contain sialic acid in their capsules, but only one serotype (III) is responsible for most cases of group B streptococcal meningitis. Moreover, both *H. influenzae* and *S. pneumoniae* can readily cause meningitis, but these organisms do not have sialic acid in their capsules.

TISSUE DAMAGE AND DISEASE

Disease is a complex phenomenon resulting from tissue invasion and destruction, toxin elaboration, and host response. Viruses cause much of their damage by exerting a cytopathic effect on host cells and inhibiting host defenses. The growth of bacterial, fungal, and protozoal parasites in tissue, which may or may not be accompanied by toxin elaboration, can also compromise tissue function and lead to disease. For some bacterial and possibly some fungal pathogens, toxin production is one of the best-characterized molecular mechanisms of pathogenesis, while host factors such as IL-1, TNF-α, kinins, inflammatory proteins, products of complement activation, and mediators derived from arachidonic acid metabolites (leukotrienes) and cellular degranulation (histamines) readily contribute to the severity of disease.

VIRAL DISEASE Viral pathogens are well known to inhibit host immune responses by a variety of mechanisms. Immune responses can be affected by downregulating production of most major histocompatibility complex (MHC) molecules (adenovirus E3 protein), by diminishing cytotoxic T-cell recognition of virus-infected cells (Epstein-Barr virus EBNA1 antigen and cytomegalovirus IE protein), by producing virus-encoded complement receptor proteins that protect infected cells from complement-mediated lysis (herpesvirus and vaccinia virus), by making proteins that interfere with the action of interferon (influenza virus and poxvirus), and by elaborating superantigen-like proteins (mouse mammary tumor virus and related retroviruses, rabies nucleocapsid, and possibly the Nef protein of HIV). Superantigens activate large populations of T cells that express particular subsets of the T cell receptor β protein, causing massive cytokine release and subsequent host reactions. Another molecular mechanism of viral virulence involves the production of peptide growth factors for host cells, which disrupt normal cellular growth, proliferation, and differentiation. In addition, viral factors can bind to and interfere with the function of host receptors for signaling molecules. Modulation of cytokine production during viral infection can stimulate viral growth inside cells with receptors for the cytokine, and virus-encoded cytokine homologues (e.g., the Epstein-Barr virus BCRF1 protein, which is highly homologous to the immunoinhibitory IL-10 molecule) can potentially prevent immune-mediated clearance of viral particles. Viruses can cause disease in neural cells by interfering with levels of neurotransmitters without necessarily destroying the cells, or they may induce either programmed cell death (apoptosis) to destroy tissues or inhibitors of apoptosis to allow for prolonged viral infection of cells. Overall, any disruption of normal cellular and tissue function due to viral infection can underlie the resultant clinical disease.

BACTERIAL TOXINS Among the first infectious diseases to be understood were those due to toxin-elaborating bacteria. Diphtheria, botulism, and tetanus toxins are responsible for the diseases associated with local infections due to *Corynebacterium diphtheriae*, *Clostridium botulinum*, and *Clostridium tetani*, respectively. Enterotoxins produced by *E. coli*, *Salmonella*, *Shigella*, *Staphylococcus*, and *V. cholerae* contribute to diarrheal disease caused by these organisms. Staphylococci, streptococci, *P. aeruginosa*, and *Bordetella* elaborate various toxins that cause or contribute to disease, including toxic shock syndrome toxin 1 (TSST-1); erythrogenic toxin; exotoxins A, S, and U; and pertussis toxin. A number of these toxins (e.g., cholera toxin, diphtheria toxin, pertussis toxin, *E. coli* heat-labile toxin, and *P. aeruginosa* exotoxin) have adenosine diphosphate (ADP)-ribosyltransferase activity; i.e., the toxins enzymatically catalyze the transfer of the ADP-ribosyl portion of nicotinamide adenine diphosphate to target proteins and inactivate them. The staphylococcal enterotoxins, TSST-1, and the streptococcal pyogenic exotoxins behave as superantigens, stimulating certain T cells to proliferate without processing of the protein toxin by antigen-presenting cells. Part of this process involves stimulation of the antigen-presenting cells to produce IL-1 and TNF-α, which have been implicated in many of the clinical features of diseases like toxic shock syndrome and scarlet fever. A number of gram-negative pathogens (*Salmonella*, *Yersinia*, and *P. aeruginosa*) can inject toxins directly into host target cells by means of a complex set of proteins referred to as the type III secretion system. Loss or inactivation of this virulence system usually greatly reduces the capacity of a bacterial pathogen to cause disease.

ENDOTOXIN The lipid A portion of gram-negative LPS has potent biologic activities that cause many of the clinical manifestations of gram-negative bacterial sepsis, including fever, muscle proteolysis, uncontrolled intravascular coagulation, and shock. The effects of lipid A appear to be mediated by the production of potent cytokines due to LPS binding to CD14 and signal transduction via TLRs, particularly TLR4. Cytokines exhibit potent hypothermic activity through effects on the hypothalamus; they also increase vascular permeability, alter the activity of endothelial cells, and induce endothelial-cell procoagulant activity. Numerous therapeutic strategies aimed at neutralizing the effects of endotoxin are under investigation, but so far the results have been disappointing.

INVASION Many diseases are caused primarily by pathogens growing in tissue sites that are normally sterile. Pneumococcal pneumonia is mostly attributable to the growth of *S. pneumoniae* in the lung and the attendant host inflammatory response, although specific factors that enhance this process (e.g., pneumolysin) may be responsible for some of the pathogenic potential of the pneumococcus. Disease that follows bacteremia and invasion of the meninges by meningitis-producing bacteria such as *N. meningitidis*, *H. influenzae*, *E. coli* K1, and group B streptococci appears to be due solely to the ability of these organisms to gain access to these tissues, multiply in them, and provoke cytokine production leading to tissue-damaging host inflammation.

Specific molecular mechanisms accounting for tissue invasion by fungal and protozoal pathogens are less well described. Except for studies pointing to factors like capsule and melanin production by *C. neoformans* and possibly levels of cell wall glucans in some pathogenic fungi, the molecular basis for fungal invasiveness is not well defined. Melanism has been shown to protect the fungal cell against death caused by phagocyte factors such as nitric oxide, superoxide, and hypochlorite. Morphogenic variation and production of proteases (e.g., the *Candida* aspartyl proteinase) have been implicated in fungal invasion of host tissues.

If pathogens are effectively to invade host tissues (particularly the blood), they must avoid the major host defenses represented by complement and phagocytic cells. Bacteria most often avoid these defenses through their cell surface polysaccharides—either capsular polysaccharides or long O-side-chain antigens characteristic of the smooth LPS of gram-negative bacteria. These molecules can prevent the activation and/or deposition of complement opsonins or limit the access

of phagocytic cells with receptors for complement opsonins to these molecules when they are deposited on the bacterial surface below the capsular layer. Another potential mechanism of microbial virulence is the ability of some organisms to present the capsule as an apparent self antigen through molecular mimicry. For example, the polysialic acid capsule of group B *N. meningitidis* is chemically identical to an oligosaccharide found on human brain cells.

Immunochemical studies of capsular polysaccharides have led to an appreciation of the tremendous chemical diversity that can result from the linking of a few monosaccharides. For example, three hexoses can link up in more than 300 different, potentially serologically distinct ways, while three amino acids have only six possible peptide combinations. Capsular polysaccharides have been used as effective vaccines against meningococcal meningitis as well as against pneumococcal and *H. influenzae* infections and may prove to be of value as vaccines against any organisms that express a nontoxic, immunogenic capsular polysaccharide. In addition, most encapsulated pathogens become virtually avirulent when capsule production is interrupted by genetic manipulation; this observation emphasizes the importance of this structure in pathogenesis.

HOST RESPONSE The inflammatory response of the host is critical for interruption and resolution of the infectious process but also is often responsible for the signs and symptoms of disease. Infection promotes a complex series of host responses involving the complement, kinin, and coagulation pathways. The production of cytokines such as IL-1, TNF-α, and other factors regulated in part by the NF-κB transcription factor leads to fever, muscle proteolysis, and other effects, as noted above. An inability to kill or contain the microbe usually results in further damage due to the progression of inflammation and infection. For example, in many chronic infections, degranulation of host inflammatory cells can lead to release of host proteases, elastases, histamines, and other toxic substances that can degrade host tissues. Chronic inflammation in any tissue can lead to the destruction of that tissue and to clinical disease associated with loss of organ function, such as sterility from pelvic inflammatory disease caused by chronic infection with *N. gonorrhoeae*.

The nature of the host response elicited by the pathogen often determines the pathology of a particular infection. Local inflammation produces local tissue damage, while systemic inflammation, such as that seen during sepsis, can result in the signs and symptoms of septic shock. The severity of septic shock is associated with the degree of production of host effectors. Disease due to intracellular parasitism results from the formation of granulomas, wherein the host attempts to wall off the parasite inside a fibrotic lesion surrounded by fused epithelial cells that make up so-called multinucleated giant cells. A number of pathogens, particularly anaerobic bacteria, staphylococci, and streptococci, provoke the formation of an abscess, probably because of the presence of zwitterionic surface polysaccharides such as the capsular polysaccharide of *Bacteroides fragilis*. The outcome of an infection depends on the balance between an effective host response that eliminates a pathogen and an excessive inflammatory response that is associated with an inability to eliminate a pathogen and with the resultant tissue damage that leads to disease.

TRANSMISSION TO NEW HOSTS

As part of the pathogenic process, most microbes are shed from the host, often in a form infectious for susceptible individuals. However, the rate of transmissibility may not necessarily be high, even if the disease is severe in the infected individual, as these traits are not linked. Most pathogens exit via the same route by which they entered: respiratory pathogens by aerosols from sneezing or coughing or through salivary spread, gastrointestinal pathogens by fecal-oral spread, sexually transmitted diseases by venereal spread, and vector-borne organisms by either direct contact with the vector through a blood meal or indirect contact with organisms shed into environmental sources such as water. Microbial factors that specifically promote transmission are not well characterized. Respiratory shedding is facilitated by overproduction of mucous secretions, with consequently enhanced sneezing and coughing. Diarrheal toxins such as cholera toxin, *E. coli* heat-labile toxins, and *Shigella* toxins probably facilitate fecal-oral spread of microbial cells in the high volumes of diarrheal fluid produced during infection. The ability to produce phenotypic variants that resist hostile environmental factors (e.g., the highly resistant cysts of *E. histolytica* shed in feces) represents another mechanism of pathogenesis relevant to transmission. Blood parasites such as *Plasmodium* spp. change phenotype after ingestion by a mosquito—a prerequisite for the continued transmission of this pathogen. Venereally transmitted pathogens may undergo phenotypic variation due to the production of specific factors to facilitate transmission, but shedding of these pathogens into the environment does not result in the formation of infectious foci.

In summary, the molecular mechanisms used by pathogens to colonize, invade, infect, and disrupt the host are numerous and diverse. Each phase of the infectious process involves a variety of microbial and host factors interacting in a manner that can result in disease. Recognition of the coordinated genetic regulation of virulence factor elaboration when organisms move from their natural environment into the mammalian host emphasizes the complex nature of the host-parasite interaction. Fortunately, the need for diverse factors in successful infection and disease implies that a variety of therapeutic strategies may be developed to interrupt this process and thereby prevent and treat microbial infections.

106 APPROACH TO THE ACUTELY ILL INFECTED FEBRILE PATIENT

Tamar F. Barlam, Dennis L. Kasper

The physician treating the acutely ill febrile patient must be able to recognize infections that require emergent attention. If such infections are not adequately evaluated and treated at initial presentation, the opportunity to alter an adverse outcome may be lost. In this chapter, the clinical presentations of and approach to patients with relatively common infectious disease emergencies are discussed. These infectious processes are discussed in detail in other chapters. →***Noninfectious causes of fever are not covered in this chapter; information on the approach to fever of unknown origin, including that eventually shown to be of noninfectious etiology, is presented in Chap. 18.***

GENERAL CONSIDERATIONS

APPEARANCE A physician must have a consistent approach to acutely ill patients. Even before the history is elicited and a physical examination performed, an immediate assessment of the patient's general appearance yields valuable information. The perceptive physician's subjective sense that a patient is septic or toxic often proves accurate. Visible agitation or anxiety in a febrile patient can be a harbinger of critical illness.

HISTORY Presenting symptoms are frequently nonspecific. In addition to a general description of symptoms, it is important to obtain a sense of disease progression. Detailed questions should be asked about the onset and duration of symptoms and about changes in severity or rate of progression over time. Host factors and comorbid conditions may enhance the risk of infection with certain organisms or of a more fulminant course than is usually seen. Lack of splenic function, alcoholism with significant liver disease, intravenous drug use, HIV infection, diabetes, malignancy, and chemotherapy all predispose to specific infections and frequently to increased severity. The patient should be questioned about factors that might help identify a nidus for invasive infection, such as recent upper respiratory tract infections, influenza, or varicella; prior trauma; disruption of cutaneous barriers due to lacerations, burns, surgery, or decubiti; and the presence of foreign bodies, such as nasal packing after rhinoplasty, barrier contraceptives, tampons, arteriovenous fistulas, or prosthetic joints. Travel, contact with pets or other animals, or activities that might result in tick exposure can lead to diagnoses that would not otherwise be considered. Recent dietary intake, medication use, social or occupational contact with ill individuals, vaccination history, recent sexual contacts, and menstrual history may be relevant. A review of systems should focus on any neurologic signs or sensorium alterations, rashes or skin lesions, and focal pain or tenderness and should also include a general review of respiratory, gastrointestinal, or genitourinary symptoms. It is especially important to determine the duration and progression of these symptoms in order to gain an appreciation of the pace and urgency of the process.

PHYSICAL EXAMINATION A complete physical examination should be performed, with special attention to some areas that are sometimes given short shrift in routine examinations. Assessment of the patient's general appearance and vital signs, skin and soft tissue examination, and the neurologic evaluation are of particular importance.

The patient may appear either anxious and agitated or lethargic and apathetic. Fever is usually present, although elderly patients and compromised hosts (e.g., patients who are uremic or cirrhotic and those who are taking glucocorticoids or nonsteroidal anti-inflammatory agents) may be afebrile despite serious underlying infection. Measurement of blood pressure, heart rate, and respiratory rate helps determine the degree of hemodynamic and metabolic compromise. The patient's airway must be evaluated to rule out the risk of obstruction from an invasive oropharyngeal infection.

The etiologic diagnosis may become evident in the context of a thorough skin examination (see also Chap. 17). Petechial rashes are typically seen with meningococcemia or Rocky Mountain spotted fever (RMSF); erythroderma is usual with toxic shock syndrome (TSS) and drug fever. The soft tissue and muscle examination is critical. Areas of erythema or duskiness, edema, and tenderness may indicate underlying necrotizing fasciitis, myositis, or myonecrosis. The neurologic examination must include a careful assessment of mental status for signs of early encephalopathy. Evidence of nuchal rigidity or focal neurologic findings should be sought. Focal findings, depressed mental status, or papilledema should be evaluated by brain imaging prior to lumbar puncture, which, in this setting, could initiate herniation.

DIAGNOSTIC WORKUP After a quick clinical assessment, diagnostic material should be obtained rapidly and antibiotic and supportive treatment begun. Blood (for cultures; baseline complete blood count with differential; measurement of serum electrolytes, blood urea nitrogen, serum creatinine, and serum glucose; and liver function tests) can be obtained at the time an intravenous line is placed and before antibiotics are administered. For patients with possible acute endocarditis, three sets of blood cultures should be performed. Asplenic patients should have a blood smear examined to confirm the presence of Howell-Jolly bodies (indicating the absence of splenic function) and a buffy coat examined for bacteria; these patients can have $>10^6$ organisms per milliliter of blood (compared with 10^4/mL in patients with an intact spleen). Blood smears from patients at risk for severe parasitic disease, such as malaria or babesiosis, must be examined for the diagnosis and quantitation of parasitemia. Blood smears may also be diagnostic in ehrlichiosis.

Patients with possible meningitis should have cerebrospinal fluid (CSF) obtained before the initiation of antibiotic therapy. *If focal neurologic signs, abnormal mental status, or papilledema mandates brain imaging before a lumbar puncture, antibiotics should be administered prior to imaging but after blood for cultures has been drawn.* If CSF cultures are negative, laboratory examination of CSF by latex agglutination or immunoprecipitation can be attempted to make an etiologic diagnosis. However, blood cultures will provide the diagnosis in 50 to 70% of cases.

Focal abscesses necessitate immediate computed tomography or magnetic resonance imaging (MRI) as part of an evaluation for surgical intervention. Other diagnostic procedures, such as cultures of wounds or scraping of skin lesions, should not delay the initiation of treatment for more than minutes. Once emergent evaluation, diagnostic procedures, and (if appropriate) surgical consultation (see below) have been completed, other laboratory tests can be conducted. Appropriate radiography, computed axial tomography, MRI, urinalysis, erythrocyte sedimentation rate (ESR) determination, and transthoracic or transesophageal echocardiography may all prove important.

℞ TREATMENT

In the acutely ill patient, empirical antibiotic therapy is critical and should be administered without undue delay. Table 106-1 lists first-line treatments for the infections considered in this chapter. (For a more detailed discussion of treatment, see specific chapters.) In addition to the initiation of parenteral antibiotic therapy, several of these infections require urgent surgical attention. General surgery for possible necrotizing fasciitis or myonecrosis, neurosurgical evaluation for subdural empyema or spinal epidural abscess, otolaryngologic surgery for possible mucormycosis, and cardiothoracic surgery for critically ill patients with acute endocarditis are as important as the rapid commencement of antibiotic therapy. For infections such as necrotizing fasciitis and clostridial myonecrosis, rapid surgical intervention supersedes other diagnostic or therapeutic maneuvers.

Adjunctive treatments, such as intravenous immunoglobulin administration for TSS, can be considered after initial stabilization. Some adjunctive treatments, such as dexamethasone for bacterial meningitis or protein C replacement for meningococcemia, must be considered in conjunction with the initiation of antibiotic treatment.

SPECIFIC PRESENTATIONS

For most infections, there is time for careful evaluation, diagnostic testing, and consultation with other physicians before therapy commences. However, the infections considered below according to common clinical presentation can have rapidly catastrophic outcomes, and their immediate recognition and treatment can be life-saving. Recommended empirical therapeutic regimens are presented in Table 106-1.

SEPSIS WITHOUT AN OBVIOUS FOCUS OF PRIMARY INFECTION These patients initially have a brief prodrome of nonspecific symptoms and signs that progresses quickly to hemodynamic instability with hypotension, tachycardia, tachypnea, or respiratory distress. A patient may display altered mental status. Disseminated intravascular coagulation (DIC)

TABLE 106-1 *Common Infectious Disease Emergencies*

Clinical Syndrome	Possible Etiologies	Treatment	Comments	Reference(s)
SEPSIS WITHOUT A CLEAR FOCUS				
Gram-negative sepsis	*Pseudomonas* spp., gram-negative enteric bacilli	Piperacillin/tazobactam (3.75 g q4h) ***or*** Ceftazidime (2 g q8h) ***plus*** Tobramycin (5 mg/kg per day)	See Chap. 254.	136, 254
Gram-positive sepsis	*Staphylococcus* spp., *Streptococcus* spp.	Vancomycin (1 g q12h) ***plus*** Gentamicin (5 mg/kg per day)	If a β-lactam-sensitive strain is identified, antibiotics should be altered.	120, 121, 254
Overwhelming post-splenectomy sepsis	*Streptococcus pneumoniae*, *Haemophilus influenzae*, *Neisseria meningitidis*	Ceftriaxone (2 g q12h)[a]	If the isolate is penicillin-sensitive, penicillin is the drug of choice.	254
Babesiosis	*Babesia microti* (U.S.), *B. divergens* (Europe)	***Either:*** Clindamycin (600 mg tid) ***plus*** Quinine (650 mg tid) ***or*** Atovaquone (750 mg q12h) ***plus*** Azithromycin (500-mg loading dose, then 250 mg/d)	Atovaquone and azithromycin have been shown to be as effective as clindamycin and quinine and are associated with fewer side effects. Treatment with doxycycline (100 mg bid) for potential coinfection with *Borrelia burgdorferi* or *Ehrlichia* spp. may be prudent.	193, 195
SEPSIS WITH SKIN FINDINGS				
Petechiae: Meningococcemia	*N. meningitidis*	Penicillin (4 mU q4h) ***or*** Ceftriaxone (2 g q12h)	Consider protein C replacement in fulminant meningococcemia.	127, 158
Rocky Mountain spotted fever	*Rickettsia rickettsii*	Doxycycline (100 mg bid)	If both meningococcemia and Rocky Mountain spotted fever are being considered, use chloramphenicol (50–75 mg/kg per day in four divided doses). *Do not add doxycycline to a regimen including a β-lactam agent.* If Rocky Mountain spotted fever is diagnosed, doxycycline is the proven superior agent.	
Purpura fulminans	*S. pneumoniae*, *H. influenzae*, *N. meningitidis*	Ceftriaxone (2 g q12h)[a]	If the isolate is penicillin-sensitive, penicillin is the drug of choice.	127, 254
Erythroderma: toxic shock syndrome	Group A *Streptococcus*, *Staphylococcus aureus*	Penicillin (2 mU q4h) ***or*** Oxacillin (2 g q4h) ***plus*** Clindamycin (600 mg q8h)	Site of toxigenic bacteria should be debrided; if necessary, intravenous immunoglobulin can be used in severe cases. The optimal dose of IVIG has not been determined, but the median dose in observational studies is 2 g/kg (total dose administered over 1–5 days).	120, 121
SEPSIS WITH SOFT TISSUE FINDINGS				
Necrotizing fasciitis	Group A *Streptococcus*, mixed aerobic/anaerobic flora	Penicillin (2 mU q4h) ***plus*** Clindamycin (600 mg q8h) ***plus*** Gentamicin (5 mg/kg per day)	Urgent surgical evaluation is critical.	110, 121
Clostridial myonecrosis	*Clostridium perfringens*	Penicillin (2 mU q4h) ***plus*** Clindamycin (600 mg q8h)	Urgent surgical evaluation is critical.	126
NEUROLOGIC INFECTIONS				
Bacterial meningitis	*S. pneumoniae*, *N. meningitidis*	Ceftriaxone (2 g q12h)[a]	If the isolate is penicillin-sensitive, penicillin is the drug of choice. If the patient is >50 years old, add ampicillin for *Listeria* coverage. Dexamethasone (10 mg q6h × 4 days) improves outcome in adult patients with meningitis (especially that due to *S. pneumoniae*) and cloudy CSF, positive CSF Gram's stain, or CSF leukocyte count >1000/μL.	360
Suppurative intracranial infections	*Staphylococcus* spp., *Streptococcus* spp., anaerobes, gram-negative bacilli	Oxacillin (2 g q4h)[b] ***plus*** Metronidazole (500 mg tid) ***plus*** Ceftriaxone (2 g q12h)	Urgent surgical evaluation is critical.	360
Brain abscess	*Streptococcus* spp., anaerobes, *Staphylococcus* spp.	Penicillin (4 mU q4h) ***or*** Oxacillin (2 g q4h)[b] ***plus*** Metronidazole (500 mg tid)	Surgical evaluation is essential.	360

(continued)

TABLE 106-1—*(Continued)*

Clinical Syndrome	Possible Etiologies	Treatment	Comments	Reference(s)
Cerebral malaria	*Plasmodium falciparum*	Quinine (650 mg tid for 3 days) ***plus*** Tetracycline (250 mg tid for 7 days)	Do not use glucocorticoids.	193, 195
Spinal epidural abscess	*Staphylococcus* spp.	Oxacillin (2 g q4h)[c]	Surgical evaluation is essential.	356
FOCAL INFECTIONS				
Acute bacterial endocarditis	*S. aureus*, β-hemolytic streptococci, HACEK group,[d] *Neisseria* spp., *S. pneumoniae*	Ceftriaxone (2 g q12h) ***plus*** Vancomycin (1 g q12h)	Adjust treatment when culture data become available. Surgical evaluation is essential.	109

[a] If resistant pneumococci are prevalent, add vancomycin (1 g q12h).
[b] Vancomycin (1 g q12h) should replace oxacillin if methicillin-resistant strains are highly prevalent.
[c] In HIV-infected intravenous drug users with suspected spinal epidural abscess, empirical therapy must cover gram-negative rods and methicillin-resistant *S. aureus*.
[d] *Haemophilus aphrophilus*, *H. paraphrophilus*, *H. parainfluenzae*, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella kingae*.
Note: References refer to chapters.

with clinical evidence of a hemorrhagic diathesis is a poor prognostic sign.

Septic Shock (See also Chap. 254) Patients with bacteremia leading to septic shock may have a primary site of infection (e.g., pneumonia, pyelonephritis, or cholangitis) that is not evident initially. Elderly patients with comorbid conditions, hosts compromised by malignancy and neutropenia, or patients who have recently undergone a surgical procedure or hospitalization are at increased risk for an adverse outcome. Gram-negative bacteremia with organisms such as *Pseudomonas aeruginosa*, *Aeromonas hydrophila*, or *Escherichia coli* and gram-positive infection with organisms such as *Staphylococcus aureus* or group A streptococci can present as intractable hypotension and multiorgan failure. Treatment can usually be initiated empirically on the basis of the presentation (Table 254-4).

Overwhelming Infection in Asplenic Patients (See also Chap. 254) Patients without splenic function are at risk for overwhelming bacterial sepsis. Asplenic adult patients succumb to sepsis at 58 times the rate of the general population; 50 to 70% of cases occur within the first 2 years after splenectomy, with a mortality rate of up to 80%. However, in the asplenic individual, an increased risk of overwhelming sepsis continues throughout life. In asplenia, encapsulated bacteria cause the majority of infections, and adults are at lower risk than children because they are more likely to have antibody to these organisms. *Streptococcus pneumoniae* infection is most common, causing 50 to 70% of cases, but the risk of infection with *Haemophilus influenzae* or *Neisseria meningitidis* is also high. Severe clinical manifestations of infections due to *E. coli*, *S. aureus*, group B streptococci, *P. aeruginosa*, *Capnocytophaga*, *Babesia*, and *Plasmodium* have been described.

Babesiosis (See also Chap. 195) A history of recent travel to endemic areas should raise the possibility of infection with *Babesia*. Between 1 and 4 weeks after a tick bite, the patient experiences chills, fatigue, anorexia, myalgia, arthralgia, shortness of breath, nausea, and headache; ecchymosis and/or petechiae are occasionally seen. The tick that most commonly transmits *Babesia*, *Ixodes scapularis*, also transmits *Borrelia burgdorferi* (the agent of Lyme disease) and *Ehrlichia*, and co-infection can occur, resulting in more severe disease. Infection with the European species *Babesia divergens* is more frequently fulminant than that due to the U.S. species *Babesia microti*, causing a febrile syndrome with hemolysis, jaundice, hemoglobinemia, and renal failure and a mortality rate of >50%. Severe babesiosis is especially common in asplenic hosts but does occur in hosts with normal splenic function, particularly those >60 years of age. Complications include renal failure, acute respiratory failure, and DIC.

Other Sepsis Syndromes Tularemia (Chap. 142) is seen throughout the United States but occurs primarily in Arkansas, Oklahoma, and Missouri. This disease is associated with wild rabbit, tick, and tabanid fly contact. The uncommon typhoidal form can be associated with gram-negative septic shock and a mortality rate of >30%. In the United States, plague (Chap. 143) occurs primarily in New Mexico, Arizona, and Colorado after contact with ground squirrels, prairie dogs, or chipmunks. The septic form is particularly rare and is associated with shock, multiorgan failure, and a 30% mortality rate. These rare infections should be considered in the appropriate epidemiologic setting. Tularemia and plague, along with anthrax, are listed by the Centers for Disease Control and Prevention as important biological agents that might be intentionally used for bioterrorism (Table 106-2 and Chap. 205).

SEPSIS WITH SKIN MANIFESTATIONS (See also Chap. 17) Maculopapular rashes may reflect early meningococcal or rickettsial disease but are usually associated with nonemergent infections. Exanthems are usually viral. It is noteworthy that primary HIV infection commonly presents with rash. Untreated, symptomatic HIV-seroconversion illness is associated with rapid progression to late-stage disease. The rash is typically maculopapular and involves the upper part of the body but can spread to the palms and soles. In addition, the patient is febrile and can have lymphadenopathy, severe headache, dysphagia, diarrhea, myalgias, and arthralgias. Recognition of this syndrome not only can prevent the spread of HIV to other individuals but also provides an opportunity for early treatment and improved prognosis.

Petechiae Petechial rashes caused by viruses are seldom associated with hypotension or a toxic appearance, although severe measles can be an exception. In other settings, petechial rashes require more urgent attention.

MENINGOCOCCEMIA (See also Chap. 127) Almost three-quarters of patients with bacteremic *N. meningitidis* infection have a rash. Meningococcemia most often affects young children (i.e., those 6 months to 5 years old, often in day care). However, sporadic cases and outbreaks occur in schools (grade school through college) and army barracks. Between 10 and 20% of all cases have a fulminant course, with shock, DIC, and multiorgan failure. Of these patients, 50 to 60% die, and survivors often require extensive debridement or amputation of gangrenous extremities. Patients may exhibit fever, headache, nausea, vomiting, myalgias, change in mental status, and meningismus. However, the rapidly progressive form of disease is not usually associated with meningitis. The rash is initially pink, blanching, and maculopapular, appearing on the trunk and extremities, but then becomes hemorrhagic, forming petechiae. Petechiae are first seen at the ankles, wrists, axillae, mucosal surfaces, and palpebral and bulbar conjunctiva, with subsequent spread to the lower extremities and trunk. A cluster of petechiae may be seen at pressure points—e.g., where a blood pressure cuff has been inflated. In rapidly progressive meningococcemia, the petechial rash quickly becomes purpuric (see Fig. 46-5) and patients develop DIC. Hypotension with petechiae for <12 h is associated with significant mortality. The mortality rate can exceed 90% among patients without meningitis who have rash, hypotension, and a normal or low white blood cell count and ESR. Cyanosis, coma, oliguria, metabolic acidosis, and elevated partial thromboplastin time are also associated with a fatal outcome. A better prognosis has been re-

TABLE 106-2 *Presentation of Severe Manifestations of Category A Agents[a] of Bioterrorism*

Clinical Presentation	Agent	Signs and Symptoms	First-Line Treatment[b]	Comments	Reference Chapters
Sepsis without an obvious focus	Plague[c] Tularemia[d]	Fever, fatigue, headache, dyspnea, chest pain progressing to fulminant course of sepsis, shock, multiorgan failure, DIC	Streptomycin (1 g IM q12h) ***or*** Gentamicin (5 mg/kg per day) ***plus*** Ciprofloxacin (400 mg IV q12h)	Alternatives: Doxycycline (100 mg IV q12h) ***or*** Chloramphenicol (15 mg/kg IV q6h) ***or*** A different fluoroquinolone	142, 143, 180, 181, 205
	Smallpox[e] and hemorrhagic fevers[f]	Patients can present before rash develops with severe nonspecific febrile illness.			
Sepsis with skin manifestations	Hemorrhagic fevers	Viral prodrome, high fevers, myalgias, encephalitis, bleeding diatheses with progression to petechial rash and mucous membrane hemorrhages	Provide supportive care and begin ribavirin. Continue if an arenavirus or bunyavirus is identified.	Person-to-person transmission with arenaviruses, Ebola virus, and Marburg virus	180, 181, 205
	Smallpox	Fever, myalgias, toxicity. Rash begins on face, extremities—vesicular lesions in one crop progressing to deep pustules	Supportive care	Person-to-person transmission Petechial or hemorrhagic forms described	
Neurologic infections with/without septic shock	Botulism[g]	No fever, sensation intact, mental status normal, symmetric cranial-nerve palsies, symmetric descending flaccid paralysis starting in bulbar region	Supportive care and antitoxin	Distinguish from Guillain-Barré and poliomyelitis—no antecedent infection, normal CSF, no sensory signs	125, 205
	Anthrax	Hemorrhagic meningitis can be associated with presentation.	Include rifampin, penicillin, or chloramphenicol along with primary treatment below.		
Focal infection with fulminant course	Anthrax[h] (inhalational)	Fever, cough, sweats, chest pain, abnormal chest x-rays—mediastinal widening, effusions	Ciprofloxacin (400 mg IV q12h) ***or*** Doxycycline (100 mg q12h) ***plus*** 1–2 additional agents	Consider clindamycin (600 mg q8h) for possible inhibition of toxin production.	142, 143, 205
	Plague	Fever, cough, cyanosis; bloody, watery sputum	See above.		
	Tularemia	Fulminant pneumonia	See above.		

[a] For details, see Chap. 205. The Centers for Disease Control and Prevention has defined three categories of biological agents that can be used as weapons of terror on the basis of their ease of dissemination or transmission, potential for public health impact, potential for public panic, and requirements for preparedness. Category A agents are those of greatest concern.

[b] Recommendations for mass casualty situations and special populations differ. Consult appropriate consensus statements.

ported in cases where antibiotics are given before admission by the primary care provider. This observation suggests that early initiation of treatment may be life-saving. In addition, several small experimental and clinical studies have suggested that correction of the protein C deficiency that is evident in meningococcal purpura fulminans can improve outcome.

ROCKY MOUNTAIN SPOTTED FEVER (See also Chap. 158) RMSF occurs throughout the United States. A history of known tick bite is common; however, if such a history is lacking, a history of travel or outdoor activity (e.g., camping in tick-infested areas) can be ascertained. RMSF is caused by *Rickettsia rickettsii*. For the first 3 days, headache, fever, malaise, myalgias, nausea, vomiting, and anorexia are present. By day 3, half of patients have skin findings. Blanching macules develop initially on the wrists and ankles and then spread over the legs and trunk. The lesions become hemorrhagic and are frequently petechial. The rash spreads to palms and soles later in the course. The centripetal spread is a classic feature of RMSF. However, 10 to 15% of patients with RMSF never develop a rash. The patient can be hypotensive and develop noncardiogenic pulmonary edema, confusion, lethargy, and encephalitis progressing to coma. The CSF contains 10 to 100 cells/μL, usually with a predominance of mononuclear cells. The CSF glucose level is often normal; the protein concentration may be slightly elevated. Renal and hepatic injury and bleeding secondary to vascular damage are noted. Untreated infection has a mortality rate of 30%.

Purpura Fulminans (See also Chaps. 127 and 254) Purpura fulminans is the cutaneous manifestation of DIC and presents as large ecchymotic areas and hemorrhagic bullae. Progression of petechiae to purpura and ecchymoses is associated with congestive heart failure, septic shock, acute renal failure, acidosis, hypoxia, hypotension, and death. Purpura fulminans has been associated primarily with *N. meningitidis* but, in splenectomized patients, may be associated with *S. pneumoniae* and *H. influenzae*.

Ecthyma Gangrenosum Septic shock caused by *P. aeruginosa* and *A. hydrophila* can be associated with ecthyma gangrenosum (see Fig. 136-1): hemorrhagic vesicles surrounded by a rim of erythema with central necrosis and ulceration. These gram-negative bacteremias are most common among patients with neutropenia, extensive burns, and hypogammaglobulinemia.

Other Emergent Infections Associated with Rash *Vibrio vulnificus* and other noncholera *Vibrio* bacteremic infections (Chap. 140) can cause focal skin lesions and overwhelming sepsis in the host with liver disease. After ingestion of contaminated shellfish, there is a sudden onset of

malaise, chills, fever, and hypotension. The patient develops bullous or hemorrhagic skin lesions, usually on the lower extremities, and 75% of patients have leg pain. The mortality rate can be as high as 50%. *Capnocytophaga canimorsus* can cause septic shock in asplenic patients. Infection with this fastidious gram-negative rod typically presents after a dog bite as fever, chills, myalgia, vomiting, diarrhea, dyspnea, confusion, and headache. Findings can include an exanthem or erythema multiforme (see Fig. 46-9), cyanotic mottling or peripheral cyanosis, petechiae, and ecchymosis. About 30% of patients with this fulminant form die of overwhelming sepsis and DIC, and survivors may require amputation because of gangrene.

Erythroderma TSS (Chaps. 120 and 121) is usually associated with erythroderma. The patient presents with fever, malaise, myalgias, nausea, vomiting, diarrhea, and confusion. There is a sunburn-type rash that may be subtle and patchy but is usually diffuse and is found on the face, trunk, and extremities. Erythroderma, which desquamates after 1 to 2 weeks, is more common in *Staphylococcus*-associated than in *Streptococcus*-associated TSS. Hypotension develops rapidly—often within hours—after the onset of symptoms. Multiorgan failure is seen. Commonly there is no indication of a primary focal infection, although possible cutaneous or mucosal portals of entry for the organism can be ascertained when a careful history is taken. Colonization rather than overt infection of the vagina or a postoperative wound, for example, is typical with staphylococcal TSS, and the mucosal areas appear hyperemic but not infected. Early renal failure may precede hypotension and distinguishes this syndrome from other septic shock syndromes. Clinical evaluation constitutes the diagnosis because TSS is defined by the clinical criteria of fever, rash, hypotension, and multiorgan involvement. The mortality rate is 5% for menstruation-associated TSS, 10 to 15% for nonmenstrual TSS, and 30 to 70% for streptococcal TSS.

SEPSIS WITH A SOFT TISSUE/MUSCLE PRIMARY FOCUS (See also Chap. 110)

Necrotizing Fasciitis This infection may arise at a site of minimal trauma or postoperative incision and may also be associated with recent varicella, childbirth, or muscle strain. The most common causes of necrotizing fasciitis are group A streptococci alone (Chap. 121) and a mixed facultative and anaerobic flora (Chap. 110). Diabetes mellitus, peripheral vascular disease, and intravenous drug use are associated risk factors. Use of nonsteroidal anti-inflammatory agents adversely affects granulocyte chemotaxis, phagocytosis, and bacterial killing, allowing progression of skin or soft tissue infections. The patient may have bacteremia and hypotension without other organ-system failure. Physical findings are minimal compared with the severity of pain and the degree of fever. The examination is often unremarkable except for soft tissue edema and erythema. The infected area is red, hot, shiny, swollen, and exquisitely tender. In untreated infection, the overlying skin develops blue-gray patches after 36 h, and cutaneous bullae and necrosis develop after 3 to 5 days. Necrotizing fasciitis due to a mixed flora, but not that due to group A streptococci, can be associated with gas production. Without treatment, pain decreases because of thrombosis of the small blood vessels and destruction of the peripheral nerves—an ominous sign. The mortality rate is >30% overall, >70% in association with TSS, and nearly 100% without surgical intervention. Life-threatening necrotizing fasciitis may also be due to *Clostridium perfringens* (Chap. 126); in this condition, the patient is extremely toxic and the mortality rate is high. Within 48 h, rapid tissue invasion and systemic toxicity associated with hemolysis and death ensue. The distinction between this entity and clostridial myonecrosis is made by muscle biopsy.

Clostridial Myonecrosis (See also Chap. 126) Myonecrosis is often associated with trauma or surgery but can be spontaneous. The incubation period is usually 12 to 24 h long, and massive necrotizing gangrene develops within hours of onset. Systemic toxicity, shock, and death can occur within 12 h. The patient's pain and toxic appearance are out of proportion to physical findings. On examination, the patient is febrile, apathetic, tachycardic, and tachypneic and may express a feeling of impending doom. Hypotension and renal failure develop later, and hyperalertness is evident preterminally. The skin over the affected area is bronze-brown, mottled, and edematous. Bullous lesions with serosanguineous drainage and a mousy or sweet odor can be present. Crepitus can occur secondary to gas production in muscle tissue. The mortality rate is >65% with spontaneous myonecrosis, which is often associated with *Clostridium septicum* and underlying malignancy. The mortality rates associated with trunk and limb infection are 63 and 12%, respectively, and any delay in surgical treatment increases the risk of death.

NEUROLOGIC INFECTIONS WITH OR WITHOUT SEPTIC SHOCK

Bacterial Meningitis (See also Chap. 360) Bacterial meningitis is one of the most common infectious emergencies involving the central nervous system. Although hosts with cell-mediated immune deficiency (including transplant recipients, diabetic patients, elderly patients, and cancer patients treated with certain chemotherapeutic agents) are at particular risk for *Listeria monocytogenes* meningitis, most cases in adults are due to *S. pneumoniae* (30 to 50%) and *N. meningitidis* (10 to 35%). An early presentation of headache, meningismus, and fever is classic but is seen in only one-half to two-thirds of patients. The elderly can present without fever or meningeal signs despite lethargy and confusion. Cerebral dysfunction is evidenced by confusion, delirium, and lethargy that can progress to coma. The presentation is fulminant, with sepsis and brain edema, in some cases; papilledema at presentation is unusual and suggests another diagnosis (e.g., an intracranial lesion). Focal signs, including cranial nerve palsies (IV, VI, VII), can be seen in 10 to 20% of cases; 50 to 60% of patients have bacteremia. A poor outcome is associated with coma at any time during the course, hypotension, meningitis due to *S. pneumoniae*, or a CSF glucose level of <0.6 mmol/L (<10 mg/dL). Mortality is associated with coma, respiratory distress, shock, a CSF protein level of >2.5 g/L, a peripheral white blood cell count of <5000/μL, and a serum sodium level of <135 mmol/L.

Suppurative Intracranial Infections (See also Chap. 360) Other rare intracranial lesions that present with sepsis and hemodynamic instability are subdural empyema, septic cavernous sinus thrombosis, and septic superior sagittal sinus thrombosis. Rapid recognition of the toxic patient with central neurologic signs is crucial to improvement of the dismal prognosis of these entities.

SUBDURAL EMPYEMA This infection arises from the paranasal sinus in 60 to 70% of cases. Microaerophilic streptococci and staphylococci are the predominant etiologic organisms. The patient is toxic, with fever, headache, and nuchal rigidity. Of all patients, 75% have focal signs and 6 to 20% die. Despite improved survival rates, 15 to 44% of patients are left with permanent neurologic deficits.

SEPTIC CAVERNOUS SINUS THROMBOSIS This condition follows a facial or sphenoid sinus infection; 70% of cases are due to staphylococci and the remainder are due primarily to aerobic or anaerobic streptococci. A unilateral or retroorbital headache progresses to a toxic appearance and fever within days. Three-quarters of patients have unilateral periorbital edema that becomes bilateral and then progresses to ptosis, proptosis, ophthalmoplegia, and papilledema. The mortality rate is as high as 30%.

SEPTIC THROMBOSIS OF THE SUPERIOR SAGITTAL SINUS This infection spreads from the ethmoid or maxillary sinuses. Its bacterial causes include *S. pneumoniae*, other streptococci, and staphylococci. The fulminant course is characterized by headache, nausea, vomiting, rapid progression to confusion and coma, nuchal rigidity, and brainstem signs. If the sinus is totally thrombosed, the mortality rate exceeds 80%.

Brain Abscess (See also Chap. 360) Brain abscess often occurs without systemic signs. Almost half of patients are afebrile, and presentations are more consistent with a space-occupying lesion in the brain; 70% of patients have headache, 50% have focal neurologic signs, and 25% have papilledema. Abscesses can present as single or multiple lesions

resulting from contiguous foci or hematogenous infection, such as unrecognized endocarditis. The infection progresses over several days from cerebritis to an abscess with a mature capsule. More than half of infections are polymicrobial, with an etiology consisting of aerobic bacteria (primarily streptococcal species) and anaerobes. Abscesses arising hematogenously are especially apt to rupture into the ventricular space, causing a sudden and severe deterioration in clinical status and high mortality. Otherwise, mortality is low but morbidity is high (30 to 55%). Patients presenting with stroke and a parameningeal infectious focus, such as sinusitis or otitis, may have a brain abscess, and physicians must maintain a high level of suspicion. Prognosis worsens in patients with a fulminant course, delayed diagnosis, abscess rupture into the ventricles, multiple abscesses, or abnormal neurologic status at presentation.

Cerebral Malaria (See also Chap. 195) This entity should be urgently considered if patients who have recently traveled to areas endemic for malaria present with a febrile illness and lethargy or other neurologic signs. Fulminant malaria is caused by *Plasmodium falciparum* and is associated with temperatures of >40°C (>104°F), hypotension, jaundice, adult respiratory distress syndrome, and bleeding. By definition, any patient with a change in mental status or repeated seizure in the setting of fulminant malaria has cerebral malaria. In adults, this nonspecific febrile illness progresses to coma over several days; occasionally, coma occurs within hours and death within 24 h. Nuchal rigidity and photophobia are rare. On physical examination, symmetric encephalopathy is typical, and upper motor neuron dysfunction with decorticate and decerebrate posturing can be seen in advanced disease. Unrecognized infection results in a 20 to 30% mortality rate.

SPINAL EPIDURAL ABSCESSES (See also Chap. 356) Patients with spinal epidural abscesses often present with back pain and develop neurologic deficits late in their course. At-risk patients include those with diabetes mellitus; intravenous drug use; chronic alcohol abuse; recent spinal trauma, surgery, or epidural anesthesia; and other comorbid conditions, such as HIV infection. The thoracic or lumbar spine is the most common location, and staphylococci are the most common etiologic agents; in HIV-infected intravenous drug users, therapy must cover gram-negative rods and methicillin-resistant *S. aureus*. If a patient gives a history of antecedent back pain and has new neurologic symptoms, this diagnosis must immediately be considered. Almost 60% of patients have fever and almost 90% have back pain. Paresthesia, bowel and bladder dysfunction, radicular pain, and weakness are frequent neurologic complaints, and examination of the patient may reveal abnormal reflexes and motor and sensory deficits. The ESR and leukocyte counts are usually elevated. Rapid recognition and treatment, including immediate drainage, can prevent or minimize permanent neurologic sequelae.

FOCAL SYNDROMES WITH A FULMINANT COURSE Infection at virtually any primary focus (e.g., osteomyelitis, pneumonia, pyelonephritis, or cholangitis) can result in bacteremia and sepsis. TSS has been associated with focal infections such as septic arthritis, peritonitis, sinusitis, and wound infection. Death occurs secondary to septic shock or toxin production with hemodynamic instability and multiorgan failure. Rapid clinical deterioration and death can be associated with destruction of the primary site of infection, as is seen in endocarditis and in necrotizing infections of the oropharynx (in which edema suddenly compromises the airway).

Rhinocerebral Mucormycosis (See also Chap. 189) Patients with diabetes or malignancy are at risk for invasive rhinocerebral mucormycosis. Patients present with low-grade fever, dull sinus pain, diplopia, decreased mental status, decreased ocular motion, chemosis, proptosis, dusky or necrotic nasal turbinates, and necrotic hard-palate lesions that respect the midline. Without rapid recognition and intervention, the process continues an inexorable invasive course with high mortality.

Acute Bacterial Endocarditis (See also Chap. 109) This entity presents with a much more aggressive course than subacute endocarditis. Bacteria such as *S. aureus*, *S. pneumoniae*, *L. monocytogenes*, *Haemophilus* spp., and streptococci of groups A, B, and G attack native valves. Mortality rates range from 10 to 40%. The host may have comorbid conditions such as underlying malignancy, diabetes mellitus, intravenous drug use, or alcoholism. The patient presents with fever, fatigue, and malaise <2 weeks after onset of infection. On physical examination, a changing murmur and congestive heart failure may be noted. Hemorrhagic macules on palms or soles (*Janeway lesions*) sometimes develop. Petechiae, Roth's spots, splinter hemorrhages, and splenomegaly are unusual. Rapid valvular destruction, particularly of the aortic valve, results in pulmonary edema and hypotension. Myocardial abscesses can form, eroding through the septum or into the conduction system and causing life-threatening arrhythmias or high-degree conduction block. Large friable vegetations can result in major arterial emboli, metastatic infection, or tissue infarction. Emboli can lead to stroke, change in mental status, visual disturbances, aphasia, ataxia, headache, meningismus, brain abscess, cerebritis, spinal cord infarct with paraplegia, arthralgia, osteomyelitis, splenic abscess, septic arthritis, and hematuria. Older patients with *S. aureus* endocarditis are especially likely to present with nonspecific symptoms—a circumstance that delays diagnosis and worsens prognosis. Rapid intervention is crucial for a successful outcome.

Inhalational Anthrax (See also Chap. 205) Inhalational anthrax, the most severe form of disease caused by *Bacillus anthracis*, had not been reported in the United States for more than 25 years until the recent use of this organism as an agent of bioterrorism (Table 106-2 and Chap. 205). Patients presented with malaise, fever, cough, nausea, drenching sweats, shortness of breath, and headache. Rhinorrhea was unusual. All patients had abnormal chest roentgenograms at presentation. Mediastinal widening, pulmonary infiltrates, and pleural effusions were the most common findings. All patients who developed fulminant disease before receiving antibiotics died. Hemorrhagic meningitis has been seen in up to 50% of patients in other large outbreaks. Without urgent intervention with antimicrobial agents and supportive care, inhalational anthrax progresses rapidly to hypotension, cyanosis, and death.

CONCLUSION

Acutely ill febrile patients, with the syndromes discussed in this chapter, require close observation, aggressive supportive measures, and—in most cases—admission to intensive care units. The most important task of the physician is to distinguish these patients from other infected febrile patients who will not progress to fulminant disease. The alert physician must recognize the acute infectious emergency and then proceed with appropriate urgency.

107 IMMUNIZATION PRINCIPLES AND VACCINE USE

Gerald T. Keusch, Kenneth J. Bart, Mark Miller

Most humans live their lives ignoring the certainty of their own mortality. Perhaps this fact explains why the adage "an ounce of prevention is worth a pound of cure" has so little effect on their everyday behavior. Even when it comes to acting to protect their young, parents are capable of ignoring the potential for the death of their children in the developed world and of accepting the certainty of childhood deaths in the developing world. In both settings, parents all too often fail to seek out and demand the best preventive measures available. Unless mandated by the law in wealthy societies or provided by benevolent organizations or governments in poor nations, universal immunization has invariably remained an unattained goal.

Vaccination is ranked as one of the greatest public health achievements of the twentieth century and is the principal factor contributing to the reduction of morbidity and mortality among children around the world. The integration of immunization practices (a major component of primary disease prevention) into routine health care services has provided caregivers with control over a substantial proportion of the disease and mortality that plagued the United States during the first half of the twentieth century (Table 107-1). For society today, immunization is one of the few cost-saving interventions to prevent infectious disease. At present, >50 biologic products are licensed in the United States. A total of 21 antigens, many in the form of combined vaccines, are used for routine immunization during the first 18 months of life, including diphtheria/tetanus/acellular pertussis (DTaP) vaccine, trivalent inactivated poliovirus vaccine (IPV), measles/mumps/rubella (MMR) vaccine, *Haemophilus influenzae* type b (Hib) vaccine, hepatitis B (HepB) and hepatitis A (HepA) vaccines, and varicella vaccine. Recently, a heptavalent pneumococcal vaccine has been recommended for routine use in children, as has influenza vaccine (given annually). Five vaccines are designed for routine use in adults: tetanus/diphtheria (Td) toxoids formulated for adult use; HepB vaccine; influenza virus vaccine; polyvalent pneumococcal polysaccharide vaccine; and varicella vaccine. Some preparations are designated as special-use vaccines for outbreak response, prophylaxis in travelers, or regional use (e.g., vaccines against *Neisseria meningitidis*, Japanese B encephalitis virus, yellow fever virus, and *Salmonella typhi* and HepA vaccine). Unfortunately, vaccines for eukaryotic pathogens (protozoa and helminths), which affect a large proportion of the world's population, have been difficult to develop and remain only a hope for the future.

Healthy People 2010 Objectives for the Nation includes a set of immunization indicators. By 2010, 80% of children should have received DTaP, poliovirus, MMR, Hib, and HepB vaccines, while 90% of adults are expected to have received influenza and pneumococcal vaccines.

IMPACT OF IMMUNIZATION The epidemiologically appropriate use of vaccines has resulted in the global eradication of smallpox and, until recently, the cessation of smallpox vaccination. Immunization has eliminated naturally transmitted poliomyelitis from the Western Hemisphere, Europe, and the Western Pacific. Similarly, measles, which had a nearly 100% infectivity rate in the prevaccination era, has been effectively eliminated from most of the Western Hemisphere by widespread immunization. Current debate centers around whether it is possible to eradicate an organism from the world and cease immunization or whether the best that can be hoped for is the elimination of clinical disease worldwide, with continued routine immunization. Already achieved in the United States are the virtual elimination of congenital rubella syndrome, tetanus, and diphtheria as well as a dramatic reduction in pertussis, rubella, measles, and mumps. The introduction of Hib conjugate vaccines for immunization of infants has all but eliminated invasive *Haemophilus* infections (including meningitis and pneumonia) because this vaccine both elicits durable immunity by the time maternal-derived antibodies have dissipated and reduces nasopharyngeal carriage of Hib, thereby reducing the risk of transmission. Polyvalent pneumococcal polysaccharide conjugate vaccine is having a significant impact on invasive pneumococcal disease, including otitis media.

DEFINITIONS *Vaccination* and *immunization* are often used as interchangeable terms. However, the former denotes only the administration of a vaccine, whereas the latter describes the process of inducing or providing immunity by any means, whether active or passive. Thus, vaccination does not guarantee immunization. Active immunization refers to the induction of immune defenses by the administration of antigens in appropriate forms, whereas passive immunization involves the provision of temporary protection by the administration of exogenously produced immune substances (Table 107-2).

PRINCIPLES OF IMMUNIZATION Artificial induction of immunity closely follows two well-tested principles of nature. The first, active immunization, can be traced at least as far back as Thucydides, who noted that people surviving epidemics of plague in Athens were spared during later outbreaks of the same disease. The second, passive immunization, is a natural process as well and is exemplified by the transplacental transmission of maternal antibodies to the fetus to provide protection against several diseases during the first months of life. Use of the two measures together may produce a complementary effect (as with HepB vaccine plus hepatitis B immune globulin) or may actually interfere with the development of immunity (as when measles vaccine is administered within 6 weeks of measles immunoglobulin). Depending on whether there are multiple species or serotypes of an organism and—if so—whether there are common, cross-reactive, protective antigens, a specific vaccine may induce protection against all representative forms of an infectious agent or against the immunizing strain only. One of the intrinsic virtues of whole-organism vaccines is that they potentially contain all protective antigens of the organism. However, this virtue is counterbalanced by an inherent problem with such vaccines: the possibility of adverse responses to reactive but nonprotective antigens present in the mix. Because the immune response to specific antigens is controlled genetically, all individuals cannot be expected to respond identically to the same vaccine.

APPROACHES TO ACTIVE IMMUNIZATION The two standard approaches to active immunization are (1) the use of live, generally attenuated, in-

TABLE 107-1 *Reduction in Morbidity due to Vaccine-Preventable Diseases in the United States, 1900–2002*

Disease	Reporting Period	Annual Morbidity Prior to Vaccine	2001 Morbidity	2002 Morbidity[a]	Decrease, %[b]
Smallpox	1900–1904	48,164	0	0	100
Diphtheria	1920–1922	175,885	2	1	100
Pertussis	1922–1925	147,271	7580	8296	94.6

TABLE 107-2 *Definitions of Immunizing Agents*

Term	Definition
Vaccine	A preparation of attenuated live or killed microorganisms or antigenic portions of these agents presented to a potential host to induce immunity and prevent disease
Toxoid	A modified bacterial toxin that has been made nontoxic but retains the capacity to stimulate the formation of antitoxin
Immune globulin	An antibody-containing protein fraction derived from human plasma and used primarily for maintenance of the immunity of persons with immunodeficiency disorders or for passive immunization when there is no opportunity for active immunization[a]
Antitoxin	An antibody derived from the serum of animals after stimulation with specific antigens and used to provide passive immunity to the toxin protein to which it is directed

[a] Both intramuscular and intravenous preparations are available.

fectious agents (e.g., measles virus); and (2) the use of inactivated agents or their constituents or products obtained by genetic recombination (e.g., acellular pertussis vaccines). For many diseases (e.g., poliomyelitis), both approaches have been employed.

Live attenuated vaccines consisting of selected or genetically altered organisms that are avirulent or dramatically attenuated, yet remain immunogenic, generally produce long-lasting immunity. These agents are expected to cause a subclinical illness and immunologic response mimicking natural infection (except for the lack of clinically significant disease). They offer the advantage of replication in vivo, which increases the antigenic load presented to the host's immune system; they may confer lifelong protection with one dose; they present all expressed antigens, thus overcoming immunogenetic restrictions in some hosts; they may reach the local sites most relevant to the induction of protective immunity; and they may produce important protective antigens in vivo that are not efficiently expressed in vitro.

Inactivated vaccines typically require multiple doses and periodic boosters thereafter for the maintenance of immunity. The exception to this rule is pure polysaccharide vaccine, whose effects cannot be boosted by additional exposures. Nonviable vaccines administered parenterally fail to elicit mucosal IgA-mediated immunity, as they lack a delivery system that can effectively transport them to local antigen-processing cells. However, killed vaccines can be extremely successful. For example, the nonviable HepA vaccine formulation appears to be close to 100% effective in inducing protective immunity. Currently available nonviable vaccines consist of inactivated whole organisms (e.g., plague vaccine); detoxified protein exotoxins (e.g., tetanus toxoid); recombinant protein antigens (e.g., HepB vaccine); or carbohydrate antigens, either present as soluble purified capsular material (e.g., *Streptococcus pneumoniae* polysaccharides) or conjugated to a protein carrier (e.g., Hib polysaccharide conjugated to diphtheria or tetanus toxoids).

Despite their advantages, live vaccines are not always preferable. For example, live oral poliovirus vaccine (OPV) is contraindicated for use in children with immune deficiency diseases or their adult contacts. In addition, even though killed poliovirus vaccine does not completely immunize the gut or immunize contacts of vaccine recipients, the United States has now switched to a four-dose schedule of this vaccine because of the rare but real risk of vaccine-associated polio posed by live OPV.

APPROACHES TO PASSIVE IMMUNIZATION Passive immunization is generally used to provide temporary immunity in an unimmunized subject exposed to an infectious disease when active immunization either is unavailable (e.g., for respiratory syncytial virus) or has not been implemented before exposure (e.g., for rabies). Passive immunization is used in the treatment of certain disorders associated with toxins (e.g., diphtheria), in certain bites (those of snakes and spiders), and as a specific or nonspecific immunosuppressant [Rho(D) immune globulin and antilymphocyte globulin, respectively]. Three types of preparations are used in passive immunization: (1) standard human immune serum globulin for general use (e.g., γ globulin), administered intramuscularly or intravenously; (2) special immune serum globulins with a known content of antibody to specific agents [e.g., hepatitis B virus (HBV) or varicella-zoster immune globulin]; and (3) animal sera and antitoxins.

ROUTE OF ADMINISTRATION The route of administration in part determines the rapidity and nature of the immune responses to vaccines. Vaccines can be administered orally, intranasally, intradermally, subcutaneously, or intramuscularly. Parenterally administered vaccine may not induce mucosal secretory IgA, and mucosal immunization may not induce good systemic responses. Vaccines must be administered by the licensed route to ensure immunogenicity and safety. For example, administration of HepB vaccine into the gluteal rather than the deltoid muscle often fails to induce an adequate immune response, while subcutaneous rather than intramuscular administration of diphtheria/tetanus/pertussis vaccine (DTP) increases the risk of reactions.

AGE Because age influences the response to vaccines, schedules for immunization are based on age-dependent responses determined empirically from clinical trials. The presence of high levels of maternal antibody and/or the immaturity of the immune system in the early months of life impairs the initial immune response to some vaccines (e.g., measles or Hib polysaccharide) but not to others (e.g., HepB). In the elderly, vaccine responses may be diminished because of natural waning of the immune system. Hence, larger amounts of an antigen may be required to produce the desired response (e.g., in vaccination against influenza).

ADJUVANT POTENTIATION The immune response to some antigens is potentiated by the addition of adjuvants such as aluminum salts or, in the case of polysaccharides (e.g., the polyribose phosphate oligosaccharide of Hib), by conjugation to a carrier protein. Adjuvants—nonspecific boosters of immune responses—are used with inactivated products such as diphtheria and tetanus toxoids, acellular pertussis vaccine, and HepB vaccine. The mechanism for adjuvant enhancement of immunogenicity is not well defined but relates in part to the rendering of soluble antigens into a particulate form; the mobilization of phagocytes to the site of antigen deposition; and the slowing down of the release of antigens, which prolongs stimulation of the immune response.

THE IMMUNE RESPONSE While many constituents of infectious microorganisms and their products, such as exotoxins, are or can be made to be immunogenic, only a limited number stimulate a protective immune response. The immune system is complex, and antigen composition and presentation are critical for stimulation of the desired immune responses.

The Primary Response In the primary response to a vaccine antigen, an apparent latent period of several days precedes the detection of humoral and cell-mediated immunity. Although the immune response begins with initial recognition of the antigen by the immune system, measurable circulating antibodies do not appear for 7 to 10 days. The immunoglobulin class of the response also changes over time. The primary response is characterized by early-appearing IgM antibodies. These generally exhibit only low affinity for the antigen, whereas later-appearing IgG antibodies display high affinity. For "thymus-dependent" antigens, CD4+ T-helper lymphocytes control the switch from IgM to IgG. Some individuals do not respond, even when presented repeatedly with a vaccine antigen, often because they lack the major histocompatibility complex determinants required to recognize the antigen. This situation is known as *primary vaccine failure*.

The Secondary Response Heightened humoral or cell-mediated responses are elicited by a second exposure to the same antigen and

occur rapidly, usually within 4 or 5 days. The secondary response depends on immunologic memory after the first exposure and is characterized by a marked proliferation of IgG antibody–producing B lymphocytes and/or effector T cells. Whereas polysaccharide vaccines, such as that for *S. pneumoniae*, evoke immune responses that are independent of T cells and are not enhanced by repeated administration, conjugation to proteins converts the polysaccharides to T cell–dependent antigens that induce immunologic memory and secondary responses to revaccination. Although levels of vaccine-induced antibodies may decline over time (*secondary vaccine failure*), revaccination or exposure to the organism generally elicits a rapid protective secondary response consisting of IgG antibodies with little or no detectable IgM. This anamnestic response indicates that immunity has persisted. Thus, lack of measurable antibody does not necessarily mean that the individual is unprotected. Furthermore, the mere presence of detectable antibodies after the administration of some vaccines and toxoids does not ensure clinical protection. A minimal circulating level of antibody is known to be required for protection from some diseases (e.g., 0.01 IU/mL for tetanus antitoxin).

Hypersensitivity Reactions Independent of antibody production, the stimulation of the immune system by vaccination may elicit unanticipated responses, especially hypersensitivity reactions. In the past, killed measles vaccine induced incomplete humoral immunity and cell-mediated hypersensitivity, resulting in the development of a syndrome of atypical measles in some children after subsequent exposure; thus this type of vaccine is no longer in use.

Mucosal Immunity Some pathogens are confined to and replicate only at mucosal surfaces (e.g., *Vibrio cholerae*), while others are able to penetrate the mucosa and replicate (e.g., poliovirus, rubella virus, and influenza virus). At the mucosal site, these organisms induce secretory IgA. The induction of secretory IgA by vaccines may be an efficient way to block the essential first steps in pathogenesis, whether the organism is restricted to mucosal surfaces or invades the host across mucosal surfaces.

Measurement of the Immune Response Immune responses to vaccines are often gauged by the concentration of specific antibody in serum. While seroconversion serves as a dependable indicator of an immune response, it measures only one immunologic parameter and does not necessarily indicate protection. The development of circulating antibodies after immunization often correlates directly with clinical protection (e.g., against measles or rubella). Some responses may not in themselves confer immunity but may be sufficiently associated with protection that they remain useful proxy measures of protective immunity (e.g., vibriocidal serum antibodies in cholera).

HERD IMMUNITY Vaccination provides direct protection against infection of individuals, thereby decreasing the percentage of susceptible persons within a population. At a definable prevalence of immunity in the population (*herd immunity*), an organism can no longer circulate freely among the susceptibles. This indirect protection of unvaccinated (nonimmune) persons is called the *herd immunity effect*. The level of vaccination coverage needed to elicit a herd immunity effect is dependent on the mixing patterns of the population and the biology of the specific infectious agents. For example, measles and varicella viruses have high transmission rates and therefore require a higher level of vaccine coverage to elicit herd immunity than do organisms with lower transmission rates, such as *S. pneumoniae*. Wherever herd immunity for poliomyelitis and measles has been induced with vaccines, transmission of infection has ceased. It is not surprising that herd immunity may wane if immunization programs are interrupted (as was the case for diphtheria in the former Soviet Union) or if a sufficient percentage of individuals refuse to be immunized (as occurred for pertussis in the United Kingdom and Japan because concern about infrequent—albeit severe—vaccine reactions came to exceed the fear of the disease itself). In each setting, loss of herd immunity led to renewed circulation of the organism and subsequent large outbreaks.

TARGET POPULATIONS AND TIMING OF IMMUNIZATION Different age groups have different disease attack rates, and the effectiveness of vaccines depends on a variety of factors, including the individual's responsiveness to vaccines, the demographic features of the populations at risk, and the duration and character of the immunologic response. In vaccination programs, which are as much community as individual endeavors, schedules for immunization are based on careful consideration of the variables affecting age-dependent responses and population interactions (e.g., school entry, college enrollment, military induction) as well as the feasibility of implementation.

For common and highly communicable childhood diseases like measles, the target population is the universe of susceptible individuals, and the time to immunize is as early in life as is feasible. Yet epidemiologic differences in measles transmission in different settings dictate different strategies for immunization. In the industrialized world, immunization with live-virus vaccine at 12 to 15 months of age has been the norm because the vaccine protects >95% of those immunized at this age and there is little measles morbidity or mortality among very young infants. In contrast, in the developing world, measles is a significant cause of death in young infants. Thus, it is desirable to immunize children earlier to narrow the window of vulnerability between the rapid decline of maternal antibody after 4 to 6 months and the development of vaccine-induced active immunity.

Hib causes meningitis, epiglottitis, and pneumonia in early childhood, with rates rising sharply after the disappearance of maternally derived antibody. The first Hib polysaccharide vaccines often failed when administered during infancy, mainly because of an age-related inability to respond to polysaccharide antigens. To overcome this problem, the protective polysaccharide was converted to a T cell–dependent antigen by conjugation to proteins to which infants could respond.

In contrast, rubella is primarily a threat to the fetus; young infants and children are not at risk of serious illness. An ideal strategy would be to immunize all women of reproductive age before pregnancy. Because it is difficult to systematically vaccinate adolescent and young-adult females and to assure the protection of as many women as possible, rubella is included in a combination vaccine (MMR vaccine) that is administered during infancy. Screening for rubella antibodies during pregnancy should be followed up with postpartum vaccination of seronegative individuals.

Some vaccines were originally formulated primarily for adults. For example, influenza virus and polyvalent pneumococcal polysaccharide vaccines are used to prevent pneumonia, hospitalizations, and deaths among the elderly. Unfortunately, these vaccines are underutilized, in part because physicians and otherwise-healthy individuals in the target group ignore the indications and in part because there is still a tendency to think about disease prevention with vaccines as a strategy for children. With the advent of pneumococcal conjugate vaccines and the cold-adapted influenza strain as well as of administration by nasal spray, infants can also be targeted to receive these vaccines.

THE DEVELOPMENT OF VACCINES

BIOLOGIC IMPEDIMENTS There are often major technical problems to overcome in vaccine development. Although just one major antigenic type of influenza virus is typically in circulation at any one time, the virus is characterized biologically by its antigenic drift. Thus, a new antigenic version capable of causing a global pandemic emerges regularly, and a new vaccine must be rapidly devised, produced, distributed, and administered. In contrast, many prevalent pneumococcal polysaccharide serotypes circulate at all times. Because immunity to the pneumococcus is serotype specific, an individual is susceptible to all serotypes against which he or she lacks antibody. Serotype-specific protection has made it more difficult to develop an effective pneumococcal vaccine than it was to develop a vaccine against *H. influenzae*, of which one capsular serotype (type b) is associated with nearly all cases of severe disease. To overcome this problem, pneumococcal

vaccine currently includes 23 polysaccharides that represent ~80% of the virulent serotypes commonly encountered in the United States. Unfortunately, some serotypes are poorly immunogenic, and immunized individuals remain susceptible to the serotypes not included in the vaccine.

STRATEGY FOR VACCINE DEVELOPMENT Vaccine development depends on the systematic application of a four-phase strategy: (1) studies in animals to identify protective antigens, (2) determination of how to present this antigen effectively to the immune system, (3) assessment of the safety and immunogenicity of the preparation in small and then in large human populations at various ages, and (4) evaluation of safety and efficacy in the target population. Each of these steps is simple in concept but difficult in execution; failure at any level stops the process. Progress in immunology has taught us much about the organization and function of the immune system (Chap. 295); it has also taught us that the immune system is complex and that details of antigen composition and presentation are critical for stimulating desired immune responses.

Ultimately, vaccines for humans must be tested in humans. After initial animal studies and small phase 1 and 2 human studies to assess immune responses, optimal dosage, and safety, clinical trials of vaccine efficacy are performed with informed volunteers who are challenged with a virulent strain. Larger clinical effectiveness trials in the community, typically involving 1000 to 10,000 vaccinees, may lead to application for licensure. Because of their limited size, however, these trials cannot be expected to detect rare adverse effects. Thus, licensing does not guarantee that a new vaccine is completely safe, and postlicensing monitoring is needed to ensure effectiveness and to document the occurrence of adverse events of low frequency. In 1999, the recently licensed rhesus rotavirus vaccine was withdrawn because postmarketing surveillance suggested an association with a rare event in infants: intussusception of the bowel.

The development of vaccines goes beyond technology and proof of principle to issues such as development costs, manufacturers' liability and indemnity, perceived public health needs, and the likelihood that a product will be used or sold. Given the complex science required, the costs of vaccine development are high and success is uncertain, adding risk to the development decision. It is unfortunate that the one sure implication of uncertainty in vaccine development is increased cost. In addition, a rational assignment of costs for development between the public and private sectors in the United States has never been achieved.

VACCINE FORMULATIONS Studies of clinical immunology have shown that living and dead antigens do not induce the same immune responses and that the requirements for the development of protective immunity may differ with the organism. These insights, together with the refinement of epidemiologic concepts surrounding immunization, have changed the strategy of vaccine development. The goal is not only to select the correct antigens but also to ensure that the vaccines will result in the type of immune response needed for protection, whether T cell–mediated activation of macrophages or the generation of cytotoxic T cells, B cell–mediated secretory IgA, or a particular IgG subtype response to a specific polysaccharide epitope. To create a deliverable vaccine, constituents other than antigens are also required (Table 107-3). These constituents can affect the immunogenicity, efficacy, and safety of a vaccine and can render one formulation superior to another.

PRODUCTION OF VACCINES As products to be given to healthy individuals to prevent disease, vaccines must not only be efficacious but also cause no harm. In the United States, quality assurance is the responsibility of vaccine manufacturers. Standards of manufacture of biologics (known as good manufacturing practices, or GMPs) are regulated and supervised by the U.S. Food and Drug Administration (FDA). Proof of the safety, efficacy, sterility, and purity of products is required before licensure, and sterility and purity are continually monitored for all lots of vaccine after licensure. Postmarketing studies of safety (phase 4 studies) are part of routine regulatory control. On rare occasions, either GMP or quality assurance breaks down; for example, the release of incompletely killed Salk polio vaccine in 1955 caused an outbreak of poliomyelitis in nearly 200 vaccine recipients and their contacts. Unregulated and/or uncontrolled manufacture of vaccines in developing countries has sometimes led to immunization with inactive products that fail to provide the expected protective immunity (e.g., tetanus toxoid produced in Bangladesh).

TABLE 107-3 Constituents of Vaccines

Constituent(s)	Examples/Purpose
Preservatives, stabilizers, antibiotics	These components are used to prevent deterioration of the vaccine before use, to inhibit or prevent bacterial growth, or to stabilize the vaccine. Any of these additions can cause allergic responses.
Adjuvants	This type of additive (e.g., aluminum salts, or alum) is intended to enhance the immune response (e.g., to toxoids, hepatitis B vaccine).
Suspending fluid	The suspending fluid can be sterile water, saline, buffer, or more complex fluids derived from the growth medium or biologic system in which the agent is produced (e.g., egg antigens, cell culture ingredients, serum proteins).

There is a serious new problem affecting the production of vaccines. For various reasons, including the high costs of vaccine development and the prospect of much higher profitability from investments in other products, the number of vaccine manufacturers in the United States has declined and the cost of some basic childhood vaccines has increased. These changes raise concerns about the future availability of these essential biologics for national use. Furthermore, pricing decisions made within the private-sector pharmaceutical industry can have a major impact on vaccine use. This situation has stimulated an initiative toward increased public involvement in supplying vaccine to individuals for whom price is an issue as well as in oversight of the vaccine supply and of price negotiations with industry.

ADMINISTRATION OF VACCINES Health care workers administering vaccines must take the precautions necessary to minimize the risk of spreading disease—for example, hand washing between immunizations. Different vaccines should not be mixed in the same syringe unless such a practice is specifically endorsed by licensure. Disposable needles and syringes must be safely discarded to prevent inadvertent needlestick injury or, in resource-poor settings, the reuse of these items.

The addition of new, individually injectable vaccines to the childhood immunization schedule has heightened parental concerns about multiple injections being administered at a single clinic visit. The development and use of combinations of vaccines are intended to mitigate these concerns. Even when multiple injections are required, providers must make every effort to administer all indicated vaccines at each visit.

Wherever effective primary health care systems ensure access to medical services for the majority and the population is educated about the need for and efficacy of vaccines, coverage rates for basic immunization are usually high, regardless of the route of vaccine administration or the number of doses necessary. However, without systematic attention to the completion of multiple-dose vaccine schedules, coverage rates for second, third, and booster doses may drop off significantly.

USE OF VACCINES

Several professional groups develop recommendations for vaccine use in the United States: the Advisory Committee on Immunization Practices, the American Academy of Pediatrics (AAP), the American Academy of Family Practice, the American College of Obstetricians and Gynecologists, the American College of Physicians, and the Infectious Diseases Society of America. These recommendations are the

TABLE 107-4 *Routinely Recommended Vaccines for Infants, Children, and Adults*

Vaccine	Year Licensed	Type of Immunizing Agent	Protective Antibody	Route of Administration	Efficacy, %	Adverse Events
DT, Td (adult)	1949	Toxoid	Diphtheria and tetanus neutralizing antitoxins, 0.1 IU/mL each	IM	D: 95 T: 95	Local reactions; hypersensitivity to tetanus toxoid
aP	1991	Inactivated bacterial antigen	Not established	IM	80–90	Reduced local reactions compared with whole-cell pertussis vaccines; no serious reactions reported
DTaP	1996	Acellular	Not established	IM	80–90	
Hib	1987	Bacterial polysaccharide–protein conjugate	Antibody to capsular polysaccharide, 0.15 μg/mL	IM	90	Few local, no serious reactions reported
HepB	1981	Inactivated serum-derived antigen	Antibody to surface antigen, 10 mIU/mL	IM	80–95	Few (? Guillain-Barré syndrome)
	1987	Recombinant antigen				
Influenza	1945	Inactivated virus or viral components	Neutralizing antibody	IM	40–60	? Guillain-Barré syndrome with swine influenza vaccine
MMR	1971	Live viruses	Neutralizing measles antibody, 200 mIU/mL; not known for mumps or rubella	SC	M: 95 Mu: 90 R: 95	Acute encephalopathy (measles) Rare parotitis or orchitis (mumps) Arthralgia and rare arthropathy (rubella)
Pneumococcal polysaccharide	1983	Capsular polysaccharide (23 types)	Antibody to polysaccharides	IM or SC	60–80	Local reactions; rare anaphylaxis
Pneumococcal conjugate	2000	Polysaccharide-protein conjugates (7–11 types)	Antibody to polysaccharides	IM	73–94	None thus far
IPV	1967	Inactivated virus of 3 types, enhanced immunogenicity	Neutralizing antibody	SC	95	No significant reactions
Varicella	1995	Live virus	Neutralizing antibody	SC	86–100	Local reaction; varicella-like rash

Abbreviations: DT, diphtheria and tetanus toxoids, adsorbed; Td, tetanus and diphtheria toxoids, adsorbed, for adult use; aP, acellular pertussis; DTaP, diphtheria/tetanus/acellular pertussis vaccine; Hib, *Haemophilus influenzae* type b; HepB, hepatitis B virus vaccine; MMR, measles/mumps/rubella; IPV, inactivated poliovirus vaccine.

result of a collaborative process among the recommending groups, the pharmaceutical industry, and the FDA.

Vaccines recommended in 2003 for routine administration to infants, children, and adults are shown in Table 107-4; vaccines recommended for special use are shown in Table 107-5; and schedules for immunization of children and adolescents and of adults are shown in Fig. 107-1 and Fig. 107-2, respectively. The recommendations on route, site, and dosages for vaccination have been derived from theoretical considerations, experimental trials, and clinical experience; deviation from these recommendations can result in inadequate protection. The administration of doses at intervals longer than those recommended does not diminish the ultimate protective response but merely delays it. In contrast, giving vaccines at shorter-than-recommended intervals may result in poor responses. When a scheduled dose is missed, it is not necessary to restart from the beginning or to add an extra dose (www.cdc.gov/nip/recs/child-catchup.pdf).

RECORDING AND REPORTING REQUIREMENTS Certain aspects of vaccine use are regulated by the National Childhood Vaccine Injury Act (NCVIA) of 1986 (modified in 1995 and 2002). The act requires that all mandated childhood vaccinations be recorded by health care providers in the child's permanent medical record, including date of administration, manufacturer and lot number, and name of the provider administering the vaccine. State-based immunization information systems and electronic registries have been developed to help public and private providers manage their immunization activities and particularly to address the problem of assessing immunization coverage when an individual's records are divided among multiple medical facilities. By permitting active and targeted recall of children who are overdue for immunization and by providing data on immunization status at the time of an office visit, these systems improve vaccination rates and offer important public health benefits.

Parents must be informed about the benefits and risks of immunization and should maintain an up-to-date immunization record on their children. Educational materials providing the required information (Vaccine Information Statements) are available from the AAP or the Centers for Disease Control and Prevention (CDC; www.cdc.gov/nip/publications/vis/). The National Network for Immunization Information website (www.immunizationinfo.org) is an excellent source of authoritative information for parents.

VACCINES FOR ROUTINE USE ■ Infants and Children (See Fig. 107-1 and www.cdc.gov/nip/recs/child-catchup.pdf) It is current practice for all children in the United States to receive DTaP, poliovirus, MMR, Hib, HepB, varicella, and pneumococcal conjugate vaccines unless there are specific contraindications. The administration of HepA vaccine is currently recommended when there is a special risk of exposure to infection due to residence in communities with elevated rates of hepatitis A or travel to highly endemic countries. Influenza vaccine is recommended for children 6 to 24 months of age, especially those who have certain risk factors or who reside with persons with certain chronic disorders. In several European countries, meningococcal C conjugate vaccine is routinely recommended.

Adults (See Fig. 107-2) Immunization recommendations for adults (>18 years old) fall into four categories: (1) routine vaccines for all adults; (2) vaccines for high-risk exposure groups (health care and other institutional workers, prisoners, students, military personnel, travelers to endemic areas, injection drug users, men who have sex with men); (3) vaccines for persons at high risk for severe outcomes of infection (pregnant women; the elderly; persons with chronic medical conditions, including diabetes, alcoholism, immunodeficiency, and renal, hepatic, respiratory, or cardiac disease); and (4) vaccines for household contacts of persons in group 3. A substantial proportion of adults in the United States no longer have protective levels of antibodies against tetanus or diphtheria. All adults who completed the pediatric series should be boosted with Td (adult formulation) every 10 years (once after age 50). If not previously immunized, however, adults require a primary immunizing course of Td. Young adults without laboratory evidence or a reliable history of past vaccination or disease should be immunized against measles, mumps, rubella, and varicella. A second dose of MMR vaccine is recommended for groups with a higher risk of exposure and for health care workers with certain other indications. Unless they have documented proof of immunity, rubella vaccine should be given to all nonpregnant women of childbearing age. Rubella-susceptible pregnant women should be vacci-

TABLE 107-5 *Special Vaccines for Infants, Children, and Adults*

Vaccine	Year Licensed	Type of Immunizing Agent	Route of Administration	Indications	Efficacy	Adverse Events
Anthrax	1970	Inactivated avirulent bacteria	SC (6 doses primary; annual booster)	For high risk of exposure (e.g., persons in contact with or involved in manufacture of animal hides, furs, bone meal, wool, goat hair) and military risk of biowarfare exposure	90% antibody response; efficacy uncertain	No serious adverse effects known
Tuberculosis (BCG)	1950	Living bacteria (attenuated *Mycobacterium bovis*)	ID	PPD-negative individuals in prolonged contact with active TB patients	Controversial, maximal for children <15 years	Regional adenitis, disseminated BCG in immunocompromised hosts
HepA	1995	Killed virus antigen	IM	Travelers or persons living in high-risk areas	94%	Local reactions, mild
Cholera	1914	Inactivated whole bacteria	SC or IM	Not recommended for public health use because of limited efficacy; two new vaccines licensed in Europe	?50% (short duration)	Frequent fever and local reactions, pain, swelling
Meningococcus A, C, Y, W-135	1981	Bacterial polysaccharides from 4 serotypes, not type B	SC	Military personnel; travelers to endemic areas; college students in dormitories	90% for 2- to 3-year olds	Rare
Plague	1994	Inactivated bacteria	IM	Laboratory workers; foresters in endemic areas; ? travelers	90% antibody response; efficacy uncertain	10% local reactions; rare sterile abscesses and hypersensitivity
Rabies (human diploid)	1980	Inactivated virus grown in cell culture	IM or ID	Travelers; laboratory workers; veterinarians	Virtually 100%	25% local reactions; 6% arthropathy, arthritis, angioedema
Yellow fever	1978	Live attenuated virus	SC	Laboratory workers	High	Encephalitis, encephalopathy, death
Japanese B encephalitis	1992	Inactivated virus	SC	Travelers to endemic areas	80–90%	Anaphylactic/severe delayed allergic reactions common; recipient should be observed for 10 days
Typhoid	1952	Heat- or phenol-killed bacteria	IM	Not routinely recommended in U.S.; used for travelers, contacts of carriers	50–70% (short duration)	Frequent fever, local swelling, pain
		Purified Vi polysaccharide	IM	Travelers	70–75%	Local reactions, mild
Lyme disease	1998	Recombinant outer-membrane protein	IM	For high risk of exposure to infected ticks	76% (3 doses)	Local reactions

Abbreviations: SC, subcutaneous; BCG, bacille Calmette-Guérin; PPD, purified protein derivative; TB, tuberculosis.

Source: Recommendations of the Advisory Committee on Immunization Practices, the American Academy of Pediatrics, and the American College of Physicians.

nated as early as possible in the postpartum period. Live-virus vaccines, such as MMR and varicella vaccines, are contraindicated in pregnant women and immunosuppressed individuals. Routine immunization against polio is not recommended for adults unless they are at particular risk of exposure because of travel to the remaining endemic areas. College students, particularly freshmen living at close quarters, are at increased risk of meningococcal meningitis and should be offered the meningococcal polysaccharide vaccine for serogroups A, C, Y, and W-135.

Current recommendations also include influenza vaccine for routine annual administration to individuals with chronic illness at any age, to persons living in the same household as chronically ill individuals, and to all adults >50 years of age. Polyvalent pneumococcal polysaccharide vaccine is similarly recommended for adults ≥65 years of age and for all chronically ill persons. HepB vaccine is recommended for individuals at high risk from clinical, occupational, behavioral, and travel exposures, including patients undergoing hemodialysis, routine recipients of clotting factors, health care workers exposed to potentially infected blood or blood products, individuals living and working in institutions for the mentally handicapped, travelers to highly endemic countries, persons at elevated risk for sexually transmitted diseases, injection drug users, and household contacts of known carriers of hepatitis B surface antigen. HepA vaccine is recommended for these same groups and for persons with clotting disorders or chronic liver disease. There are a number of other special-use vaccines whose administration is related to travel and occupational exposures (e.g., Japanese B encephalitis, typhoid, yellow fever, rabies); specific recommendations for the use of these vaccines in the United States can be found at www.cdc.gov/nip.

Adverse Events Given the success of vaccination programs and the virtual disappearance of many vaccine-preventable diseases in the United States, concerns about vaccine safety have sometimes become inflated in conjunction with complacency about the consequences of infection. An *adverse reaction* or *vaccine side effect* is an untoward effect caused by a vaccine that is extraneous to its primary purpose (to produce immunity). In contrast, an *adverse event* can be either a true vaccine reaction or a coincidental event. A small number of highly publicized claims unsubstantiated by valid data have heightened the suspicion that some or all vaccines routinely cause unacceptable adverse events. Antivaccine advocacy groups actively encourage avoidance of immunization because of the unproven belief that vaccines can cause certain disorders (e.g., autism). Websites maintained by such groups commonly appear in the first 10 listings identified by search engines. This situation presents a challenge to physicians and public health officials who must educate parents about vaccine benefits and risks.

In fact, modern vaccines, while safe and effective, are associated with adverse events that range from infrequent and mild to rare and

life-threatening. The decision to recommend the use of a vaccine involves an assessment of the risks of disease and the benefits and risks of vaccination. Because these factors may change over time, continual assessment of the balance between societal benefits and individual risks is essential. Valid and invalid contraindications to childhood immunization and appropriate precautions in the use of specific vaccines can be found at www.cdc.gov/nip/recs/contraindications.pdf.

Ironically, ongoing efforts to enhance vaccine safety through quality improvement and changes in vaccine policy (e.g., the decision to eliminate the mercury-based preservative thimerosol from vaccines) have actually led to an even greater awareness of the possible adverse events associated with routine vaccine administration. It has been claimed that increased rates of diabetes mellitus in the general pediatric population are due to an increase in exposure to vaccine antigens in childhood, although rigorous studies have refuted this hypothesis. A putative link of measles immunization to autism has been the subject of intense international controversy. The Institute of Medicine issued four recent reports whose findings (1) fail to support hypotheses that vaccines are associated with multiple sclerosis, neurodevelopmental disorders, or immune dysfunction; (2) provide no evidence for a temporal association of these conditions with vaccination; and (3) elucidate no biologically plausible basis for the purported relationships.

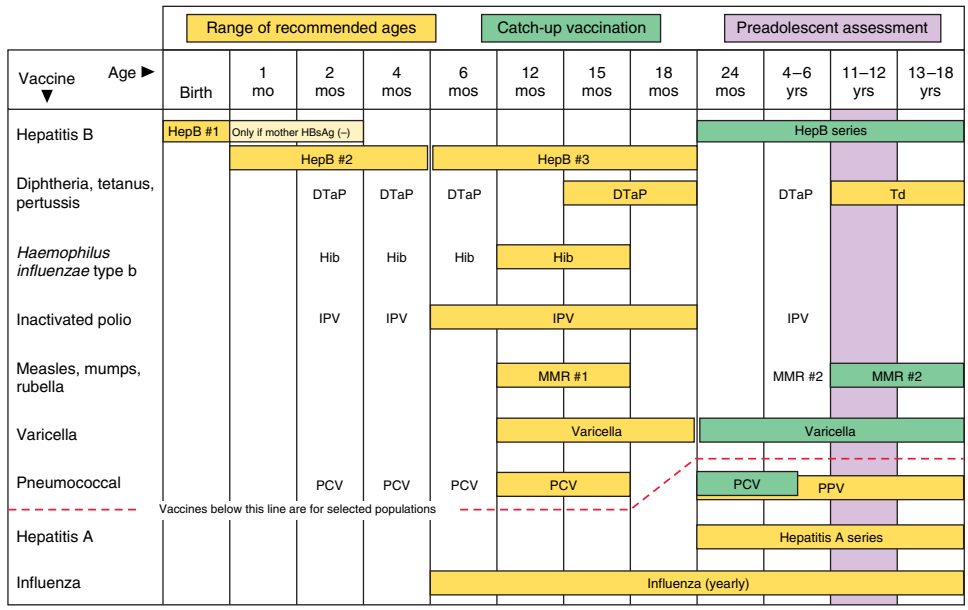

FIGURE 107-1 Recommended childhood and adolescent immunization schedule—United States, 2003. Any dose not given at the recommended age should be given at any subsequent time when indicated and feasible. Green bars indicate age groups that warrant special efforts to administer those vaccines not previously given. Infants born to mothers positive for hepatitis B surface antigen (HBsAg) should receive hepatitis B vaccine (HepB) and 0.5 mL of hepatitis B immune globulin (HBIG) at separate sites within 12 h of birth. The second dose of HepB is recommended at at age 1 to 2 months. The last dose in the series should not be administered before age 6 months. Infants born to mothers whose HBsAg status is unknown should receive the first dose of the HepB series within 12 h of birth. The mother's HBsAg status should be tested as soon as possible; if positive, the infant should receive HBIG as soon as possible. The number of *Haemophilus influenzae* type b (Hib) conjugate vaccine doses depends on the vaccine used. PRP-OMP (PedvaxHIB or ComVax) is administered just twice: at ages 2 and 4 months. Diphtheria/tetanus/acellular pertussis (DtaP)/Hib combination products should not be used for primary immunization but can be used as boosters following a primary series with any Hib vaccine. Influenza vaccine is now recommended annually for children age ≥6 months with certain risk factors (including but not limited to asthma, cardiac disease, sickle cell disease, HIV infection, and diabetes mellitus) and household members of persons in groups at high risk; it can be administered to all others wishing to obtain immunity. If feasible, influenza vaccination of healthy children age 6 to 23 months is encouraged because of a substantially increased risk for influenza-related hospitalizations in this group. Children ≥12 years old should receive influenza vaccine in a dosage appropriate for their age. Children ≤8 years old who are receiving influenza vaccine for the first time should receive two doses separated by at least 4 weeks. Hepatitis A vaccine is recommended for children and adolescents in selected states and regions and for certain high-risk groups; hepatitis A immunization can begin during any visit, and the two doses should be administered at least 6 months apart. The heptavalent pneumococcal conjugate vaccine (PCV) is recommended for all children age 2 to 23 months. It is also recommended for certain children age 24 to 59 months. Pneumococcal polysaccharide vaccine (PPV) is recommended in addition to the conjugate vaccine for certain high-risk groups. Further information can be obtained via the National Immunization Program website (www.cdc.gov/nip) or at the National Immunization Information Hotline (800-232-2522 for English and 800-232-0233 for Spanish). MMR, measles/mumps/rubella vaccine; IPV, inactivated poliovirus vaccine; Td, tetanus and diphtheria toxoids, adsorbed, for adult use. (*Adapted from recommendations approved by the Advisory Committee on Immunization Practices, the American Academy of Pediatrics, and the American College of Family Physicians.*)

Within 9 months of the introduction of routine administration of the rhesus reassortant rotavirus vaccine (Rotashield) in the United States, cases of intussusception were reported by the CDC to be temporally associated with administration of the initial dose. This report led first to the cessation of the vaccine's use and subsequently to the withdrawal of the vaccine from the market and the discontinuation of its production. Although other analyses have failed to support the association, rotavirus vaccine has not been introduced into developing countries, where the risk of any real increase in intussusception would be dramatically outweighed by the benefit of decreased rotavirus mortality.

The ramifications of these events for future vaccine development and introduction have yet to be assessed. Vaccine components, including protective antigens, animal proteins introduced during vaccine production, and antibiotics or other preservatives or stabilizers, can certainly cause allergic reactions in some recipients. These reactions may be local or systemic and include urticaria and serious anaphylaxis. The most common extraneous allergen is egg protein introduced when vaccines such as those for measles, mumps, influenza, and yellow fever are prepared in embryonated eggs. Gelatin, which is used as a heat stabilizer, has been implicated in rare but severe allergic reactions. Local or systemic reactions (probably due to antigen-antibody complexes) can result from too-frequent administration of vaccines such as Td, diphtheria/tetanus vaccine, or rabies vaccine. Because live-virus vaccines can interfere with tuberculin test responses, necessary tuberculin testing should be done either on the day of immunization or at least 6 weeks later. When influenza vaccine is given to children <13 years old, only "split-virus" preparations should be used since whole-virus vaccines are associated with higher rates of adverse reactions in this age group.

The U.S. government conducts vaccine safety surveillance through a network of active and passive reporting. All detected adverse events whose occurrence is temporally related to vaccination must be reported to both the local health department and the vaccine manufacturer. For the purpose of postlicensure passive surveillance of vaccines, health care providers are required to report certain suspected adverse events following the administration of a mandated vaccine to the FDA's Vaccine Adverse Events Reporting System. The NCVIA has established criteria for reimbursable vaccine-related adverse events (www.hrsa.gov/osp/vicp/table.htm). Although a temporal relationship does not establish cause and effect, this surveillance system remains the only mechanism for collecting the data needed for analysis, conclusions, and decision-making. The CDC has established an active-surveillance system for ongoing evaluation of vaccine safety in large populations of vaccinated individuals. The Vaccine Safety Datalink is a population-based network in which four large health maintenance organizations (HMOs) continuously monitor immunization records linked to the medical records of 600,000 children <7 years of age. A

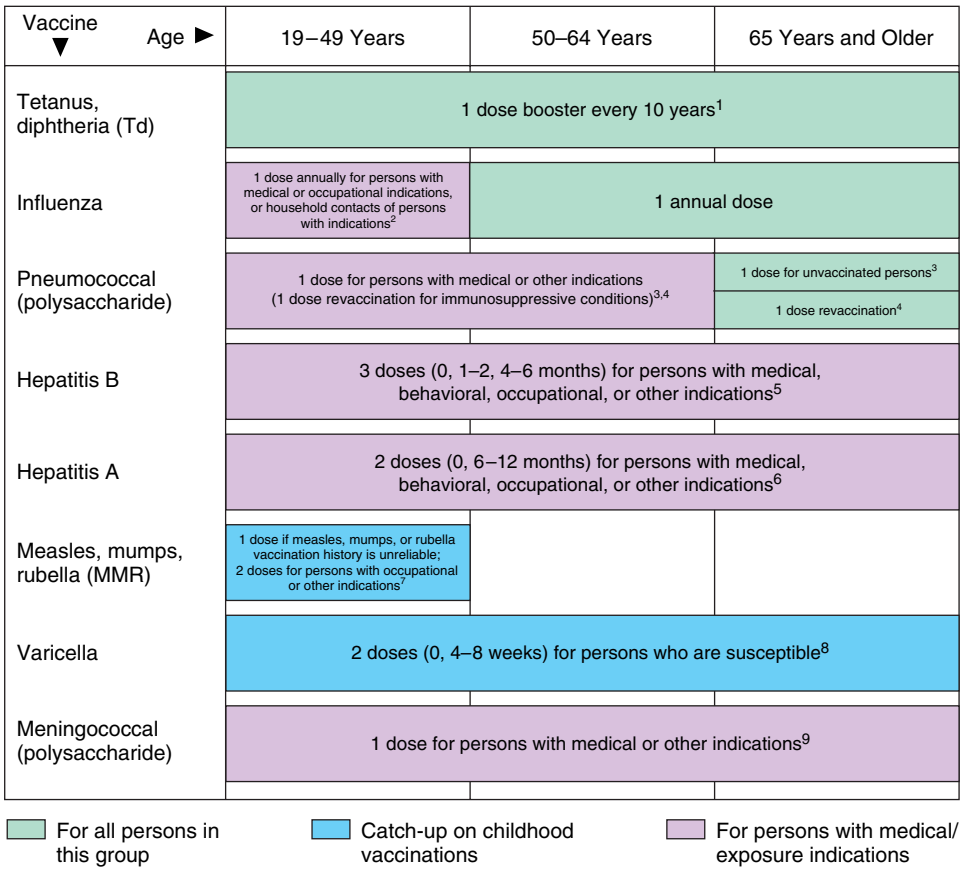

FIGURE 107-2 Recommended adult immunization schedule—United States, 2002–2003. (1) *Tetanus and diphtheria (Td)*: A primary series for adults is 3 doses, with the first 2 doses at least 4 weeks apart and the third dose 6 to 12 months after the second. One dose suffices if a primary series was completed >10 years before. In addition to a teenage/young adult booster, adults >50 years of age who have completed the full series plus booster should receive one more dose. (2) *Influenza vaccination*: Indications include chronic cardiovascular or pulmonary disease, asthma, diabetes, renal disease, hemoglobinopathy, immunosuppression (due to medications or HIV infection), pregnancy (second or third trimester during the influenza season), health care employment, residence in a nursing home or another long-term-care facility, and high likelihood of transmitting influenza to those at high risk. (3) *Pneumococcal polysaccharide vaccination*: Indications include chronic cardiovascular or pulmonary disease (except asthma), diabetes, chronic liver disease, chronic renal failure or nephrotic syndrome, asplenia, immunosuppression, certain cancer chemotherapy, and long-term systemic glucocorticoid therapy. Vaccination is also indicated in Alaskan natives, certain Native American populations, and residents of nursing homes and other long-term-care facilities. (4) *Revaccination with pneumococcal polysaccharide vaccine*: One-time revaccination after age 5 is indicated for persons with chronic renal failure or nephrotic syndrome, asplenia, immunosuppression, certain cancer chemotherapy, or long-term systemic glucocorticoid therapy. Persons >65 years old should undergo one-time revaccination if their prior vaccination was at least 5 years before and was given before age 65. (5) *Hepatitis B vaccination*: Vaccination is indicated for hemodialysis patients, patients receiving clotting factor concentrates, health care workers and public safety workers exposed to blood, students in the health professions, injection drug users, persons with multiple sex partners within 6 months, patients with recent sexually transmitted disease (STD), clients of STD clinics, men who have sex with men, household contacts and sex partners of persons with chronic hepatitis B virus infection, clients and staff of institutions for the mentally disabled, inmates of correctional institutions, and international travelers to countries with high prevalence. (6) *Hepatitis A vaccination*: For the combined HepA/HepB vaccine, use 3 doses at 0, 1, and 6 months. Hepatitis A vaccination is indicated in persons with clotting factor disorders or chronic liver disease, men who have sex with men, users of injection and noninjection illegal drugs, persons working with hepatitis A virus–infected primates or working with the virus in a laboratory, and persons traveling to or working in countries with high prevalence. (7) *Measles/mumps/rubella vaccination (MMR)*: *Measles component*: Adults born before 1957 are considered immune to measles. Adults born after 1957 should have at least 1 dose of MMR vaccine barring a medical contraindication or documentation of prior immunization. A second dose is recommended for adults who have recently been exposed to measles in an outbreak setting, who have previously received killed measles vaccine, who were vaccinated with an unknown measles vaccine between 1963 and 1967, who are students at a college or university, who work in health care facilities, or who plan to travel internationally. *Mumps component*: 1 dose of MMR vaccine is adequate. *Rubella component*: 1 dose of MMR vaccine should be given to women whose history is unreliable, with counseling to avoid becoming pregnant for 4 weeks. The rubella immune status of women of childbearing age should be ascertained and counseling provided regarding congenital rubella. (8) *Varicella vaccination*: Vaccination is recommended for all persons without a reliable clinical history of varicella or serologic evidence of immunity, health care workers, family contacts of immunosuppressed persons, those who live or work in high-risk settings (teachers of young children, daycare workers, residents and staff members working in institutional settings), adolescents and adults living in households with children, and women who are not pregnant but intend to become pregnant in the future. (9) *Meningococcal vaccine, quadrivalent*: Vaccination should be considered for adults with terminal complement component deficiencies, those with anatomical or functional asplenia, college freshmen (especially those living in dormitories), and travelers to the "meningitis belt" in sub-Saharan Africa or to Mecca for the Hajj. High-risk persons can be revaccinated in 5 years. (*Adapted from recommendations approved by the Advisory Committee on Immunization Practices and accepted by the American College of Obstetricians and Gynecologists and the American Academy of Family Physicians.*)

similar system is in place for immunized adult members of four HMOs.

USE OF VACCINES IN SPECIAL CIRCUMSTANCES

Influenza Pandemic Preparedness Influenza pandemics occur at irregular intervals and are characterized by excess deaths, hospitalizations, public concern, and social and economic disruption. A National Preparedness Plan has been developed to assess the incidence of disease and the antigenic characteristics of the prevalent strain and to promote flexibility in vaccine manufacture and vaccination. This plan is based on enhancement of current capacities for virologic surveillance, disease surveillance, and emergency medical responses.

Pregnancy Because of the theoretical risk to the fetus and the real risk of litigation to the practitioner, routine immunization of pregnant women is best avoided. However, wherever hygienic conditions during delivery cannot be guaranteed, it is essential to ensure that pregnant women are immune to tetanus because the transfer of maternal antitoxin is an important means of preventing neonatal tetanus. Pregnant women can safely receive tetanus as well as diphtheria toxoids. Live-virus vaccines, such as rubella, measles, mumps, and varicella, should be withheld during pregnancy. However, if the risk of exposure is great, polio and yellow fever vaccines may be safely administered. If indicated, some inactivated vaccines (e.g., HepB, influenza, and pneumococcal vaccines) may be given during the second and third trimesters of pregnancy (Fig. 107-3).

Breast Feeding Neither killed nor live vaccine affects the safety of breast feeding for either mother or infant. Breast-fed infants can be immunized on a normal schedule.

Occupational Exposure Immunization recommendations for most occupational groups remain to be developed. Specific practices are now mandated by the Occupational Safety and Health Administration for the immunization of health care workers against hepatitis B in the United States. Rubella is transmitted to and from health care workers in medical facilities, particularly in pediatric practice. Health care workers who might transmit rubella to pregnant patients should be immune to rubella; it is prudent to screen these employees for antibodies to rubella virus and to immunize susceptible individuals. Persons providing health care are also at greater risk from measles and varicella than the general public, and those who are likely to come into contact with measles- and varicella-infected patients should be im-

mune. Persons employed in caring for patients with chronic diseases can transmit influenza; such workers should be vaccinated annually.

HIV Infection and Other Immunocompromised States Limited studies in HIV-infected individuals have found no increase in the risk of adverse events from live or inactivated vaccines. However, immune responses may not be as vigorous in immunocompromised individuals as in those with a normal immune system. Persons known to be infected with HIV should be immunized with recommended vaccines in the same manner as individuals with a normal immune system and as early in the course of their disease as possible, before immune function becomes significantly impaired (Fig. 107-3). Live attenuated MMR vaccine can be administered to this group. When vaccination against polio is indicated, IPV should be administered to immunocompromised HIV-infected individuals and to their household contacts. Albeit prudent, it is not necessary in practice to test for HIV before making decisions about the immunization of asymptomatic individuals from known HIV risk groups.

Live attenuated vaccines are also contraindicated in other immunocompromised patients, including those with congenital immunodeficiency syndromes and those receiving immunosuppressive therapy. Passive immunization with immunoglobulin preparations or antitoxins can be considered in individual cases, either as postexposure prophylaxis or as part of the treatment of established infection.

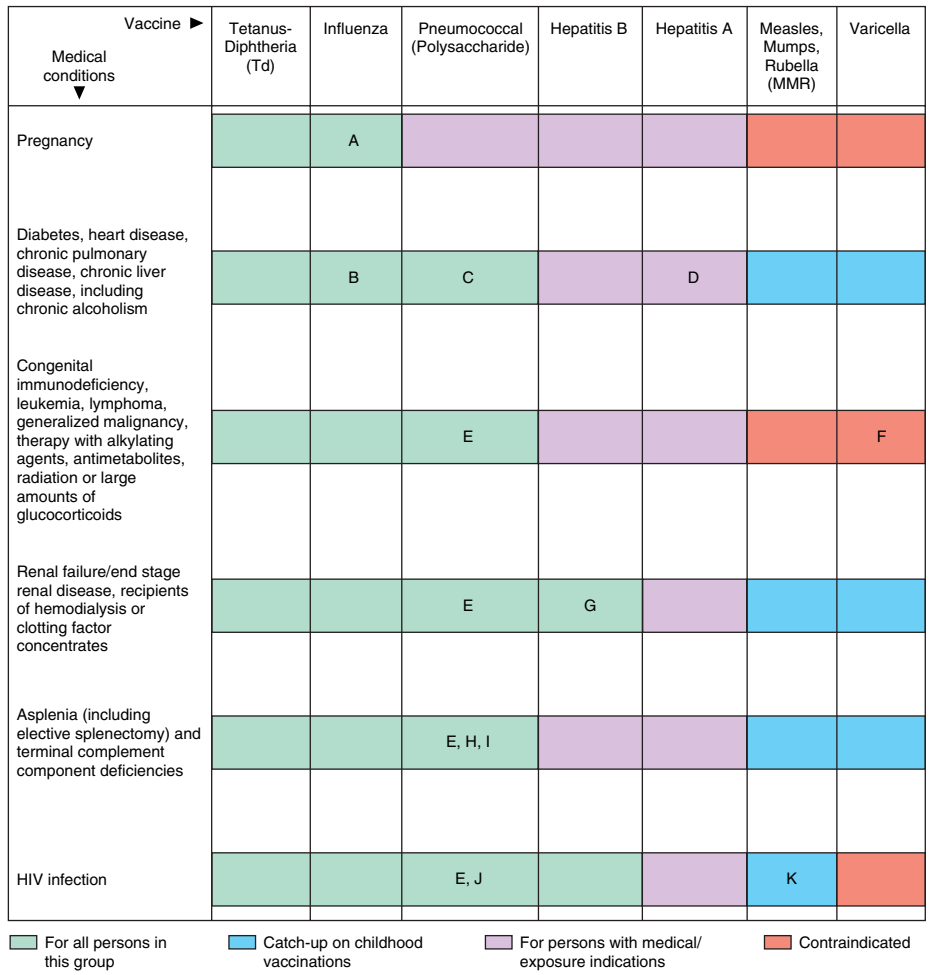

FIGURE 107-3 Recommended immunizations for adults with medical conditions—United States, 2002–2003. **A.** Vaccine may be given if pregnancy is at second or third trimester during influenza season. **B.** Although chronic liver disease and alcoholism are not indicator conditions for influenza vaccination, give 1 dose annually if the patient is ≥50 years old, has other indications for influenza vaccine, or requests vaccination. **C.** Asthma is an indicator condition for influenza vaccination but not for pneumococcal vaccination. **D.** Vaccinate all persons with chronic liver disease. **E.** Revaccinate once after ≥5 years have elapsed since initial vaccination. **F.** Persons with impaired humoral (but not cellular) immunity may be vaccinated [*MMWR* 1999; 48 (RR-06), 1–5]. **G.** *Hemodialysis patients*: Use special formulation of vaccine (40 μg/mL) or two 1.0-mL, 20-μg doses given at one site. Vaccinate early in the course of renal disease. Assess antibody titers to hepatitis B surface antigen annually; administer additional doses if titers decline to <10 mIU/mL. **H.** Also administer meningococcal vaccine. **I.** In persons undergoing elective splenectomy, vaccinate at least 2 weeks before surgery. **J.** Vaccinate as close to diagnosis as possible, when CD4+ cell counts are highest. **K.** Withhold MMR or other measles-containing vaccines from HIV-infected persons with evidence of severe immunosuppression [*MMWR* 1996; 45, 603–606; *MMWR* 1992; 41 (RR-17), 1–19]. (*Approved by the Advisory Committee on Immunization Practices and accepted by the American College of Obstetricians and Gynecologists and the American Academy of Family Physicians.*)

Postexposure Immunization For certain infections, active or passive immunization soon after exposure prevents or attenuates disease expression. Recommended postexposure immunization regimens are compiled in Table 107-6. Measles immune globulin given within 6 days of exposure may prevent or modify infection, and measles vaccine given within the first few days after exposure may prevent symptomatic infection. Although clinical manifestations of rubella in pregnant women are minimized by postexposure passive immunization, this approach may not prevent maternal viremia, fetal infection, and congenital rubella syndrome. Therefore, the administration of immune globulin is recommended only for women developing rubella during pregnancy who will not consider abortion under any circumstances. Proper immunization for tetanus plays an important role in wound management. The need for active immunization—with or without passive immunization—depends on the condition of the wound and the patient's immunization history (Table 107-7). Rarely have cases of tetanus occurred in persons with a documented primary series of tetanus toxoid. Tetanus immune globulin is useful in patients with tetanus. Survivors with no history of tetanus immunization should receive a primary series of toxoid since disease does not produce protective levels of antitoxin. Administration of rabies immune globulin plus rabies vaccine in the immediate postexposure period is highly effective in preventing disease. Similarly, for persons who have not been actively immunized, the use of hepatitis A immune globulin within 2 weeks of exposure to hepatitis A is likely to prevent clinical illness. Sound data indicate the efficacy of human hepatitis B immune globulin in preventing disease after exposure. While no high-titer preparation is available for postexposure protection against non-A, non-B hepatitis, standard human immune serum globulin is efficacious.

Simultaneous Administration of Multiple Vaccines There are no contraindications to the simultaneous administration of several vaccines. The use of combination vaccines can potentially reduce the required number of injections from 9 to 3 during a child's first 6 months of life and from 21 to 13 during the first 2 years. Simultaneous administration of the most widely used live and inactivated vaccines has not resulted in impaired antibody responses or in increased rates of adverse reactions. Moreover, this approach increases the probability that a child will ultimately be fully immunized. Simultaneous administration is useful in any age group when the potential exists for exposure to multiple infectious diseases during travel to endemic countries. Combination DTaP/Hib vaccines should not be used for primary immunization of infants because the result is a blunted, suboptimal response to Hib; however, the combination may be used for booster immunizations.

TABLE 107-6 *Recommended Postexposure Immunization with Immunoglobulin Preparations in the United States*

Disease	Indicated	Comments
Measles	Yes	Standard human immune globulin is recommended for exposed infants and adults with normal immunocompetence (but with a contraindication to measles vaccine) and for immunocompromised patients exposed to measles (regardless of immunization status). Patients should be actively immunized 3 to 6 months after immunoglobulin administration. Recommended dose: 0.25–0.50 mL/kg (40–80 mg of IgG/kg) IM; 80 mg of IgG/kg for immunocompromised contact; maximum, 15 mL.
Rubella	No	Efficacy is unreliable; therefore, standard human immune globulin is recommended for administration only to antibody-negative pregnant women in the first trimester who have a documented rubella exposure and will not consider terminating the pregnancy. Recommended dose is 0.55 mL/kg (90 mg of IgG/kg) IM.
Tetanus	Yes	Human tetanus immune globulin (TIG) has replaced equine tetanus antitoxin because of the risk of serum sickness with equine serum. Recommended dose for postexposure prophylaxis is 250–500 units of TIG (10–20 mg of IgG/kg) IM. Recommended dose for treatment of tetanus is 3000–6000 units of TIG IM.
Rabies	Yes	Human rabies immune globulin (RIG) is preferred over equine rabies antiserum because of the risk of serum sickness with equine serum. RIG or antiserum is recommended for nonimmunized individuals with animal bites in whom rabies cannot be ruled out and with other exposures to known rabid animals. Recommended dose of RIG is 20 IU/kg (22 mg of IgG/kg). Recommended dose of antiserum is 40 IU/kg. Rabies vaccine is given as well at 0, 3, 7, 14, and 28 days.
Hepatitis A	Yes	Standard immune serum globulin is given in a single dose of 0.02–0.04 mL/kg or (for continuous exposure) in a dose up to 0.06 mL/kg every 5 months. Postexposure treatment with hepatitis A immune globulin has not been studied.

When live-virus vaccines are not given together on the same day, an interval of at least 30 days should be allowed.

Because high doses of immune globulin may inhibit the efficacy of measles and rubella vaccines, an interval of at least 3 months is recommended between the administration of immune globulin and that of MMR vaccine or its components. Postpartum vaccination of rubella-susceptible women should not be delayed because of the administration of anti-Rho(D) immune globulin or any other blood product during the last trimester or at delivery. Should administration of an immune globulin preparation become necessary after vaccination, it should be postponed, if possible, for at least 14 days to allow time for vaccine-virus replication and development of immunity. In general, there is little interaction of immune globulin with inactivated vaccines, and postexposure passive prophylaxis can be given together with HepB vaccine or tetanus toxoid, resulting in both immediate and long-lasting protection.

Travel (See also Chap. 108) The International Sanitary Regulations allow countries to impose requirements for yellow fever and killed cholera vaccines as a condition for admission, even though the latter is not an effective public health tool. Travelers should know whether these vaccines are required for entry into the countries on their itinerary to avoid being turned back or immunized on the spot, with the inherent danger of unsafe injections. Infants, children, and adults should have all routine immunizations updated before traveling, with particular attention to polio, measles, and DTP/DTaP or Td vaccines. The use of HepA vaccine may be advisable for travelers to some locales. Special-use vaccines (Table 107-5), including rabies, meningococcal polysaccharide, typhoid, Japanese B encephalitis, and plague vaccines, should be considered for those individuals who expect to go beyond the usual tourist routes or to spend extended periods in rural areas in disease-endemic regions. Most U.S. cities have travel clinics that maintain up-to-date epidemiologic information and can provide the appropriate vaccines. The CDC also maintains a website for travelers (www.cdc.gov/travel).

DELIVERY OF VACCINES Over the past 25 years, considerable progress has been made to ensure that every child in the United States is fully immunized by the time of school entry. All 50 states now require immunization for school entry, and most have laws addressing attendance at preschools and day-care centers. Despite the dramatic impact of immunization and of other improvements in the health care provided to the American population on the incidence of vaccine-preventable illness (Table 107-1), many children are not fully immunized—both in poor communities (as a result of inadequate health services) and in affluent communities (where parental concern about potential adverse events may exceed concern about now-uncommon diseases). The failure to vaccinate preschool children was largely responsible for the resurgence of measles in the United States between 1989 and 1991, with >55,000 cases and >130 measles-related deaths. Outbreaks of pertussis, mumps, and congenital rubella syndrome have occurred wherever immunization rates among preschool children are low. While measles (36 cases in 2002) and rubella (14 cases in 2002) have reached historic lows, the risk of imported infection and spread to susceptibles persists.

ACCESS TO IMMUNIZATION Four major barriers to infant and childhood immunization have been identified within the health care system: (1) low public awareness and lack of public demand for immunization, (2) inadequate access to immunization services, (3) missed opportunities to administer vaccines, and (4) inadequate resources for public health and preventive programs. These problems are sources of public concern, and their solution must be a priority for national health policy in the United States. At the national level, outreach and educational campaigns promote parental awareness of the value of vaccination and encourage health care providers to use every opportunity to vaccinate the children in their care. At the state and local levels, community and business groups, religious and service groups, schools, and the media have joined together in community-based networks. Those who remain unvaccinated do so largely because health care practices and providers do not always perform optimally in delivering vaccines. The AFIX Program (*A*ssessment of coverage, *F*eedback of diagnostic information, *I*ncentives or recognition, and e*X*change of information among providers) is one effort by the CDC to change the attitude of health care personnel who lack an appreciation of low immunization rates in their practices to one of awareness, concern, and knowledge. The CDC has also developed two approaches to immunization assessment: CASA (Clinic Assessment Software Application) and LQA (Lot Quality Assessment). CASA requires review of up to 200 immunization records to assess whether record keeping and documentation are adequate, whether children start their vaccine series on time, whether and when patients drop out of the system, whether recall is used effectively, and whether vaccines are given simultaneously. LQA requires the review of only 30 records and does not yield a precise immunization rate or a diagnosis of the problem. A National Immunization Week each April has been established to focus attention on the vac-

TABLE 107-7 *Tetanus Wound Management*

Vaccination History	Clean, Minor Wounds		All Other Wounds	
	Td	TIG	Td	TIG

3 doses	No[a]	No	No[b]	No

[a] Yes, if >10 years since last dose.
[b] Yes, if >5 years since last dose.

TABLE 107-8 Standards for Immunization Practice

Pediatric Practice

1. Immunization services are readily available.
2. There are no barriers to or unnecessary prerequisites for the receipt of vaccines.
3. Immunization services are available free or for a minimal fee.
4. Providers use all clinical encounters to screen and, when indicated, immunize children.
5. Providers educate parents and guardians about immunization in general terms.
6. Providers question parents or guardians about contraindications and, before immunizing a child, inform them in specific terms about the risks and benefits of the immunizations their child is to receive.
7. Providers follow only true contraindications.
8. Providers administer simultaneously all vaccine doses for which a child is eligible at the time of each visit.
9. Providers use accurate and complete recording procedures.
10. Providers coschedule immunization appointments in conjunction with appointments for other child health services.
11. Providers report adverse events following immunization promptly, accurately, and completely.
12. Providers operate a tracking system.
13. Providers adhere to appropriate procedures for vaccine management.
14. Providers conduct semiannual audits to assess immunization coverage levels and to review immunization records for the patient populations they serve.
15. Providers maintain up-to-date, easily retrievable medical protocols at all locations where vaccines are administered.
16. Providers operate with patient-oriented and community-based approaches.
17. Vaccines are administered by properly trained individuals.
18. Providers receive ongoing education and training on current immunization recommendations.

Adult Practice

1. Appropriate vaccine use is promoted through information campaigns for health care practitioners and trainees, employers, and the public about the benefits of immunizations.
2. Providers are completely immunized to protect themselves and prevent transmission to patients.
3. Providers routinely determine the immunization status of their adult patients, offer vaccines to those for whom they are indicated, and maintain complete immunization records.
4. Providers identify high-risk patients in need of influenza vaccine and develop a system to recall them for annual immunization.
5. Providers and institutions identify high-risk adult patients in hospitals and other treatment centers and ensure that appropriate vaccination is considered either before discharge or as part of discharge planning.
6. Licensing/accreditation agencies support the development by health care institutions of comprehensive immunization programs for staff, trainees, volunteer workers, inpatients, and outpatients.
7. States establish preenrollment immunization requirements for colleges and other institutions of higher learning.
8. Institutions that train health care professionals, deliver health care, or provide laboratory or other medical support services require appropriate immunizations for persons at risk of contracting or transmitting vaccine-preventable diseases.
9. Health care benefit programs, third-party payers, and government health care programs provide coverage for adult immunization services.
10. A standard personal and institutional immunization record is adopted as a means of verifying the immunization status of patients and staff.

cination needs of infants and children. To improve the quality and quantity of vaccination services, expanded immunization-clinic hours and computerization of immunization records have been implemented as well. State-mandated school-entry immunity requirements have also helped to raise population immunity.

Although special vaccination target groups (e.g., college students, military personnel, and health care workers) have been successfully immunized, there has been only modest progress toward immunization goals for older adults in the United States. As many as 60,000 adults die each year of vaccine-preventable diseases for which effective vaccines are not being optimally used. More than 30% of persons >65 years of age do not receive influenza vaccine each year, and even fewer have ever received pneumococcal vaccine. Health care providers more often miss vaccination opportunities with adults than with infants and children. From 60 to 90% of adults hospitalized for or dying of influenza-associated respiratory disease have received medical care during the previous year and could have been immunized at that time. Medicare reimbursement for excess hospitalization during influenza epidemics ranges from $750 million to $1 billion. Additional efforts are required to ensure that adults receive Td and HepB vaccines as well.

A special setting for adult immunization is the administration of certain vaccines (e.g., tetanus toxoid) to pregnant women to enhance passive immunity in their offspring. In most cases, the mother herself derives important benefits as well. Immunization of the mother should be undertaken at least 6 weeks before delivery to allow for efficient transplacental transfer of antibody to the fetus.

Recent childhood vaccine shortages in the United States have prompted federal authorities to recommend deferring some vaccinations and have caused states to reduce vaccination requirements. Efforts to resolve supply-and-demand issues have yielded plans to increase national stockpiles of vaccines.

HANDLING OF VACCINES Vaccines must be handled and stored with care. Vaccines should be kept at 2° to 8°C and, with the exception of varicella vaccine, should not be frozen. Varicella should be kept frozen at −15°C. Measles vaccine must be protected from light, which inactivates the virus.

STANDARDS FOR IMMUNIZATION PRACTICE National standards of immunization for adult and pediatric practice have been established to define common policies and practices for public health clinics and physicians' private offices (Table 107-8). These standards highlight the need to distinguish between valid contraindications and conditions that are often considered to be but are not in fact contraindications (www.cdc.gov/nip/recs/contraindications.pdf). Among the valid contraindications applicable to all vaccines are a history of anaphylaxis or other serious allergic reactions to a vaccine or vaccine component and the presence of a moderate or severe illness, with or without fever. Infants who develop encephalopathy within 72 h of a dose of DTP or DTaP should not receive further doses; those who develop a "precaution" should not normally receive further doses. Because of theoretical risks to the fetus, pregnant women should not receive MMR or varicella vaccine. Diarrhea, minor respiratory illness (with or without fever), mild to moderate local reactions to a previous dose of vaccine, the concurrent or recent use of antimicrobial agents, mild to moderate malnutrition, and the convalescent phase of an acute illness are not valid contraindications to routine immunization. Failure to vaccinate children because of these conditions is increasingly viewed as a missed opportunity for immunization.

THE NATIONAL VACCINE INJURY COMPENSATION PROGRAM The use of mandated vaccines benefits society as a whole by reducing morbidity and the cost of care for preventable diseases and by reducing childhood mortality. Thus, in the United States, society has assumed the obligation to care for those injured by the administration of mandated vaccines. The NCVIA of 1986 (modified in 1995 and 2002) is the instrument in use to ensure both fairness to injured persons and protection for federal, state, and local immunization programs; private immunization providers; and vaccine manufacturers. The act was designed to implement two vital public policies: (1) to provide prompt and fair compensation to the families of children who have died or have been injured as a result of routine mandated immunization; and (2) to reduce the adverse impact of the tort system on vaccine supply, cost, and innovation/development. The success of immunization programs in the United States depends upon the continued viability of the National Vaccine Injury Compensation Program.

CONTROL OF VACCINE-PREVENTABLE DISEASE

A continuing task of public health practice is to maintain individual and herd immunity. The job is not over once a population is fully vaccinated; rather, it is imperative to immunize each subsequent generation as long as the threat of the reintroduction of the disease from anywhere in the world persists. Ongoing surveillance and prompt reporting of disease to local or state health departments are essential to this goal, ensuring a continuing awareness of the possibility of vaccine-preventable illness. Nearly all vaccine-preventable diseases are notifiable, and individual case data are routinely forwarded to the CDC. These data are used to detect outbreaks or other unusual events that require investigation and to evaluate prevention and control policies, practices, and strategies.

RESEARCH ON VACCINES AND IMMUNIZATION

The potential to eliminate selected diseases and to build sustainable immunization programs that reach every child is not being fulfilled with existing vaccines and delivery technology. New vaccines or new formulations that will not only improve protective responses but also simplify the immunization schedule are needed. The ideal would be vaccines that can be administered orally early in life, that provide lifelong protection against multiple infections, that can be given as one or only a few doses, and that are less reactive and more heat stable than current vaccines. Diseases for which safe and effective vaccines have not been achieved represent the more difficult immunologic challenges and mark the frontiers of vaccine development. To attain these ambitious goals may take decades. However, progress is already being made in combining current vaccines to facilitate complete immunization, and prototypes of new vaccines are being assessed in early clinical trials. The results will be applicable to immunization programs in both developed and developing countries.

REEMERGENCE OF CONTROLLED DISEASE AND EMERGENCE OF NEW DISEASE

The emergence of new pathogens is fostered by the genetic potential of microbes to evolve and exchange genetic material as well as by rapid changes in human demographics and behavior and in global ecology that create new or more favorable niches and hosts. Proof of the need for continuing vaccine research is provided by the emergence of new infectious diseases, including HIV infection, Lyme borreliosis, hantavirus pulmonary syndrome, hepatitis C, and—most recently—the severe acute respiratory syndrome (SARS) caused by a coronavirus; the sudden outbreak of epidemic cholera due to a previously unknown serotype (O139 Bengal); and the increase in global incidence and drug resistance of familiar diseases that were once considered under control (e.g., tuberculosis and malaria). In addition, some common illnesses without a previously known etiology, such as peptic ulcer disease and cervical and nasopharyngeal cancer, have now been epidemiologically linked to specific infectious agents and thus, by definition, are vaccine-preventable conditions.

NEW VACCINE APPROACHES The first generation of vaccines included whole killed bacteria, partially purified microbial products that induced protective antibodies (e.g., tetanus and diphtheria toxoids), or live attenuated microorganisms. The second generation of vaccines has taken advantage of molecular genetics and protein chemistry: purified proteins or subunits of organisms have been isolated and manipulated, and genetically engineered and attenuated live native organisms have been generated, as have cloned antigens expressed by harmless vector organisms. One conceptual leap is the production of edible transgenic plants (e.g., potatoes, bananas) that express protective vaccine antigens (as a result of insertion of the relevant microbial genes) and that, when eaten, induce mucosal and systemic immune responses to homologous infectious challenges. While the practical use of this technique awaits further refinement, the concept that protective immunity can be induced in this manner has been proved in both animals and humans. Ease of production, stability, ease of administration without equipment, and low cost are the obvious advantages.

TABLE 107-9 Advantages and Disadvantages of DNA Vaccines

Advantages	*Disadvantages*
Safe; cannot cause infection; stable and heat resistant	Potential risk of integration of viral genes from the vector
No need to express or purify antigens in vitro; no need for adjuvants; can be genetically engineered	Tumor promotion from integration near proto-oncogenes or tumor suppressor genes
Normal processing of gene product closely resembling native conformation	Possible induction of tolerance or autoimmunity by vaccine persistence
Persistence for prolonged periods; induction of durable immune response	Possible influence of strong promoters on expression of host genes, with adverse consequences
Induction of both humoral and cell-mediated immunity, including cytotoxic T cells	
Likely to be safe in pregnant women, immunosuppressed patients, or (in the presence of maternal antibody) infants	

Another conceptual leap has led to a third generation of vaccines, in which nucleic acids (either DNA or RNA) are used to induce immunity. The principle is simple and offers many advantages (Table 107-9). First, a DNA plasmid containing the gene sequence for the immunogenic protein or fragment of interest is assembled and placed under the control of a strong promoter and an appropriate transcription termination sequence. A single immunization with the plasmid by a number of possible routes results in DNA uptake into cells, where the gene is expressed and processed normally. The resulting protein product of the vaccine DNA induces an immune response. It should be possible to manipulate the DNA construct, its mode of administration, or the coadministration of cytokine genes to drive a T_H1, T_H2, or cytotoxic T cell response that optimizes the protective immune response. Recently, a technique known as *prime-boost* has been used to convert antibody responses to an antigen into cell-mediated responses. In prime-boost, a priming dose—most often naked DNA encoding the antigen of interest—is followed at the optimal interval by the same DNA inserted into a viral vector (e.g., the modified vaccinia virus vector MVA). DNA vaccines may be particularly useful for the induction of tumor immunity, for the treatment of allergy by suppression of IgE production, or for gene therapy. Because RNA is less stable and does not persist or integrate into the chromosome or result in insertional mutagenesis, the value of RNA vaccines would be to diminish concerns about adverse events associated with the effects of DNA integration into the chromosome (Table 107-9). These virtues of RNA paradoxically represent the hurdles to overcome in producing stable, inexpensive, and effective RNA vaccines.

INTERNATIONAL CONSIDERATIONS

Since the establishment of the Expanded Programme on Immunization (EPI) by the World Health Organization (WHO) in 1981 and the involvement of UNICEF in the program's implementation, levels of coverage for the recommended basic children's vaccines (bacille Calmette-Guérin, poliomyelitis, DTP/DTaP, and measles) have risen from 5 to ~80% worldwide, although coverage does not necessarily translate into protective immunity. Each year, at least 2.7 million deaths from measles, neonatal tetanus, and pertussis and 200,000 cases of paralysis due to polio are prevented by immunization. Despite the successes of this program, many vaccine-preventable diseases remain prevalent in the developing world. Measles, for example, continues to kill an estimated 800,000 children each year, and diphtheria, whooping cough, polio, and neonatal tetanus still occur at unacceptably high rates. An estimated 20 to 35% of all deaths of children <5 years old are still associated with vaccine-preventable diseases.

In addition to the antigens included in the EPI for routine use in the developing world, others (hepatitis B, Hib, Japanese B encephalitis, yellow fever, meningococcus, mumps, and rubella) are used re-

gionally, depending on disease epidemiology and resources. The rationale for inclusion of HepB vaccine in Africa and Asia is to prevent the subsequent development of hepatocellular carcinoma, which is strongly linked with the persistence of HBV from early childhood. The delivery of vaccines in mass campaigns on national immunization days, superseding even civil wars and insurgencies, has resulted in the cessation of transmission of poliomyelitis and the virtual elimination of clinical measles from the Western Hemisphere. Periodic vaccination campaigns complement routine infant and childhood vaccination services under the rubric "catch up, follow up, and keep up." Despite these successes, ongoing concerns remain about inadequate long-term strategies to ensure continuity, the impact of vaccine campaigns on the provision of routine services, and unsafe injection practices.

Because infectious diseases know no geographic or political boundaries, uncontrolled disease anywhere in the world poses a threat to the United States, even without the threat of bioterrorism (Chap. 205). Although the expectation of eradicating infectious agents and ceasing immunization altogether no longer seems realistic, vaccines offer the opportunity to effectively control and even eliminate some diseases through individual and herd protection. Vaccines also represent the best societal hope for stopping the pandemic of HIV infection throughout the world and efficiently controlling malaria and tuberculosis. Issues of cost, liability, risk, and profitability limit the interest of the pharmaceutical industry in the development of vaccines (e.g., for malaria) that will be used primarily in poor developing countries. Global recognition of the powerful effect that vaccines have on reduction of the disease burden has led to the creation of the Global Alliance for Vaccines and Immunization, which coordinates partnerships in public research and privately funded vaccine development. WHO, UNICEF, and other organizations (such as the International AIDS Vaccine Initiative, Rotary International, the Bill and Melinda Gates Foundation, and the Rockefeller Foundation) have helped to move the process forward with new strategies, investment in development, and implementation or with new funding for basic research. New international collaborations are being considered by wealthy industrial nations to attract increasing interest from the private sector—for example, advance-purchase schemes in which the purchase of effective vaccines is guaranteed, ensuring the profitability that the marketplace has provided for industry in wealthy countries. The effectiveness of such approaches remains to be seen, but they offer much-needed hope for at-risk populations around the world.

108 HEALTH ADVICE FOR INTERNATIONAL TRAVEL

J.S. Keystone, P.E. Kozarsky

According to the World Tourism Organization, the number of international tourist arrivals in 2001 amounted to 693 million—the highest figure ever documented. Not only are more people traveling; travelers are seeking more exotic and remote destinations. In 1999, more than 75 million people traveled from industrialized to developing countries; this figure represents a 50% increase from 1993. Studies show that between 50 and 75% of short-term travelers to the tropics or subtropics report some health impairment. Most of these health problems are minor, with only 5% requiring medical attention and fewer than 1% requiring hospitalization. Although infectious agents contribute substantially to morbidity among travelers, these pathogens account for only ~1% of deaths in this population. Cardiovascular disease and injuries are the most frequent causes of death among travelers from the United States, accounting for 49 and 22% of deaths, respectively. Age-specific rates of death due to cardiovascular disease are similar among travelers and nontravelers. In contrast, rates of death due to injury (the majority from motor vehicle, drowning, or aircraft accidents) are several times higher among travelers. Figure 108-1 summarizes the monthly incidence of health problems during travel in developing countries.

GENERAL ADVICE

Staying healthy during travel requires familiarity with the various health risks that may be encountered at a given destination. However, health maintenance recommendations are based not only on the traveler's destination but also on risk assessment, which is determined by health status, specific itinerary, and lifestyle during travel. Detailed information regarding country-specific risks and recommendations may be obtained from the Centers for Disease Control and Prevention (CDC) publication *Health Information for International Travel* (www.cdc.gov/travel).

Fitness for travel is an issue of growing concern in view of the increased numbers of elderly and chronically ill individuals journeying to exotic destinations (see "Travel and Special Hosts," below). Since most commercial aircraft are pressurized to 2500 m (8000 ft) above sea level (corresponding to a Pa_{O_2} of ~55 mmHg), individuals with serious cardiopulmonary problems should be evaluated before travel. In addition, those who have recently had surgery, a myocardial infarction, a cerebrovascular accident, or a deep-vein thrombosis (among other events) may be at high risk for adverse events in flight. A summary of current recommendations regarding fitness to fly has been

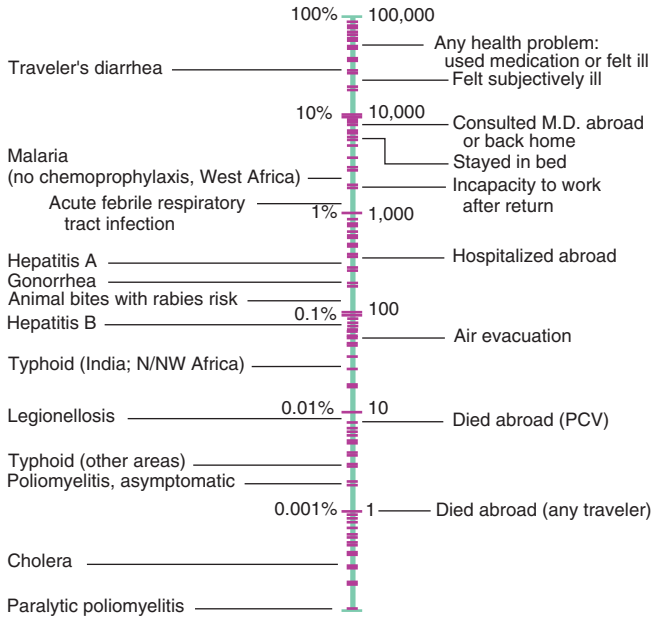

FIGURE 108-1 Incidence rate, per month, of health problems during a stay in developing countries. PCV, Peace Corps volunteer. (*From Steffen R, Lobel HO: Epidemiologic basis for the practice of travel medicine. J Wilderness Med 5:56, 1994. Reprinted with permission from Chapman and Hall, New York.*)

published by the Aerospace Medical Association Air Transport Medical Committee. A pretravel health assessment may also be advisable for individuals considering particularly adventurous recreational activities, such as mountain climbing and scuba diving.

TABLE 108-1 *Vaccines Commonly Used for Travel*

Vaccine	Primary Series	Booster Interval
Cholera, live oral (CVD 103 - HgR)	1 dose	6 months
Hepatitis A (Havrix), 1440 enzyme immunoassay U/mL	2 doses, 6–12 months apart, IM	None required
Hepatitis A (VAQTA, AVAXIM, EPAXAL)	2 doses, 6–12 months apart, IM	None required
Hepatitis A/B combined (Twinrix)	3 doses at 0, 1, and 6–12 months *or* 0, 7, and 21 days plus booster of B at 1 year, IM	None required *except* 12 months (once only, for accelerated schedule)
Hepatitis B (Engerix B): accelerated schedule	3 doses at 0, 1, and 2 months *or* 0, 7, and 21 days plus booster at 1 year, IM	12 months, once only
Hepatitis B (Engerix B or Recombivax): standard schedule	3 doses at 0, 1, and 6 months, IM	None required
Immune globulin (hepatitis A prevention)	1 dose IM	Intervals of 3–5 months, depending on initial dose
Japanese encephalitis (JEV, Biken)	3 doses, 1 week apart, SC	12–18 months (first booster), then 4 years
Meningococcus, quadrivalent	1 dose SC	>3 years (optimum booster schedule not yet determined)
Rabies (HDCV), rabies vaccine absorbed (RVA), or purified chick embryo cell vaccine (PCEC)	3 doses at 0, 7, and 21 or 28 days, IM	None required except with exposure
Typhoid Ty21a, oral live attenuated (Vivotif)	1 capsule every other day × 4 doses	5 years
Typhoid Vi capsular polysaccharide, injectable (Typhim Vi)	1 dose IM	2 years
Yellow fever	1 dose SC	10 years

IMMUNIZATIONS FOR TRAVEL Immunizations for travel fall into three broad categories: routine (childhood/adult boosters that are necessary regardless of travel), required (immunizations that are mandated by international regulations for entry into certain areas or for border crossings), and recommended (immunizations that are desirable because they confer protection against a variety of illnesses for which travel increases the risk). Vaccines commonly given to travelers are listed in Table 108-1.

Routine Immunizations ■ *Diphtheria, Tetanus, and Polio* Diphtheria continues to be a problem worldwide; large outbreaks have occurred over the past decade in the independent states formerly encompassed by the Soviet Union. Serosurveys show that tetanus antitoxin is lacking in many North Americans, especially in women over the age of 50. The risk of polio to the international traveler is extremely low, and wild poliovirus has been eradicated from the western hemisphere and Europe. However, studies in the United States have found varying levels of immunity in the general population, and data suggest that 12% of adult travelers from the United States are unprotected against at least one poliovirus serogroup. Foreign travel offers an ideal opportunity to have these immunizations updated.

Measles Measles (rubeola) continues to be a major cause of morbidity and mortality in the developing world (Chap. 176). Several outbreaks of measles in the United States have been linked to imported cases. The group at highest risk consists of persons born after 1956 and vaccinated before 1980, in many of whom primary vaccination failed. Travelers in this group should be reimmunized.

Influenza Influenza occurs year-round in the tropics and during the summer months in the southern hemisphere (coinciding with the winter months in the northern hemisphere). Vaccination should be considered for all travelers to these regions, particularly those who are elderly or chronically ill. The largest outbreak of travel-related influenza occurred in the summer of 1998 in Alaska and the Northwest Territories of Canada among cruise ship passengers and staff. Such outbreaks continue to occur; unfortunately, however, influenza vaccine is generally not available during the summer months in the United States (Chap. 171).

Pneumococcal Infection Pneumococcal vaccine should be administered routinely to persons at high risk of serious infection, such as individuals with chronic heart, lung, or renal disease and those who have been splenectomized or have sickle cell disease.

Required Immunizations ■ *Yellow Fever* Documentation of yellow fever vaccination may be required as a condition of entry into or passage through countries of sub-Saharan Africa and equatorial South America, where the disease is endemic or epidemic, or into countries that are at risk of having the infection introduced. This vaccine is given only by state-authorized yellow fever centers, and its administration must be documented on an official International Certificate of Vaccination. In Africa, the risk of yellow fever has been estimated to be as high as 1 case per 267 travelers per 2-week stay during epidemics and as low as 1 case per 2000 travelers per 2-week stay where the disease is endemic. The incidence of yellow fever among travelers is extremely low, probably because the vaccine is highly efficacious. However, recent data suggest that fewer than 50% of travelers entering areas endemic for yellow fever are immunized, and both American and European travelers have died of this very serious illness on their return home. It is also of concern that yellow fever–endemic areas may be expanding. Education about the importance of preventing this illness is crucial.

Cholera According to the World Health Organization, cholera vaccination should no longer be required for en-

try into any country. The inactivated injectable vaccine is no longer available in the United States.

Meningococcal Meningitis Protection against meningitis (using the quadrivalent polysaccharide vaccine) is required for entry into Saudi Arabia during the Hajj.

Recommended Immunizations ■ *Hepatitis A and B* Hepatitis A is the most frequent vaccine-preventable infection of travelers; Swiss data show that the incidence of symptomatic infection during a 1-month stay in a developing country ranges from 3 to 6 cases per 1000. The risk is six times greater for travelers who stray from the usual tourist routes. The results of a recent Canadian study showed that rates of hepatitis A among short-term vacationers to Mexico and the Caribbean were considerably lower (1 case per 10,000 to 20,000 travelers per month of stay). The mortality rate for hepatitis A increases with age, reaching almost 3% among symptomatic individuals over age 50. Of the four hepatitis A vaccines currently available in North America (two in the United States), all are interchangeable and have an efficacy rate of >95%. The monthly incidence of hepatitis B infection, both symptomatic and asymptomatic, is 80 to 240 cases per 100,000. For reasons that are not entirely clear, long-stay overseas workers are at considerable risk for hepatitis B infection. A combined hepatitis A and B vaccine is now available and has been approved for administration on a 3-week accelerated schedule in Canada and Europe.

Typhoid Fever The attack rate for typhoid fever is 1 case per 30,000 per month of travel to the developing world (Chap. 137). However, the attack rates in India, Senegal, and North Africa are tenfold higher; in these areas, rates are especially high among travelers to relatively remote destinations and among persons who are returning to their homelands to stay with relatives or friends. Between 1994 and 1999 in the United States, 77% of imported cases involved the latter group. The two available vaccines—one oral and the other injectable—have an efficacy rate of ~70%.

Meningococcal Meningitis Although the risk of meningococcal disease among travelers has not been quantified, it is likely to be higher among travelers who live with poor indigenous populations in overcrowded conditions. Meningococcal polysaccharide vaccine is recommended for persons traveling to sub-Saharan Africa during the dry season or to areas of the world where there are epidemics. The vaccine, which protects against serogroups A, C, Y, and W-135, has an efficacy rate of >90%.

Japanese Encephalitis The risk of Japanese encephalitis, an infection transmitted by mosquitoes in rural Asia and Southeast Asia, is ~1 case per 5000 travelers per month of stay in an endemic area. Most symptomatic infections among U.S. residents have involved military personnel or their families. The vaccine efficacy rate is >90%; serious allergic reactions sometimes occur. The vaccine is recommended for persons staying >1 month in rural endemic areas.

Cholera The risk of cholera is extremely low, with ~1 case per 500,000 journeys to endemic areas. Cholera vaccine, no longer available in the United States, was rarely recommended but was considered for aid and health care workers in refugee camps or in disaster/war-torn areas. A more effective oral cholera vaccine is available in other countries.

Rabies Many cases of rabies have been reported in travelers, but there are no data on the risk of infection. Domestic animals, primarily dogs, are the major transmitters of rabies in developing countries (Chap. 179). Several studies have shown that the risk of rabies posed by a dog bite in an endemic area ranges from 1 to 3.6 cases per 1000 travelers per month of stay. Countries where canine rabies is highly endemic include Mexico, the Philippines, Sri Lanka, India, Thailand, and Vietnam. The three vaccines available in the United States provide >90% protection. Rabies vaccine is recommended for long-stay travelers, particularly children, and persons who may be occupationally exposed to rabies in endemic areas.

PREVENTION OF MALARIA AND OTHER INSECT-BORNE DISEASES It is estimated that more than 30,000 American and European travelers develop malaria each year (Chap. 195). The risk of malaria is highest in Oceania and sub-Saharan Africa (estimated at 1:5 and 1:50 per month of stay, respectively, among persons not using chemoprophylaxis) and during the past decade has increased by more than fivefold for travelers to Kenya. The risk is intermediate (1:250 to 1:1000 per month) for travelers to malarious areas on the Indian subcontinent and in Southeast Asia and is low (1:2500 to 1:10,000 per month) for travelers to South and Central America. Of the more than 1000 cases of malaria reported annually in the United States, 90% of those due to *Plasmodium falciparum* occur in travelers returning or immigrating from Africa and Oceania. With the worldwide increase in chloroquine- and multidrug-resistant falciparum malaria, decisions about chemoprophylaxis have become more difficult. In addition, the spread of malaria due to primaquine- and chloroquine-resistant strains of *Plasmodium vivax* has added to the complexity of treatment. The case-fatality rate of falciparum malaria in the United States is 4%; however, in only one-third of patients who die is the diagnosis of malaria considered before death.

Several recent studies indicate that fewer than 50% of travelers adhere to basic recommendations for malaria prevention. Keys to the prevention of malaria include both personal protection measures against mosquito bites, especially between dusk and dawn, and malaria chemoprophylaxis. The former measures include the use of DEET-containing insect repellents, permethrin-impregnated bed-nets and clothing, screened sleeping accommodations, and protective clothing. These practices also help prevent other insect-transmitted illnesses, such as dengue fever. Over the past decade, the incidence of dengue has increased, particularly in the Caribbean region, Latin America, and Southeast Asia. Dengue virus is transmitted by an urban-dwelling mosquito that bites at dawn and dusk.

The decision about whether to use malaria prophylaxis is based on the traveler's destination; the particular medication is determined by the destination as well as the traveler's preference and medical history. Table 108-2 lists the currently recommended drugs of choice for prophylaxis of malaria, by destination. Primaquine is an alternative medication used for prophylaxis by some physicians; although popular in parts of Europe, the chloroquine/proguanil combination is not recommended because of its low efficacy.

PREVENTION OF GASTROINTESTINAL ILLNESS Diarrhea, the leading cause of illness in travelers (Chap. 113), is usually a short-lived, self-limited condition; however, 40% of affected individuals need to alter their scheduled activities, and another 20% are confined to bed. The most important determinant of risk is the destination. Incidence rates per 2-week stay have been reported to be as low as 8% in industrialized countries and as high as 55% in parts of Africa, Central and South America, and Southeast Asia. Infants and young adults are at particularly high risk. The incidence of diarrhea is proportional to the num-

TABLE 108-2 *Malaria Chemosuppressive Regimens According to Geographic Area*[a]

Geographic Area	*Drug of Choice*	*Alternatives*

Note: See also Chap. 195.

ber of dietary indiscretions. Studies of U.S. students in Mexico showed that eating meals in restaurants and cafeterias or consuming food from street vendors was associated with increased risk.

Etiology (See also Table 113-2) The most frequently identified pathogen causing traveler's diarrhea is toxigenic *Escherichia coli*, although in some parts of the world (notably northern Africa and Southeast Asia) *Campylobacter* infections appear to predominate. Other common causative organisms include *Salmonella*, *Shigella*, rotavirus, and the Norwalk agent. Except for giardiasis, parasitic infections are uncommon causes of traveler's diarrhea. A growing problem for travelers is the development of antibiotic resistance by many bacterial pathogens, including strains of *Campylobacter* resistant to quinolones and strains of *E. coli*, *Shigella*, and *Salmonella* resistant to trimethoprim-sulfamethoxazole.

Precautions Although the mainstay of prevention of traveler's diarrhea involves food and water precautions, the literature has repeatedly documented dietary indiscretions in 98% of travelers within the first 48 h after arrival at their destination. The maxim "Boil it, cook it, peel it, or forget it!" is easy to remember but apparently difficult to follow. General food and water precautions include eating foods piping hot; avoiding foods that are raw, poorly cooked, or sold by street vendors; and drinking only boiled or commercially bottled beverages, particularly those that are carbonated. Heating kills diarrhea-causing organisms, whereas freezing does not; therefore, ice cubes made from unpurified water should be avoided.

Self-Treatment (See also Table 113-4) As traveler's diarrhea often occurs despite rigorous food and water precautions, travelers should carry medications for self-treatment. For mild to moderate diarrhea, loperamide and fluid replacement may be sufficient. An antibiotic is useful in reducing the frequency of bowel movements and duration of illness in moderate to severe diarrhea. The standard regimen is a 3-day course of a quinolone taken twice daily (or, in the case of some newer formulations, once daily). However, studies have shown that a single double dose of a quinolone may be equally effective, particularly if infection with a multidrug-resistant organism is not suspected. For diarrhea acquired in areas such as Thailand, where >90% of *Campylobacter* infections are quinolone resistant, azithromycin may be a better alternative.

Prophylaxis Prophylaxis of traveler's diarrhea with bismuth subsalicylate is widely used but only ~60% effective. For certain individuals (e.g., athletes, persons with a repeated history of traveler's diarrhea, and persons with chronic diseases), a single daily dose of a quinolone during travel of <1 month's duration is highly effective.

Illness after Return Although extremely common, acute traveler's diarrhea is usually self-limited or amenable to antibiotic therapy. Persistent bowel problems after the traveler returns home have a less well-defined etiology and may require medical attention from a specialist. Infectious agents appear to be responsible for only a small proportion of cases with persistent bowel symptoms. Of the pathogens detected in these instances, *Giardia lamblia* (Chap. 199) is by far the most common; *Cyclospora cayetanensis*, *Cryptosporidium* species, and *Entamoeba histolytica* are rarely isolated. Studies suggest that enteroadherent *E. coli* may be important. By far the most frequent causes of persistent diarrhea after travel are postinfectious sequelae, such as lactose intolerance or an irritable bowel syndrome. In the latter, intermittent diarrhea often alternates with constipation. When no infectious etiology can be identified, a trial of metronidazole therapy for presumed giardiasis, a strict lactose-free diet for 1 week, or a several-week trial of high-dose hydrophilic mucilloid (plus lactulose for persons with constipation) relieves the symptoms of many patients.

PREVENTION OF OTHER TRAVEL-RELATED PROBLEMS Travelers are at high risk for *sexually transmitted diseases*. Surveys have shown that large numbers engage in casual sex, and there is a reluctance to use condoms consistently. An increasing number of travelers are being diagnosed with *schistosomiasis*. Travelers should be cautioned to avoid bathing, swimming, or wading in freshwater lakes, streams, or rivers in parts of tropical South America, the Caribbean, Africa, and Southeast Asia where this infection can be acquired. Prevention of *travel-associated injury* depends mostly on common-sense precautions. Riding on motorcycles and in overcrowded public vehicles is not recommended; in particular, individuals should not travel by road after dark in rural areas. In addition to its association with motor vehicle accidents, excessive alcohol use has been a significant factor in drownings, assaults, and injuries. Travelers are cautioned to avoid walking barefoot because of the risk of hookworm and *Strongyloides* infections (Chap. 201) and snakebites (Chap. 378).

THE TRAVELER'S MEDICAL KIT A traveler's medical kit is strongly advisable, particularly for long-stay travelers. The contents may vary widely, depending on the itinerary, duration of stay, style of travel, and local medical facilities. While many medications are available abroad, often over the counter, directions for their use may be nonexistent or in a foreign language, or a product may be outdated or counterfeit. Therefore, if possible, a complete supply of medications should accompany the traveler. In the kit, the short-term traveler should consider carrying an analgesic, an antidiarrheal agent, antihistamines, a laxative, oral rehydration salts, a sunscreen with a skin-protection factor of at least 30, a DEET-containing insect repellent for the skin, an insecticide for clothing (permethrin), and (if necessary) an antimalarial drug. To these medications the long-stay traveler might add a broad-spectrum general-purpose antibiotic (levofloxacin or azithromycin), an antibacterial eye and skin ointment, and a topical antifungal cream. Regardless of the duration of travel, a first-aid kit containing such items as scissors, tweezers, and bandages should be considered.

TRAVEL AND SPECIAL HOSTS

PREGNANCY AND TRAVEL A woman's medical history and itinerary, the quality of medical care at her destinations, and her degree of flexibility determine whether travel is wise during pregnancy. According to the American College of Obstetrics and Gynecology, the safest part of pregnancy in which to travel is between 18 and 24 weeks, when there is the least danger of spontaneous abortion or premature labor. Some obstetricians prefer that women stay within a few hundred miles of home after the 28th week of pregnancy in case problems arise; in general, however, healthy women may be advised that it is acceptable to travel.

Despite this general recommendation, there are some relative contraindications to international travel during pregnancy, including certain obstetric risk factors: a history of miscarriage, premature labor, incompetent cervix, or toxemia. General medical problems such as diabetes, heart failure, severe anemia, or a history of thromboembolic disease should also prompt the pregnant woman to postpone her travels. Finally, regions in which the pregnant woman and her fetus may be at excessive risk (e.g., those at high altitudes and those where live-virus vaccines are required or where multidrug-resistant malaria is endemic) are not ideal destinations during any trimester.

Malaria Malaria during pregnancy carries a significant risk of morbidity and death. Levels of parasitemia are highest and failure to clear the parasites after treatment is most frequent among primigravidae. Severe disease, with complications such as cerebral malaria, massive hemolysis, and renal failure, is especially likely in pregnancy. Fetal sequelae include spontaneous abortion, stillbirth, preterm delivery, and congenital infection.

Traveler's Diarrhea Because dehydration due to traveler's diarrhea can lead to inadequate placental blood flow, pregnant travelers must be extremely cautious regarding their food and beverage intake. The exclusive consumption of bottled (carbonated) or boiled drinks without ice, the eating of well-cooked meats and pasteurized dairy products, and the avoidance of pre-prepared salad items should help protect

against traveler's diarrhea due to the usual causes as well as against infections such as toxoplasmosis, hepatitis E, and listeriosis, which can have serious sequelae in pregnancy.

The mainstay of therapy for traveler's diarrhea is rehydration. Loperamide may be used if necessary, but many of the usual antibiotics are contraindicated during pregnancy. Ampicillin alone or with clavulanic acid may be used, but many strains of *E. coli* and other organisms implicated in traveler's diarrhea are resistant. Azithromycin may be the best option.

Because of the major problems encountered when infants are given local foods and beverages, women are strongly encouraged to breast-feed when traveling with a neonate. A nursing mother with traveler's diarrhea should not stop breast-feeding but should increase her fluid intake.

Air Travel and High-Altitude Destinations Commercial air travel is not a risk to the healthy pregnant woman or to the fetus. Fetal oxygenation is not adversely affected by decreased cabin pressures because of the fetal hemoglobin dissociation curve; the higher radiation levels reported at altitudes of >10,500 m (>35,000 ft) should pose no problem to the healthy pregnant traveler. Since each airline has a policy regarding pregnancy and flying, it is best to check with the specific carrier when booking reservations. Domestic air travel is usually permitted until the 36th week, whereas international air travel is generally curtailed after the 32nd week.

There are no known risks for pregnant women who travel to high-altitude destinations and stay for short periods. However, there are likewise no data on the safety of pregnant women at altitudes of >4500 m (15,000 ft). Because of the harsh conditions usually associated with such trips, they are generally contraindicated for other reasons.

THE HIV-INFECTED TRAVELER The traveler infected with HIV is at special risk of serious infections due to a number of pathogens that may be more prevalent at travel destinations than at home. However, the degree of risk depends primarily on the state of the immune system at the time of travel. For persons whose CD4+ cell counts are normal or >500/μL, no data suggest a greater risk during travel than for persons without HIV infection. Individuals with AIDS (CD4+ cell counts of <200/μL) and others who are symptomatic need special counseling and should visit a travel medicine practitioner before departure, especially when traveling to the developing world.

Several countries now routinely deny entry to HIV-positive individuals, even though no data show that these restrictions decrease rates of transmission of the virus. In general, HIV testing is required of those individuals who wish to stay abroad >3 months or who intend to work or study abroad. Some countries will accept an HIV serologic test done within 6 months of departure, whereas others will not accept a blood test done at any time in the traveler's home country. In addition, border officials often have the authority to make inquiries of individuals entering a country and to check the medications they are carrying. If a drug such as zidovudine is identified, the person may be barred from entering the country. Information on testing requirements for specific countries is available from consular offices but is subject to frequent change.

Health insurance policies should be checked to make sure they are valid for care in other countries. The HIV-positive traveler should strongly consider obtaining trip cancellation insurance and evacuation insurance in case of illness. It is ideal to have the name of a physician at the travel destination who is familiar with the treatment of patients with AIDS, as the clinical findings associated with infection may be atypical in a patient with AIDS, and several infections may exist simultaneously. The traveler should be encouraged to visit the physician promptly if problems arise.

Immunizations All of the HIV-infected traveler's routine immunizations should be up to date (Chap. 107). The response to immunization may be impaired at CD4+ cell counts of <200/μL (and in some cases at even higher counts). Thus HIV-infected persons should be vaccinated as early as possible to ensure adequate immune response to all vaccines. In patients receiving highly active antiretroviral therapy, at least 3 months must elapse before regenerated CD4+ cells can be considered fully functional; therefore, in these patients, vaccinations should be delayed, if possible, until the CD4+ cell count has been stable for this length of time. However, when the risk of illness is high or the sequelae of illness are serious, immunization is recommended. In certain circumstances, it may be prudent to check the adequacy of the serum antibody response before departure (e.g., yellow fever neutralization inhibition if exposure is unavoidable).

Because of the increased risk of infections due to *Streptococcus pneumoniae* and other bacterial pathogens that cause pneumonia following influenza, pneumococcal polysaccharide and influenza vaccines should be administered. The estimated rates of response to influenza vaccine are >80% among persons with asymptomatic HIV infection and <50% among those with AIDS.

In general, live attenuated vaccines are contraindicated for persons with immune dysfunction. Because measles (rubeola) can be a severe and lethal infection in HIV-positive patients, these patients should receive the measles vaccine (or the combination measles-mumps-rubella vaccine) unless they are severely immunocompromised (CD4+ cell count, <200/μL). Between 18 and 58% of symptomatic HIV-infected vaccinees develop adequate antibody titers, and between 50 and 100% of asymptomatic persons infected with HIV seroconvert. Immune globulin should be considered for measles-susceptible, severely immunosuppressed HIV-infected persons who are planning to travel to measles-endemic countries.

The decision of whether to administer any of the special vaccines to an HIV-infected traveler should be based on the individual's risk. Inactivated vaccines can be administered without concern for safety but with concern about adequate protection. For example, data suggest that HIV-infected persons do not have as strong an antibody response to the meningococcal meningitis vaccine as do uninfected persons. Moreover, few data are available on the efficacy of many of the other vaccines (e.g., those for hepatitis A and typhoid).

It is recommended that the live yellow fever vaccine not be given to HIV-infected travelers. Although the potential adverse affects of a live vaccine in an HIV-infected individual are always a consideration, there appear to have been no reported cases of illness in those who have inadvertently received this vaccine. Nonetheless, if the CD4+ count is <200/μL, an alternative itinerary that poses no risk of exposure to yellow fever is recommended. If the traveler is passing through or traveling to an area where the vaccine is required but the disease risk is low, a physician's waiver should be issued. Bacille Calmette-Guérin vaccine should not be given because of reports of disseminated infection in HIV-infected persons.

A transient increase in viremia (lasting days to weeks) has been demonstrated in HIV-infected individuals following immunization with vaccines for such diseases as influenza, pneumococcal infection, and tetanus (Chap. 173). However, at this point, there is no evidence that this transient increase in HIV levels in the bloodstream is detrimental over time. Furthermore, it is likely that immune activation associated with infection with the live organisms in question would result in increases in viremia of greater magnitude and duration than those associated with vaccination. Therefore, the vaccination recommendations discussed above need not be modified at this time.

Gastrointestinal Illness Decreased levels of gastric acid, abnormal gastrointestinal mucosal immunity, other complications of HIV infection, and medications taken by HIV-infected patients make traveler's diarrhea especially problematic in these individuals. Traveler's diarrhea is likely to occur more frequently, be more severe, and be more difficult to treat in association with HIV infection. *Salmonella*, *Shigella*, and *Campylobacter* infections are also more protracted and more often accompanied by bacteremia in HIV-infected persons.

Cryptosporidium (Chap. 199), a common cause of diarrhea in tropical countries, produces severe chronic diarrhea and cholecystitis with

increased mortality among patients with AIDS. *Isospora belli* causes infections at high rates among AIDS patients in the developing world; this infection is associated with malabsorption, weight loss, and relapses after treatment. Persistent diarrhea due to microsporidiosis has been reported.

Because of these potential problems, the HIV-infected traveler must be careful to consume only appropriately prepared foods and beverages. In addition, this group of individuals may benefit from prophylaxis for traveler's diarrhea, using bismuth subsalicylate or a daily antibiotic (ideally a quinolone derivative) for short-term travel to the developing world. If the traveler is already taking a sulfonamide preparation for prophylaxis of *Pneumocystis* pneumonia, a regimen of self-treatment with a quinolone would be appropriate.

Other Travel-Related Infections Data are lacking on the severity of many vector-borne diseases in HIV-infected individuals. Malaria is especially severe in asplenic and certain immunocompromised hosts, including those with AIDS. *Babesia* infection is known to cause serious illness and to recur in HIV-infected patients; this tick-transmitted illness occurs in parts of the United States but is not known to be a widespread problem.

Visceral leishmaniasis (Chap. 196) has been reported in numerous HIV-infected travelers. The diagnosis may be difficult to make, given that splenomegaly and hyperglobulinemia are often lacking and serologic results are frequently negative. This infection is difficult to treat, and its associated mortality is high. Even short-term travelers to southern Europe have developed the illness; thus the avoidance of sandfly bites is critical.

Certain respiratory illnesses, such as histoplasmosis and coccidioidomycosis, cause greater morbidity and mortality among patients with AIDS than in the general population. Although tuberculosis is common among HIV-infected persons (especially in developing countries), the acquisition of this infection by the short-term traveler is not a major concern. The possibility of acquiring *Legionella* infections from spas should be considered, although no data confirm an increase in the severity of such infections in AIDS.

Finally, the HIV-infected traveler should always be cautioned about safe sexual practices, which may help prevent both the transmission of HIV to others and the acquisition by the traveler of other sexually transmitted diseases that may be drug resistant or may result in serious sequelae (e.g., syphilis).

Medications Adverse events due to medications and drug interactions are common and raise complex issues for HIV-infected persons. Rates of cutaneous reaction (e.g., increased cutaneous sensitivity to sulfonamides) are unusually high among patients with AIDS. Physicians advising HIV-infected travelers need to consider the problems that may arise from the use of agents such as antimalarial drugs, medications for altitude acclimation, or antidiarrheal compounds. Since zidovudine is metabolized by hepatic glucuronidation, inhibitors of this process may elevate serum levels of the drug. Concomitant administration of mefloquine and ritonavir may result in decreased plasma levels of ritonavir. In contrast, no significant influence of concomitant mefloquine administration on plasma levels of indinavir or nelfinavir was detected in two HIV-infected travelers.

CHRONIC ILLNESS, DISABILITY, AND TRAVEL

Chronic health problems should not prevent travel, but special measures can make the journey safer and more comfortable.

Heart Disease Cardiovascular events are the main cause of deaths among travelers and of in-flight emergencies on commercial aircraft. Persons with underlying heart disease should review their itineraries with a physician prior to departure; travel in harsh environments or to remote destinations is not wise. Extra supplies of all medications should be kept in carry-on luggage, along with a copy of a recent electrocardiogram and the name and telephone number of the traveler's physician at home. Pacemakers are not affected by airport security devices, but electronic telephone checks of pacemaker function cannot be transmitted by international satellites. The traveler may benefit from supplemental oxygen, which should be ordered by a physician (since oxygen delivery systems are not standard) 48 to 72 h before flight time. Personal oxygen tanks are not permitted aboard aircraft. Travelers should request aisle seating and should walk, perform stretching and flexing exercises, and remain hydrated during the flight to prevent venous thrombosis and pulmonary embolism.

Chronic Lung Disease Chronic obstructive pulmonary disease is one of the most common diagnoses in patients who require emergency-room evaluation for symptoms occurring during airline flights. Patients with such disease experience dyspnea, edema, wheezing, cyanosis, and chest pain. The best predictor of the development of these symptoms is the sea level Pa_{O_2}. A Pa_{O_2} of at least 72 mmHg corresponds to an in-flight arterial Pa_{O_2} of ~55 mmHg when the cabin is pressurized to 2500 m (8000 ft). Therefore, if the traveler's baseline Pa_{O_2} is <72 mmHg, the provision of supplemental oxygen during the flight should be considered. Pulmonary function is also maximized by continuing bronchodilator treatment and the use of glucocorticoids as prescribed. Contraindications to flight include active bronchospasm, lower respiratory infection, lower-limb deep-vein phlebitis, pulmonary hypertension, and recent thoracic surgery (within the preceding 3 weeks) or pneumothorax. Consideration should be given to decreasing the amount of outdoor activity at the destination if there is excessive air pollution.

Diabetes Mellitus Alterations in glucose control and changes in insulin requirements are common problems among patients with diabetes who travel. Changes in time zone, in the amount and timing of food intake, and in physical activity demand more vigilant assessment of metabolic control. The traveler with diabetes should pack medication (including a bottle of regular insulin for emergencies), insulin syringes and needles, equipment and supplies for glucose monitoring, and snacks in carry-on luggage. Insulin is stable for ~3 months at room temperature but should be kept as cool as possible. The name and telephone number of the home physician and a card and necklace listing the patient's medical problems and the type and dose of insulin used should accompany the traveler. When six or more time zones are crossed, insulin requirements may be temporarily altered, depending on food intake and physical activity. In traveling eastward (e.g., from the United States to Europe), the morning insulin dose on arrival may need to be decreased. The blood glucose can then be checked during the day to determine whether additional insulin is required. For flights westward, with lengthening of the day, an additional dose of regular insulin may be required. Comfortable footwear is essential for the traveler with diabetes.

Other Special Groups Other groups for whom special travel measures are encouraged include patients undergoing dialysis, those with transplants, and those with other disabilities. Up to 13% of travelers have some disability, but few advocacy groups and tour companies dedicate themselves to this growing population. The key to safe travel in each case is adequate research ahead of time. Patients undergoing chronic ambulatory peritoneal dialysis may ship their dialysis solutions to their destinations before traveling. They should carry essential medical records as well as antibiotics for self-treatment of presumed peritonitis. Hemodialysis patients need to reserve appointments at dialysis centers prior to their departure from home. Travel by transplant recipients to distant destinations should ideally be scheduled at least 1 year after surgery, as most rejection episodes occur early. Medication interactions are a source of serious concern for these travelers, and appropriate medical information should be carried, along with the home physician's name and telephone number. Some travelers taking glucocorticoids carry stress doses in case they become ill. Immunization of these immunocompromised travelers may result in less than adequate protection against certain diseases. Thus the traveler and physician must carefully consider which destinations are appropriate.

PROBLEMS AFTER RETURN

The most common medical problems encountered by travelers after their return home are diarrhea, fever, respiratory illnesses, and skin diseases. Frequently ignored problems are fatigue and emotional stress, especially in long-stay travelers. The approach to diagnosis requires some knowledge of geographic medicine, in particular the epidemiology and clinical presentation of infectious disorders. A geographic history should focus on the traveler's exact itinerary, including dates of arrival and departure; exposure history (food indiscretions, drinking-water sources, freshwater contact, sexual activity, animal contact, insect bites); location and style of travel (urban vs. rural, first-class hotel accommodation vs. camping); immunization history; and use of antimalarial chemosuppression.

DIARRHEA See "Prevention of Gastrointestinal Illness," above.

FEVER Fever in a traveler who has returned from a malarious area should be considered a medical emergency because death from *P. falciparum* malaria can follow an illness of only several days' duration. Although "fever from the tropics" does not always have a tropical cause, malaria should be the first diagnosis considered. The risk of *P. falciparum* malaria is highest among travelers returning from Africa or Oceania and among those who become symptomatic within the first 2 months after return. Other important causes of fever after travel include viral hepatitis (hepatitis A and E), typhoid fever, bacterial enteritis, arbovirus infections (e.g., dengue fever), rickettsial infections (including tick and scrub typhus and Q fever), and—in rare instances—leptospirosis, acute HIV infection, and amebic liver abscess. In at least 25% of cases, no etiology can be found, and the illness resolves spontaneously. Clinicians should keep in mind that no present-day antimalarial agent guarantees protection from malaria and that some immunizations (notably, that against typhoid fever) are only partially protective.

As noted above, the approach to the febrile returned traveler begins with a detailed medical and geographic history. Knowing exact dates of arrival and departure from tropical areas enables the physician to ascertain the shortest and longest possible incubation periods for illnesses in the differential diagnosis. For example, a traveler who develops fever <1 week after arrival in a malarious area cannot have malaria because the incubation period is too short, whereas a fever whose onset comes >2 weeks after departure from an endemic area cannot be dengue fever because the incubation period is too long. In the physical examination, particular attention should be given to the skin so as not to miss a subtle rash or eschar.

When no specific diagnosis is forthcoming, the following investigations, where applicable, are suggested: complete blood count, liver function tests, thick/thin blood films for malaria (repeated twice if necessary), urinalysis, urine and blood cultures (repeated once), chest x-ray, and collection of an acute-phase serum sample to be held for subsequent examination along with a paired convalescent-phase serum sample.

SKIN DISEASES Pyodermas, sunburn, insect bites, skin ulcers, and cutaneous larva migrans are the most common skin conditions encountered in travelers after their return home. In those with persistent skin ulcers, a diagnosis of cutaneous leishmaniasis, mycobacterial infection, or fungal infection should be considered. Careful, complete inspection of the skin is important in detecting the rickettsial eschar in a febrile patient or the central breathing hole in a "boil" due to myiasis.

EMERGING INFECTIOUS DISEASES In recent years, travel and commerce have fostered the worldwide spread of HIV infection, led to the reemergence of cholera as a global health threat, and created considerable fear about the possible spread of Ebola virus infection and severe acute respiratory syndrome (SARS). For travelers, there are more realistic concerns. One of the largest outbreaks of dengue fever ever documented is now raging in Latin America; schistosomiasis is being described in previously unaffected lakes in Africa; and antibiotic-resistant strains of sexually transmitted and enteric pathogens are emerging at an alarming rate in the developing world. In addition, concerns have been raised regarding the potential for bioterrorism involving not only standard strains of unusual agents but mutant strains as well. Time will tell whether travelers (as well as persons at home) will routinely be vaccinated against diseases such as anthrax and smallpox. As Nobel Laureate Dr. Joshua Lederberg pointed out, "The microbe that felled one child in a distant continent yesterday can reach yours today and seed a global pandemic tomorrow." The vigilant clinician understands that the importance of a thorough travel history cannot be overemphasized.

Section 2 Clinical Syndromes: Community-Acquired Infections

109 INFECTIVE ENDOCARDITIS

Adolf W. Karchmer

The proliferation of microorganisms on the endothelium of the heart results in infective endocarditis. The prototypic lesion at the site of infection, the *vegetation* (Fig. 109-1), is a mass of platelets, fibrin, microcolonies of microorganisms, and scant inflammatory cells. Infection most commonly involves heart valves (either native or prosthetic) but may also occur on the low-pressure side of the ventricular septum at the site of a defect, on the mural endocardium where it is damaged by aberrant jets of blood or foreign bodies, or on intracardiac devices themselves. The analogous process involving arteriovenous shunts, arterioarterial shunts (patent ductus arteriosus), or a coarctation of the aorta is called *infective endarteritis*.

Endocarditis may be classified according to the temporal evolution

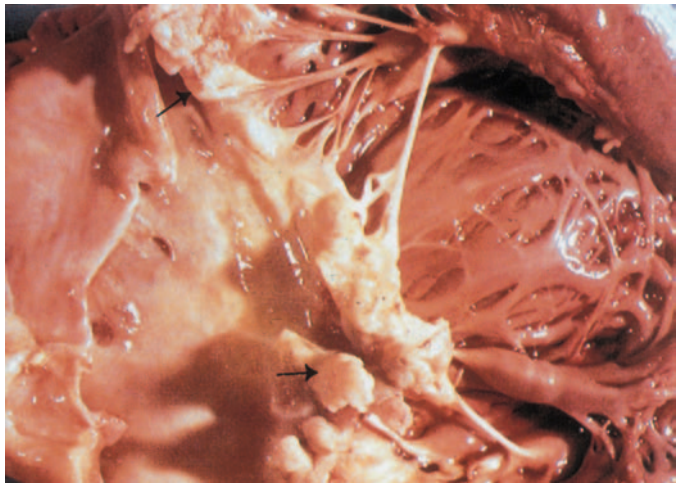

FIGURE 109-1 Vegetations (*arrows*) due to viridans streptococcal endocarditis involving the mitral valve.

of disease, the site of infection, the cause of infection, or a predisposing risk factor such as injection drug use. While each classification criterion provides therapeutic and prognostic insight, none is sufficient alone. The classification of endocarditis as acute and subacute was initially used to describe the illness and the time elapsed until death; presently it is applied to the features and progression of infection until diagnosis. *Acute endocarditis* is a hectically febrile illness, rapidly damages cardiac structures, hematogenously seeds extracardiac sites, and, if untreated, progresses to death within weeks. *Subacute endocarditis* follows an indolent course; causes structural cardiac damage only slowly, if at all; rarely causes metastatic infection; and is gradually progressive unless complicated by a major embolic event or ruptured mycotic aneurysm.

In developed countries, the incidence of endocarditis ranges from 1.5 to 6.2 cases per 100,000 population per year. In the late 1980s in a metropolitan area of the United States (Philadelphia), endocarditis occurred in 9.3 persons per 100,000 population per year. However, half of these cases arose as a consequence of injection drug use. The incidence of endocarditis is notably increased among the elderly. The cumulative rate of prosthetic valve endocarditis is 1.5 to 3.0% at 1 year after valve replacement and 3 to 6% at 5 years; the risk is greatest during the first 6 months after valve replacement.

ETIOLOGY Many species of bacteria and fungi have been reported to cause sporadic episodes of endocarditis; nevertheless, a small number of bacterial species cause the majority of cases (Table 109-1). The causative microorganisms vary somewhat among the major clinical types of endocarditis, in part because of the different portals of entry. The oral cavity, skin, and upper respiratory tract are the respective primary portals for the viridans streptococci, staphylococci, and HACEK organisms (*Haemophilus*, *Actinobacillus*, *Cardiobacterium*, *Eikenella*, and *Kingella*) causing community-acquired native valve endocarditis. *Streptococcus bovis* originates from the gastrointestinal tract, where it is associated with polyps and colonic tumors, and enterococci enter the bloodstream from the genitourinary tract. Nosocomial native valve endocarditis is largely the consequence of bacteremia arising from intravascular catheters and less commonly from nosocomial wound and urinary tract infection. Endocarditis complicates 6 to 25% of episodes of catheter-associated *Staphylococcus aureus* bacteremia; the higher rates are detected by careful transesophageal echocardiography (TEE) screening (see "Echocardiography," below).

Prosthetic valve endocarditis arising within 2 months of valve surgery is generally the result of intraoperative contamination of the prosthesis or a bacteremic postoperative complication. The nosocomial nature of these infections is reflected in their primary microbial causes: coagulase-negative staphylococci, *S. aureus*, facultative gram-negative bacilli, diphtheroids, and fungi. The portals of entry and organisms causing cases beginning >12 months after surgery are similar to those in community-acquired native valve endocarditis. Epidemiologic evidence suggests that prosthetic valve endocarditis due to coagulase-negative staphylococci that presents between 2 and 12 months after surgery is often nosocomial in origin but with a delayed onset. At least 85% of coagulase-negative staphylococci that cause prosthetic valve endocarditis within 12 months of surgery are methicillin-resistant; the rate of methicillin resistance decreases to 25% among coagulase-negative staphylococci causing prosthetic endocarditis that presents >1 year after valve surgery.

Transvenous pacemaker lead– and/or implanted defibrillator–associated endocarditis is usually a nosocomial infection. The majority of episodes occur within weeks of implantation or generator change and are caused by *S. aureus* or coagulase-negative staphylococci.

Endocarditis occurring among injection drug users, especially when infection involves the tricuspid valve, is commonly caused by *S. aureus* strains, many of which are methicillin-resistant. Left-sided valve infections in addicts have a more varied etiology and involve abnormal valves, often ones damaged by prior episodes of endocarditis. A number of these cases are caused by *Pseudomonas aeruginosa*

TABLE 109-1 Organisms Causing Major Clinical Forms of Endocarditis

	Percent of Cases							
	Native Valve Endocarditis		Prosthetic Valve Endocarditis at Indicated Time of Onset (Months) after Valve Surgery			Endocarditis in Injection Drug Users		
Organism	Community-Acquired (n = 683)	Nosocomial (n = 82)	< 2 (n = 144)	2–12 (n = 31)	> 12 (n = 194)	Right-Sided (n = 346)	Left-Sided (n = 204)	Total (n = 675)
Streptococci[a]	32	7	1	9	31	5	15	12
Pneumococci	1	—	—	—	—	—	—	—
Enterococci	8	16	8	12	11	2	24	9
Staphylococcus aureus	35	55	22	12	18	77	23	57
Coagulase-negative staphylococci	4	10	33	32	11	—	—	—
Fastidious gram-negative coccobacilli (HACEK group)[b]	3	—	—	—	6	—	—	—

Culture-negative	5	2	5	6	8	3	3	3

[a] Includes viridans streptococci; *Streptococcus bovis*; other non–group A, groupable streptococci; and *Abiotrophia* spp. (nutritionally variant, pyridoxal-requiring streptococci).

[b] Includes *Haemophilus* spp., *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella* spp., and *Kingella kingae*.

Note: Data are compiled from multiple studies.

and *Candida* species, and sporadic cases are due to unusual organisms such as *Bacillus*, *Lactobacillus*, and *Corynebacterium* species. Polymicrobial endocarditis occurs more frequently in injection drug users than in patients who do not inject drugs. The presence of HIV in this population does not significantly impact the causes of endocarditis.

From 5 to 15% of patients with endocarditis have negative blood cultures; in one-third to one-half of these cases, cultures are negative because of prior antibiotic exposure. The remainder of these patients are infected by fastidious organisms, such as pyridoxal-requiring streptococci (now designated *Abiotrophia* species), the gram-negative coccobacillary HACEK organisms, *Bartonella henselae*, or *Bartonella quintana*. Some fastidious organisms that cause endocarditis have characteristic epidemiologic settings (e.g., *Coxiella burnetii* in Europe, *Brucella* species in the Middle East). *Tropheryma whipplei* causes an indolent, culture-negative, afebrile form of endocarditis.

PATHOGENESIS Unless it is injured, the normal endothelium is resistant to infection by most bacteria and to thrombus formation. Endothelial injury (e.g., at the site of impact of high-velocity jets or on the low-pressure side of a cardiac structural lesion) causes aberrant flow and allows either direct infection by virulent organisms or the development of an uninfected platelet-fibrin thrombus—a condition called *nonbacterial thrombotic endocarditis* (NBTE). The thrombus subsequently serves as a site of bacterial attachment during transient bacteremia. The cardiac lesions most commonly resulting in NBTE are mitral regurgitation, aortic stenosis, aortic regurgitation, ventricular septal defects, and complex congenital heart disease. These lesions result from rheumatic heart disease (particularly in the developing world, where rheumatic fever remains prevalent), mitral valve prolapse, degenerative heart disease, and congenital malformations. NBTE also arises as a result of a hypercoagulable state; this phenomenon gives rise to the clinical entity of *marantic endocarditis* (uninfected vegetations seen in patients with malignancy and chronic diseases) and to bland vegetations complicating systemic lupus erythematosus and the antiphospholipid antibody syndrome.

Organisms that cause endocarditis generally enter the bloodstream from mucosal surfaces, the skin, or sites of focal infection. Except for more virulent bacteria (e.g., *S. aureus*) that can adhere directly to intact endothelium or exposed subendothelial tissue, microorganisms in the blood adhere to thrombi. If resistant to the bactericidal activity of serum and the microbicidal peptides released by platelets, the organisms proliferate and induce a procoagulant state at the site by eliciting tissue factor from adherent monocytes or, in the case of *S. aureus*, from monocytes and from intact endothelium. Fibrin deposition, resulting from tissue factor initiation of the coagulation cascade, combines with platelet aggregation, stimulated by tissue factor and independently by proliferating microorganisms, to generate an infected vegetation. The organisms that commonly cause endocarditis bear surface components that facilitate adherence to injured endothelium and host proteins or, in the case of *S. aureus*, to intact endothelial cells or to thrombi. Fibronectin-binding proteins present on many gram-positive bacteria, clumping factor (a fibrinogen- and fibrin-binding surface protein) on *S. aureus*, and glucans on streptococci facilitate adherence. Fibronectin-binding proteins are required for *S. aureus* invasion of intact endothelium; thus these surface proteins may facilitate infection of previously normal valves. In the absence of host defenses, organisms enmeshed in the growing platelet-fibrin vegetation proliferate to form dense microcolonies. Organisms deep in vegetations are metabolically inactive (nongrowing) and relatively resistant to killing by antimicrobial agents. Proliferating surface organisms are shed into the bloodstream continuously, whereupon some are cleared by the reticuloendothelial system and others are redeposited on the vegetation and stimulate further vegetation growth.

The pathophysiologic consequences and clinical manifestations of endocarditis—other than constitutional symptoms, which are probably a result of cytokine production—arise from damage to intracardiac structures; embolization of vegetation fragments, leading to infection or infarction of remote tissues; hematogenous infection of sites during bacteremia; and tissue injury due to the deposition of circulating immune complexes or immune responses to deposited bacterial antigens.

CLINICAL MANIFESTATIONS The clinical syndrome of infective endocarditis is highly variable and spans a continuum between acute and subacute presentations. Native valve endocarditis (whether acquired in the community or nosocomially), prosthetic valve endocarditis, and endocarditis due to injection drug use share clinical and laboratory manifestations (Table 109-2). Although the relationship is not absolute, the causative microorganism is primarily responsible for the temporal course of endocarditis. β-Hemolytic streptococci, *S. aureus*, and pneumococci typically result in an acute course, although *S. aureus* occasionally causes subacute disease. Endocarditis caused by *Staphylococcus lugdunensis* (a coagulase-negative species) or by enterococci may present acutely. Subacute endocarditis is typically caused by viridans streptococci, enterococci, coagulase-negative staphylococci, and the HACEK group. Endocarditis caused by *Bartonella* species and the agent of Q fever, *C. burnetii*, is exceptionally indolent.

The clinical features of endocarditis are nonspecific. However, these symptoms in a febrile patient with valvular abnormalities or a behavior pattern (injection drug use) that predisposes to endocarditis suggest the diagnosis, as do bacteremia with organisms that frequently cause endocarditis, otherwise-unexplained arterial emboli, and progressive cardiac valvular incompetence. In patients with subacute presentations, fever is typically low-grade and rarely exceeds 39.4°C (103°F); in contrast, temperatures between 39.4 and 40°C (103 and 104°F) are often noted in acute endocarditis. Fever may be blunted or absent in patients who are elderly or severely debilitated or who have marked cardiac or renal failure.

Cardiac Manifestations Although heart murmurs are usually indicative of the predisposing cardiac pathology rather than of endocarditis, valvular damage and ruptured chordae may result in new regurgitant murmurs. In acute endocarditis involving a normal valve, murmurs are heard on presentation in only 30 to 45% of patients but ultimately are detected in 85%. Congestive heart failure develops in 30 to 40% of patients; it is usually a consequence of valvular dysfunction but occasionally is due to endocarditis-associated myocarditis or an intracardiac fistula. The temporal progression of heart failure is variable; failure due to aortic valve dysfunction progresses more rapidly than that due to mitral valve dysfunction. Extension of infection beyond valve leaflets into adjacent annular or myocardial tissue results in perivalvular abscesses, which in turn may cause fistulae (from the root of

TABLE 109-2 *Clinical and Laboratory Features of Infective Endocarditis*

Feature	Frequency, %
Fever	80–90
Chills and sweats	40–75
Anorexia, weight loss, malaise	25–50
Myalgias, arthralgias	15–30
Back pain	7–15
Heart murmur	80–85
New/worsened regurgitant murmur	10–40
Arterial emboli	20–50
Splenomegaly	15–50
Clubbing	10–20
Neurologic manifestations	20–40
Peripheral manifestations (Osler's nodes, subungual hemorrhages, Janeway lesions, Roth's spots)	2–15
Petechiae	10–40
Laboratory manifestations	
Anemia	70–90
Leukocytosis	20–30
Microscopic hematuria	30–50
Elevated erythrocyte sedimentation rate	>90
Rheumatoid factor	50
Circulating immune complexes	65–100
Decreased serum complement	5–40

the aorta into cardiac chambers or between cardiac chambers) with new murmurs. Abscesses may burrow from the aortic valve annulus through the epicardium, causing pericarditis. Extension of infection into paravalvular tissue adjacent to either the right or the noncoronary cusp of the aortic valve may interrupt the conduction system in the upper interventricular septum, leading to varying degrees of heart block. Although perivalvular abscesses arising from the mitral valve may potentially interrupt conduction pathways near the atrioventricular node or in the proximal bundle of His, such interruption occurs infrequently. Emboli to a coronary artery may result in myocardial infarction; nevertheless, embolic transmural infarcts are rare.

Noncardiac Manifestations The classic nonsuppurative peripheral manifestations of subacute endocarditis are related to the duration of infection and, with early diagnosis and treatment, have become infrequent. In contrast, septic embolization mimicking some of these lesions (subungual hemorrhage, Osler's nodes) is common in patients with acute *S. aureus* endocarditis (Fig. 109-2). Musculoskeletal symptoms, including nonspecific inflammatory arthritis and back pain, usually remit promptly with treatment but must be distinguished from focal metastatic infection. Hematogenously seeded focal infection may involve any organ but most often is clinically evident in the skin, spleen, kidneys, skeletal system, and meninges. Arterial emboli are clinically apparent in up to 50% of patients. Vegetations >10 mm in diameter (as measured by echocardiography) and those located on the mitral valve are more likely to embolize than are smaller or nonmitral vegetations. Embolic events—often with infarction—involving the extremities, spleen, kidneys (Fig. 109-3), bowel, or brain are often noted at presentation. With antibiotic treatment, the frequency of embolic events decreases from 13 per 1000 patient-days during the initial week to 1.2 per 1000 patient-days after the third week. Emboli occurring late during or after effective therapy do not in themselves constitute evidence of failed antimicrobial treatment. Neurologic symptoms, most often resulting from embolic strokes, occur in up to 40% of patients. Other neurologic complications include aseptic or purulent meningitis, intracranial hemorrhage due to hemorrhagic infarcts or ruptured mycotic aneurysms, seizures, and encephalopathy. (*Mycotic aneurysms* are focal dilations of arteries occurring at points in the artery wall that have been weakened by infection in the vasa vasorum or where septic emboli have lodged.) Microabscesses in brain and meninges occur commonly in *S. aureus* endocarditis; surgically drainable abscesses are infrequent.

Immune complex deposition on the glomerular basement membrane causes diffuse hypocomplementemic glomerulonephritis and renal dysfunction, which typically improve with effective antimicrobial therapy. Embolic renal infarcts cause flank pain and hematuria but rarely cause renal dysfunction.

FIGURE 109-2 Septic emboli with hemorrhage and infarction due to acute *Staphylococcus aureus* endocarditis. *(Courtesy of L. Baden.)*

FIGURE 109-3 Computed tomography of the abdomen showing large embolic infarcts in the spleen and left kidney of a patient with *Bartonella* endocarditis.

Manifestations of Specific Predisposing Conditions In almost 50% of patients who have endocarditis associated with injection drug use, infection is limited to the tricuspid valve. These patients present with fever, faint or no murmur, and (in 75% of cases) prominent pulmonary findings, including cough, pleuritic chest pain, nodular pulmonary infiltrates, and occasionally pyopneumothorax. Infection involving valves on the left side of the heart presents with the typical clinical features of endocarditis.

Nosocomial endocarditis (defined as that which results from hospital care within the prior month and most commonly presenting as intravascular catheter–associated bacteremia), if not associated with a retained intracardiac device, has typical manifestations. Endocarditis associated with flow-directed pulmonary artery catheters is often cryptic, with symptoms masked by comorbid critical illness, and is commonly diagnosed at autopsy. Transvenous pacemaker lead– and/or implanted defibrillator–associated endocarditis commonly follows initial implantation or a generator unit change; may be associated with obvious or cryptic generator pocket infection; and results in fever, minimal murmur, and pulmonary symptoms similar to those encountered in addicts with tricuspid endocarditis.

Prosthetic valve endocarditis presents with typical clinical features. Cases arising within 60 days of valve surgery (early onset) lack peripheral vascular manifestations and may be obscured by comorbidity associated with recent surgery. In both early-onset and more delayed presentations, paravalvular infection is common and often results in partial valve dehiscence, regurgitant murmurs, congestive heart failure, or disruption of the conduction system.

DIAGNOSIS ■ The Duke Criteria The diagnosis of infective endocarditis is established with certainty only when vegetations obtained at cardiac surgery, at autopsy, or from an artery (an embolus) are examined histologically and microbiologically. Nevertheless, a highly sensitive and specific diagnostic schema—known as the *Duke criteria*—has been developed on the basis of clinical, laboratory, and echocardiographic findings (Table 109-3). Documentation of two major criteria, of one major and three minor criteria, or of five minor criteria allows a clinical diagnosis of definite endocarditis. The diagnosis of endocarditis is rejected if an alternative diagnosis is established, if symptoms resolve and do not recur with ≤4 days of antibiotic therapy, or if surgery or autopsy after ≤4 days of antimicrobial therapy yields no histologic evidence of endocarditis. Illnesses not classified as definite endocarditis or rejected are considered cases of possible infective endocarditis when either one major and one minor criteria or three minor criteria are identified. Requiring the identification of clinical features of en-

docarditis for classification as possible infective endocarditis increases the specificity of the schema without significantly reducing its sensitivity.

The roles of bacteremia and echocardiographic findings in the diagnosis of endocarditis are appropriately emphasized in the Duke criteria. That multiple blood cultures obtained over time are positive is consistent with the known continuous low-density nature of bacteremia characteristic of patients with endocarditis (≤100 organisms per milliliter). Among untreated endocarditis patients who ultimately have a positive blood culture, 95% of all blood cultures are positive, and in 98% of cases one of the initial two sets of cultures yields the microorganism. The diagnostic criteria attach significance to the species of organism isolated from blood cultures. To fulfill a major criterion, the isolation of an organism that causes both endocarditis and bacteremia in the absence of endocarditis (e.g., *S. aureus*, enterococci) must take place repeatedly (i.e., persistent bacteremia) and in the absence of a primary focus of infection. Organisms that rarely cause endocarditis but commonly contaminate blood cultures (e.g., diphtheroids, coagulase-negative species) must be isolated repeatedly if their isolation is to serve as a major criterion.

TABLE 109-3 The Duke Criteria for the Clinical Diagnosis of Infective Endocarditis

MAJOR CRITERIA
1. Positive blood culture
Typical microorganism for infective endocarditis from two separate blood cultures
Viridans streptococci, *Streptococcus bovis*, HACEK group, *Staphylococcus aureus*, *or*
Community-acquired enterococci in the absence of a primary focus, *or*
Persistently positive blood culture, defined as recovery of a microorganism consistent with infective endocarditis from:
Blood cultures drawn >12 h apart; *or*
All of three or a majority of four or more separate blood cultures, with first and last drawn at least 1 h apart
Single positive blood culture for *Coxiella burnetii* or phase I IgG antibody titer of >1:800
2. Evidence of endocardial involvement
Positive echocardiogram
Oscillating intracardiac mass on valve or supporting structures or in the path of regurgitant jets or in implanted material, in the absence of an alternative anatomic explanation, *or*
Abscess, *or*
New partial dehiscence of prosthetic valve, *or*
New valvular regurgitation (increase or change in preexisting murmur not sufficient)
MINOR CRITERIA
1. Predisposition: predisposing heart condition or injection drug use
2. Fever ≥38.0°C (≥100.4°F)
3. Vascular phenomena: major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhages, Janeway lesions
4. Immunologic phenomena: glomerulonephritis, Osler's nodes, Roth's spots, rheumatoid factor
5. Microbiologic evidence: positive blood culture but not meeting major criterion as noted previously[a] or serologic evidence of active infection with organism consistent with infective endocarditis

[a] Excluding single positive cultures for coagulase-negative staphylococci and diphtheroids, which are common culture contaminants, and organisms that do not cause endocarditis frequently, such as gram-negative bacilli.

Note: HACEK, *Haemophilus* spp., *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, *Kingella kingae*.

Blood Cultures Isolation of the causative microorganism from blood cultures is critical not only for diagnosis but also for determination of antimicrobial susceptibility and planning of treatment. In the absence of prior antibiotic therapy, a total of three blood culture sets, ideally with the first separated from the last by at least 1 h, should be obtained from different venipuncture sites over 24 h. If the cultures remain negative after 48 to 72 h, two or three additional blood cultures, including a lysis-centrifugation culture, should be obtained, and the laboratory should be asked to pursue fastidious microorganisms by prolonging incubation time and performing special subcultures. Empirical antimicrobial therapy should not be administered initially to hemodynamically stable patients with subacute endocarditis, especially those who have received antibiotics within the preceding 2 weeks; thus, if necessary, additional blood cultures can be obtained without the confounding effect of empirical treatment. Patients with acute endocarditis or with deteriorating hemodynamics that may require urgent surgery should be treated empirically immediately after the initial three sets of blood cultures are obtained.

Non-Blood-Culture Tests for the Etiologic Agent Serologic tests can be used to identify some organisms causing endocarditis that are difficult to recover by blood culture: *Brucella*, *Bartonella*, *Legionella*, and *C. burnetii*. Pathogens can also be identified in vegetations by culture, by microscopic examination with special stains (i.e., the periodic acid–Schiff stain for *T. whipplei*), and by use of polymerase chain reaction to recover unique microbial DNA or 16S rRNA.

Echocardiography Cardiac imaging with echocardiography allows anatomic confirmation of infective endocarditis, sizing of vegetations, detection of intracardiac complications, and assessment of cardiac function. A two-dimensional study with color flow and continuous as well as pulsed Doppler is optimal. Transthoracic echocardiography (TTE) is noninvasive and exceptionally specific; however, it cannot image vegetations <2 mm in diameter, and in 20% of patients it is technically inadequate because of emphysema or body habitus. Thus, TTE detects vegetations in only 65% of patients with definite clinical endocarditis (i.e., it has a sensitivity of 65%). Moreover, TTE is not adequate for evaluating prosthetic valves or detecting intracardiac complications. TEE is safe and significantly more sensitive than TTE. It detects vegetations in >90% of patients with definite endocarditis; nevertheless, false-negative studies are noted in 6 to 18% of endocarditis patients. TEE is the optimal method for the diagnosis of prosthetic endocarditis or the detection of myocardial abscess, valve perforation, or intracardiac fistulae.

Experts favor echocardiographic evaluation of all patients with a clinical diagnosis of endocarditis; however, the test should not be used to screen patients with otherwise-explained positive blood cultures or patients with unexplained fever. In patients with a low pretest likelihood of endocarditis (<5%), a high-quality TTE that is negative is sufficient to exclude endocarditis. For patients whose habitus makes them difficult to study with TTE and for those who may have prosthetic valve endocarditis or who are at high risk of intracardiac complications, TEE is the preferred imaging modality. For patients with a pretest probability of endocarditis ranging from 5 to 50%, initial evaluation by TEE—in lieu of a sequential strategy of TTE, which, if negative, will be followed by TEE—is cost-effective. A negative TEE when endocarditis is likely does not exclude the diagnosis but rather warrants repetition of the study in 7 to 10 days with optimal multiplanar technique.

Other Studies Many laboratory studies that do not aid in diagnostic evaluation are nevertheless important in the management of patients with endocarditis; these studies include complete blood counts, creatinine measurement, chest radiography, and electrocardiography. The erythrocyte sedimentation rate, C-reactive protein level, circulating immune complex titer, and rheumatoid factor concentration are commonly increased in endocarditis (Table 109-2). Cardiac catheterization is useful primarily to assess coronary artery patency in older individuals who are to undergo surgery for endocarditis.

Rx TREATMENT

ANTIMICROBIAL THERAPY It is difficult to eradicate bacteria from the avascular vegetation in infective endocarditis because this site is rel-

atively inaccessible to host defenses and because the bacteria are nongrowing and metabolically inactive. Since all bacteria in the vegetation must be killed, therapy for endocarditis must be bactericidal and must be given for prolonged periods. Antibiotics are generally given parenterally and must reach high serum concentrations that will, through passive diffusion, lead to effective concentrations in the depths of the vegetation. The choice of effective therapy requires precise knowledge of the susceptibility of the causative microorganisms. The initiation of treatment before a cause is defined must balance the need to establish a microbiologic diagnosis against the potential progression of disease or the need for urgent surgery (see "Blood Cultures," above). The individual vulnerabilities of the patient should be weighed in the selection of therapy—e.g., simultaneous infection at other sites (such as meningitis), allergies, end-organ dysfunction, interactions with concomitant medications, and risks of adverse events.

Although given for several weeks longer, the regimens recommended for the treatment of endocarditis involving prosthetic valves (except for staphylococcal infections) are similar to those used to treat native valve infection (Table 109-4). Recommended doses and duration of therapy should be adhered to unless alterations are required by adverse events.

Organism-Specific Therapies ■ *STREPTOCOCCI* Although most strains of viridans streptococci and *S. bovis* that cause endocarditis are susceptible to penicillin [minimum inhibitory concentration (MIC) ≤0.1 μg/mL], recent reports indicate increasing penicillin resistance among viridans streptococci recovered from blood cultures. In the selection of optimal therapy, the penicillin MIC must be determined (Table 109-4). The 2-

TABLE 109-4 *Antibiotic Treatment for Infective Endocarditis Caused by Common Organisms*[a]

Organism	*Drug, Dose, Duration*	*Comments*
Streptococci		
Penicillin-susceptible[b] streptococci, *S. bovis*	Penicillin G 2–3 million units IV q4h for 4 weeks	—
	Penicillin G 2–3 million units IV q4h *plus* gentamicin[c] 1 mg/kg IM or IV q8h, both for 2 weeks	Avoid penicillin plus gentamicin if risks of aminoglycoside toxicity are increased or case is complicated
	Ceftriaxone 2 g/d IV as single dose for 4 weeks	Can use ceftriaxone in patients with nonimmediate penicillin allergy
	Vancomycin[d] 15 mg/kg IV q12h for 4 weeks	Use vancomycin in patients with severe or immediate β-lactam allergy
Relatively penicillin-resistant[e] streptococci	Penicillin G 3 million units IV q4h for 4–6 weeks *plus* gentamicin[c] 1 mg/kg IV q8h for 2 weeks	Preferred for treatment of prosthetic valve endocarditis caused by penicillin-susceptible streptococci; continue penicillin for 6 weeks in this setting
Moderately penicillin-resistant[f] streptococci, pyridoxal-requiring streptococci (*Abiotrophia* spp.)	Penicillin G 3–4 million units IV q4h *plus* gentamicin[c] 1 mg/kg IV q8h, both for 4–6 weeks	—
Enterococci[g]	Penicillin G 3–4 million units IV q4h *plus* gentamicin[c] 1 mg/kg IV q8h, both for 4–6 weeks	Can use streptomycin 7.5 mg/kg q12h in lieu of gentamicin if there is not high-level resistance to streptomycin
	Ampicillin 2 g IV q4h *plus* gentamicin[c] 1 mg/kg IV q8h, both for 4–6 weeks	Do not use cephalosporins or carbapenems for treatment of enterococcal endocarditis
	Vancomycin[d] 15 mg/kg IV q12h *plus* gentamicin[c] 1 mg/kg IV q8h, both for 4–6 weeks	Use vancomycin plus gentamicin for penicillin-allergic patients or desensitize to penicillin
Staphylococci		
Methicillin-susceptible, infecting native valves (no foreign devices)	Nafcillin or oxacillin 2 g IV q4h for 4–6 weeks *plus* (optional) gentamicin[c] 1 mg/kg IM or IV q8h for 3–5 days	May use penicillin 3–4 million units q6h if isolate is penicillin-susceptible (does not produce β-lactamase)
	Cefazolin 2 g IV q8h for 4–6 weeks *plus* (optional) gentamicin[c] 1 mg/kg IM or IV q8h for 3–5 days	Can use cefazolin regimen for patients with nonimmediate penicillin allergy
	Vancomycin[d] 15 mg/kg IV q12h for 4–6 weeks	Use vancomycin for patients with immediate (urticarial) or severe penicillin allergy
Methicillin-resistant, infecting native valves (no foreign devices)	Vancomycin[d] 15 mg/kg IV q12h for 4–6 weeks	No role for routine use of rifampin
Methicillin-susceptible, infecting prosthetic valves	Nafcillin or oxacillin 2 g IV q4h for 6–8 weeks *plus* gentamicin[c] 1 mg/kg IM or IV q8h for 2 weeks *plus* rifampin[h] 300 mg PO q8h for 6–8 weeks	Use gentamicin during initial 2 weeks; determine susceptibility to gentamicin before initiating rifampin (see text); if patient is highly allergic to penicillin, use regimen for methicillin-resistant staphylococci; if β-lactam allergy is of the minor, nonimmediate type, can substitute cefazolin for oxacillin/nafcillin
Methicillin-resistant, infecting prosthetic valves	Vancomycin[d] 15 mg/kg IV q12h for 6–8 weeks *plus* gentamicin[c] 1 mg/kg IM or IV q8h for 2 weeks *plus* rifampin[h] 300 mg PO q8h for 6–8 weeks	Use gentamicin during initial 2 weeks; determine gentamicin susceptibility before initiating rifampin (see text)
HACEK organisms	Ceftriaxone 2 g/d IV as single dose for 4 weeks	May use another third-generation cephalosporin at comparable dosage
	Ampicillin 2 g IV q4h *plus* gentamicin[c] 1 mg/kg IM or IV q8h, both for 4 weeks	Determine ampicillin susceptibility; do not use ampicillin if β-lactamase is produced

[a] Doses are for adults with normal renal function. Doses of gentamicin, streptomycin, and vancomycin must be adjusted for reduced renal function. Ideal body weight is used to calculate doses per kilogram (men = 50 kg + 2.3 kg per inch over 5 feet; women = 45.5 kg + 2.3 kg per inch over 5 feet).

[b] MIC ≤ 0.1 μg/mL.

[c] Aminoglycosides should not be administered as single daily doses and should be introduced as part of the initial treatment. Target peak and trough serum concentrations of gentamicin 1 h after a 20- to 30-min infusion or IM injection are 3–5 μg/mL and ≤1 μg/mL, respectively; the target peak serum concentration of streptomycin (timing as with gentamicin) is 20–25 μg/mL.

[d] Desirable peak vancomycin level 1 h after completion of a 1-h infusion is 30–45 μg/mL.

[e] MIC > 0.1 μg/mL and <0.5 μg/mL.

[f] MIC ≥ 0.5 μg/mL and <8.0 μg/mL.

[g] Antimicrobial susceptibility must be evaluated; see text.

[h] Rifampin increases warfarin and dicumarol requirements for anticoagulation.

week penicillin/gentamicin regimen should not be used to treat complicated native valve infection or prosthetic valve endocarditis. Although small studies have suggested that a 2-week regimen of single daily doses of ceftriaxone (2 g IV) plus gentamicin (3 mg/kg) or netilmicin (4 mg/kg) is effective for penicillin-susceptible streptococcal endocarditis, the data are not sufficient to support routine use of this regimen. Penicillin/gentamicin is recommended for the treatment of endocarditis caused by group B streptococci.

ENTEROCOCCI Enterococci are resistant to oxacillin, nafcillin, and the cephalosporins and are inhibited only by penicillin, ampicillin, teicoplanin (not available in the United States), and vancomycin. To kill enterococci requires the synergistic interaction of a cell wall–active antibiotic (penicillin, ampicillin, vancomycin, or teicoplanin) that is effective at achievable serum concentrations and an aminoglycoside (gentamicin or streptomycin) to which the isolate does not exhibit high-level resistance. An isolate's resistance to cell wall–active agents or ability to replicate in the presence of gentamicin at ≥500 μg/mL or streptomycin at 2000 μg/mL—a phenomenon called *high-level aminoglycoside resistance*—indicates that the ineffective antimicrobial cannot participate in the interaction to produce killing. High-level resistance to gentamicin predicts that tobramycin, netilmicin, amikacin, and kanamycin will also be ineffective. In fact, even when enterococci are not highly resistant to gentamicin, it is difficult to predict the ability of these other aminoglycosides to participate in synergistic killing; consequently, they should not in general be used to treat enterococcal endocarditis.

Clearly, enterococci causing endocarditis must be tested for high-level resistance to streptomycin and gentamicin, β-lactamase production, and susceptibility to penicillin and ampicillin (MIC ≤ 16 μg/mL) and to vancomycin (MIC ≤ 8 μg/mL). If the isolate produces β-lactamase, ampicillin/sulbactam or vancomycin can be used as the cell wall–active component; if the penicillin/ampicillin MIC is >16 μg/mL, vancomycin can be considered; and if the vancomycin MIC is >8 μg/mL, penicillin or ampicillin may be considered. Based on the absence of high-level resistance, gentamicin or streptomycin should be used as the aminoglycoside. If there is high-level resistance to both these drugs, no aminoglycoside should be given; instead, an 8- to 12-week course of a single cell wall–active agent is suggested. If single-drug therapy fails or the isolate is resistant to all of the commonly used agents, surgical treatment is advised. The role of newer agents potentially active against multidrug-resistant enterococci (quinupristin/dalfopristin, linezolid, and daptomycin) in the treatment of endocarditis has not been established. Although the dose of gentamicin used to achieve bactericidal synergy in treating enterococcal endocarditis is smaller than that used in standard therapy, nephrotoxicity is not uncommon during treatment with recommended regimens for 4 to 6 weeks. Regimens wherein gentamicin treatment has been truncated at 2 to 3 weeks because of nephrotoxicity have been curative. Thus, discontinuation of gentamicin is recommended when progressive nephrotoxicity develops in patients with enterococcal endocarditis who have responded satisfactorily to therapy.

STAPHYLOCOCCI The regimens used to treat staphylococcal endocarditis are not based upon coagulase production but rather upon the presence or absence of a prosthetic valve or foreign device, the native valve(s) involved, and the resistance of the isolate to penicillin and methicillin. Penicillinase is produced by 95% of staphylococci; thus, all isolates should be considered penicillin-resistant until shown not to produce this enzyme. The addition of gentamicin (if the isolate is susceptible) to a β-lactam antibiotic to enhance therapy for native mitral or aortic valve endocarditis is optional. Its addition hastens eradication of bacteremia but does not improve survival rates. If added, gentamicin should be limited to the initial 3 to 5 days of therapy to avoid nephrotoxicity. Gentamicin generally is not added to the vancomycin regimen in this setting.

Methicillin-susceptible *S. aureus* endocarditis that is uncomplicated and limited to the tricuspid or pulmonic valve—a condition occurring almost exclusively in injection drug users—can often be treated with a 2-week course that combines oxacillin or nafcillin (but not vancomycin) with gentamicin. Prolonged fevers (≥5 days) during therapy suggest that these patients should receive standard therapy.

Staphylococcal prosthetic valve endocarditis is treated for 6 to 8 weeks with a multidrug regimen. Rifampin is an essential component because it kills staphylococci that are adherent to foreign material. Two other agents (selected on the basis of susceptibility testing) are combined with rifampin to prevent in vivo emergence of resistance. Because many staphylococci, particularly methicillin-resistant *S. aureus* and *S. epidermidis*, are resistant to gentamicin, the utility of gentamicin should be established before rifampin treatment is begun. If the isolate is resistant to gentamicin, another aminoglycoside or a fluoroquinolone (chosen in light of susceptibility results) should be substituted.

OTHER ORGANISMS Endocarditis caused by *Streptococcus pneumoniae*, with a penicillin MIC ≤ 1.0 can be treated with intravenous penicillin (4 million units every 4 h), ceftriaxone (2 g/d as a single dose), or cefotaxime (at a comparable dosage). Infection caused by strains with a penicillin MIC ≥ 2.0 should be treated with vancomycin. Until the strain's susceptibility to penicillin is established, therapy should consist of vancomycin plus ceftriaxone, especially if concurrent meningitis is suspected. *P. aeruginosa* endocarditis is treated with an antipseudomonal penicillin (ticarcillin or piperacillin) and high doses of tobramycin (8 mg/kg per day in three divided doses). Endocarditis caused by Enterobacteriaceae is treated with a potent β-lactam antibiotic plus an aminoglycoside. Corynebacterial endocarditis is treated with penicillin plus an aminoglycoside (if the organism is susceptible to the aminoglycoside) or with vancomycin, which is highly bactericidal for most strains. Therapy for *Candida* endocarditis consists of amphotericin B plus flucytosine and early surgery; long-term (if not indefinite) suppression with fluconazole is used increasingly.

Empirical Therapy In designing and executing therapy without culture data (i.e., before culture results are known or when cultures are negative), clinical and epidemiologic clues to etiology must be weighed, and both the pathogens associated with the specific endocarditis syndrome and the hazards of suboptimal therapy must be considered. Thus, empirical therapy for acute endocarditis in an injection drug user should cover methicillin-resistant *S. aureus* and gram-negative bacilli. The initiation of treatment with vancomycin plus gentamicin immediately after blood is obtained for cultures covers these as well as many other potential causes. In treating culture-negative episodes, marantic endocarditis must be excluded and fastidious organisms sought serologically. In the absence of confounding prior antibiotic therapy, it is unlikely that *S. aureus*, coagulase-negative staphylococcal, or enterococcal infection will present with negative blood cultures. Thus, in this situation, these organisms are not the determinants of therapy for subacute endocarditis. Blood culture–negative subacute native valve endocarditis is treated with ceftriaxone plus gentamicin; these two antimicrobials plus vancomycin should be used if prosthetic valves are involved.

Outpatient Antimicrobial Therapy Fully compliant patients who have sterile blood cultures, are afebrile during therapy, and have no clinical or echocardiographic findings that suggest an impending complication may complete therapy as outpatients. Careful follow-up and a stable home setting are necessary, as are predictable intravenous access and selection of antimicrobials that are stable in solution.

Monitoring Antimicrobial Therapy The serum bactericidal titer—the highest dilution of the patient's serum during therapy that kills 99.9% of the standard inoculum of the infecting organism—is no longer recommended for assessment of patients receiving standard regimens. However, in the treatment of endocarditis caused by unusual organisms, this measurement, although not standardized and difficult to interpret, may provide a patient-specific assessment of in vivo antibiotic effect. Serum concentrations of aminoglycosides and vancomycin should be monitored.

TABLE 109-5 *Indications for Cardiac Surgical Intervention in Patients with Endocarditis*

Surgery required for optimal outcome
Moderate to severe congestive heart failure due to valve dysfunction
Partially dehisced unstable prosthetic valve
Persistent bacteremia despite optimal antimicrobial therapy
Lack of effective microbicidal therapy (e.g., fungal or *Brucella* endocarditis)
S. aureus prosthetic valve endocarditis with an intracardiac complication
Relapse of prosthetic valve endocarditis after optimal antimicrobial therapy
Surgery to be strongly considered for improved outcome[a]
Perivalvular extension of infection
Poorly responsive *S. aureus* endocarditis involving the aortic or mitral valve
Large (>10-mm diameter) hypermobile vegetations with increased risk of embolism
Persistent unexplained fever (≥10 days) in culture-negative native valve endocarditis
Poorly responsive or relapsed endocarditis due to highly antibiotic-resistant enterococci or gram-negative bacilli

[a] Surgery must be carefully considered; findings are often combined with other indications to prompt surgery.

Antibiotic toxicities, including allergic reactions, occur in 25 to 40% of patients and commonly arise during the third week of therapy. Blood tests to detect antibiotic-specific potential end-organ toxicity should be performed periodically.

In most patients, effective antibiotic therapy results in subjective improvement and resolution of fever within 5 to 7 days. Blood cultures should be repeated daily until sterile, rechecked if there is recrudescent fever, and performed again 4 to 6 weeks after therapy to document cure. Blood cultures become sterile within 2 days after the start of appropriate therapy when infection is caused by viridans streptococci, enterococci, or HACEK organisms. In *S. aureus* endocarditis, β-lactam therapy results in sterile cultures in 3 to 5 days, whereas positive cultures may persist for 7 to 9 days with vancomycin treatment. When fever persists for 7 days in spite of appropriate antibiotic therapy, patients should be evaluated for paravalvular abscess and for extracardiac abscesses (spleen, kidney) or complications (embolic events). Recrudescent fever raises the question of these complications but also of drug reactions or complications of hospitalization. Serologic abnormalities (e.g., erythrocyte sedimentation rate, rheumatoid factor) resolve slowly and do not reflect response to treatment. Vegetations become smaller with effective therapy, but at 3 months after cure half are unchanged and 25% are slightly larger.

SURGICAL TREATMENT Intracardiac and central nervous system complications of endocarditis are important causes of the morbidity and mortality associated with this infection. In some cases, effective treatment for these complications requires surgery. Most of the clinical indications for surgical treatment of endocarditis are not absolute (Table 109-5). The risks and benefits as well as the timing of surgical treatment must therefore be individualized (Table 109-6).

Intracardiac Surgical Indications Most surgical interventions are warranted by intracardiac findings, often detected by echocardiography. Because of the highly invasive nature of prosthetic valve endocarditis, as many as 40% of affected patients merit surgical treatment. In many patients, coincident rather than single intracardiac events necessitate surgery.

CONGESTIVE HEART FAILURE Moderate to severe refractory congestive heart failure caused by new or worsening valve dysfunction is the major indication for cardiac surgical treatment of endocarditis. Of patients with moderate to severe heart failure due to valve dysfunction who are treated medically, 60 to 90% die within 6 months. In the setting of similar hemodynamic dysfunction, surgical treatment is associated with mortality rates of 20 to 40% with native valve endocarditis and 35 to 55% with prosthetic valve infection. Surgery may be required to relieve functional stenosis due to large vegetations or to restore competence to damaged regurgitant valves.

PERIVALVULAR INFECTION This complication, which occurs in 10 to 15% of native valve and 45 to 60% of prosthetic valve infections, is suggested by persistent unexplained fever during appropriate therapy, new electrocardiographic conduction disturbances, and pericarditis. Extension can occur from any valve but is most common with aortic valve infection. TEE with color Doppler is the test of choice to detect perivalvular abscesses (sensitivity ≥ 85%). Although occasional perivalvular infections are cured medically, surgery is warranted when fever persists, fistulae develop, prostheses are dehisced and unstable, and invasive infection relapses after appropriate treatment. Cardiac rhythm must be monitored since high-grade heart block may require insertion of a pacemaker.

UNCONTROLLED INFECTION Continued positive blood cultures or otherwise-unexplained persistent fevers (in patients with either blood culture–positive or –negative endocarditis) despite optimal antibiotic therapy may reflect uncontrolled infection and warrant surgery. Surgical treatment is also advised for endocarditis caused by those organisms against which clinical experience indicates that effective antimicrobial

TABLE 109-6 *Timing of Cardiac Surgical Intervention in Patients with Endocarditis*

	Indication for Surgical Intervention	
Timing	*Strong Supporting Evidence*	*Conflicting Evidence, but Majority of Opinions Favor Surgery*
Emergent (same day)	Acute aortic regurgitation plus preclosure of mitral valve Sinus of Valsalva abscess ruptured into right heart Rupture into pericardial sac	
Urgent (within 1–2 days)	Valve obstruction by vegetation Unstable (dehisced) prosthesis Acute aortic or mitral regurgitation with heart failure (New York Heart Association class III or IV) Septal perforation Perivalvular extension of infection with/without new electrocardiographic conduction system changes Lack of effective antibiotic therapy	Major embolus plus persisting large vegetation (>10 mm in diameter)
Elective (earlier usually preferred)	Progressive paravalvular prosthetic regurgitation Valve dysfunction plus persisting infection after ≥7–10 days of antimicrobial therapy Fungal (mold) endocarditis	Staphylococcal PVE Early PVE (≤2 months after valve surgery) Fungal endocarditis (*Candida* spp.) Antibiotic-resistant organisms

Abbreviation: PVE, prosthetic valve endocarditis.

TABLE 109-7 Procedures for which Endocarditis Prophylaxis Is Advised in Patients at High or Moderate Risk for Endocarditis[a]

Dental procedures
Extractions
Periodontal procedures, cleaning causing gingival bleeding
Implant placement, reimplantation of avulsed teeth
Endodontic instrumentation (root canal) or surgery beyond the apex
Subgingival placement of antibiotic fibers or strips
Placement of orthodontic bands but not brackets
Intraligamentary injections (anesthetic)
Respiratory procedures
Operations involving the mucosa
Bronchoscopy with rigid bronchoscope
Gastrointestinal procedures[b]
Esophageal: Sclerotherapy of varices, stricture dilation
Biliary tract: Endoscopic retrograde cholangiography with biliary obstruction, biliary tract surgery
Intestinal tract: Surgery involving the mucosa
Genitourinary procedures
Urethral dilation, prostate or urethral surgery
Cystoscopy

[a] Prophylaxis is optional for high-risk patients undergoing bronchoscopy or gastrointestinal endoscopy with/without biopsy, vaginal delivery, vaginal hysterectomy, or transesophageal echocardiography.
[b] Prophylaxis is recommended for high-risk patients and optional for moderate-risk group (see Table 109-8).

therapy is lacking. This category includes infections caused by yeasts, fungi, *P. aeruginosa*, other highly resistant gram-negative bacilli, *Brucella* species, and probably *C. burnetii*.

S. AUREUS ENDOCARDITIS Mortality rates for *S. aureus* prosthetic valve endocarditis exceed 70% with medical treatment but are reduced to 25% with surgical treatment. In patients with intracardiac complications associated with *S. aureus* prosthetic valve infection, surgical treatment reduces mortality by twentyfold. Surgical treatment should be considered for patients with *S. aureus* native aortic or mitral valve infection who have TTE-demonstrable vegetations and remain septic during the initial week of therapy. Isolated tricuspid valve endocarditis, even with persistent fever, rarely requires surgery.

PREVENTION OF SYSTEMIC EMBOLI Mortality and persisting morbidity due to emboli are largely limited to patients suffering occlusion of cerebral or coronary arteries. Echocardiographic determination of vegetation size and anatomy, although predictive of patients at high risk of systemic emboli, does not identify those patients in whom the benefits of surgery to prevent emboli clearly exceed the risks of the surgical procedure and an implanted prosthetic valve. Net benefits favoring surgery are most likely when the risk of embolism is high and other surgical benefits can be achieved simultaneously—e.g., repair of a moderately dysfunctional valve or debridement of a paravalvular abscess. Reduced overall risks of surgical intervention (e.g., use of vegetation resection and valve repair to avoid insertion of a prosthesis) make the benefit-to-risk ratio more favorable and this intervention more attractive.

TABLE 109-8 Cardiac Lesions for which Endocarditis Prophylaxis Is Advised

High Risk	Moderate Risk
Prosthetic heart valves	Congenital cardiac malformations (other than high-/low-risk lesions), ventricular septal defect, bicuspid aortic valve
Prior bacterial endocarditis	Acquired aortic and mitral valve dysfunction
Complex cyanotic congenital heart disease; other complex congenital lesions after correction (see text)	Hypertrophic cardiomyopathy (asymmetric septal hypertrophy)
Patent ductus arteriosus	Mitral valve prolapse with valvular regurgitation and/or thickened leaflets
Coarctation of the aorta	
Surgically constructed systemic-pulmonary shunts	

TABLE 109-9 Cardiac Conditions That Are Considered to Pose a Low Risk of Endocarditis and for which Antibiotic Prophylaxis Is Not Recommended

Isolated secundum ASD
Surgically repaired ASD, VSD, PDA (without residual defect, >6 months after repair)
Prior coronary artery bypass graft
Mitral valve prolapse without regurgitation or thickened leaflets
Physiologic or functional murmur
Prior Kawasaki disease or acute rheumatic fever without valve dysfunction
Cardiac pacemakers or implanted defibrillators

Abbreviations: ASD, atrial septal defect; VSD, ventricular septal defect; PDA, patent ductus arteriosus.
Source: Adapted from AS Dajani et al: JAMA 277:1794, 1997; with permission.

Timing of Cardiac Surgery In general, when indications for surgical treatment of infective endocarditis are identified, surgery should not be delayed simply to permit additional antibiotic therapy, since this course of action increases the risk of death (Table 109-6). Delay is justified only when infection is controlled and congestive heart failure is fully compensated with medical therapy. Recrudescent endocarditis involving a prosthetic valve follows surgery in 2% of patients with culture-positive native valve endocarditis and in 6 to 15% of patients with active prosthetic valve endocarditis. These risks are more acceptable than the high mortality rates that result when surgery is inappropriately delayed or not performed.

Among patients who have experienced a neurologic complication of endocarditis, further neurologic deterioration can occur as a consequence of cardiac surgery. The risk of significant neurologic exacerbation is related to the interval between the complication and surgery. Where feasible, cardiac surgery should be delayed for 2 to 3 weeks after a nonhemorrhagic embolic stroke and for 4 weeks after a

TABLE 109-10 Antibiotic Regimens for Prophylaxis of Endocarditis in Adults at Moderate or High Risk[a]

I. Oral cavity, respiratory tract, or esophageal procedures[b]
A. Standard regimen
1. Amoxicillin 2.0 g PO 1 h before procedure
B. Inability to take oral medication
1. Ampicillin 2.0 g IV or IM within 30 min of procedure
C. Penicillin allergy
1. Clarithromycin 500 mg PO 1 h before procedure
2. Cephalexin[c] or cefadroxil[c] 2.0 g PO 1 h before procedure
3. Clindamycin 600 mg PO 1 h before procedure or IV 30 min before procedure
D. Penicillin allergy, inability to take oral medication
1. Cefazolin[c] 1.0 g IV or IM 30 min before procedure
II. Genitourinary and gastrointestinal tract[d] procedures
A. High-risk patients
1. Ampicillin 2.0 g IV or IM *plus* gentamicin 1.5 mg/kg (not to exceed 120 mg) IV or IM within 30 min of procedure; repeat ampicillin 1.0 g IV or IM or amoxicillin 1.0 g PO 6 h later
B. High-risk, penicillin-allergic patients
1. Vancomycin 1.0 g IV over 1–2 h *plus* gentamicin 1.5 mg/kg (not to exceed 120 mg) IV or IM within 30 min before procedure; no second dose recommended
C. Moderate-risk patients
1. Amoxicillin 2.0 g PO 1 h before procedure or ampicillin 2.0 g IV or IM within 30 min before procedure
D. Moderate-risk, penicillin-allergic patients
1. Vancomycin 1.0 g IV infused over 1–2 h and completed within 30 min of procedure

[a] Dosing for children: for amoxicillin, ampicillin, cephalexin, or cefadroxil, use 50 mg/kg PO; cefazolin, 25 mg/kg IV; clindamycin, 20 mg/kg PO, 25 mg/kg IV; clarithromycin, 15 mg/kg PO; gentamicin, 1.5 mg/kg IV or IM; and vancomycin, 20 mg/kg IV.
[b] For patients at high risk (Table 109-8), administer a half-dose 6 h after the initial dose.
[c] Do not use cephalosporins in patients with immediate hypersensitivity (urticaria, angioedema, anaphylaxis) to penicillin.
[d] Excludes esophageal procedures.
Source: Adapted from AS Dajani et al: JAMA 277:1794, 1997; with permission.

hemorrhagic embolic stroke. A ruptured mycotic aneurysm should be clipped and cerebral edema allowed to resolve prior to cardiac surgery.

Extracardiac Complications Splenic abscess develops in 3 to 5% of patients with endocarditis. Effective therapy requires either computed tomography–guided percutaneous drainage or splenectomy. Mycotic aneurysms occur in 2 to 15% of endocarditis patients; half of these cases involve the cerebral arteries and present as headaches, focal neurologic symptoms, or hemorrhage. Cerebral aneurysms should be monitored by angiography. Some will resolve with effective antimicrobial therapy, but those that persist, enlarge, or leak should be treated surgically if possible. Extracerebral aneurysms present as local pain, a mass, local ischemia, or bleeding; generally these aneurysms are treated by resection.

OUTCOME The outcome of infective endocarditis is affected by a variety of factors, some of which are interrelated. Factors with an adverse impact include older age, severe comorbid conditions, delayed diagnosis, involvement of prosthetic valves or the aortic valve, an invasive (*S. aureus*) or antibiotic-resistant (*P. aeruginosa*, yeast) pathogen, intracardiac complications, and major neurologic complications. Death and poor outcome often are related not to failure of antibiotic therapy but rather to the interactions of comorbidities and endocarditis-related end-organ complications. The overall survival rate for patients with native valve endocarditis caused by viridans streptococci, HACEK organisms, or enterococci (susceptible to synergistic therapy) ranges from 85 to 90%. For *S. aureus* native valve endocarditis in patients who do not inject drugs, survival rates are 55 to 70%, whereas 85 to 90% of injection drug users survive this infection. Prosthetic valve endocarditis beginning within 2 months of valve replacement results in mortality rates of 40 to 50%, whereas rates are only 10 to 20% in later-onset cases.

PREVENTION Antibiotics have been administered in conjunction with selected procedures considered to entail a risk for bacteremia and endocarditis. The benefits of antibiotic prophylaxis are not established and in fact may be modest: only 50% of patients with native valve endocarditis know that they have a valve lesion predisposing to infection, most endocarditis cases do not follow a procedure, and 35% of cases are caused by organisms not targeted by prophylaxis. Dental treatments, the procedures most widely accepted as predisposing to endocarditis, are no more frequent during the 3 months preceding this diagnosis than in uninfected matched controls. Nevertheless, an expert committee of the American Heart Association, along with similar advisory groups in other developed countries, has identified procedures that may precipitate bacteremia with organisms that cause endocarditis (Table 109-7), patients who should receive prophylaxis based on the relative risk for developing endocarditis and the severity of subsequent infection (Table 109-8), patients who are at low risk and do not require prophylaxis (Table 109-9), and regimens that may be used for prophylaxis (Table 109-10). Except for an isolated secundum atrial septal defect and a totally corrected patent ductus arteriosus, ventricular septal defect, or pulmonary stenosis, patients with congenital heart defects continue to experience high rates of endocarditis despite total surgical correction of the defect. In vulnerable patients, maintaining good dental hygiene and aggressively treating local infections may reduce the risk of endocarditis.

110 INFECTIONS OF THE SKIN, MUSCLE, AND SOFT TISSUES

Dennis L. Stevens

ANATOMICAL RELATIONSHIPS: CLUES TO THE DIAGNOSIS OF SOFT TISSUE INFECTIONS Protection against infection of the epidermis is dependent on the mechanical barrier afforded by the stratum corneum, since the epidermis itself is devoid of blood vessels (Fig. 110-1). Disruption of this layer by burns or bites, abrasions, foreign bodies, primary dermatologic disorders (e.g., herpes simplex, varicella, and ecthyma gangrenosum), surgery, or vascular or pressure ulcer allows penetration of bacteria to the deeper structures. Similarly, the hair follicle can serve as a portal either for components of the normal flora (e.g., *Staphylococcus*) or for extrinsic bacteria (e.g., *Pseudomonas* in hot-tub folliculitis). Intracellular infection of the squamous epithelium with vesicle formation may arise from cutaneous inoculation, as in infection with herpes simplex virus (HSV) type 1; from the dermal capillary plexus, as in varicella and infections due to other viruses associated with viremia; or from cutaneous nerve roots, as in herpes zoster. Bacteria infecting the epidermis, such as *Streptococcus pyogenes*, may be translocated laterally to deeper structures via lymphatics, an event that results in the rapid superficial spread of erysipelas. Later, engorgement or obstruction of lymphatics causes flaccid edema of the epidermis, another characteristic of erysipelas.

The rich plexus of capillaries beneath the dermal papillae provides nutrition to the stratum germinativum, and physiologic responses of this plexus produce important clinical signs and symptoms. For ex-

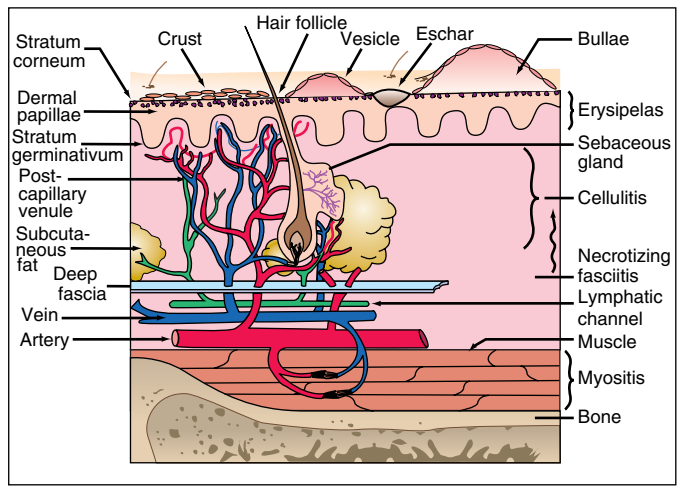

FIGURE 110-1 Structural components of the skin and soft tissue, superficial infections, and infections of the deeper structures. The rich capillary network beneath the dermal papillae plays a key role in the localization of infection and in the development of the acute inflammatory reaction.

ample, infective vasculitis of the plexus results in petechiae, Osler's nodes, Janeway lesions, and palpable purpura, which, if present, are important clues to the existence of endocarditis (Chap. 109). In addition, metastatic infection within this plexus can result in cutaneous manifestations of disseminated fungal infection (Chap. 187), gonococcal infection (Chap. 128), *Salmonella* infection (Chap. 137), *Pseudomonas* infection (i.e., ecthyma gangrenosum; Chap. 136), meningococcemia (Chap. 127), and staphylococcal infection (Chap. 120). The plexus also provides access for bacteria to the circulation, thereby facilitating local spread or bacteremia. The postcapillary venules of this plexus are a major site of polymorphonuclear leukocyte sequestration, diapedesis, and chemotaxis to the site of cutaneous infection.

Exaggeration of these physiologic mechanisms by excessive levels of cytokines or bacterial toxins causes leukostasis, venous occlusion, and pitting edema. Edema with purple bullae, ecchymosis, and cutaneous anesthesia suggests loss of vascular integrity and necessitates exploration of the deeper structures for evidence of necrotizing fasciitis or myonecrosis. An early diagnosis requires a high level of suspicion in instances of unexplained fever and of pain and tenderness in the soft tissue, even in the absence of acute cutaneous inflammation.

INFECTIONS ASSOCIATED WITH VESICLES (Table 110-1) Vesicle formation due to infection is caused by viral proliferation within the epidermis. In varicella and variola, viremia precedes the onset of a diffuse centripetal rash that progresses from macules to vesicles, then to pustules, and finally to scabs over the course of 1 to 2 weeks. Vesicles of varicella have a "dewdrop" appearance and develop in crops randomly about the trunk, extremities, and face over 3 to 4 days (see Fig. 164-1). Herpes zoster occurs in a single dermatome; the appearance of vesicles is preceded by pain for several days (see Figs. 164-2 and 164-3). Zoster may occur in persons of any age but is most common among immunosuppressed individuals and elderly patients, whereas most cases of varicella occur in young children. Vesicles due to HSV are found on or around the lips (HSV-1) or genitals (HSV-2) but may appear on the head and neck of young wrestlers (herpes gladiatorum) or on the digits of health care workers (herpetic whitlow). Recurrent herpes labialis (HSV-1) and herpes genitalis are common following primary infection. Coxsackievirus A16 characteristically causes vesicles on the hands, feet, and mouth of children. Orf is caused by a DNA virus related to smallpox virus and infects the fingers of individuals who work around goats and sheep. Molluscum contagiosum virus induces flaccid vesicles on the skin of healthy and immunocompromised individuals. Although variola (smallpox) in nature was eradicated as of 1977, recent terrorist events have renewed interest in this devastat-

Pyomyositis	*S. aureus*	120
Streptococcal necrotizing myositis	*S. pyogenes*	121
Gas gangrene	*Clostridium* spp.	126
Nonclostridial (crepitant) myositis	Mixed aerobic and anaerobic bacteria	148
Synergistic nonclostridial anaerobic myonecrosis	Mixed aerobic and anaerobic bacteria	148

ing infection (see Chap. 205). Viremia beginning after an incubation period of 12 days is followed by a diffuse maculopapular rash, with rapid evolution to vesicles, pustules, and then scabs. Secondary cases can occur among close contacts.

Rickettsialpox begins after mite-bite inoculation of *Rickettsia akari* into the skin. A papule with a central vesicle evolves to form a 1- to 2.5-cm painless crusted black eschar with an erythematous halo and proximal adenopathy. While more common in the northeastern United States and the Ukraine in 1940–1950, rickettsialpox has recently been described in Ohio, Arizona, and Utah. Blistering dactylitis is a painful, vesicular, localized *Staphylococcus aureus* or group A streptococcal infection of the pulps of the distal digits of the hands.

INFECTIONS ASSOCIATED WITH BULLAE (Table 110-1) Staphylococcal scalded-skin syndrome (SSSS) in neonates is caused by a toxin (exfoliatin) from phage group II *S. aureus*. SSSS must be distinguished from toxic epidermal necrolysis (TEN), which occurs primarily in adults, is drug-induced, and has a higher mortality. Punch biopsy with frozen section is useful in making this distinction since the cleavage plane is the stratum corneum in SSSS (Fig. 110-1) and the stratum germinativum in TEN. Intravenous γ-globulin is a promising treatment for TEN. Necrotizing fasciitis and gas gangrene also induce bulla formation (see "Necrotizing Fasciitis," below). Halophilic vibrio infection can be as aggressive and fulminant as necrotizing fasciitis; a helpful clue in its diagnosis is a history of exposure to waters of the Gulf of Mexico or the Atlantic seaboard or (in a patient with cirrhosis) the ingestion of raw seafood. The etiologic organism (*Vibrio vulnificus*) is highly susceptible to tetracycline.

INFECTIONS ASSOCIATED WITH CRUSTED LESIONS (Table 110-1) Impetigo contagiosa is caused by *S. pyogenes*, and bullous impetigo is due to *S. aureus* (see Fig. 121-2). Both skin lesions may have an early bullous stage but then appear as thick crusts with a golden-brown color. Streptococcal lesions are most common among children 2 to 5 years of age, and epidemics may occur in settings of poor hygiene, particularly among children of lower socioeconomic status in tropical climates. It is important to recognize impetigo contagiosa because of its relationship to poststreptococcal glomerulonephritis. Rheumatic fever is not a complication of skin infection caused by *S. pyogenes*. Superficial dermatophyte infection (ringworm) can occur on any skin surface, and skin scrapings with KOH staining are diagnostic. Primary infections with dimorphic fungi such as *Blastomyces dermatitidis* and *Sporothrix schenckii* can initially present as crusted skin lesions resembling ringworm. Disseminated infection with *Coccidioides immitis* can also involve the skin, and biopsy and culture should be performed on crusted lesions in patients from endemic areas. Crusted nodular lesions caused by *Mycobacterium chelonei* have been described in HIV-seropositive patients. Treatment with clarithromycin looks promising.

FOLLICULITIS (Table 110-1) Hair follicles serve as portals for a number of bacteria, although *S. aureus* is the most common cause of localized folliculitis. Sebaceous glands empty into hair follicles and ducts and, if blocked, form sebaceous cysts, which may resemble staphylococcal abscesses or may become secondarily infected. Infection of sweat glands (hidradenitis suppurativa) can also mimic infection of hair follicles, particularly in the axillae. Chronic folliculitis is uncommon except in acne vulgaris, where constituents of the normal flora (e.g., *Propionibacterium acnes*) may play a role.

Diffuse folliculitis occurs in two settings. "Hot-tub folliculitis" is caused by *Pseudomonas aeruginosa* in waters that are insufficiently chlorinated and maintained at temperatures between 37 and 40°C. Infection is usually self-limited, though bacteremia and shock have been reported. Swimmer's itch occurs when a skin surface is exposed to water infested with freshwater avian schistosomes. Warm water temperatures and alkaline pH are suitable for mollusks that serve as intermediate hosts between birds and humans. Free-swimming schistosomal cercariae readily penetrate human hair follicles or pores but quickly die and elicit a brisk allergic reaction, causing intense itching and erythema.

PAPULAR AND NODULAR LESIONS (Table 110-1) Raised lesions of the skin occur in many different forms. *Mycobacterium marinum* infections of the skin may present as cellulitis or as raised erythematous nodules. Erythematous papules are early manifestations of cat-scratch disease (primary site of inoculation) and bacillary angiomatosis (*Bartonella henselae*). Raised serpiginous or linear eruptions are characteristic of cutaneous larva migrans, which is caused by burrowing larvae of dog or cat hookworms (*Ancylostoma braziliense*) and which humans acquire through contact with soil that has been contaminated with dog or cat feces. Similar burrowing raised lesions are present in dracunculiasis caused by migration of the adult female nematode *Dracunculus medinensis*. Nodules caused by *Onchocerca volvulus* may range from 1 to 10 cm in diameter and occur largely in persons bitten by *Simulium* flies in Africa. The nodules contain the adult worm encased in fibrous tissue. Migration of microfilariae into the eyes may result in blindness. Verruca peruana is caused by *Bartonella bacilliformis*, which is transmitted to humans by the sandfly *Phlebotomus*. This condition can take the form of single gigantic lesions (several centimeters in diameter) or multiple small lesions (several millimeters in diameter). Numerous subcutaneous nodules may also be present in cysticercosis caused by larvae of *Taenia solium*. Multiple erythematous papules develop in schistosomiasis; each represents a cercarial invasion site. Skin nodules as well as thickened subcutaneous tissue are prominent features of lepromatous leprosy. Large nodules or gummas are features of tertiary syphilis, whereas flat papulosquamous lesions are characteristic of secondary syphilis. Human papillomavirus may cause singular warts (verruca vulgaris) or multiple warts in the anogenital area (condylomata acuminata). The latter are major problems in HIV-infected individuals.

ULCERS WITH OR WITHOUT ESCHARS (Table 110-1) Cutaneous anthrax begins as a pruritic papule, which develops within days into an ulcer with surrounding vesicles and edema and then into an enlarging ulcer with a black eschar. Cutaneous anthrax may cause chronic nonhealing ulcers with an overlying dirty-gray membrane, although lesions may also mimic psoriasis, eczema, or impetigo. Ulceroglandular tularemia may have associated ulcerated skin lesions with painful regional adenopathy. Although buboes are the major cutaneous manifestation of plague, ulcers with eschars, papules, or pustules are also present in 25% of cases.

Mycobacterium ulcerans typically causes chronic skin ulcers on the extremities of individuals living in the tropics. *Mycobacterium leprae* may be associated with cutaneous ulcerations in patients with lepromatous leprosy related to Lucio's phenomenon, in which immune-mediated destruction of tissue bearing high concentrations of *M. leprae* bacilli occurs, usually several months after initiation of effective therapy. *Mycobacterium tuberculosis* may also cause ulcerations, papules, or erythematous macular lesions of the skin in both normal and immunocompromised patients.

Decubitus ulcers are due to tissue hypoxia secondary to pressure-induced vascular insufficiency and may become secondarily infected with components of the skin and gastrointestinal flora, including anaerobes. Ulcerative lesions on the anterior shins may be due to pyoderma gangrenosum, which must be distinguished from similar lesions of infectious etiology by histologic evaluation of biopsy sites. Ulcerated lesions on the genitals may be either painful (chancroid) or painless (primary syphilis).

ERYSIPELAS (Table 110-1) Erysipelas is due to *S. pyogenes* and is characterized by an abrupt onset of fiery-red swelling of the face or extremities. The distinctive features of erysipelas are well-defined indurated margins, particularly along the nasolabial fold; rapid progression; and intense pain (see Fig. 121-3). Flaccid bullae may develop during the second or third day of illness, but extension to deeper soft tissues is rare. Treatment with penicillin is effective; swelling may progress despite appropriate treatment, although fever, pain, and the intense red color diminish. Desquamation of the involved skin

occurs 5 to 10 days into the illness. Infants and elderly adults are most commonly afflicted, and the severity of systemic toxicity varies.

CELLULITIS (Table 110-1) Cellulitis is an acute inflammatory condition of the skin that is characterized by localized pain, erythema, swelling, and heat. Cellulitis may be caused by indigenous flora colonizing the skin and appendages (e.g., *S. aureus* and *S. pyogenes*) or by a wide variety of exogenous bacteria. Because the exogenous bacteria involved in cellulitis occupy unique niches in nature, a thorough history (including epidemiologic data) provides important clues to etiology. When there is drainage, an open wound, or an obvious portal of entry, Gram's stain and culture provide a definitive diagnosis. In the absence of these findings, the bacterial etiology of cellulitis is difficult to establish, and in some cases staphylococcal and streptococcal cellulitis may have similar features. Even with needle aspiration of the leading edge or a punch biopsy of the cellulitis tissue itself, cultures are positive in only 20% of cases. This observation suggests that relatively low numbers of bacteria may cause cellulitis and that the expanding area of erythema within the skin may be a direct effect of extracellular toxins or of the soluble mediators of inflammation elicited by the host.

Bacteria may gain access to the epidermis through cracks in the skin, abrasions, cuts, burns, insect bites, surgical incisions, and intravenous catheters. Cellulitis caused by *S. aureus* spreads from a central localized infection, such as an abscess, folliculitis, or an infected foreign body (e.g., a splinter, a prosthetic device, or an intravenous catheter). In contrast, cellulitis due to *S. pyogenes* is a more rapidly spreading, diffuse process frequently associated with lymphangitis and fever. Recurrent streptococcal cellulitis of the lower extremities may be caused by organisms of group A, C, or G in association with chronic venous stasis or with saphenous venectomy for coronary artery bypass surgery. Streptococci also cause recurrent cellulitis among patients with chronic lymphedema resulting from elephantiasis, lymph node dissection, or Milroy's disease. Recurrent staphylococcal cutaneous infections are more common among individuals who have eosinophilia and elevated serum levels of IgE (Job's syndrome) and among nasal carriers of staphylococci. Cellulitis caused by *Streptococcus agalactiae* (group B *Streptococcus*) occurs primarily in elderly patients and those with diabetes mellitus or peripheral vascular disease. *Haemophilus influenzae* typically causes periorbital cellulitis in children in association with sinusitis, otitis media, or epiglottitis. It is unclear whether this form of cellulitis will (like meningitis) become less common as a result of the impressive efficacy of the *H. influenzae* type b vaccine.

Many other bacteria also cause cellulitis. Fortunately, these organisms occur in such characteristic settings that a good history provides useful clues to the diagnosis. Cellulitis associated with cat bites and, to a lesser degree, with dog bites is commonly caused by *Pasteurella multocida*, although in the latter case *Staphylococcus intermedius* and *Capnocytophaga canimorsus* (formerly DF-2) must also be considered. Sites of cellulitis and abscesses associated with dog bites and human bites also contain a variety of anaerobic organisms, including *Fusobacterium*, *Bacteroides*, aerobic and anaerobic streptococci, and *Eikenella corrodens*. *Pasteurella* is notoriously resistant to dicloxacillin and nafcillin but is sensitive to all other β-lactam antimicrobials as well as to quinolones, tetracycline, and erythromycin. Ampicillin/clavulanate, ampicillin/sulbactam, and cefoxitin are good choices for the treatment of animal or human bite infections. *Aeromonas hydrophila* causes aggressive cellulitis in tissues surrounding lacerations sustained in fresh water (lakes, rivers, and streams). This organism remains sensitive to aminoglycosides, fluoroquinolones, chloramphenicol, trimethoprim-sulfamethoxazole, and third-generation cephalosporins; it is resistant to ampicillin, however.

P. aeruginosa causes three types of soft tissue infection: ecthyma gangrenosum in neutropenic patients, hot-tub folliculitis, and cellulitis following penetrating injury. Most commonly, *P. aeruginosa* is introduced into the deep tissues when a person steps on a nail. Treatment includes surgical inspection and drainage, particularly if the injury also involves bone or joint capsule. Choices for empirical treatment while antimicrobial susceptibility data are awaited include an aminoglycoside, a third-generation cephalosporin (ceftazidime, cefoperazone, or cefotaxime), a semisynthetic penicillin (ticarcillin, mezlocillin, or piperacillin), or a fluoroquinolone (although drugs of the last class are not indicated for the treatment of children $<$13 years old).

Gram-negative bacillary cellulitis, including that due to *P. aeruginosa*, is most common among hospitalized, immunocompromised hosts. Cultures and sensitivity tests are critically important in this setting because of multidrug resistance (Chap. 136).

The gram-positive aerobic rod *Erysipelothrix rhusiopathiae* is most often associated with fish and domestic swine and causes cellulitis primarily in bone renderers and fishmongers. *E. rhusiopathiae* remains susceptible to most β-lactam antibiotics (including penicillin), erythromycin, clindamycin, tetracycline, and cephalosporins but is resistant to sulfonamides, chloramphenicol, and vancomycin. Its resistance to vancomycin, which is unusual among gram-positive bacteria, is of potential clinical significance since this agent is sometimes used in empirical therapy for skin infection. Fish food containing the water flea *Daphnia* is sometimes contaminated with *M. marinum*, which can cause cellulitis or granulomas on skin surfaces exposed to the water in aquariums or injured in swimming pools. Rifampin plus ethambutol has been an effective therapeutic combination in some cases, although no comprehensive studies have been undertaken. In addition, some strains of *M. marinum* are susceptible to tetracycline or to trimethoprim-sulfamethoxazole.

NECROTIZING FASCIITIS (Table 110-1) Necrotizing fasciitis, formerly called streptococcal gangrene, may be associated with group A *Streptococcus* or mixed aerobic-anaerobic bacteria or may occur as part of gas gangrene caused by *Clostridium perfringens*. Early diagnosis may be difficult when pain or unexplained fever is the only presenting manifestation. Swelling then develops and is followed by brawny edema and tenderness. With progression, dark red induration of the epidermis appears, along with bullae filled with blue or purple fluid. Later the skin becomes friable and takes on a bluish, maroon, or black color. By this stage, thrombosis of blood vessels in the dermal papillae (Fig. 110-1) is extensive. Extension of infection to the level of the deep fascia causes this tissue to take on a brownish-gray appearance. Rapid spread occurs along fascial planes, through venous channels and lymphatics. Patients in the later stages are toxic and frequently manifest shock and multiorgan failure.

Necrotizing fasciitis caused by mixed aerobic-anaerobic bacteria begins with a breach in the integrity of a mucous membrane barrier, such as the mucosa of the gastrointestinal or genitourinary tract. The portal can be a malignancy, diverticulum, hemorrhoid, anal fissure, or urethral tear. Other predisposing factors include peripheral vascular disease, diabetes mellitus, surgery, and penetrating injury to the abdomen. Leakage into the perineal area results in a syndrome called *Fournier's gangrene*, characterized by massive swelling of the scrotum and penis with extension into the perineum or the abdominal wall and legs.

Necrotizing fasciitis caused by *S. pyogenes* has increased in frequency and severity since 1985. It frequently begins deep at the site of a nonpenetrating minor trauma, such as a bruise or a muscle strain. Seeding of the site via transient bacteremia is likely, although most patients deny antecedent streptococcal infection. Alternatively, *S. pyogenes* may reach the deep fascia from a site of cutaneous infection or penetrating trauma. Toxicity is severe, and renal impairment may precede the development of shock. In 20 to 40% of cases, myositis occurs concomitantly, and, as in gas gangrene (see below), serum creatine phosphokinase values may be markedly elevated. Necrotizing fasciitis due to mixed aerobic-anaerobic bacteria may be associated with gas in the deep tissue, but gas is not usually present when the cause is *S. pyogenes*. Prompt surgical exploration down to the deep fascia and muscle is essential. Necrotic tissue must be surgically removed, and Gram's staining and culture of excised tissue are useful

in establishing whether group A streptococci, mixed aerobic-anaerobic bacteria, or *Clostridium* species are present (see "Treatment," below).

MYOSITIS/MYONECROSIS (Table 110-1) Muscle involvement can occur with viral infection (e.g., influenza, dengue, or coxsackievirus B infection) or parasitic invasion (e.g., trichinellosis, cysticercosis, or toxoplasmosis). Although myalgia can occur in most of these infections, severe muscle pain is the hallmark of pleurodynia (coxsackievirus B), trichinellosis, and bacterial infection. Acute rhabdomyolysis predictably occurs with clostridial and streptococcal myositis but may also be associated with influenza virus, echovirus, coxsackievirus, Epstein-Barr virus, and *Legionella* infection.

Pyomyositis is usually due to *S. aureus*, is common in tropical areas, and generally has no known portal of entry. Infection remains localized, and shock does not develop unless organisms produce toxic shock syndrome toxin 1 or certain enterotoxins and the patient lacks antibodies to the toxin produced by the infecting organisms. In contrast, *S. pyogenes* may induce primary myositis (referred to as *streptococcal necrotizing myositis*) in association with severe systemic toxicity. Myonecrosis occurs concomitantly with necrotizing fasciitis in ~50% of cases. Both are part of the streptococcal toxic shock syndrome.

Gas gangrene usually follows severe penetrating injuries that result in interruption of the blood supply and introduction of soil into wounds. Such cases of traumatic gangrene are usually caused by the clostridial species *C. perfringens*, *C. septicum*, or *C. histolyticum*. Rarely, latent or recurrent gangrene can occur years after penetrating trauma; dormant spores that reside at the site of previous injury are most likely responsible. Spontaneous nontraumatic gangrene among patients with neutropenia, gastrointestinal malignancy, diverticulosis, or recent radiation therapy to the abdomen is caused by several clostridial species, of which *C. septicum* is the most commonly involved. The tolerance of this anaerobe to oxygen probably explains why it can initiate infection spontaneously in normal tissue anywhere in the body.

Synergistic nonclostridial anaerobic myonecrosis, also known as necrotizing cutaneous myositis and synergistic necrotizing cellulitis, is a variant of necrotizing fasciitis caused by mixed aerobic and anaerobic bacteria with the exclusion of clostridial organisms (see "Necrotizing Fasciitis," above).

DIAGNOSIS This chapter has emphasized the physical appearance and location of lesions within the soft tissues as important diagnostic clues. The temporal progression of the lesions as well as the patient's travel history, animal exposure or bite history, age, underlying disease status, and lifestyle are also crucial considerations in the formulation of a narrowed differential diagnosis. However, even the astute clinician may find it challenging to diagnose all infections of the soft tissues by history and inspection alone. Soft tissue radiography, computed tomography, and magnetic resonance imaging may be useful in determining the depth of infection and should be performed in patients with rapidly progressing lesions or in those with evidence of systemic inflammatory response syndrome. These tests are particularly valuable

TABLE 110-2 *Treatment of Common Infections of the Skin*

Diagnosis/Condition	Primary Treatment	Alternative Treatment	See Also Chap(s).
Animal bite (prophylaxis or early infection)[a]	Amoxicillin/clavulanate, 875/125 mg PO bid	Doxycycline, 100 mg PO bid	. . .
Animal bite[a] (established infection)	Ampicillin/sulbactam, 1.5–3.0 g IV q6h	Clindamycin, 600–900 mg IV q8h *plus* Ciprofloxacin, 400 mg IV q12h *or* Cefoxitin, 2 g IV q6h	. . .
Bacillary angiomatosis	Erythromycin, 500 mg PO qid	Doxycycline, 100 mg PO bid	144
Herpes simplex (primary genital)	Acyclovir, 400 mg PO tid for 10 days	Famciclovir, 250 mg PO tid for 5–10 days *or* Valacyclovir, 1000 mg PO bid for 10 days	163
Herpes zoster (immunocompetent host >50 years of age)	Acyclovir, 800 mg PO 5 times daily for 7–10 days	Famciclovir, 500 mg PO tid for 7–10 days *or* Valacyclovir, 1000 mg PO tid for 7 days	164
Cellulitis (staphylococcal or streptococcal[b,c])	Nafcillin or oxacillin, 2 g IV q4–6h	Cefazolin, 1–2 g q8h *or* Ampicillin/sulbactam, 1.5–3.0 g IV q6h *or* Erythromycin, 0.5–1.0 g IV q6h *or* Clindamycin, 600–900 mg IV q8h	120, 121
Necrotizing fasciitis (group A streptococcal[b])	Clindamycin, 600–900 mg IV q6–8h *plus* Penicillin G, 4 million units IV q4h	Clindamycin, 600–900 mg IV q6–8h *plus* Cephalosporin (first- or second-generation)	121
Necrotizing fasciitis (mixed aerobes and anaerobes)	Ampicillin, 2 g IV q4h *plus* Clindamycin, 600–900 mg IV q6–8h *plus* Ciprofloxacin, 400 mg IV q6–8h	Vancomycin, 1 g IV q6h *plus* Metronidazole, 500 mg IV q6h *plus* Ciprofloxacin, 400 mg IV q6–8h	148
Gas gangrene	Clindamycin, 600–900 mg IV q6–8h *plus* Penicillin G, 4 million units IV q4–6h	Clindamycin, 600–900 mg IV q6–8h *plus* Cefoxitin, 2 g IV q6h	126

[a] *Pasteurella multocida*, a species commonly associated with both dog and cat bites, is resistant to cephalexin, dicloxacillin, clindamycin, and erythromycin. *Eikenella corrodens*, a bacterium commonly associated with human bites, is resistant to clindamycin, penicillinase-resistant penicillins, and metronidazole but is sensitive to trimethoprim-sulfamethoxazole and fluoroquinolones.

[b] The frequency of erythromycin resistance in group A *Streptococcus* is currently ~5% in the United States but has reached 70 to 100% in some other countries. Most, but not all, erythromycin-resistant group A streptococci are susceptible to clindamycin. Approximately 90 to 95% of *Staphylococcus aureus* strains are sensitive to clindamycin.

[c] Severe hospital-acquired *S. aureus* infections or community-acquired *S. aureus* infections that are not responding to the β-lactam antibiotics recommended in this table may be caused by methicillin-resistant strains, requiring a switch to vancomycin or linezolid.

for defining a localized abscess or detecting gas in tissue. Unfortunately, they may reveal only soft tissue swelling and thus are not specific for fulminant infections such as necrotizing fasciitis or myonecrosis caused by group A *Streptococcus*, where gas is not found in lesions.

Aspiration of the leading edge or punch biopsy with frozen section may be helpful if the results are positive, but false-negative results occur in ~80% of cases. There is some evidence that aspiration alone may be superior to injection and aspiration using normal saline. Frozen sections are especially useful in distinguishing SSSS from TEN and are quite valuable in cases of necrotizing fasciitis. Open surgical inspection with debridement as indicated is clearly the best way to determine the extent and severity of infection and to obtain material for Gram's staining and culture. Such an aggressive approach is important and may be lifesaving if undertaken early in the course of fulminant infections where there is evidence of systemic toxicity.

TREATMENT

A full description of the treatment of all the clinical entities described herein is beyond the scope of this chapter. As a guide to the clinician in selecting appropriate treatment, the antimicrobial agents useful in the most common and the most fulminant cutaneous infections are listed in Table 110-2.

Early and aggressive surgical exploration is essential in patients with suspected necrotizing fasciitis, myositis, or gangrene in order to (1) visualize the deep structures, (2) remove necrotic tissue, (3) reduce compartment pressure, and (4) obtain suitable material for Gram's staining and for aerobic and anaerobic cultures. Appropriate empirical antibiotic treatment for mixed aerobic-anaerobic infections could consist of ampicillin/sulbactam, cefoxitin, or the following combination: (1) clindamycin (600 to 900 mg intravenously every 8 h) or metronidazole (750 mg every 6 h) plus (2) ampicillin or ampicillin/sulbactam (2 to 3 g intravenously every 6 h) plus (3) gentamicin (1.0 to 1.5 mg/kg every 8 h). Group A streptococcal and clostridial infection of the fascia and/or muscle carries a mortality rate of 20 to 50% with penicillin treatment. In experimental models of streptococcal and clostridial necrotizing fasciitis/myositis, clindamycin has exhibited markedly superior efficacy, but no comparative trials have been performed in humans. Hyperbaric oxygen treatment may also be useful in gas gangrene due to clostridial species. Antibiotic treatment should be continued until all signs of systemic toxicity have resolved, all devitalized tissue has been removed, and granulation tissue has developed (Chaps. 121, 126, and 148).

In summary, infections of the skin and soft tissues are diverse in presentation and severity and offer a great challenge to the clinician. This chapter provides an approach to diagnosis and understanding of the pathophysiologic mechanisms involved in these infections. More in-depth information is found in chapters on specific infections.

111 OSTEOMYELITIS

Jeffrey Parsonnet, James H. Maguire

Osteomyelitis, an infection of bone, is caused most commonly by pyogenic bacteria and mycobacteria. As a useful framework for evaluating the patient and planning treatment, cases are classified on the basis of the causative agent; the route, duration, and anatomical location of infection; and local and systemic host factors.

PATHOGENESIS AND PATHOLOGY Microorganisms enter bone by the hematogenous route, by direct introduction from a contiguous focus of infection, or by a penetrating wound. Trauma, ischemia, and foreign bodies enhance the susceptibility of bone to microbial invasion by exposing sites to which bacteria can bind. Phagocytes attempt to contain the infection and, in the process, release enzymes that lyse bone. Bacteria escape host defenses by adhering tightly to damaged bone, by entering and persisting within osteoblasts, and by coating themselves and underlying surfaces with a protective polysaccharide-rich biofilm. Pus spreads into vascular channels, raising intraosseous pressure and impairing the flow of blood; as the untreated infection becomes chronic, ischemic necrosis of bone results in the separation of large devascularized fragments (*sequestra*). When pus breaks through the cortex, subperiosteal or soft tissue abscesses form, and the elevated periosteum deposits new bone (an *involucrum*) around the sequestrum.

Microorganisms, infiltrates of neutrophils, and congested or thrombosed blood vessels are the principal histologic findings of acute osteomyelitis. The distinguishing feature of chronic osteomyelitis is necrotic bone, which is characterized by the absence of living osteocytes. Mononuclear cells predominate in chronic infections, and granulation and fibrous tissues replace bone that has been resorbed by osteoclasts. In the chronic stage, organisms may be too few to be seen on staining.

HEMATOGENOUS OSTEOMYELITIS Hematogenous infection accounts for ~20% of cases of osteomyelitis and primarily affects children, in whom the long bones are infected, and older adults and intravenous drug users, in whom the spine is the most common site of infection.

Acute Hematogenous Osteomyelitis Infection usually involves a single bone, most commonly the tibia, femur, or humerus in children and vertebral bodies in older adults and injection drug users. Bacteria settle in the well-perfused metaphysis of growing bones where functioning phagocytes are scarce, a network of venous sinusoids slows the flow of blood, and fenestrations in capillaries allow organisms to escape into the extravascular space. Because vascular anatomy changes with age, hematogenous infection of long bones is uncommon during adulthood and, when it occurs, usually involves the diaphysis.

On presentation, the child with osteomyelitis usually appears acutely ill, with high fever, chills, and localized pain and tenderness and often with restriction of movement or difficulty bearing weight. Cutaneous erythema and swelling indicate extension of pus through the cortex. During infancy and after puberty, infection may spread through the epiphysis into the joint space. In children of other ages, extension of infection through the cortex results in involvement of joints if the metaphysis is intracapsular. Thus, septic arthritis of the elbow, shoulder, and hip may complicate osteomyelitis of the proximal radius, humerus, and femur, respectively. In children, the source of bacteremia is usually inapparent. A history is often obtained of recent blunt trauma to the area involved; presumably, this event results in a small intraosseous hematoma or vascular obstruction. Adults with osteomyelitis may present in the context of an apparent infection elsewhere, such as the lung, sinuses, or urinary tract, or without an obvious source of bacteremia.

Plain radiographs obtained early in the course of infection may show soft tissue swelling, but the first change in bone—a periosteal

reaction—is not evident until at least 10 days after the onset of infection. Lytic changes can be detected after 2 to 6 weeks, when 50 to 75% of bone density has been lost. Rarely, a well-circumscribed lytic lesion, or *Brodie's abscess*, is seen in a child who has been in pain for several months but has had no fever.

Vertebral Osteomyelitis The vertebral bodies are the most common sites of acute hematogenous osteomyelitis in adults. Organisms reach the well-perfused vertebral body via spinal arteries and quickly spread from the end plate into the disk space and then to the adjacent vertebral body. The infection may originate in the urinary tract, and it does so particularly often among men over age 50. Other sources of bacteremia include endocarditis, dental abscess, soft tissue infection, and a contaminated intravenous line; these sources may or may not be obvious. Diabetes mellitus, hemodialysis, and injection drug use carry an increased risk of spinal infection. Many patients have a history of degenerative joint disease involving the spine, and some report an episode of trauma preceding the onset of infection. Penetrating injuries and surgical procedures to the spine may cause nonhematogenous vertebral osteomyelitis or infection localized to the disk.

Most patients with vertebral osteomyelitis report neck or back pain; patients may describe atypical pain in the chest, the abdomen, or an extremity that is due to irritation of nerve roots. Symptoms are localized to the lumbar spine more often than to the thoracic spine (>50% vs. 35% of cases) or the cervical spine in pyogenic infections, but the thoracic spine is involved most commonly in tuberculous spondylitis (Pott's disease). More than 50% of patients experience a subacute illness in which a vague, dull pain gradually intensifies over 2 to 3 months. Fever is usually low grade or absent, but some patients recall having had an episode of fever and chills prior to or at the onset of pain. An acute presentation with high fever and toxicity is less common and suggests ongoing bacteremia. Percussion over the involved vertebra elicits tenderness, and physical examination may reveal spasm of the paraspinal muscles and limitation of motion.

Laboratory findings at the time of presentation include a normal or modestly elevated white blood cell count and, almost invariably, an increased erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) level. Blood cultures are positive only 20 to 50% of the time.

Usually, by the time the patient seeks medical attention, plain radiographs show irregular erosions in the end plates of adjacent vertebral bodies and narrowing of the intervening disk space. This radiographic pattern is virtually diagnostic of bacterial infection because tumors and other diseases of the spine rarely cross the disk space. Computed tomography (CT) or magnetic resonance imaging (MRI) may demonstrate epidural, paraspinal, retropharyngeal, mediastinal, retroperitoneal, or psoas abscesses that originate in the spine.

A spinal epidural abscess may evolve suddenly or over several weeks; the classic clinical presentation is spinal pain progressing to radicular pain and/or weakness. Irreversible paralysis may result from failure to recognize epidural abscess before the development of neurologic deficits. MRI is the best procedure for detection of epidural abscess and should be performed in all cases of vertebral osteomyelitis accompanied by subjective weakness or objective neurologic abnormalities.

Microbiology More than 95% of cases of hematogenous osteomyelitis are caused by a single organism. *Staphylococcus aureus* accounts for 50% of isolates. Other common pathogens include group B streptococci and *Escherichia coli* during the newborn period and group A streptococci in early childhood. Vertebral osteomyelitis is due to *E. coli* and other enteric bacilli in ~25% of cases. *S. aureus*, *Pseudomonas aeruginosa*, and *Serratia* infections are associated with intravenous drug use in some parts of the United States and may involve the sacroiliac, sternoclavicular, or pubic joints as well as the spine. *Salmonella* spp. and *S. aureus* are the major causes of long-bone osteomyelitis complicating sickle cell anemia and other hemoglobinopathies. Tuberculosis and brucellosis affect the spine more often than other bones. Other common sites of tuberculous osteomyelitis include the small bones of the hands and feet, the metaphyses of long bones, the ribs, and the sternum.

Unusual causes of hematogenous osteomyelitis include disseminated histoplasmosis, coccidioidomycosis, and blastomycosis in endemic areas. Immunocompromised persons on rare occasions develop osteomyelitis due to atypical mycobacteria, *Bartonella henselae*, or *Pneumocystis* or to species of *Candida*, *Cryptococcus*, or *Aspergillus*. Hematogenous osteomyelitis with *Mycobacterium bovis* has been reported following intravesicular instillation of bacille Calmette-Guérin (BCG) for cancer of the bladder. The etiology of chronic relapsing multifocal osteomyelitis, an inflammatory condition of children that is characterized by recurrent episodes of painful lytic lesions in multiple bones, has not been identified.

OSTEOMYELITIS SECONDARY TO A CONTIGUOUS FOCUS OF INFECTION ■ Clinical Features This broad category of osteomyelitis accounts for ~80% of all cases and occurs most commonly in adults. It includes infections introduced by penetrating injuries, such as bites, puncture wounds, and open fractures; by surgical procedures; and by direct extension of infection from adjacent soft tissues. Generalized vascular insufficiency and the presence of a foreign body are important predisposing factors and make infection more difficult to cure.

Frequently, the diagnosis of this type of osteomyelitis is not made until the infection has already become chronic. The pain, fever, and inflammatory signs due to acute infection may be attributed to the original injury or to overlying soft tissue infection. An indolent infection may become apparent only weeks or months later, when a sinus tract develops, a surgical wound breaks down, or a fracture fails to heal. It may be impossible to distinguish radiographic abnormalities due to osteomyelitis from those due to the precipitating condition.

A special type of contiguous-focus osteomyelitis occurs in the setting of peripheral vascular disease and nearly always involves the small bones of the feet of adult diabetic patients. This type of infection is a major cause of morbidity and hospitalization for patients with diabetes and results in many thousands of amputations per year. Diabetic neuropathy exposes the foot to frequent trauma and pressure sores, and the patient may be unaware of infection as it spreads into bone. Poor tissue perfusion impairs normal inflammatory responses and wound healing and creates a milieu that is conducive to anaerobic infections. It is often during the evaluation of a nonhealing ulcer, a swollen toe, or acute cellulitis that a radiograph provides the first evidence of osteomyelitis. If bone is palpable during examination of the base of an ulcer with a blunt surgical probe, osteomyelitis is likely.

Microbiology *S. aureus* is a pathogen in more than half of cases of contiguous-focus osteomyelitis. However, in contrast to hematogenous osteomyelitis, these infections are often polymicrobial and are more likely to involve gram-negative and anaerobic bacteria. Hence a mixture of staphylococci, streptococci, enteric organisms, and anaerobic bacteria may be isolated from a diabetic foot infection or pelvic osteomyelitis underlying a decubitus ulcer. Aerobic and anaerobic bacteria cause osteomyelitis following surgery or soft tissue infection of the oropharynx, paranasal sinuses, gastrointestinal tract, or female genital tract. A human bite may result in mixed infection of the hand, with anaerobes included among the etiologic agents. *S. aureus* is the principal cause of postoperative infections; coagulase-negative staphylococci are common pathogens after implantation of orthopedic appliances; and these organisms as well as gram-negative enteric bacilli, atypical mycobacteria, and *Mycoplasma* may cause sternal osteomyelitis after cardiac surgery. Infection with *P. aeruginosa* is frequently associated with puncture wounds of the foot (especially by a nail through a sneaker) or with thermal burns, and *Pasteurella multocida* infection commonly follows cat bites.

CHRONIC OSTEOMYELITIS With prompt treatment, fewer than 5% of cases of acute hematogenous osteomyelitis progress to chronic osteomyelitis. Chronic osteomyelitis is more likely to develop in contiguous-focus than in hematogenous osteomyelitis. The presence of a foreign body makes establishment of chronic infection especially likely.

A protracted clinical course, long periods of quiescence, and recurrent exacerbations are characteristic of chronic osteomyelitis. Sinus tracts between bone and skin may drain purulent material and occasionally pieces of necrotic bone. An increase in drainage, pain, or ESR signals an exacerbation. Fever is unusual except when obstruction of a sinus tract leads to soft tissue infection. Rare late complications include pathologic fractures, squamous cell carcinoma of the sinus tract, and amyloidosis.

DIAGNOSIS Early diagnosis of acute osteomyelitis is critical because prompt antibiotic therapy may prevent the necrosis of bone. The ESR and CRP levels are elevated in most cases of active osteomyelitis, including those in which constitutional symptoms and leukocytosis are lacking. These findings are not specific to osteomyelitis, however, and the ESR is occasionally normal in early infections. Baseline values are often useful in monitoring the efficacy of treatment. A variety of radiologic tests are available for evaluation of osteomyelitis (Table 111-1). Evaluation usually begins with plain radiographs because of their ready availability, although they frequently show no abnormalities during early infection. Three-phase bone scans (^{99}Tc-monodiphosphonate) offer high sensitivity but often have low specificity, especially in the presence of underlying bony abnormalities. There is a lack of consensus over the optimal use of other radionuclide studies, and there is considerable variation between institutions in their use. Although the use of MRI (Fig. 111-1) is expanding because of high sensitivity and specificity, this modality is not available at all institutions.

The role of diagnostic imaging in chronic osteomyelitis is to detect active infection and delineate the extent of debridement necessary to remove necrotic bone and abnormal soft tissues. Although plain films accurately reflect chronic changes, CT is more sensitive for the detection of sequestra, sinus tracts, and soft tissue abscesses. Both CT and ultrasound are useful for guiding percutaneous aspiration of subperiosteal and soft tissue fluid collections. Sequential technetium and gallium or indium scans may help determine whether infection is active and may distinguish infection from noninflammatory bone changes. MRI provides superior information about the anatomical extent of infection but does not always distinguish osteomyelitis from healing fractures and tumors. MRI is particularly useful in distinguishing cellulitis from osteomyelitis in the diabetic foot; however, no imaging modality consistently distinguishes infection from neuropathic osteopathy.

FIGURE 111-1 Osteomyelitis of the thoracic spine demonstrated on a sagittal, fat-suppressed T1-weighted magnetic resonance image after the administration of intravenous gadolinium. At T8–T9, there is involvement of the adjacent vertebral bodies and intervening disk. Abnormally enhancing inflammatory tissue extends from the disk space anteriorly (*white arrow*) as well as posteriorly into the epidural space, compressing the thecal sac (*black arrow*).

TABLE 111-1 *Diagnostic Imaging Studies for Osteomyelitis*

Type of Study	*Comments*
Plain radiographs	Insensitive, especially in early osteomyelitis. May show periosteal elevation after 10 days, lytic changes after 2–6 weeks. Useful to look for anatomical abnormalities (e.g., fractures, bony variants, or deformities), foreign bodies, and soft tissue gas.
Three-phase bone scan (^{99m}Tc-MDP)	Characteristic finding in osteomyelitis: increased uptake in all three phases of scan. Highly sensitive (~95%) in acute infection; somewhat less sensitive if blood flow to bone is poor. Specificity moderate if plain films are normal, but poor in presence of neuropathic arthropathy, fractures, tumor, infarction.
Other radionuclide scans	Examples: ^{67}Ga-citrate, ^{111}In-labeled WBCs. ^{111}In-WBCs more specific than gallium but not always available. Often used in conjunction with bone scan because its greater specificity for inflammation than ^{99m}Tc-MDP helps to distinguish infectious from noninfectious processes. Lack of consensus over role in routine evaluation.
Ultrasound	May detect subperiosteal fluid collection or soft tissue abscess adjacent to bone, but largely supplanted by CT and MRI.
CT	Limited role in acute osteomyelitis. In chronic osteomyelitis, excellent for detection of sequestra, cortical destruction, soft tissue abscesses, and sinus tracts. Use may be limited by metallic foreign body.
MRI	As sensitive as ^{99m}Tc-MDP bone scan for acute osteomyelitis (~95%); detects changes in water content of marrow before disruption of cortical bone. High specificity (~87%), with better anatomical detail than nuclear studies. Procedure of choice for vertebral osteomyelitis because of high sensitivity for epidural abscess. Use may be limited by metallic foreign body.

Abbreviations: CT, computed tomography; MDP, monodiphosphonate; MRI, magnetic resonance imaging; WBCs, white blood cells.

The results of culture of specimens obtained by swabbing of a sinus tract or the base of an ulcer correlate poorly with the organisms infecting the bone. For this reason, in cases of chronic osteomyelitis and contiguous-focus osteomyelitis, samples for aerobic and anaerobic culture should be obtained from several sites by percutaneous needle aspiration, percutaneous biopsy, or intraoperative biopsy at the time of debridement. Isolates of coagulase-negative staphylococci and other organisms of low virulence should not automatically be disregarded as contaminants, especially in the presence of prosthetic materials. Special culture media may be necessary for the isolation of mycobacteria, fungi, and less common pathogens. In some cases, histopathologic examination of biopsy specimens may be the only way to make a diagnosis.

Appropriate samples for microbiologic studies should be obtained in all cases of suspected osteomyelitis before the initiation of antimicrobial therapy. Blood cultures are indicated in acute cases and are positive in more than one-third of cases of hematogenous osteomyelitis in children and in 25% of cases of vertebral osteomyelitis in adults. The presence of sepsis occasionally requires initiation of empirical therapy after blood samples alone have been obtained for culture. If blood cultures are negative, samples from needle aspiration of pus in bone or soft tissues or from a bone biopsy should be obtained for culture; in the case of vertebral osteomyelitis, these samples can usually be obtained with the guidance of fluoroscopy or CT scan.

℞ TREATMENT

Antibiotic Therapy (Table 111-2) Antibiotics are administered only after appropriate specimens have been obtained for culture. The antibiotics selected should be bactericidal, should be given at a high dose, and—at least initially—should be given intravenously. When necessary, empirical therapy is guided by findings on Gram's staining of a specimen from the bone or abscess or is chosen to cover the most

TABLE 111-2 *Selection of Antibiotics for Treatment of Acute Osteomyelitis*

Organism	Suggested Regimen[a]	
	Primary	Alternative[b]
Staphylococcus aureus		
Penicillin-resistant, methicillin-sensitive (MSSA)	Nafcillin or oxacillin, 2 g IV q4h	Cefazolin, 1 g IV q8h; ceftriaxone, 1 g IV q24h; clindamycin, 900 mg IV q8h[c]
Penicillin-sensitive	Penicillin 3–4 million U IV q4h	Cefazolin, ceftriaxone, clindamycin (as above)
Methicillin-resistant (MRSA)	Vancomycin, 15 mg/kg (up to 1 g) IV q12h	Clindamycin[c] (as above); linezolid, 600 mg IV or PO q12h[d]; daptomycin, 4–6 mg/kg per day IV[d]
Streptococci (including *S. milleri*, β-hemolytic streptococci)	Penicillin (as above)	Cefazolin, ceftriaxone, clindamycin (as above)
Gram-negative aerobic bacilli		
Escherichia coli, other "sensitive" species	Ampicillin, 2 g IV q4h; cefazolin, 1 g IV q8h	Ceftriaxone, 1 g IV q24h; parenteral or oral fluoroquinolone (e.g., ciprofloxacin, 400 mg IV or 750 mg PO q12h)[e]
Pseudomonas aeruginosa	Extended-spectrum β-lactam agent (e.g., piperacillin, 3–4 g IV q4–6h or ceftazidime, 2 g IV q12h) *plus* tobramycin, 5–7 mg/kg q24h[f]	May substitute parenteral or oral fluoroquinolone for β-lactam agent
Enterobacter spp., other "resistant" species	Extended-spectrum β-lactam agent IV or fluoroquinolone IV or PO[e] (as above)	
Mixed infections possibly involving anaerobic bacteria	Ampicillin/sulbactam, 1.5–3 g IV q6h; piperacillin/tazobactam 3.375 g IV q6h	Cefotetan, 1–2 g IV q12h; combination of fluoroquinolone plus clindamycin (as above)

[a] Duration of treatment is discussed in the text.
[b] Cephalosporins may be used for the treatment of patients allergic to penicillin whose reaction did not consist of anaphylaxis or urticaria (immediate-type hypersensitivity).
[c] Because of the possibility of inducible resistance, clindamycin must be used with caution for the treatment of strains resistant to erythromycin. Consult clinical microbiology laboratory.
[d] Experience is limited; there are anecdotal reports of efficacy.
[e] Oral fluoroquinolones must not be coadministered with divalent cations (calcium, magnesium, iron, aluminum), which block the drugs' absorption.
[f] Tobramycin levels and renal function must be monitored closely to minimize the risks of nephro- and ototoxicity.

likely pathogens. Empirical therapy in most cases should include high doses of an agent active against *S. aureus* (such as oxacillin, nafcillin, cefazolin, or vancomycin) and—if gram-negative organisms are likely to be involved—a third-generation cephalosporin, an aminoglycoside, or a fluoroquinolone.

Specific intravenous therapy is based on the in vitro susceptibility of the organism(s) isolated from bone or blood. At-home intravenous administration of antibiotics or oral therapy is appropriate for motivated and medically stable patients and represents a significant advance in management. Antibiotics that require infrequent dosing, such as ceftriaxone, may facilitate home therapy. Many antibiotics can be given automatically by portable infusion pump, which decreases the disruption otherwise caused by the frequent administration of drug. Use of a peripherally inserted central catheter (PICC line) also facilitates outpatient administration of antibiotics. Outpatient therapy requires close coordination of nursing, pharmacy, and physician care, with clear delineations of responsibility for monitoring safety and efficacy.

Children with acute hematogenous osteomyelitis routinely receive oral antibiotics after 5 to 10 days of parenteral therapy if signs of active infection have resolved; such treatment has been as successful as standard parenteral therapy. The doses of oral penicillins or cephalosporins required for the treatment of osteomyelitis are several times higher than the doses of these drugs given for common infections. Adults may not tolerate these high doses as well as children, and, except in the case of the fluoroquinolones and rifampin, few data support the use of oral antibiotics by adults. For treatment of osteomyelitis due to Enterobacteriaceae, oral administration of a fluoroquinolone has been as successful as intravenous administration of β-lactam antibiotics. Caution should be exercised in the use of fluoroquinolones as the sole agents for treatment of infection due to *S. aureus* or *P. aeruginosa* because resistance may develop during therapy. Addition of rifampin to a fluoroquinolone or a β-lactam agent has yielded encouraging results in infections due to *S. aureus*, but potential drug toxicity and drug interactions make this option desirable only for selected patients, such as those with necrotic bone that cannot be adequately debrided. Oral administration of clindamycin (300 to 450 mg every 6 h) or metronidazole (500 mg every 8 h) results in high drug levels in serum and can take the place of intravenous regimens for the treatment of *Bacteroides* infections. Oral clindamycin has produced good results for continuation treatment of osteomyelitis due to *S. aureus*, but consultation with the microbiology laboratory is advised because of inducible resistance exhibited by some strains. The bacteriostatic drug linezolid (600 mg by mouth every 12 h) and the bactericidal drug daptomycin (4 to 6 mg/kg per day intravenously) have been used successfully in a small number of patients with infection caused by methicillin-resistant *S. aureus* and vancomycin-resistant *Enterococcus*, but data are currently insufficient to recommend their routine use. Data do not support the routine use of the serum minimal bactericidal concentration in guiding therapy.

Acute Hematogenous Osteomyelitis Early treatment of acute hematogenous osteomyelitis of childhood with 4 to 6 weeks of an appropriate antibiotic is usually successful; treatment for <3 weeks has resulted in a 10-fold greater rate of failure. Surgical intervention in childhood cases is indicated for intraosseous or subperiosteal abscesses, concomitant septic arthritis, and failure of the acute signs of infection to improve in 24 to 48 h. Acute hematogenous osteomyelitis of bones other than the spine in adults often requires surgical debridement.

Vertebral Osteomyelitis A 4- to 6-week course of treatment with an appropriate antibiotic is usually sufficient to cure vertebral osteomyelitis. Failure of the ESR to drop by two-thirds or more of its pretreatment level or of CRP to normalize is an indication for reevaluation and (possibly) longer treatment. Surgery is seldom necessary, even in cases of many months' duration, except in instances of spinal instability, new or progressive neurologic deficits, or large soft-tissue abscesses that cannot be drained percutaneously. All but small and asymptomatic epidural abscesses should be surgically drained. Patients should maintain bed rest until back pain has declined to the point at which ambulation is possible. Body casts are no longer used except for comfort.

Contiguous-Focus Osteomyelitis Even when diagnosed early, contiguous-focus osteomyelitis usually requires surgery in addition to 4 to 6 weeks of appropriate antibiotic therapy because of underlying soft tissue infection or damage to bone from an injury or surgery. A 2-week course of antibiotics following thorough debridement and soft tissue coverage has yielded excellent results in the treatment of superficial osteomyelitis involving only the outer cortex of bone.

Chronic Osteomyelitis The risks and benefits of aggressive therapy for chronic osteomyelitis should be weighed before any attempt is made to eradicate the infection. Some patients with extensive disease prefer to live with their infections rather than undergo multiple surgical procedures, take prolonged courses of antimicrobial therapy, and face the

risk of loss of an extremity. Such persons often benefit from intermittent courses of oral antibiotics to suppress acute exacerbations.

Once the decision has been made to treat chronic osteomyelitis aggressively, the patient's nutritional and metabolic status should be optimized to expedite healing of soft tissues and bone. Antibiotic administration should be started several days before surgery to reduce inflammation if the etiology of the infection is known; if not, antibiotic therapy should be withheld until debridement. A 4- to 6-week course of appropriate antibiotic therapy is given postoperatively on the basis of the susceptibility pattern of organisms isolated from bone. The benefit of prolonged oral antibiotic therapy after 4 to 6 weeks of parenteral therapy remains unproven. There is insufficient information to recommend either the routine use of hyperbaric oxygen or the use of antibiotic-impregnated methacrylate beads or other depots to deliver high levels of antibiotics to the bone. The success of therapy for chronic osteomyelitis still rests largely on the complete surgical removal of necrotic bone and abnormal soft tissues. In the past, the inability to repair large defects in bone and soft tissue limited the extent of debridement. Muscle flaps and skin grafts are now used routinely to cover large soft-tissue defects and to fill dead space, and bone grafts and vascularized bone transfer may restore a seriously compromised bone to a functional state.

In infections of recent fractures, internal fixators are often left in place, and the infection is controlled by limited debridement and suppressive antibiotic therapy. Definitive surgical/antimicrobial therapy is delayed until after bony union of the fracture is achieved. If there is nonunion of the fracture or loosening of the fixator, the appliance must be removed, the bone debrided, and an external fixator or a new internal fixator applied.

Osteomyelitis of the small bones of the feet in persons with vascular disease usually requires surgical treatment. The effectiveness of the surgery is limited by the blood supply to the site and the body's ability to heal the wound. Revascularization of the extremity is indicated if the vascular disease involves large arteries. In cases of decreased perfusion due to small-vessel disease, foot-sparing surgery may fail, and the best option is often suppressive therapy or amputation. The duration of antibiotic therapy depends on the surgical procedure performed. When the infected bone is removed entirely but residual infection of soft tissues remains, antibiotic therapy should be given for 2 weeks; if amputation eliminates infected bone and soft tissue, standard surgical prophylaxis is given; otherwise, postoperative antibiotics must be given for 4 to 6 weeks.

112 INTRAABDOMINAL INFECTIONS AND ABSCESSES

Dennis L. Kasper, Dori F. Zaleznik

Intraperitoneal infections generally arise because a normal anatomical barrier is disrupted. This disruption may occur when the appendix, a diverticulum, or an ulcer ruptures; when the bowel wall is weakened by ischemia, tumor, or inflammation (e.g., in inflammatory bowel disease); or with adjacent inflammatory processes, such as pancreatitis or pelvic inflammatory disease, in which enzymes (in the former case) or organisms (in the latter) may leak into the peritoneal cavity. Whatever the inciting event, once inflammation develops and organisms usually contained within the bowel or another organ enter the normally sterile peritoneal space, a predictable series of events takes place. Intraabdominal infections occur in two stages: peritonitis and—if the patient survives this stage and goes untreated—abscess formation. The types of microorganisms predominating in each stage of infection are responsible for the pathogenesis of disease.

PERITONITIS

Peritonitis is a life-threatening event that is often accompanied by bacteremia and sepsis syndrome (Chap. 254). The peritoneal cavity is large but is divided into compartments. The upper and lower peritoneal cavities are divided by the transverse mesocolon; the greater omentum extends from the transverse mesocolon and from the lower pole of the stomach to line the lower peritoneal cavity. The pancreas, duodenum, and ascending and descending colon are located in the anterior retroperitoneal space; the kidneys, ureters, and adrenals are found in the posterior retroperitoneal space. The other organs, including liver, stomach, gallbladder, spleen, jejunum, ileum, transverse and sigmoid colon, cecum, and appendix, are found within the peritoneal cavity itself. Normally the cavity is lined with a serous membrane that can serve as a conduit for fluids—a property utilized in peritoneal dialysis. A small amount of fluid, sufficient to allow movement of organs, is normally present in the peritoneal space. This fluid is serous, with a protein content (consisting mainly of albumin) of <30 g/L and <300 white blood cells (WBCs, generally mononuclear cells) per microliter. In the presence of infection, some compartments collect fluid or pus more often than others. These compartments include the pelvis (the lowest portion), the subphrenic spaces on the right and left sides, and Morrison's pouch, which is a posterosuperior extension of the subhepatic spaces and is the lowest part of the paravertebral groove when a patient is recumbent. The falciform ligament separating the right and left subphrenic spaces appears to act as a barrier to the spread of infection; consequently, it is unusual to find bilateral subphrenic collections. In bacterial infections, leukocyte recruitment into the infected peritoneal cavity consists of an early influx of polymorphonuclear leukocytes (PMNs) and a prolonged subsequent phase of mononuclear cell migration. The phenotype of the infiltrating leukocytes during the course of inflammation is regulated primarily by resident-cell chemokine synthesis.

PRIMARY (SPONTANEOUS) BACTERIAL PERITONITIS Peritonitis is either primary (without an apparent source of contamination) or secondary. The types of organisms found and the clinical presentations of these two processes are different. In adults, primary bacterial peritonitis (PBP) occurs most commonly in conjunction with cirrhosis of the liver (frequently the result of alcoholism). However, the disease has been reported in adults with metastatic malignant disease, postnecrotic cirrhosis, chronic active hepatitis, acute viral hepatitis, congestive heart failure, systemic lupus erythematosus, and lymphedema as well as in patients with no underlying disease. PBP virtually always develops in patients with ascites. Nevertheless, it is not a common event, occurring

in ≤10% of cirrhotic patients. The cause of PBP has not been established definitively but is believed to involve hematogenous spread of organisms in a patient in whom a diseased liver and altered portal circulation result in a defect in the usual filtration function. Organisms are able to multiply in ascites, a good medium for growth. The proteins of the complement cascade have been found in peritoneal fluid, with lower levels in cirrhotic patients than in patients with ascites of other etiologies. The opsonic and phagocytic properties of neutrophils are diminished in patients with advanced liver disease.

The presentation of PBP differs from that of secondary peritonitis. The most common manifestation is fever, which is reported in as many as 80% of patients. Ascites is found but virtually always predates infection. Abdominal pain, an acute onset of symptoms, and peritoneal irritation detected during physical examination can be helpful diagnostically, but the absence of any of these findings does not exclude this often-subtle diagnosis. It is vital to sample the peritoneal fluid of any cirrhotic patient with ascites and fever. The finding of >300 PMNs per microliter is diagnostic for PBP, according to Conn. This criterion does not apply to secondary peritonitis (see below). The microbiology of PBP is also distinctive. While enteric gram-negative bacilli such as *Escherichia coli* are most commonly encountered, gram-positive organisms such as streptococci, enterococci, or even pneumococci are sometimes found. In PBP, a single organism is typically isolated; anaerobes are found less frequently in PBP than in secondary peritonitis, in which a mixed flora including anaerobes is the rule. In fact, if PBP is suspected and multiple organisms including anaerobes are recovered from the peritoneal fluid, the diagnosis must be reconsidered and a source of secondary peritonitis sought.

The diagnosis of PBP is not easy. It depends on the exclusion of a primary intraabdominal source of infection. Contrast-enhanced computed tomography (CT) is very useful in identifying an intraabdominal source for infection. It may be difficult to recover organisms from cultures of peritoneal fluid, presumably because the burden of organisms is low. However, the yield can be improved if 10 mL of peritoneal fluid is placed directly into a blood culture bottle. Since bacteremia frequently accompanies PBP, blood should be cultured simultaneously. No specific radiographic studies are helpful in the diagnosis of PBP. A plain film of the abdomen would be expected to show ascites. Chest and abdominal radiography should be performed in patients with abdominal pain to exclude free air, which signals a perforation.

Rx TREATMENT

Treatment for PBP is directed at the isolate from blood or peritoneal fluid. Gram's staining of peritoneal fluid often gives negative results in PBP. Therefore, until culture results become available, empirical therapy should cover gram-negative aerobic bacilli and gram-positive cocci. Third-generation cephalosporins such as cefotaxime [2 g q8h, administered intravenously (IV)] provide reasonable initial coverage in moderately ill patients. Broad-spectrum antibiotics, such as penicillin/β-lactamase inhibitor combinations (e.g., piperacillin/tazobactam, 3.375 g q6h IV) or ceftriaxone (2 g q24h IV), are also options. Empirical coverage for anaerobes is not necessary. After the infecting organism is identified, therapy should be narrowed to target the specific pathogen. Patients with PBP usually respond within 72 h to appropriate antibiotic therapy. Antimicrobial therapy can be administered for as little as 5 days if rapid improvement occurs and blood cultures are negative, but a course of up to 2 weeks may be required for patients with bacteremia and for those whose improvement is slow. Persistence of leukocytes in the ascitic fluid after therapy should initiate a search for additional diagnoses.

Prevention PBP has a high rate of recurrence. Up to 70% of patients reportedly experience a recurrence within 1 year. Antibiotic prophylaxis reduces the rate of recurrence to <20%. Recommended prophylactic regimens include fluoroquinolones (ciprofloxacin, 750 mg weekly; norfloxacin, 400 mg/d) or trimethoprim-sulfamethoxazole (one double-strength tablet per day). However, long-term administration of broad-spectrum antibiotics in this setting has been shown to increase the risk of severe hospital-acquired staphylococcal infections and of high-level resistance to antibiotics.

SECONDARY PERITONITIS Secondary peritonitis develops when bacteria contaminate the peritoneum as a result of spillage from an intraabdominal viscus. The organisms found almost always constitute a mixed flora in which facultative gram-negative bacilli and anaerobes predominate, especially when the contaminating source is colonic. Early in the course of infection, when the host response is directed toward containment of the infection, exudate containing fibrin and PMNs is found. Early death in this setting is attributable to gram-negative bacillary sepsis and to potent endotoxins circulating in the bloodstream (Chap. 254). Gram-negative bacilli, particularly *E. coli*, are common bloodstream isolates, but *Bacteroides fragilis* bacteremia occurs as well. The severity of abdominal pain and the clinical course depend on the inciting process. The species of organisms isolated from the peritoneum also vary with the source of the initial process and the normal flora present at that site. Secondary peritonitis can result primarily from chemical irritation or bacterial contamination. For example, as long as the patient is not achlorhydric, a ruptured gastric ulcer will release low-pH gastric contents that will serve as a chemical irritant. The normal flora of the stomach comprises the same organisms found in the oropharynx (Chap. 148) but in lower numbers. The surfaces of teeth contain $\sim 10^7$ aerobic and 10^7 anaerobic organisms per milliliter of saliva; the normally acidic stomach contains an equal ratio of aerobic and anaerobic species, but in concentrations more in the range of 10^5/mL. After meals, when gastric acidity is highest, this number may fall to 10^3/mL. Thus, the bacterial burden in a ruptured gastric ulcer—or even a duodenal ulcer—is negligible compared with that in a ruptured appendix. The normal flora of the colon below the ligament of Treitz contains $\sim 10^{11}$ anaerobic organisms per gram of feces but only 10^8 aerobes per gram; therefore, anaerobic species account for 99% of the bacteria. Leakage of colonic contents (pH 7 to 8) does not cause significant chemical peritonitis, but infection is intense because of the heavy bacterial load.

Depending on the inciting event, local symptoms may initially be found in secondary peritonitis—for example, epigastric pain from a ruptured gastric ulcer. In appendicitis (Chap. 281), the initial presenting symptoms are often vague, with periumbilical discomfort and nausea followed in a number of hours by pain more localized to the right lower quadrant. Unusual locations of the appendix (including a retrocecal position) can complicate this presentation further. Once infection has spread to the peritoneal cavity, however, pain increases, particularly with infection involving the parietal peritoneum, which is innervated extensively. Patients usually lie motionless, often with knees drawn up to avoid stretching the nerve fibers of the peritoneal cavity. Coughing and sneezing, which increase pressure within the peritoneal cavity, are associated with sharp pain. There may or may not be pain localized to the infected or diseased organ from which secondary peritonitis has arisen. Patients with secondary peritonitis generally have abnormal findings on abdominal examination, with marked voluntary and involuntary guarding of the anterior abdominal musculature. Later findings include tenderness, especially rebound tenderness. In addition, there may be localized findings in the area of the inciting event. In general, patients are febrile, with marked leukocytosis and a left shift of the WBCs to earlier granulocyte forms.

While recovery of organisms from peritoneal fluid is easier in secondary than in primary peritonitis, a tap of the abdomen is rarely the procedure of choice in secondary peritonitis. An exception is in cases involving trauma, where the possibility of a hemoperitoneum may need to be excluded early. Etiologic studies to find the source of peritoneal contamination should be undertaken.

TREATMENT

Treatment for secondary peritonitis includes early administration of antibiotics aimed particularly at aerobic gram-negative bacilli and anaerobes (see below). Mild to moderate disease can be treated with many drugs covering these organisms, including broad-spectrum penicillin/β-lactamase inhibitor combinations (e.g., ticarcillin/clavulanate, 3.1 g q6h IV) or cefoxitin (2 g q24h IV). Patients requiring hospitalization in intensive care should receive imipenem (500 mg q6h IV), meropenem (1 g q8h IV), or combinations of drugs, such as ampicillin plus metronidizole plus ciprofloxacin. Secondary peritonitis usually requires both surgical intervention to address the inciting process and antibiotic administration to treat early bacteremia, to decrease the incidence of abscess formation and wound infection, and to prevent more distant spread of infection. Whereas surgery is rarely indicated in PBP in adults, it may be life-saving in secondary peritonitis.

PERITONITIS IN PATIENTS UNDERGOING CAPD A third type of peritonitis arises in patients who are undergoing continuous ambulatory peritoneal dialysis (CAPD). Unlike primary and secondary peritonitis, which are caused by endogenous bacteria, peritonitis in CAPD patients usually involves skin organisms. The pathogenesis of infection is similar to that of intravascular-device infection, in which skin organisms migrate along the catheter, which both serves as an entry point and exerts the effects of a foreign body. Exit-site or tunnel infection may or may not accompany CAPD peritonitis. Like PBP, CAPD peritonitis is usually caused by a single organism. Peritonitis is, in fact, the most common reason for discontinuation of CAPD. Improvements in equipment design, especially that of the Y-set connector, have resulted in a decrease from one case of peritonitis per 9 months of CAPD to one case per 15 months.

The clinical presentation of CAPD peritonitis resembles that of secondary peritonitis in that diffuse pain and peritoneal signs are common. The dialysate is usually cloudy and contains >100 WBCs per microliter, >50% of which are neutrophils. The most common etiologic organism is coagulase-negative *Staphylococcus*, which accounts for ~30% of cases. *Staphylococcus aureus* causes ~10% of cases, is more commonly identified among patients who are nasal carriers of the organism, and is the most frequent pathogen in those with an overt exit-site infection. Gram-negative bacilli and fungi such as *Candida* species are also found. Vancomycin-resistant enterococci (VRE) and vancomycin-intermediate *S. aureus* (VISA) have been reported to produce peritonitis in CAPD patients. The finding of more than one organism in dialysate culture should prompt a search for a cause of secondary peritonitis. As with primary peritonitis, culture of dialysate fluid in blood culture bottles improves the yield. To facilitate diagnosis, several hundred milliliters of removed dialysis fluid should be concentrated by centrifugation before culture.

TREATMENT

Empirical therapy for CAPD peritonitis should be directed at *S. aureus*, coagulase-negative *Staphylococcus*, and gram-negative bacilli until the results of cultures are available. Since the advent of VRE and VISA, a first-generation cephalosporin such as cefazolin and a third-generation cephalosporin such as ceftazidime constitute the treatment of choice. A loading dose of cefazolin is administered intraperitoneally along with ceftazidime; doses depend on the dialysis method and the patient's renal function. If methicillin-resistant *S. aureus* is a relatively common isolate in a community, vancomycin may be a reasonable first choice for empirical therapy, especially in a toxic-appearing patient or a patient with an overt exit-site infection. The dose (2 g) is allowed to remain in the peritoneal cavity for 6 h. If the patient is severely ill, intravenous antibiotics similar to those in the dialysis bag should be added to the regimen at doses appropriate for the patient's degree of renal failure. The clinical response to an empirical treatment regimen should be rapid; if the patient has not responded after 48 h of treatment, catheter removal should be considered.

TUBERCULOUS PERITONITIS See Chap. 150.

FAMILIAL MEDITERRANEAN FEVER (See Chap. 279) Familial Mediterranean fever is an autosomal recessive disorder usually presenting with episodic bouts of peritonitis without an infectious etiology.

INTRAPERITONEAL ABSCESSES

Abscess formation is common in untreated peritonitis if overt gram-negative sepsis either does not develop or develops but is not fatal. In experimental models of abscess formation, mixed aerobic and anaerobic organisms have been implanted intraperitoneally. Without therapy directed at anaerobes, animals develop intraabdominal abscesses. As in humans, these experimental abscesses may stud the peritoneal cavity, lie within the omentum or mesentery, or even develop on the surface of or within viscera such as the liver.

PATHOGENESIS AND IMMUNITY There is often disagreement about whether an abscess represents a disease state or a host response. In a sense, it represents both: While an abscess is an infection in which viable infecting organisms and PMNs are contained in a fibrous capsule, it is also a process by which the host confines microbes to a limited space, thereby preventing further spread of infection. In any event, abscesses do cause significant symptoms, and patients with abscesses can be quite ill. Experimental work has helped to define both the host cells and the bacterial virulence factors responsible—most notably, in the case of *B. fragilis*. This organism, although accounting for only 0.5% of the normal colonic flora, is the anaerobe most frequently isolated from intraabdominal infections, is especially prominent in abscesses, and is the most common anaerobic bloodstream isolate. On clinical grounds, therefore, *B. fragilis* appears to be uniquely virulent. Moreover, *B. fragilis* acts alone to cause abscesses in animal models of intraabdominal infection, whereas most other *Bacteroides* species must act synergistically with a facultative organism to induce abscess formation.

Of the several virulence factors identified in *B. fragilis*, one is critical: the capsular polysaccharide complex (CPC) found on the bacterial surface. The CPC comprises at least eight distinct surface polysaccharides. Structural analysis of some of the polysaccharides in the CPC has shown an unusual motif of oppositely charged sugars. Polysaccharides having these *zwitterionic* characteristics, such as polysaccharide A (PS A), evoke a host response in the peritoneal cavity that localizes bacteria into abscesses. *B. fragilis* and PS A have been found to adhere to primary mesothelial cells in vitro; this adherence, in turn, stimulates the production of tumor necrosis factor α (TNF-α) and intercellular adhesion molecule 1 (ICAM-1) by peritoneal macrophages. Although abscesses characteristically contain PMNs, the process of abscess induction depends on the stimulation of T lymphocytes by these unique zwitterionic polysaccharides. The stimulated CD4+ lymphocytes secrete leukoattractant cytokines and chemokines. The alternative pathways of complement and fibrinogen also participate in abscess formation.

While antibodies to the CPC enhance bloodstream clearance of *B. fragilis*, CD4+ T cells are critical in immunity to abscesses. When administered subcutaneously, *B. fragilis* PS A has immunomodulatory characteristics and stimulates CD4+ T regulatory (Treg) cells via an interleukin (IL) 2–dependent mechanism to produce IL-10. IL-10 downregulates the inflammatory response, thereby preventing abscess formation.

CLINICAL PRESENTATION Most intraperitoneal abscesses result from fecal spillage from a colonic source, such as an inflamed appendix. Of all intraabdominal abscesses, 74% are intraperitoneal or retroperitoneal and are not visceral. Abscesses can also arise from a number of other processes. They usually form within weeks of the development of peritonitis and may be found in a variety of locations—from omentum to mesentery, pelvis to psoas muscles, and subphrenic space to a vis-

ceral organ such as the liver, where they may develop either on the surface of the organ or within it. Periappendiceal and diverticular abscesses occur commonly. Diverticular abscesses are least likely to rupture. Infections of the female genital tract and pancreatitis are also among the more common causative events. When abscesses occur in the female genital tract—either as a primary infection (e.g., tuboovarian abscess) or as an infection extending into the pelvic cavity or peritoneum—*B. fragilis* figures prominently among the organisms isolated. *B. fragilis* is not found in large numbers in the normal vaginal flora. It is encountered less commonly in pelvic inflammatory disease and endometritis, for example, without an associated abscess. In pancreatitis with leakage of damaging pancreatic enzymes, inflammation is prominent. Therefore, clinical findings such as fever, leukocytosis, and even abdominal pain do not distinguish pancreatitis itself from complications such as pancreatic pseudocyst, pancreatic abscess (Chap. 294), or intraabdominal collections of pus. Especially in cases of necrotizing pancreatitis, in which the incidence of local pancreatic infection may be as high as 30%, needle aspiration under CT guidance is performed as often as once a week to sample fluid for culture. Many centers prescribe prophylactic antibiotics to prevent infection in patients with necrotizing pancreatitis. Imipenem is the drug most frequently used for this purpose since it reaches high tissue levels in the pancreas (although it is not unique in this regard). If needle aspiration yields infected fluid, most experts agree that surgery is superior to percutaneous drainage.

DIAGNOSIS A variety of scanning procedures have considerably facilitated the diagnosis of intraabdominal abscesses. Abdominal CT probably has the highest yield, although ultrasonography is particularly useful for the right upper quadrant, kidneys, and pelvis. Both indium-labeled WBCs and gallium tend to localize in abscesses and may be useful in finding a collection. Since gallium is taken up in the bowel, indium-labeled WBCs may have a slightly greater yield for abscesses near the bowel. Neither indium-labeled WBC nor gallium scans serve as a basis for a definitive diagnosis, however; both need to be followed by other, more specific studies, such as CT, if an area of possible abnormality is identified. Abscesses contiguous with or contained within outpouchings of bowel are particularly difficult to diagnose with scanning procedures. Occasionally, a barium enema may detect a diverticular abscess not diagnosed by other procedures, although barium should not be injected if a free perforation is suspected. If one study is negative, a second study sometimes reveals a collection. Although exploratory laparotomy has been less commonly used since the advent of CT, this procedure still must be undertaken on occasion if an abscess is strongly suspected on clinical grounds.

TREATMENT

An algorithm for the management of patients with intraabdominal abscesses is presented in Fig. 112-1. The treatment of intraabdominal infections involves the determination of the initial focus of infection, the administration of broad-spectrum antibiotics targeted at organisms involved in the associated infection, and the performance of a drainage procedure if one or more definitive abscesses have already formed. Antimicrobial therapy, in general, is adjunctive to drainage and/or surgical correction of an underlying lesion or process in intraabdominal abscesses. Unlike the intraabdominal abscesses precipitated by most infections, for which drainage of some kind is generally required, abscesses associated with diverticulitis usually wall off locally after rupture of a diverticulum, so that surgical intervention is not routinely required.

A number of antimicrobial agents exhibit excellent activity against aerobic gram-negative bacilli. Since mortality in intraabdominal sepsis is linked to gram-negative bacteremia, empirical therapy for intraabdominal infection always needs to include adequate coverage of gram-negative aerobic, facultative, and anaerobic organisms. Even if anaerobes are not cultured from clinical specimens, they still must be covered by the therapeutic regimen. Broad-spectrum empirical antibiotic therapy should be the same as that discussed above for secondary peritonitis.

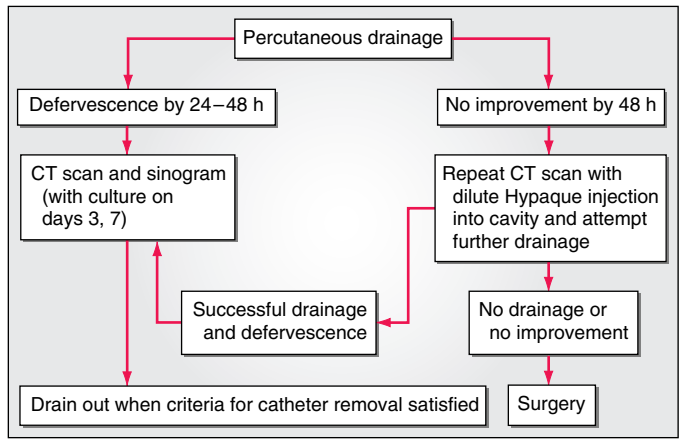

FIGURE 112-1 Algorithm for the management of patients with intraabdominal abscesses using percutaneous drainage. Antimicrobial therapy should be administered concomitantly. CT, computed tomography. [*Reprinted with permission from B Lorber (ed): Atlas of Infectious Diseases, vol VII: Intra-abdominal Infections, Hepatitis, and Gastroenteritis. Philadelphia, Current Medicine, 1995, pp 1–101, as adapted from OD Rotstein, RL Simmons, in SL Gorbach et al (eds): Infectious Diseases, Philadelphia, Saunders, 1992, p. 668.*]

VISCERAL ABSCESSES ■ Liver Abscesses The liver is the organ most subject to the development of abscesses. In one study of 540 intraabdominal abscesses over a 12-year period, 26% of these abscesses were visceral. Liver abscesses made up 13% of the total number of abscesses, or 48% of all visceral abscesses. Liver abscesses may be solitary or multiple; they may arise from hematogenous spread of bacteria or from local spread from contiguous sites of infection within the peritoneal cavity. In the past, appendicitis with rupture and subsequent spread of infection was the most common route for the development of a liver abscess. Currently, associated disease of the biliary tract is most often the etiology. Suppurative pylephlebitis (suppurative thrombosis of the portal vein), usually arising from infection in the pelvis but sometimes from infection elsewhere in the peritoneal cavity, is another common source for bacterial seeding of the liver.

Fever is the most common presenting sign of liver abscess. Some patients, particularly those with active associated disease of the biliary tract, have symptoms and signs localized to the right upper quadrant, including pain, guarding, punch tenderness, and even rebound tenderness. Nonspecific symptoms, such as chills, anorexia, weight loss, nausea, and vomiting, may also develop. Only 50% of patients with liver abscesses, however, have hepatomegaly, right-upper-quadrant tenderness, or jaundice; thus, half of patients have no symptoms or signs that would direct attention to the liver. Fever of unknown origin (FUO) may be the only presenting manifestation of liver abscess, especially in the elderly. Diagnostic studies of the abdomen, especially the right upper quadrant, should be a part of any FUO workup. The single most reliable laboratory finding is an elevated serum concentration of alkaline phosphatase, which is documented in 70% of patients with liver abscesses. Other tests of liver function may yield normal results, but 50% of patients have elevated serum levels of bilirubin, and 48% have elevated concentrations of aspartate aminotransferase. Other associated laboratory findings include leukocytosis in 77% of patients, anemia (usually normochromic, normocytic) in 50%, and hypoalbuminemia in 33%. Concomitant bacteremia is found in one-third of patients. A liver abscess is sometimes suggested by chest radiography, especially if a new elevation of the right hemidiaphragm is seen; other suggestive findings include a right basilar infiltrate and a right pleural effusion.

Imaging studies are the most reliable methods for diagnosing liver abscesses. These studies include ultrasonography, CT (Fig. 112-2), indium-labeled WBC or gallium scans, and magnetic resonance im-

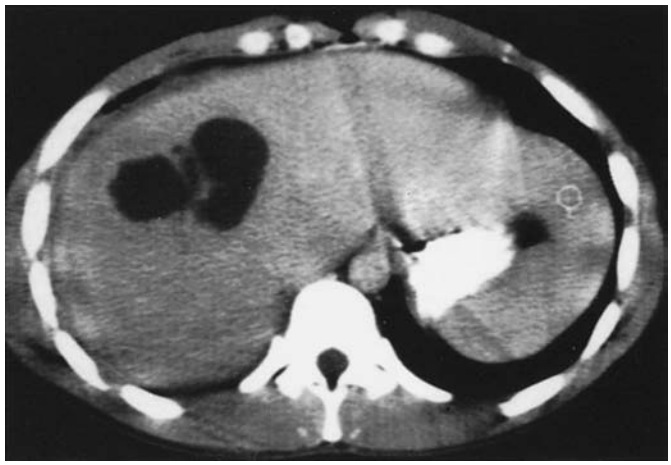

FIGURE 112-2 Multilocular liver abscess on computed tomography scan. Multiple or multilocular abscesses are more common than solitary abscesses. [*Reprinted with permission from B Lorber (ed): Atlas of Infectious Diseases, Vol VII: Intra-abdominal Infection, Hepatitis, and Gastroenteritis. Philadelphia, Current Medicine, 1996, Fig. 1-70.*]

aging. In an occasional case, more than one such study may be required. Organisms recovered from liver abscesses vary with the etiology. In liver infection arising from the biliary tree, enteric gram-negative aerobic bacilli and enterococci are common isolates. Unless previous surgery has been performed, anaerobes are not generally involved in liver abscesses arising from biliary infections. In contrast, in liver abscesses arising from pelvic and other intraperitoneal sources, a mixed flora including both aerobic and anaerobic species is common; *B. fragilis* is the species most frequently isolated. With hematogenous spread of infection, usually only a single organism is encountered; this species may be *S. aureus* or a streptococcal species such as *S. milleri*. Results of cultures obtained from drain sites are not reliable for defining the etiology of infections. Liver abscesses may also be caused by *Candida* species; such abscesses usually follow fungemia in patients receiving chemotherapy for cancer and often present when neutrophils return after a period of neutropenia. However, the recovery of *Candida* from a drain site does not necessarily implicate this organism as a cause of infection. Amebic liver abscesses are not an uncommon problem (Chap. 194). Amebic serologic testing gives positive results in >95% of cases; thus, a negative result helps to exclude this diagnosis.

TREATMENT

While drainage—either percutaneous (with a pigtail catheter kept in place) or surgical—remains the mainstay of therapy for intraabdominal abscesses (including liver abscesses), there is growing interest in medical management alone for pyogenic liver abscesses. The drugs used for empirical broad-spectrum antibiotic therapy include the same ones used in intraabdominal sepsis and secondary bacterial peritonitis. Usually, a diagnostic aspirate of abscess contents should be obtained before the initiation of empirical therapy, with antibiotic choices adjusted when the results of Gram's staining and culture become available. Cases treated without definitive drainage generally require longer courses of antibiotic therapy. When percutaneous drainage was compared with open surgical drainage, the average length of hospital stay for the former was almost twice that for the latter, although both the time required for fever to resolve and the mortality rate were the same for the two procedures. Mortality was appreciable despite treatment, averaging 15%. Several factors may predict the failure of percutaneous drainage and therefore may favor primary surgical intervention. These factors include the presence of multiple, sizable abscesses; viscous abscess contents that tend to plug the catheter; associated disease (e.g., disease of the biliary tract) that requires surgery; or the lack of a clinical response to percutaneous drainage in 4 to 7 days.

Treatment of candidal liver abscesses usually entails lengthy administration of amphotericin B, although reports have described successful maintenance therapy with fluconazole after an initial course of amphotericin (Chap. 187).

Splenic Abscesses Splenic abscesses are much less common than liver abscesses. The incidence of splenic abscesses has ranged from 0.14 to 0.7% in various autopsy series. The clinical setting and the organisms isolated usually differ from those for liver abscesses. The degree of clinical suspicion for splenic abscess needs to be high, as this condition is frequently fatal if left untreated. Even in the most recently published series, diagnosis was made only at autopsy in 37% of cases. While splenic abscesses may arise occasionally from contiguous spread of infection or from direct trauma to the spleen, hematogenous spread of infection is the usual mode of development. Bacterial endocarditis is the most common associated infection (Chap. 109). Splenic abscesses can develop in patients who have received extensive immunosuppressive therapy (particularly those with malignancy involving the spleen) and in patients with hemoglobinopathies or other hematologic disorders (especially sickle cell anemia).

While ~50% of patients with splenic abscesses have abdominal pain, the pain is localized to the left upper quadrant in only half of these cases. Splenomegaly is found in ~50% of cases. Fever and leukocytosis are generally present; the development of fever preceded diagnosis by an average of 20 days in one series. Left-sided chest findings may include abnormalities to auscultation, and chest radiographic findings may include an infiltrate or a left-sided pleural effusion. When splenic abscesses are being considered in a differential diagnosis, CT scan of the abdomen has been the most sensitive diagnostic tool. Ultrasonography can yield the diagnosis, but cases have been missed with this modality. Liver-spleen scan or gallium scan may also be useful. Streptococcal species are the most common bacterial isolates from splenic abscesses, and *S. aureus* is the next most common; presumably these prevalences reflect the bacterial cause of the associated endocarditis. An increase in the frequency of isolation of gram-negative aerobic organisms from splenic abscesses has been reported; these organisms often derive from a urinary tract focus, with associated bacteremia, or from another intraabdominal source. *Salmonella* species are seen fairly commonly, especially in patients with sickle cell hemoglobinopathy. Anaerobic species accounted for only 5% of isolates in the largest collected series, but the reporting of a number of "sterile abscesses" may indicate that optimal techniques for the isolation of anaerobes were not employed.

TREATMENT

Because of the high mortality figures reported for splenic abscesses, the treatment of choice is splenectomy with adjunctive antibiotics. However, percutaneous drainage has been successful. The most important factor in successful treatment of splenic abscesses is early consideration of the diagnosis.

Perinephric and Renal Abscesses Perinephric and renal abscesses are not common: The former accounted for only ~0.02% of hospital admissions and the latter for ~0.2% in Altemeier's series of 540 intraabdominal abscesses. While liver abscesses generally arise from contiguous foci of infection or track from other intraabdominal sources and splenic abscesses usually arise from hematogenous spread (e.g., spread from bacterial endocarditis), perinephric and renal abscesses have a different pathogenesis. Before antibiotics became available, most renal and perinephric abscesses were hematogenous in origin, with *S. aureus* most commonly recovered. Now, in contrast, >75% of perinephric and renal abscesses arise from an initial urinary tract infection. Infection ascends from the bladder to the kidney, with pyelonephritis occurring first. Bacteria may directly invade the renal parenchyma from medulla to cortex. Local vascular channels within the kidney may also facilitate the transport of organisms. Areas of abscess developing within the parenchyma may rupture into the perinephric space. The

kidneys and adrenal glands are surrounded by a layer of perirenal fat that, in turn, is surrounded by Gerota's fascia, which extends superiorly to the diaphragm and inferiorly to the pelvic fat. When abscesses extend into the perinephric space, tracking may occur through Gerota's fascia into the psoas or transversalis muscles, into the anterior peritoneal cavity, superiorly to the subdiaphragmatic space, or inferiorly to the pelvis. Of the several risk factors that have been associated with the development of perinephric abscesses, the most important is the presence of concomitant nephrolithiasis producing local obstruction to urinary flow. Of patients with perinephric abscess, 20 to 60% have renal stones. In addition, other structural abnormalities of the urinary tract, a history of urologic surgery, trauma, and diabetes mellitus have all been identified as risk factors.

The organisms most frequently encountered in perinephric and renal abscesses are *E. coli*, *Proteus* species, and *Klebsiella* species. *E. coli*, the aerobic species most commonly found in the colonic flora, seems to have unique virulence properties in the urinary tract, including factors promoting adherence to uroepithelial cells. The urease of *Proteus* species splits urea, thereby creating a more alkaline and more hospitable environment for bacterial proliferation. *Proteus* species are frequently found in association with large struvite stones caused by the precipitation of magnesium ammonium sulfate in an alkaline environment. These stones serve as a nidus for recurrent urinary tract infection. While a single bacterial species is usually recovered from a perinephric or renal abscess, multiple species may also be found. If a urine culture is not contaminated with periurethral flora and is found to contain more than one organism, a perinephric abscess or renal abscess should be considered in the differential diagnosis. Urine cultures may also be polymicrobial in cases of bladder diverticulum.

Candida species should be considered in the etiology of renal abscesses. This fungus may spread to the kidney via the hematogenous route or by ascension from the bladder. The hallmark of the latter route of infection is ureteral obstruction with large fungal balls.

The presentation of perinephric and renal abscesses is quite nonspecific. Flank pain and abdominal pain are common. At least 50% of patients are febrile. Pain may be referred to the groin or leg, particularly with extension of infection. The diagnosis of perinephric abscess, like that of splenic abscess, is frequently delayed, and the mortality rate in some series is appreciable, although lower than in the past. Perinephric or renal abscess should be most seriously considered when a patient presents with symptoms and signs of pyelonephritis and remains febrile after 4 or 5 days, by which time the fever should have resolved. Moreover, when a urine culture yields a polymicrobial flora, when a patient is known to have renal stone disease, or when fever and pyuria coexist with a sterile urine culture, the diagnosis of perinephric or renal abscess should be entertained.

Renal ultrasonography and abdominal CT are the most useful diagnostic modalities. If a renal abscess or perinephric abscess is diagnosed, nephrolithiasis should be excluded, especially when a high urinary pH suggests the presence of a urea-splitting organism.

TREATMENT

Treatment for perinephric or renal abscesses, like that for other intra-abdominal abscesses, includes drainage of pus and antibiotic therapy directed at the organism(s) recovered. For perinephric abscesses, percutaneous drainage is usually successful.

Psoas Abscesses The psoas muscle is another location in which abscesses are encountered. Psoas abscesses may arise from a hematogenous source, by contiguous spread from an intraabdominal or pelvic process, or by contiguous spread from nearby bony structures (e.g., vertebral bodies). Associated osteomyelitis due to spread from bone to muscle or from muscle to bone is common in psoas abscesses. When Pott's disease was common, *Mycobacterium tuberculosis* was a frequent cause of psoas abscess. Currently, either *S. aureus* or a mixture of enteric organisms including aerobic and anaerobic gram-negative bacilli is usually isolated from psoas abscesses in the United States. *S. aureus* is most likely to be isolated when a psoas abscess arises from hematogenous spread or a contiguous focus of osteomyelitis; a mixed enteric flora is the most likely etiology when the abscess has an intraabdominal or pelvic source. Patients with psoas abscesses frequently present with fever, lower abdominal or back pain, or pain referred to the hip or knee. CT is the most useful diagnostic technique.

TREATMENT

Treatment includes surgical drainage and the administration of an antibiotic regimen directed at the inciting organism(s).

Pancreatic Abscesses See Chap. 294.

113 ACUTE INFECTIOUS DIARRHEAL DISEASES AND BACTERIAL FOOD POISONING

Joan R. Butterton, Stephen B. Calderwood

Ranging from mild annoyances during vacations to devastating dehydrating illnesses that can kill within hours, acute gastrointestinal illnesses rank second only to acute upper respiratory illnesses as the most common diseases worldwide. In children <5 years old, attack rates range from 2 to 3 illnesses per child per year in developed countries to as high as 10 to 18 illnesses per child per year in developing countries. In Asia, Africa, and Latin America, acute diarrheal illnesses are not only a leading cause of morbidity in children—with an estimated 1 billion cases per year—but also a major cause of mortality, being responsible for 4 to 6 million deaths per year, or a sobering total of 12,600 deaths per day. In some areas, >50% of childhood deaths are directly attributable to acute diarrheal illnesses. In addition, by contributing to malnutrition and thereby reducing resistance to other infectious agents, gastrointestinal illnesses may be indirect factors in a far greater burden of disease.

The wide range of clinical manifestations of acute gastrointestinal illnesses is matched by the wide variety of infectious agents involved, including viruses, bacteria, and parasitic pathogens (Table 113-1). This

chapter will discuss factors that enable gastrointestinal pathogens to cause disease, will review host defense mechanisms, and will delineate an approach to the evaluation and treatment of patients presenting with acute diarrhea. Individual organisms causing acute gastrointestinal illnesses are discussed in detail in subsequent chapters.

TABLE 113-1 *Gastrointestinal Pathogens Causing Acute Diarrhea*

Mechanism	Location	Illness	Stool Findings	Examples of Pathogens Involved
Noninflammatory (enterotoxin)	Proximal small bowel	Watery diarrhea	No fecal leukocytes; mild or no increase in fecal lactoferrin	*Vibrio cholerae*, enterotoxigenic *Escherichia coli* (LT and/or ST), *Clostridium perfringens*, *Bacillus cereus*, *Staphylococcus aureus*, *Aeromonas hydrophila*, *Plesiomonas shigelloides*, rotavirus, Norwalk-like viruses, enteric adenoviruses, *Giardia lamblia*, *Cryptosporidium* spp., *Cyclospora* spp., microsporidia
Inflammatory (invasion or cytotoxin)	Colon or distal small bowel	Dysentery or inflammatory diarrhea	Fecal polymorphonuclear leukocytes; substantial increase in fecal lactoferrin	*Shigella* spp., *Salmonella* spp., *Campylobacter jejuni*, enterohemorrhagic *E. coli*, enteroinvasive *E. coli*, *Yersinia enterocolitica*, *Vibrio parahaemolyticus*, *Clostridium difficile*, ?*A. hydrophila*, ?*P. shigelloides*, *Entamoeba histolytica*
Penetrating	Distal small bowel	Enteric fever	Fecal mononuclear leukocytes	*Salmonella typhi*, *Y. enterocolitica*, ?*Campylobacter fetus*

PATHOGENIC MECHANISMS Enteric pathogens have developed a variety of tactics to overcome host defenses. Understanding the virulence factors employed by these organisms is important in the diagnosis and treatment of clinical disease.

Inoculum Size The number of microorganisms that must be ingested to cause disease varies considerably from species to species. For *Shigella*, enterohemorrhagic *Escherichia coli*, *Giardia lamblia*, or *Entamoeba*, as few as 10 to 100 bacteria or cysts can produce infection, while 10^5 to 10^8 *Vibrio cholerae* organisms must be ingested orally to cause disease. The infective dose of *Salmonella* varies widely, depending on the species, host, and food vehicle. The ability of organisms to overcome host defenses has important implications for transmission; *Shigella*, enterohemorrhagic *E. coli*, *Entamoeba*, and *Giardia* can spread by person-to-person contact, whereas under some circumstances *Salmonella* may have to grow in food for several hours before reaching an effective infectious dose.

Adherence Many organisms must adhere to the gastrointestinal mucosa as an initial step in the pathogenic process; thus, organisms that can compete with the normal bowel flora and colonize the mucosa have an important advantage in causing disease. Specific cell-surface proteins involved in attachment of bacteria to intestinal cells are important virulence determinants. *V. cholerae*, for example, adheres to the brush border of small-intestinal enterocytes via specific surface adhesins, including the toxin-coregulated pilus and other accessory colonization factors. Different pathogenic varieties of *E. coli* have different adherence mechanisms. Enterotoxigenic *E. coli*, which causes watery diarrhea, produces an adherence protein called *colonization factor antigen* that is necessary for colonization of the upper small intestine by the organism prior to the production of enterotoxin. Enteropathogenic *E. coli*, an agent of diarrhea in young children, and enterohemorrhagic *E. coli*, which causes hemorrhagic colitis and the hemolytic-uremic syndrome, produce virulence determinants that allow these organisms to attach to and efface the brush border of the intestinal epithelium.

Toxin Production The production of one or more exotoxins is important in the pathogenesis of numerous enteric organisms. Such toxins include *enterotoxins*, which cause watery diarrhea by acting directly on secretory mechanisms in the intestinal mucosa; *cytotoxins*, which cause destruction of mucosal cells and associated inflammatory diarrhea; and *neurotoxins*, which act directly on the central or peripheral nervous system. Some exotoxins act by more than one mechanism; *Shigella dysenteriae* type 1, for example, produces an exotoxin that has both enterotoxic and cytotoxic activities.

The prototypical enterotoxin is cholera toxin, a heterodimeric protein composed of one A and five B subunits. The A subunit contains the enzymatic activity of the toxin, while the B subunit pentamer binds holotoxin to the enterocyte surface receptor, the ganglioside G_{M1}. After the binding of holotoxin, a fragment of the A subunit is translocated across the eukaryotic cell membrane into the cytoplasm, where it catalyzes the ADP-ribosylation of a GTP-binding protein and causes persistent activation of adenylate cyclase. The end result is an increase of cyclic AMP in the intestinal mucosa, which increases Cl^- secretion and decreases Na^+ absorption, leading to loss of fluid and the production of diarrhea.

Enterotoxigenic strains of *E. coli* may produce a protein called *heat-labile enterotoxin* (LT) that is similar to cholera toxin and causes secretory diarrhea by the same mechanism. Alternatively, enterotoxigenic strains of *E. coli* may produce *heat-stable enterotoxin* (ST), one form of which causes diarrhea by activation of guanylate cyclase and elevation of intracellular cyclic GMP. Some enterotoxigenic strains of *E. coli* produce both LT and ST.

Bacterial cytotoxins, in contrast, destroy intestinal mucosal cells and produce the syndrome of dysentery, with bloody stools containing inflammatory cells. Enteric pathogens that produce such cytotoxins include *S. dysenteriae* type 1, *Vibrio parahaemolyticus*, and *Clostridium difficile*. Shiga toxin–producing strains of *E. coli* (a group that includes enterohemorrhagic strains and whose most common serotype in the United States is O157:H7) produce potent cytotoxins that are highly related to the Shiga toxin of *S. dysenteriae* type 1. Such strains of *E. coli* have been associated with outbreaks of hemorrhagic colitis and hemolytic-uremic syndrome.

Neurotoxins are usually produced by the responsible organism outside the host and therefore cause symptoms soon after ingestion. Included are the staphylococcal and *Bacillus cereus* toxins, which act on the central nervous system to produce vomiting.

Invasion Dysentery may result not only from the production of cytotoxins but also from bacterial invasion and destruction of intestinal mucosal cells. Infections due to *Shigella* and enteroinvasive *E. coli*, for example, are characterized by the organisms' invasion of mucosal epithelial cells, intraepithelial multiplication, and subsequent spread to adjacent cells. *Salmonella*, on the other hand, causes inflammatory diarrhea by invasion of the bowel mucosa but generally is not associated with the destruction of enterocytes or the full clinical syndrome of dysentery. *Salmonella typhi* and *Yersinia enterocolitica* can penetrate intact intestinal mucosa, multiply intracellularly in Peyer's patches and intestinal lymph nodes, and then disseminate through the

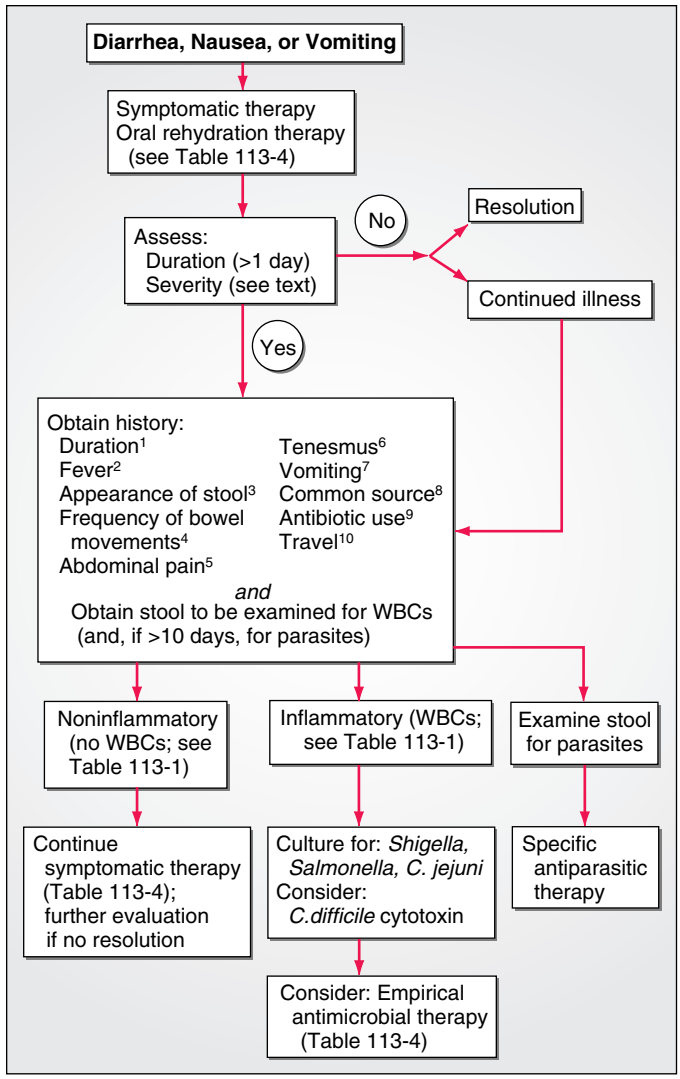

FIGURE 113-1 Clinical algorithm for the approach to patients with community-acquired infectious diarrhea or bacterial food poisoning. Key to superscripts: 1. Diarrhea lasting >2 weeks is generally defined as chronic; in such cases, many of the causes of acute diarrhea are much less likely, and a new spectrum of causes needs to be considered. 2. Fever often implies invasive disease, although fever and diarrhea may also result from infection outside the gastrointestinal tract, as in malaria. 3. Stools that contain blood or mucus indicate ulceration of the large bowel. Bloody stools without fecal leukocytes should alert the laboratory to the possibility of infection with Shiga toxin–producing enterohemorrhagic *Escherichia coli*. Bulky white stools suggest a small-intestinal process that is causing malabsorption. Profuse "rice-water" stools suggest cholera or a similar toxigenic process. 4. Frequent stools over a given period can provide the first warning of impending dehydration. 5. Abdominal pain may be most severe in inflammatory processes like those due to *Shigella*, *Campylobacter*, and necrotizing toxins. Painful abdominal muscle cramps, caused by electrolyte loss, can develop in severe cases of cholera. Bloating is common in giardiasis. An appendicitis-like syndrome should prompt a culture for *Yersinia enterocolitica* with cold enrichment. 6. Tenesmus (painful rectal spasms with a strong urge to defecate but little passage of stool) may be a feature of cases with proctitis, as in shigellosis or amebiasis. 7. Vomiting implies an acute infection (e.g., a toxin-mediated illness or food poisoning) but can also be prominent in a variety of systemic illnesses (e.g., malaria) and in intestinal obstruction. 8. Asking patients whether anyone else they know is sick is a more efficient means of identifying a common source than is constructing a list of recently eaten foods. If a common source seems likely, specific foods can be investigated. See text for a discussion of bacterial food poisoning. 9. Current antibiotic therapy or a recent history of treatment suggests *Clostridium difficile* diarrhea (Chap. 114). Stop antibiotic treatment if possible and consider tests for *C. difficile* toxins. Antibiotic use may increase the risk of other infections, such as salmonellosis. 10. See text (and Chap. 108) for a discussion of traveler's diarrhea. (*After Guerrant and Steiner; RL Guerrant, DA Bobak: N Engl J Med 325:327, 1991; with permission.*)

bloodstream to cause enteric fever, a syndrome characterized by fever, headache, relative bradycardia, abdominal pain, splenomegaly, and leukopenia.

HOST DEFENSES Given the enormous number of microorganisms ingested with every meal, the normal host must possess effective defense mechanisms to combat a constant influx of potential enteric pathogens. Studies of infections in patients with alterations in these defenses have led to a greater understanding of the variety of ways in which the normal host can protect itself against disease.

Normal Flora The large numbers of bacteria that normally inhabit the intestine act as an important host defense by preventing colonization by potential enteric pathogens. Persons with fewer intestinal bacteria, such as infants who have not yet developed normal enteric colonization or patients receiving antibiotics, are at significantly greater risk of developing infections with enteric pathogens. The composition of the intestinal flora is as important as the number of organisms present. More than 99% of the normal colonic flora is made up of anaerobic bacteria, and the acidic pH and volatile fatty acids produced by these organisms appear to be critical elements in resistance to colonization.

Gastric Acid The acidic pH of the stomach is an important barrier to enteric pathogens, and an increased frequency of infections due to *Salmonella*, *G. lamblia*, and a variety of helminths has been reported among patients who have undergone gastric surgery or are achlorhydric for some other reason. Neutralization of gastric acid with antacids or H_2 blockers—common among hospitalized patients—similarly increases the risk of enteric colonization. Some microorganisms, however, can survive the extreme acidity of the gastric environment; rotavirus, for example, is highly stable to acidity.

Intestinal Motility Normal peristalsis is the major mechanism for clearance of bacteria from the proximal small intestine, although gastric acidity and secreted immunoglobulins also play a role in limiting the number of organisms present. When intestinal motility is impaired—for example, by treatment with opiates or other antimotility drugs, anatomic abnormalities (diverticula, fistulas, or afferent-loop stasis following surgery), or hypomotility states (as in diabetes mellitus or scleroderma)—the frequency of bacterial overgrowth and infection of the small bowel with enteric pathogens is much increased. Some patients in whom *Shigella* infection is treated with diphenoxylate hydrochloride with atropine (Lomotil) experience prolonged fever and shedding of organisms, while patients treated with opiates for mild *Salmonella* gastroenteritis have a higher frequency of bacteremia than those not treated with opiates.

Immunity Both cellular immune responses and antibody production play important roles in protecting susceptible hosts from enteric infections. The wide spectrum of viral, bacterial, parasitic, and fungal gastrointestinal infections in patients with AIDS highlights the significance of cell-mediated immunity in protecting the normal host from these pathogens. Humoral immunity is also important and consists of systemic IgG and IgM as well as secretory IgA. Growing evidence supports the concept of a mucosal immune system for secretory IgA in which binding of bacterial antigens to the luminal surface of M cells in the distal small bowel and subsequent presentation of antigens to subepithelial lymphoid tissue lead to the proliferation of sensitized lymphocytes. These lymphocytes circulate and populate all of the mucosal tissues of the body as IgA-secreting plasma cells.

APPROACH TO THE PATIENT

The approach to the patient with possible infectious diarrhea or bacterial food poisoning is shown in Fig. 113-1.

History The answers to questions with high discriminating value can quickly narrow the range of potential causes of diarrhea and help determine whether treatment is needed. Important elements of the narrative history are detailed in Fig. 113-1.

Physical Examination The examination of patients for signs of dehydration provides essential information about the severity of the diarrheal illness and the need for rapid therapy. Mild dehydration is indicated by thirst, dry mouth, decreased axillary sweat, decreased urine output, and slight weight loss. Signs of moderate dehydration include an orthostatic fall in blood pressure, skin tenting, and sunken eyes (or, in infants, a sunken fontanelle). Signs of severe dehydration range from hypotension and tachycardia to confusion and frank shock.

Diagnostic Approach After the severity of illness is assessed, the most important distinction that the clinician must make is between *inflammatory* and *noninflammatory* disease. Using the history and epidemiologic features of the case as guides in making this distinction, the clinician can rapidly evaluate the need for further efforts to define a specific etiology and for therapeutic intervention. Examination of a stool sample is an important supplement to the narrative history. Grossly bloody or mucoid stool suggests an inflammatory process. A test for fecal leukocytes (preparation of a thin smear of stool on a glass slide, addition of a drop of methylene blue, and examination of the wet mount) can suggest inflammatory disease in patients presenting with diarrhea, although the predictive value of this test is still debated. A test for fecal lactoferrin, which is a marker of fecal leukocytes, is more sensitive and is available in latex agglutination and enzyme-linked immunosorbent assay formats. Causes of acute infectious diarrhea, categorized as inflammatory and noninflammatory, are listed in Table 113-1.

TABLE 113-2 *Epidemiology of Traveler's Diarrhea*

Etiologic Agent	Approximate Percentage of Cases	Comments
Enterotoxigenic *Escherichia coli*	15–50	Single most important agent, particularly in summertime in semitropical areas; percentage of cases ranges from 15% in Asia to 50% in Latin America
Enteroaggregative *E. coli*	10–20	May cause one-third of culture-negative cases
Shigella and enteroinvasive *E. coli*	10–25	Major causes of fever and dysentery
Salmonella	5–10	Causes fever and dysentery
Campylobacter jejuni	3–15	More common in winter in semitropical areas; more common in Asia
Aeromonas	5	Important in Thailand
Plesiomonas	5	Related to tropical travel and seafood consumption
Vibrio cholerae	0–10	Most common in India and Asia; also common in Central and South America
Rotavirus and Norwalk-like virus	10–40	Latin America, Asia, and Africa; Norwalk-like virus associated with seafood ingestion on cruise ships
Entamoeba histolytica	5	Particularly important in Mexico and Thailand
Giardia lamblia	<2	Zoonotic reservoirs in northern United States; affects hikers and campers who drink from freshwater streams; contaminates water supplies in Russia
Cryptosporidium	2	Affects travelers to Russia, Mexico, and Africa; causes large-scale urban outbreaks in United States
Cyclospora	<1	Affects travelers to Nepal, Haiti, and Peru; contaminates water or food
Unknown	20	Illness improves with antibacterial therapy, implicating bacterial diarrhea

Source: After Dupont.

EPIDEMIOLOGY ■ Travel History Of the several million people who travel from temperate industrialized countries to tropical regions of Asia, Africa, and Central and South America each year, 20 to 50% experience a sudden onset of abdominal cramps, anorexia, and watery diarrhea; thus *traveler's diarrhea* is the most common travel-related illness (Chap. 108). The time of onset is usually 3 days to 2 weeks after the traveler's arrival in a tropical area; most cases begin within the first 3 to 5 days. The illness is generally self-limited, lasting 1 to 5 days. The high rate of diarrhea among travelers to underdeveloped areas is related to the ingestion of contaminated food or water.

The organisms that cause traveler's diarrhea vary considerably with location (Table 113-2). In all areas, enterotoxigenic *E. coli* is the most common isolate from persons with the classic secretory traveler's diarrhea syndrome.

Location Day-care centers have particularly high attack rates of enteric infections. Rotavirus is most common among children <2 years old, with attack rates of 75 to 100% among those exposed. *G. lamblia* is more common among older children, with somewhat lower attack rates. Other common organisms, often spread by fecal-oral contact, are *Shigella*, *Campylobacter jejuni*, and *Cryptosporidium*. A characteristic feature of infection among children attending day-care centers is the high rate of secondary cases among family members.

Similarly, hospitals are sites in which enteric infections are concentrated. In medical intensive-care units and pediatric wards, diarrhea is among the most common nosocomial infections. *C. difficile* is the predominant cause of nosocomial diarrhea among adults in the United States; viral pathogens, especially rotavirus, can spread rapidly in pediatric wards. Enteropathogenic *E. coli* has been associated with outbreaks of diarrhea in nurseries for newborns. One-third of elderly patients in chronic-care institutions develop a significant diarrheal illness each year. Surveillance stool cultures suggest that 25% of the residents of these institutions harbor cytotoxin-producing *C. difficile*, which causes more than half of all cases of diarrhea in this population. Antimicrobial therapy can predispose to pseudomembranous colitis by altering the normal colonic flora and allowing the multiplication of *C. difficile* (Chap. 114).

Age Most of the morbidity and mortality from enteric pathogens involves children <5 years of age. Breast-fed infants are protected from contaminated food and water and derive some protection from maternal antibodies, but their risk of infection rises dramatically when they begin to eat solid foods. Infants and younger children are more likely than adults to develop rotavirus disease, while older children and adults are more commonly infected with Norwalk-like viruses. Other organisms with higher attack rates among children than among adults include enterotoxigenic, enteropathogenic, and enterohemorrhagic *E. coli*; *C. jejuni*; and *G. lamblia*. In children, the incidence of *Salmonella* infections is highest among those <1 year of age, while the attack rate for *Shigella* infections is greatest among those 6 months to 4 years of age.

Bacterial Food Poisoning If the history and the stool examination indicate a noninflammatory etiology of diarrhea and there is evidence of a common-source outbreak, questions concerning the ingestion of specific foods and the time of onset of the diarrhea after a meal can provide clues to the bacterial cause of the illness. Potential causes of bacterial food poisoning are shown in Table 113-3.

Bacterial disease caused by an enterotoxin elaborated outside the host, such as that due to *Staphylococcus aureus* or *B. cereus*, has the shortest incubation period (1 to 6 h) and generally lasts <12 h. Most cases of staphylococcal food poisoning are caused by contamination from infected human carriers. Staphylococci can multiply at a wide range of temperatures; thus, if food is left to cool slowly and remains at room temperature after cooking, the organisms will have the opportunity to form enterotoxin. Outbreaks following picnics where potato salad, mayonnaise, and cream pastries have been served offer classic examples of staphylococcal food poisoning. Diarrhea,

TABLE 113-3 *Bacterial Food Poisoning*

Incubation Period, Organisms	Symptoms	Common Food Sources
1 TO 6 H		
Staphylococcus aureus	Nausea, vomiting, diarrhea	Ham, poultry, potato or egg salad, mayonnaise, cream pastries
Bacillus cereus	Nausea, vomiting, diarrhea	Fried rice
8 TO 16 H		
Clostridium perfringens	Abdominal cramps, diarrhea (vomiting rare)	Beef, poultry, legumes, gravies
B. cereus	Abdominal cramps, diarrhea (vomiting rare)	Meats, vegetables, dried beans, cereals
>16 H		
Vibrio cholerae	Watery diarrhea	Shellfish
Enterotoxigenic *Escherichia coli*	Watery diarrhea	Salads, cheese, meats, water
Enterohemorrhagic *E. coli*	Bloody diarrhea	Ground beef, roast beef, salami, raw milk, raw vegetables, apple juice
Salmonella spp.	Inflammatory diarrhea	Beef, poultry, eggs, dairy products
Campylobacter jejuni	Inflammatory diarrhea	Poultry, raw milk
Shigella spp.	Dysentery	Potato or egg salad, lettuce, raw vegetables
Vibrio parahaemolyticus	Dysentery	Mollusks, crustaceans

nausea, vomiting, and abdominal cramping are common, while fever is less so.

B. cereus can produce either a syndrome with a short incubation period—the *emetic* form, mediated by a staphylococcal type of enterotoxin—or one with a longer incubation period (8 to 16 h)—the *diarrheal* form, caused by an enterotoxin resembling *E. coli* LT, in which diarrhea and abdominal cramps are characteristic but vomiting is uncommon. The emetic form of *B. cereus* food poisoning is associated with contaminated fried rice; the organism is common in uncooked rice, and its heat-resistant spores survive boiling. If cooked rice is not refrigerated, the spores can germinate and produce toxin. Frying before serving may not destroy the preformed, heat-stable toxin.

Food poisoning due to *Clostridium perfringens* also has a slightly longer incubation period (8 to 14 h) and results from the survival of heat-resistant spores in inadequately cooked meat, poultry, or legumes. After ingestion, toxin is produced in the intestinal tract, causing moderately severe abdominal cramps and diarrhea; vomiting is rare, as is fever. The illness is self-limited, rarely lasting for more than 24 h.

Not all food poisoning has a bacterial cause. Diagnostic confusion can result from diarrhea caused by nonbacterial agents of short-incubation food poisoning, including capsaicin, which is found in hot peppers, and a variety of toxins found in fish and shellfish (Chap. 378).

LABORATORY EVALUATION Many cases of noninflammatory diarrhea are self-limited or can be treated empirically, and in these instances the clinician may not need to determine a specific etiology. Potentially pathogenic *E. coli* cannot be distinguished from normal fecal flora by routine culture. Special tests to detect LT and ST are not available in most clinical laboratories. In situations in which cholera is a concern, stool should be cultured on thiosulfate–citrate–bile salts–sucrose (TCBS) agar. A latex agglutination test has made the rapid detection of rotavirus in stool practical for many laboratories, while reverse-transcriptase polymerase chain reaction and specific antigen enzyme immunoassays have been developed for the identification of Norwalk-like viruses. At least three stool specimens should be examined for *Giardia* cysts or stained for *Cryptosporidium* if the level of clinical suspicion regarding the involvement of these organisms is high.

All patients with fever and evidence of inflammatory disease acquired outside the hospital should have stool cultured for *Salmonella*, *Shigella*, and *Campylobacter*. *Salmonella* and *Shigella* can be selected on MacConkey's agar as non-lactose-fermenting (colorless) colonies or can be grown on *Salmonella-Shigella* agar or in selenite enrichment broth, both of which inhibit most organisms except these pathogens. Evaluation of nosocomial diarrhea should initially focus on *C. difficile*; stool culture for other pathogens in this setting has an extremely low yield and is not cost-effective. Pathogenic strains of *C. difficile* generally produce two toxins, A and B. Toxin B can be detected with a cytotoxin assay; if the toxin is present, a monolayer culture of fibroblasts will show cytopathic effects within 6 to 24 h. Rapid enzyme immunoassays and latex agglutination tests for both toxin A and toxin B have been developed (Chap. 114). Isolation of *C. jejuni* requires inoculation of fresh stool onto selective growth medium and incubation at 42°C in a microaerophilic atmosphere. In many laboratories in the United States, *E. coli* O157:H7 is among the most common pathogens isolated from visibly bloody stools. Strains of this enterohemorrhagic serotype can be identified in specialized laboratories by serotyping but also can be identified presumptively in hospital laboratories as lactose-fermenting, indole-positive colonies of sorbitol nonfermenters (white colonies) on sorbitol MacConkey plates. Fresh stools should be examined for amebic cysts and trophozoites.

TREATMENT

In many cases, a specific diagnosis is not necessary or not available to guide treatment. The clinician can proceed with the information obtained from the history, stool examination, and evaluation of the severity of dehydration. Empirical regimens for the treatment of traveler's diarrhea are listed in Table 113-4.

The mainstay of treatment is adequate rehydration. The treatment of cholera and other dehydrating diarrheal diseases was revolutionized by the promotion of oral rehydration solutions, the efficacy of which depends on the fact that glucose-facilitated absorption of sodium and water in the small intestine remains intact in the presence of cholera toxin. The use of oral rehydration solutions has reduced mortality due to cholera from >50% (in untreated cases) to <1%. The World Health Organization recommends a solution containing 3.5 g sodium chloride, 2.5 g sodium bicarbonate, 1.5 g potassium chloride, and 20 g glucose (or 40 g sucrose) per liter of water. Oral rehydration solutions containing rice or cereal as the carbohydrate source may be even more effective than glucose-based solutions. Patients who are severely dehydrated or in whom vomiting precludes the use of oral therapy should receive intravenous solutions such as Ringer's lactate.

Although most secretory forms of traveler's diarrhea—usually due to enterotoxigenic *E. coli*—can be treated effectively with rehydration, bismuth subsalicylate, or antiperistaltic agents, antimicrobial agents can shorten the duration of illness from between 3 and 4 days to between 24 and 36 h.

The antibiotic treatment of children who present with bloody diarrhea raises special concerns. Laboratory studies of enterohemorrhagic *E. coli* strains have demonstrated that a number of antibiotics induce replication of Shiga toxin–producing lambdoid bacteriophages, significantly increasing toxin production by these strains. Clinical studies have supported these laboratory results, and antibiotics are not recommended for the treatment of enterohemorrhagic *E. coli* infections in children.

PROPHYLAXIS Improvements in hygiene to limit fecal-oral spread of enteric pathogens will be necessary if the prevalence of diarrheal diseases is to be significantly reduced in developing countries. Travelers

TABLE 113-4 *Treatment of Traveler's Diarrhea on the Basis of Clinical Features*

Clinical Syndrome	Suggested Therapy
Watery diarrhea (no blood in stool, no fever), 1 or 2 unformed stools per day without distressing enteric symptoms	Oral fluids (Pedialyte, Lytren, or flavored mineral water) and saltine crackers
Watery diarrhea (no blood in stool, no fever), 1 or 2 unformed stools per day with distressing enteric symptoms	Bismuth subsalicylate (for adults): 30 mL or 2 tablets (262 mg/tablet) every 30 min for 8 doses; or loperamide[a]: 4 mg initially followed by 2 mg after passage of each unformed stool, not to exceed 8 tablets (16 mg) per day (prescription dose) or 4 caplets (8 mg) per day (over-the-counter dose); drugs can be taken for 2 days
Watery diarrhea (no blood in stool, no distressing abdominal pain, no fever), >2 unformed stools per day	Antibacterial drug[b] plus (for adults) loperamide[a] (see dose above)
Dysentery (passage of bloody stools) or fever (>37.8°C)	Antibacterial drug[b]
Vomiting, minimal diarrhea	Bismuth subsalicylate (for adults; see dose above)
Diarrhea in infants (<2 y old)	Fluids and electrolytes (Pedialyte, Lytren); continue feeding, especially with breast milk; seek medical attention for moderate dehydration, fever lasting >24 h, bloody stools, or diarrhea lasting more than several days
Diarrhea in pregnant women	Fluids and electrolytes; can consider attapulgite, 3 g initially, with dose repeated after passage of each unformed stool or every 2 h (whichever is earlier), for a total dosage of 9 g/d; seek medical attention for persistent or severe symptoms
Diarrhea despite trimethoprim-sulfamethoxazole prophylaxis	Fluoroquinolone—with loperamide[a] (see dose above) if no fever and no blood in stool, alone in cases of fever/dysentery
Diarrhea despite fluoroquinolone prophylaxis	Bismuth subsalicylate (see dose above) for mild to moderate disease; consult physician for moderate to severe disease or if disease persists

[a] Loperamide should not be used by patients with fever or dysentery; its use may prolong diarrhea in patients with infection due to *Shigella* or other invasive organisms.

[b] The recommended antibacterial drugs are as follows:
Travel to high-risk country other than Thailand:
Adults: A fluoroquinolone, such as ciprofloxacin, 500 mg bid; levofloxacin, 500 mg/d; norfloxacin, 400 mg bid; or ofloxacin, 400 mg bid on day 1; repeat on days 2 and 3 if diarrhea persists. Alternative agent: azithromycin, 500 mg on day 1, 250 mg on days 2 and 3 if diarrhea persists.
Children: Azithromycin, 10 mg/kg on day 1, 5 mg/kg on days 2 and 3 if diarrhea persists. Alternative agent: furazolidone, 7.5 mg/kg per day in four divided doses for 5 days.
Travel to Thailand (with risk of fluoroquinolone-resistant *Campylobacter*):
Adults: Azithromycin (at above dose for adults). Alternative agent: a fluoroquinolone (at above doses for adults).
Children: Same as for children traveling to other areas (see above).
All patients should take oral fluids (Pedialyte, Lytren, or flavored mineral water) plus saltine crackers. If diarrhea becomes moderate or severe, if fever persists, or if bloody stools or dehydration develops, the patient should seek medical attention.
Source: After Dupont.

can reduce their risk of diarrhea by eating only hot, freshly cooked food; by avoiding raw vegetables, salads, and unpeeled fruit; and by drinking only boiled or treated water and avoiding ice. In one cross-sectional epidemiologic survey, fewer than 3% of all European and North American travelers to Jamaica adhered to prescribed dietary restrictions, and travel health advice had no impact on the incidence of traveler's diarrhea; overall, the diarrhea attack rate among these travelers was 23.6%, with classic traveler's diarrhea in 11.7%.

Bismuth subsalicylate is an inexpensive agent for the prophylaxis of traveler's diarrhea; it is taken at a dosage of 2 tablets (525 mg) four times a day. Treatment appears to be effective and safe for up to 3 weeks. Prophylactic antimicrobial agents, although effective, are not generally recommended for the prevention of traveler's diarrhea, except when travelers are immunosuppressed or have other underlying illnesses that place them at high risk for morbidity from gastrointestinal infection. The risk of side effects and the possibility of developing an infection with a drug-resistant organism or with more harmful, invasive bacteria make it more reasonable to institute an empirical short course of treatment if symptoms develop.

The possibility of exerting a major impact on the worldwide morbidity and mortality associated with diarrheal diseases has led to intense efforts to develop effective vaccines against the common bacterial and viral enteric pathogens. Recent research has shown promising advances in the development of vaccines against rotavirus, *Shigella*, *V. cholerae*, *S. typhi*, and enterotoxigenic *E. coli*.

114 *CLOSTRIDIUM DIFFICILE*–ASSOCIATED DISEASE, INCLUDING PSEUDOMEMBRANOUS COLITIS

Dale N. Gerding, Stuart Johnson

DEFINITION *Clostridium difficile*–associated disease (CDAD) is a unique colon infection that is acquired almost exclusively in association with antimicrobial use and the consequent disruption of the normal colonic flora. The most commonly diagnosed diarrheal illness acquired in the hospital, CDAD results from the ingestion of spores of *C. difficile* that vegetate, multiply, and secrete toxins, causing diarrhea and pseudomembranous colitis (PMC).

ETIOLOGY AND EPIDEMIOLOGY *C. difficile* is an obligately anaerobic, gram-positive, spore-forming bacillus whose spores are found widely in nature, particularly in the environment of hospitals and chronic care facilities. CDAD occurs most frequently in hospitals and nursing homes where the level of antimicrobial use is high and the environment is contaminated by *C. difficile* spores.

Clindamycin, ampicillin, and cephalosporins were the first antibiotics associated with CDAD; the second- and third-generation cephalosporins, particularly cefotaxime, ceftriaxone, cefuroxime, and ceftazidime, are now the agents most frequently responsible for this condition. Penicillin/β-lactamase-inhibitor combinations such as ticarcillin/clavulanate and piperacillin/tazobactam pose significantly less risk. However, all antibiotics, including vancomycin and metronidazole (the agents most commonly used to treat CDAD), have been found to carry a risk of subsequent CDAD.

C. difficile is acquired exogenously, most frequently in the hospital, and is carried in the stool of symptomatic and asymptomatic patients. The rate of fecal colonization is often $\geq$20% among adult patients hospitalized for $>$1 week; in contrast, the rate is 1 to 3% among community residents. The risk of *C. difficile* acquisition increases in proportion to length of hospital stay. Asymptomatic fecal carriage of *C. difficile* in healthy neonates is very common, often exceeding 50% during the first 6 months of life. Spores of *C. difficile* are found on environmental surfaces (where the organism can persist for months) and on the hands of hospital personnel who fail to practice good hand hygiene. Hospital epidemics of CDAD have been attributed to a single *C. difficile* strain and to multiple strains present simultaneously. Other identified risk factors for CDAD include older age, greater severity of illness, use of electronic rectal thermometers, enteral tube feeding, antacid treatment, and gastrointestinal surgery.

PATHOLOGY AND PATHOGENESIS Spores of toxigenic *C. difficile* are ingested, survive gastric acidity, germinate in the small bowel, and colonize the lower intestinal tract, where they elaborate two large toxins: toxin A, an enterotoxin, and toxin B, a cytotoxin. These toxins initiate processes resulting in the disruption of epithelial-cell barrier function, diarrhea, and pseudomembrane formation. Toxin A is a potent neutrophil chemoattractant, and both toxins glucosylate the GTP-binding proteins of the Rho subfamily that regulate the actin cell cytoskeleton. Disruption of the cell cytoskeleton results in loss of cell shape, adherence, and tight junctions, with resultant fluid leakage. The pseudomembranes of PMC are confined to the colonic mucosa and initially appear as 1- to 2-mm whitish-yellow plaques. The intervening mucosa appears unremarkable, but, as the disease progresses, the pseudomembranes coalesce to form larger plaques and become confluent over the entire colon wall (Fig. 114-1). The whole colon is usually involved, but 10% of patients have rectal sparing. Viewed microscopically, the pseudomembranes have a mucosal attachment point and contain necrotic leukocytes, fibrin, mucus, and cellular debris. The epithelium is eroded and necrotic in focal areas, with neutrophil infiltration of the mucosa.

Patients colonized with *C. difficile* were initially thought to be at high risk for CDAD. However, four prospective studies have shown that colonized patients actually have a decreased risk of subsequent CDAD. At least three events are proposed as essential for the development of CDAD (Fig. 114-2). Exposure to antimicrobial agents is the first event and establishes susceptibility to *C. difficile* infection. The second event is exposure to toxigenic *C. difficile*. Given that the majority of patients do not develop CDAD after the first two events, a third event is clearly essential for its occurrence. Candidate third

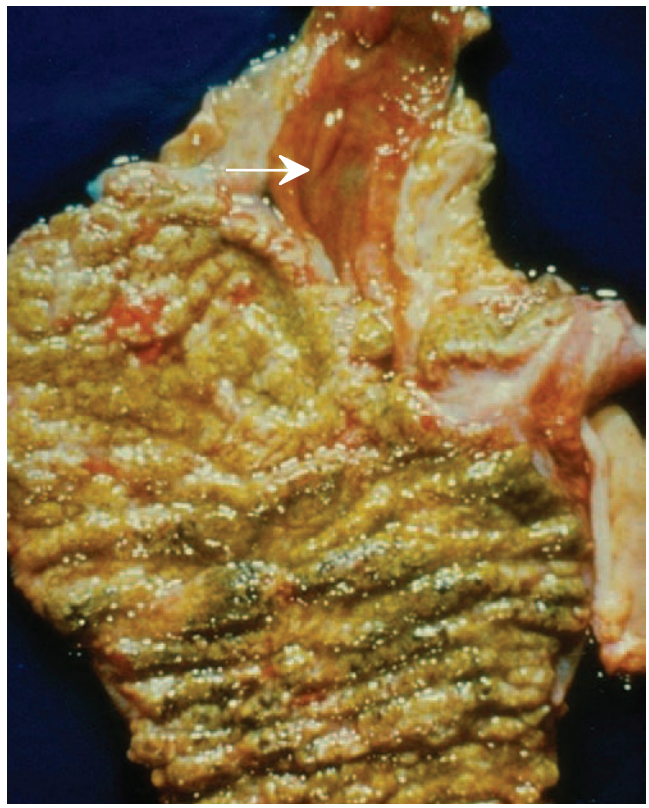

FIGURE 114-1 Autopsy specimen showing confluent pseudomembranes covering the cecum of a patient with pseudomembranous colitis. Note the sparing of the terminal ileum (*arrow*).

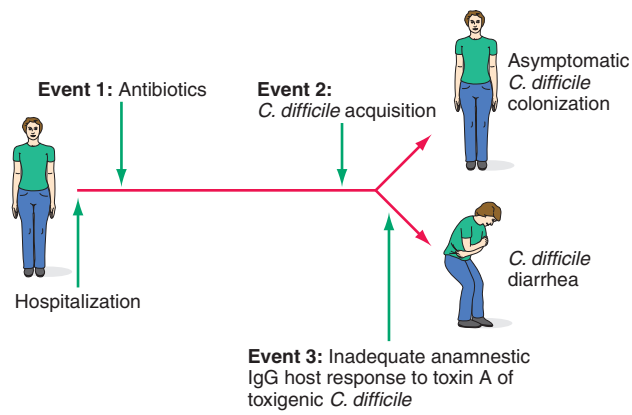

FIGURE 114-2 Pathogenesis model for hospital-acquired *Clostridium difficile*–associated diarrhea (CDAD). At least three events are integral to *C. difficile* pathogenesis. Exposure to antibiotics establishes susceptibility to infection. Once susceptible, the patient may acquire nontoxigenic (nonpathogenic) or toxigenic strains of *C. difficile* as a second event. Acquisition of toxigenic *C. difficile* may be followed by asymptomatic colonization or CDAD, depending on one or more additional events, including an inadequate host anamnestic IgG response to *C. difficile* toxin A.

events include exposure to a *C. difficile* strain of particular virulence, exposure to antimicrobial agents especially likely to cause CDAD, and an inadequate host immune response. The host anamnestic serum IgG antibody response to toxin A of *C. difficile* is the most likely third event that determines which patients will develop diarrhea and which patients will remain asymptomatic. The majority of humans first develop antibody to *C. difficile* toxins when colonized asymptomatically during the first year of life. Infants are thought not to develop symptomatic CDAD because they lack suitable mucosal toxin receptors that develop later in life. In adulthood, levels of antitoxin A IgG in serum increase more in response to infection in individuals who become asymptomatic carriers than in those who develop CDAD. For persons who develop CDAD, higher levels of antitoxin A correlate with a lower risk of recurrence of CDAD.

TABLE 114-1 *Relative Sensitivity and Specificity of Diagnostic Tests for Clostridium difficile–Associated Disease (CDAD)*

Type of Test	Relative Sensitivity[a]	Relative Specificity[a]	Comment
Stool culture for *C. difficile*	++++	+++	Most sensitive test; specificity is ++++ if the *C. difficile* isolate tests positive for toxin; with clinical data, is diagnostic of CDAD
Cell culture cytotoxin test on stool	+++	++++	With clinical data, is diagnostic of CDAD; highly specific but not as sensitive as stool culture
Enzyme immunoassay for toxin A or toxins A and B in stool	++ to +++	+++	With clinical data, is diagnostic of CDAD; rapid but not as sensitive as stool culture or cell culture cytotoxin test; rapid results
Latex test for *C. difficile* antigen in stool	++	+++	Detects glutamate dehydrogenase found in toxigenic and nontoxigenic strains of *C. difficile* and other stool organisms; less sensitive and specific than other tests; rapid results
Colonoscopy or sigmoidoscopy	+	++++	Highly specific if pseudomembranes are seen; insensitive compared with other tests

[a] According to both clinical and test-based criteria.
Note: ++++, >90%; +++, 71–90%; ++, 51–70%; +, ~50%.

CLINICAL MANIFESTATIONS Diarrhea is the most common symptom caused by *C. difficile*. Stools are almost never grossly bloody and range from soft and unformed to watery or mucoid in consistency, with a characteristic odor. Patients may have as many as 20 bowel movements per day. Clinical and laboratory findings include fever in 28% of cases, abdominal pain in 22%, and leukocytosis in 50%. When adynamic ileus (which is seen on x-ray in ~20% of cases) results in cessation of stool passage, the diagnosis of CDAD is frequently overlooked. A clue to the presence of unsuspected CDAD in these patients is unexplained leukocytosis with ≥15,000 cells/mm^3. Such patients are at high risk for complications of *C. difficile* infection, particularly toxic megacolon and sepsis.

C. difficile diarrhea recurs after treatment in ~20% of cases. Recurrences may represent either relapses due to the same strain or reinfections with a new strain. Recurrence of clinical CDAD is likely to be a result of continued disruption of the normal fecal flora by the antibiotic used to treat CDAD.

DIAGNOSIS The diagnosis of CDAD is based on a combination of clinical criteria: (1) diarrhea (≥3 unformed stools per 24 h for ≥2 days), with no other recognized cause; plus (2) toxin A or B detected in the stool, toxin-producing *C. difficile* detected by stool culture, or pseudomembranes seen in the colon. PMC is a more advanced form of CDAD and is visualized at endoscopy in only ~50% of patients with diarrhea who have a positive stool culture and toxin assay for *C. difficile* (Table 114-1). Endoscopy is a rapid diagnostic tool in seriously ill patients with suspected PMC and an acute abdomen, but a negative result in this examination does not rule out CDAD.

Despite the array of tests available for *C. difficile* and its toxins (Table 114-1), no single test has high sensitivity, high specificity, and rapid turnaround. The turnaround time for reporting of a positive result in the cell cytotoxicity test can be shortened to <24 h if cell cultures are examined at intervals as short as 4 h. However, this approach is labor intensive, and observation for 48 h is required for a conclusive test result. Most laboratory tests for toxins lack sensitivity; thus, if the first specimen is negative and diarrhea persists, testing of additional stool specimens increases the likelihood of diagnosis. Empirical treatment is appropriate if CDAD is strongly suspected on clinical grounds. Testing of asymptomatic patients is not recommended except for epidemiologic study purposes. In particular, so-called "tests of cure" of asymptomatic treated patients are not recommended because many patients continue to harbor the organism and toxin after diarrhea has ceased and test results do not correlate with recurrence of CDAD. These test results should not be used to restrict placement of patients in long-term-care or nursing home facilities.

TREATMENT

PRIMARY CDAD CDAD resolves in 15 to 23% of patients within 2 to 3 days after administration of the precipitating antimicrobial agent is discontinued, but most patients require specific treatment. General treatment guidelines include hydration and the avoidance of antiperistaltic agents and opiates, which may mask symptoms and possibly worsen disease. However, antiperistaltic agents have been used safely with vancomycin or metronidazole for mild to moderate CDAD. As mentioned above, test-of-cure cultures or toxin assays after treatment are not recommended; their results are not predictive of recurrence, and treatment of asymptomatic patients does not eradicate *C. difficile* from the stool.

Prospective randomized clinical trials show no statistical differences among the major therapeutic agents for the primary outcome end point of CDAD treatment: cessation of diarrhea (Table 114-2). The clinical response rate for bacitracin is 10 to 20% lower than that for vancomycin; therefore, bacitracin use for first-line therapy is discouraged. All drugs, particularly vancomycin, should be given orally if possible. When metronidazole is given intravenously, fecal bactericidal drug concentrations are achieved during acute diarrhea, and CDAD treatment has been successful; however, in the presence of adynamic ileus, intravenous metronidazole treatment of PMC has

TABLE 114-2 *Expected Treatment Outcomes Based on Randomized Comparative Trials of Oral Therapy for Initial Episodes of Clostridium difficile–Associated Diarrhea (CDAD)*

Treatment or Medication	Dose and Duration	Expected Resolution of Diarrhea, %	Expected Recurrence, %
Placebo or discontinuation of offending antibiotics	None	21	Unknown
Metronidazole	250 mg qid × 10 d	95	5
	500 mg tid × 10 d	94	17
Vancomycin[a]	500 mg tid × 10 d	94	17
	500 mg qid × 10 d	100	15
	125 mg qid × 7 d	86	33
	125 mg qid × 5 d	75	Unknown
Teicoplanin	400 mg bid × 10 d	96	7
	100 mg bid × 10 d	96	8
Fusidic acid	500 mg tid × 10 d	93	28
Bacitracin	25,000 U qid × 10 d	80	42

[a] Vancomycin treatment for first episodes of CDAD is discouraged because of possible development of vancomycin resistance in other nosocomial bacteria, such as enterococci.

failed. Diarrhea response rates to oral therapy with vancomycin or metronidazole are ≥94%. The mean interval to resolution of diarrhea is 2 to 4 days. Treatment should not be deemed a failure until a drug has been given for at least 6 days. On the basis of data for shorter courses of vancomycin (Table 114-2), it is recommended that treatment be given for 10 days, although no controlled comparisons are available. Metronidazole, although not approved by the U.S. Food and Drug Administration (FDA) for the treatment of CDAD, is the drug of first choice and the least expensive agent. Metronidazole-resistant isolates have been reported rarely, but treatment failure has not been attributed to resistance. Vancomycin as first-line treatment is discouraged because it may increase the incidence of vancomycin-resistant enterococci in hospitals.

Recurrent CDAD In all, 15 to 25% of patients experience recurrences of CDAD, either as relapses caused by the original organism or as reinfections following treatment (Table 114-2). Re-treatment with metronidazole is recommended for first recurrences of CDAD. There is no standard treatment for multiple recurrences. Approaches include the administration of vancomycin, metronidazole, or bacitracin followed by the yeast *Saccharomyces boulardii* or *Lactobacillus* GG; the administration of vancomycin followed by synthetic fecal bacterial enema; and the intentional colonization of the patient with a nontoxigenic strain of *C. difficile*. None of these biotherapeutic agents is available in the United States as an FDA-approved pharmaceutical for treating CDAD. Other approaches include the use of vancomycin in tapering doses over 21 days, with subsequent pulse-dosing every several days for 21 days; the administration of vancomycin followed by that of the anion-exchange binding resin cholestyramine; and combined treatment with vancomycin and rifampin—the approach the authors favor (vancomycin, 125 mg four times daily, and rifampin, 300 mg twice daily, for 10 days). In antibody-deficient children, intravenous immunoglobulin has been used successfully to treat CDAD.

Fulminant CDAD Fulminant CDAD is the most difficult treatment challenge in the rare patients who present with or develop toxic megacolon or ileus. These patients often do not have diarrhea, and their illness mimics an acute surgical abdomen. Sepsis (hypotension, fever, tachycardia, leukocytosis) may result from severe CDAD. An acute abdomen (with or without toxic megacolon) may include signs of obstruction, ileus, bowel-wall thickening, and ascites on abdominal computed tomography (CT), often with peripheral-blood leukocytosis (≥25,000 cells/mm^3). Whether or not the patient has diarrhea, the differential diagnosis of an acute abdomen, sepsis, or toxic megacolon should include CDAD if the patient has received antibiotics in the past 2 months. Cautious sigmoidoscopy or colonoscopy to visualize PMC and an abdominal CT examination are the best diagnostic tests in patients without diarrhea.

Medical management of fulminant CDAD is suboptimal because of the difficulty of delivering metronidazole or vancomycin to the colon by the oral route in the presence of ileus. Six patients with severe ileus have been successfully treated by the authors with vancomycin—given via nasogastric tube and by retention enema—plus intravenous metronidazole. Surgical intervention is indicated for patients with suspected perforation of the colon or fulminant CDAD that does not respond to medical management. The incidence of fulminant CDAD requiring colectomy may be increasing, and surgical mortality may be >50% in this setting.

PROGNOSIS The mortality rate attributed to CDAD is 0.6 to 3.5%, with the highest figures among the elderly. Most patients recover, but some have recurrences over months or years.

PREVENTION AND CONTROL Strategies for the prevention of CDAD are of two types: those aimed at preventing transmission of the organism to the patient and those aimed at reducing the risk of CDAD if the organism is transmitted. Transmission of *C. difficile* in clinical practice has been prevented by gloving of personnel and elimination of the use of contaminated electronic thermometers. CDAD outbreaks have been most successfully controlled by restricting use of specific antibiotics, such as clindamycin and second- and third-generation cephalosporins. Outbreaks of CDAD due to clindamycin-resistant strains have resolved promptly when clindamycin use was restricted.

115 SEXUALLY TRANSMITTED DISEASES: OVERVIEW AND CLINICAL APPROACH

King K. Holmes

CLASSIFICATION AND EPIDEMIOLOGY

Certain sexually transmitted diseases (STDs), such as syphilis, gonorrhea, HIV infection, hepatitis B, and chancroid, are most concentrated within "core populations" having high rates of partner change, concurrent partners, or "dense" sexual networks—for example, prostitutes and their clients, some homosexual men, and persons involved in the use of illicit drugs, particularly crack cocaine and methamphetamine. Other STDs are distributed more evenly throughout society. For example, chlamydial infections, genital infections with human papillomavirus (HPV), and genital herpes can spread efficiently in relatively low-risk populations.

In general, the product of three factors determines the initial rate of spread of any sexually transmitted infection (STI) within a population: rate of exposure of susceptible to infectious people, efficiency of transmission per exposure, and duration of infectivity of those infected. Efforts to prevent and control STIs attempt to decrease the duration of infectivity (through early diagnosis and curative or suppressive treatment), to decrease the efficiency of transmission (e.g., through promotion of condom use and safer sexual practices), and to decrease the rate of exposure of susceptibles to infected persons (e.g., through individual counseling and efforts to change the norms of sexual behavior).

In all societies, STDs rank among the most common of all infectious diseases, with >30 infections now classified as predominantly sexually transmitted or as frequently sexually transmissible (Table 115-1). In developing countries, with three-quarters of the world's population and 90% of the world's STDs, such factors as population growth (especially in adolescent and young-adult age groups), rural-to-urban migration, wars, and poverty create exceptional vulnerability to disease resulting from risky sexual behaviors. During the 1990s, in

China, Russia, the other states of the former Soviet Union, and South Africa, internal social structures changed rapidly as borders opened to the West, unleashing enormous new epidemics of HIV infection and other STDs. HIV has become the leading cause of death in some developing countries, and HPV and hepatitis B virus (HBV) remain important causes of cervical and hepatocellular carcinoma, respectively—two of the most common malignancies in the developing world. Sexually transmitted herpes simplex virus (HSV) infections now cause most genital ulcer disease throughout the world and an increasing proportion of cases of genital herpes in developing countries with generalized HIV epidemics, where the positive feedback loop between HSV and HIV transmission is a growing, intractable problem. Globally, five curable STDs—gonorrhea, chlamydial infections, syphilis, chancroid, and trichomoniasis—caused ~350 million new infections annually in the mid-1990s. Up to 50% of women of reproductive age in developing countries have bacterial vaginosis (arguably acquired sexually). All six of these curable infections have been associated with increased risk of HIV transmission or acquisition.

TABLE 115-1 *Sexually Transmitted and Sexually Transmissible Microorganisms*

Bacteria	Viruses	Other[a]
TRANSMITTED IN ADULTS PREDOMINANTLY BY SEXUAL INTERCOURSE		
Neisseria gonorrhoeae	HIV (types 1 and 2)	*Trichomonas vaginalis*
Chlamydia trachomatis	Human T-cell lymphotropic virus type I	*Phthirus pubis*
Treponema pallidum	Herpes simplex virus type 2	
Haemophilus ducreyi	Human papillomavirus (multiple genotypes)	
Calymmatobacterium granulomatis	Hepatitis B virus[b]	
Ureaplasma urealyticum	Molluscum contagiosum virus	
SEXUAL TRANSMISSION REPEATEDLY DESCRIBED BUT NOT WELL DEFINED OR NOT THE PREDOMINANT MODE		
Mycoplasma hominis	Cytomegalovirus	*Candida albicans*
Mycoplasma genitalium	Human T-cell lymphotropic virus type II	*Sarcoptes scabiei*
Gardnerella vaginalis and other vaginal bacteria	(?) Hepatitis C, D viruses	
Group B *Streptococcus*	Herpes simplex virus type 1	
Mobiluncus spp.	(?) Epstein-Barr virus	
Helicobacter cinaedi	Kaposi's sarcoma–associated herpesvirus[c]	
Sporothrix fennelliae	Transfusion-transmitted virus	
TRANSMITTED BY SEXUAL CONTACT INVOLVING ORAL-FECAL EXPOSURE; OF DECLINING IMPORTANCE IN HOMOSEXUAL MEN		
Shigella spp.	Hepatitis A virus	*Giardia lamblia*
Campylobacter spp.		*Entamoeba histolytica*

[a] Includes protozoa, ectoparasites, and fungi.
[b] Among U.S. patients for whom a risk factor can be ascertained, most hepatitis B virus infections are transmitted sexually or by injection drug use.
[c] Human herpesvirus type 8.

In the industrialized countries, fear of HIV infection since the mid-1980s, coupled with widespread behavioral interventions and better-organized systems of care for the curable STDs, have helped curb the transmission of the latter diseases. Nonetheless, foci of hyperendemic transmission persist in the southeastern United States and in most large U.S. cities. Rates of gonorrhea and syphilis remain higher in the United States than in any other Western industrialized country. The remarkable resurgence of gonorrhea and syphilis among homosexual and bisexual men in many parts of the United States and Europe since the 1990s reflects increased risk-taking since the advent of potent antiretroviral therapy and has been accompanied by increasing HIV transmission in this group. The prevalence of antibody to HSV-2 has begun to fall only recently (since the mid-1990s), and genital HPV remains the most common sexually transmitted pathogen, infecting one-third of a cohort of U.S. college women within 2 years in a study conducted during the 1990s.

MANAGEMENT OF COMMON STD SYNDROMES

Although other chapters discuss management of specific STIs, delineating treatment based on diagnosis of a specific infection, most patients are actually managed (at least initially) on the basis of presenting symptoms and signs and associated risk factors, even in industrialized countries. Table 115-2 lists some of the most common clinical STD syndromes and their microbial etiologies. Strategies for their management are outlined below. →***Chapters 172 and 173 address the management of infections with human retroviruses.***

STD care and management begin with risk assessment and proceed to clinical assessment, diagnostic testing or screening, treatment, and prevention. Indeed, the routine care of any patient begins with risk assessment (e.g., for risk of heart disease, cancer). STD/HIV risk assessment is important in primary care, urgent care, and emergency care settings as well as in specialty clinics providing adolescent, prenatal, and family planning services. STD/HIV risk assessment guides interpretation of symptoms that could reflect an STD; decisions on screening or prophylactic/preventive treatment; risk reduction counseling and intervention (e.g., hepatitis B vaccination); and notification of partners of patients with known infections. Consideration of routine demographic data (e.g., gender, age, marital status, area of residence) is a simple first step in STD/HIV risk assessment. For example, national guidelines now recommend routine screening of sexually active females ≤25 years of age for *Chlamydia trachomatis* infection. Table 115-3 provides a set of 10 STD/HIV risk-assessment questions that clinicians can pose verbally or that health care systems can adapt (with yes/no responses) into a routine self-administered questionnaire for use in clinics. The initial framing statement gives permission to discuss taboo topics.

Risk assessment is followed by clinical assessment (elicitation of information on specific current symptoms and signs of STDs). Confirmatory diagnostic tests (for persons with symptoms or signs) or screening tests (for those without symptoms or signs) may involve microscopic examination, culture, antigen detection tests, genetic probe or amplification tests, or serology. Initial syndrome-based treatment should cover the most likely causes. For certain syndromes, results of rapid tests can narrow the spectrum of this initial therapy (e.g., wet mount of vaginal fluid for women with vaginal discharge, Gram's stain of urethral discharge for men with urethral discharge, rapid plasma reagin test for genital ulcer). After the institution of treatment, STD management proceeds to the "4 C's" of prevention and control: *c*ontact tracing (see "Prevention and Control of STDs," below), ensuring *c*ompliance with therapy, and *c*ounseling on risk reduction, including *c*ondom promotion and provision.

URETHRITIS IN MEN During the 1990s, the incidence of reported gonorrhea among men in the United States fell to 126 cases per 100,000 population; the incidence figures then leveled off through 2002. The incidence of reported *C. trachomatis* infections among men has been increasing steadily (with increased testing), reaching 130 cases per 100,000 in 2002. Until recently, *C. trachomatis* caused ~30 to 40% of cases of nongonococcal urethritis (NGU); however, the proportion of cases due to this organism may have declined in some populations served by effective chlamydial-control programs. HSV and *Trichomonas vaginalis* each cause a small proportion of NGU cases in the United States. Recently, multiple studies have consistently implicated *Mycoplasma genitalium* as a probable cause of many *Chlamydia*-negative cases, while fewer studies than in the past have implicated *Ureaplasma urealyticum*. Coliform bacteria can cause urethritis in men who practice insertive anal intercourse. The initial diagnosis of urethritis in men currently includes specific tests only for *Neisseria gonorrhoeae*

TABLE 115-2 *Major STD Syndromes and Sexually Transmitted Microbial Etiologies*

Syndrome	ST Microbial Etiologies
AIDS	HIV types 1 and 2
Urethritis: males	*Neisseria gonorrhoeae*, *Chlamydia trachomatis*, *Mycoplasma genitalium*, *Ureaplasma urealyticum*, *Trichomonas vaginalis*, HSV
Epididymitis	*C. trachomatis*, *N. gonorrhoeae*
Lower genital tract infections: females	
Cystitis/urethritis	*C. trachomatis*, *N. gonorrhoeae*, HSV
Mucopurulent cervicitis	*C. trachomatis*, *N. gonorrhoeae*, *M. genitalium*
Vulvitis	*Candida albicans*, HSV
Vulvovaginitis	*C. albicans*, *T. vaginalis*
Bacterial vaginosis (BV)	BV-associated bacteria (see text)
Acute pelvic inflammatory disease	*N. gonorrhoeae*, *C. trachomatis*, BV-associated bacteria, group B streptococci, *M. genitalium*
Infertility	*N. gonorrhoeae*, *C. trachomatis*, BV-associated bacteria
Ulcerative lesions of the genitalia	HSV-1, HSV-2, *Treponema pallidum*, *Haemophilus ducreyi*, *C. trachomatis* (LGV strains), *Calymmatobacterium granulomatis*
Complications of pregnancy/puerperium	Several agents implicated
Intestinal infections	
Proctitis	*C. trachomatis*, *N. gonorrhoeae*, HSV, *T. pallidum*
Proctocolitis or enterocolitis	*Campylobacter* spp., *Shigella* spp., *Entamoeba histolytica*, other enteric pathogens
Enteritis	*Giardia lamblia*
Acute arthritis with urogenital infection or viremia	*N. gonorrhoeae* (e.g., DGI), *C. trachomatis* (e.g., Reiter's syndrome), HBV
Genital and anal warts	HPV (30 genital types)
Mononucleosis syndrome	CMV, HIV, EBV
Hepatitis	Hepatitis viruses, *T. pallidum*, CMV, EBV
Neoplasias	
Squamous cell dysplasias and cancers of the cervix, anus, vulva, vagina, or penis	HPV (especially types 16, 18, 31, 45)
Kaposi's sarcoma, body-cavity lymphomas	HHV-8
T cell leukemia	HTLV-I
Hepatocellular carcinoma	HBV
Tropical spastic paraparesis	HTLV-I
Scabies	*Sarcoptes scabiei*
Pubic lice	*Phthirus pubis*

Note: HSV, herpes simplex virus; LGV, lymphogranuloma venereum; DGI, disseminated gonococcal infection; HPV, human papillomavirus; CMV, cytomegalovirus; EBV, Epstein-Barr virus; HBV, hepatitis B virus; HTLV, human T-cell lymphotropic virus; HHV-8, human herpesvirus type 8.

and *C. trachomatis*. The following summarizes the approach to the patient with suspected urethritis:

1. *Establish the presence of urethritis*. If proximal-to-distal "milking" of the urethra does not express a purulent or mucopurulent discharge, even after the patient has not voided for several hours or preferably overnight, a Gram's-stained smear of overt discharge or of an anterior urethral specimen obtained by passage of a small urethrogenital swab 2 to 3 cm into the urethra usually reveals ≥5 neutrophils per 1000× field in areas containing cells; in gonococcal infection, such a smear usually reveals gram-negative intracellular diplococci as well. Alternatively, the centrifuged sediment of the first 20 to 30 mL of voided urine can be examined for inflammatory cells, either by microscopy showing ≥10 leukocytes per high-power field or by the leukocyte esterase test. Patients with symptoms who lack objective evidence of urethritis may have functional rather than organic problems and generally do not benefit from repeated courses of antibiotics.
2. *Evaulate for complications or alternative diagnoses*. A brief history and examination will exclude epididymitis and systemic complications, such as disseminated gonococcal infection (DGI) and Reiter's syndrome. Although digital examination of the prostate gland seldom contributes to the evaluation of sexually active young men with urethritis, men with dysuria who lack evidence of urethritis as well as sexually inactive men with urethritis should undergo prostate palpation, urinalysis, and urine culture to exclude bacterial prostatitis and cystitis.
3. *Evaluate for gonococcal and chlamydial infection*. An absence of typical gram-negative diplococci on Gram's-stained smear of urethral exudate containing inflammatory cells warrants a preliminary diagnosis of NGU and should lead to testing of the urethral specimen for *C. trachomatis*. Culture or DNA detection tests for *N. gonorrhoeae* may be positive when Gram's staining is negative; certain strains of *N. gonorrhoeae* can result in negative urethral Gram's stains in up to 30% of cases of urethritis. Results of tests for gonococcal and chlamydial infection predict the patient's prognosis (with greater risk for recurrent NGU if neither chlamydiae nor gonococci are found than if either is detected) and can

TABLE 115-3 *Ten-Question STD/HIV Risk Assessment*

Framing Statement:
In order to provide the best care for you today and to understand your risk for certain infections, it is necessary for us to talk about your sexual behavior.

Screening Questions:
(1) Do you have any reason to think you might have a sexually transmitted disease? If so, what reason?
(2) For all adolescents <18 years old: Have you begun having any kind of sex yet?

STD History:
(3) Have you ever had any sexually transmitted diseases or any genital infections? If so, which ones?

Sexual Preference:
(4) Have you had sex with men, women, or both?

Injection Drug Use:
(5) Have you ever injected yourself ("shot up") with drugs? (If yes, have you ever shared needles or injection equipment?)
(6) Have you ever had sex with a gay or bisexual man or with anyone who had ever injected drugs?

Characteristics of Partner(s):
(7) Has your sex partner(s) had any sexually transmitted infections? If so, which ones?

STD Symptoms Checklist:
(8) Have you recently developed any of these symptoms?

For Men	For Women
(a) Discharge of pus (drip) from the penis	(a) Abnormal vaginal discharge (increased amount, abnormal odor, abnormal yellow color)
(b) Genital sores (ulcers) or rash	(b) Genital sores (ulcers), rash, or itching

Sexual Practices, Past 2 Months (for patients answering yes to any of the above questions, to guide examination and testing):
(9) Now I'd like to ask what parts of your body may have been sexually exposed to an STD (e.g., your penis, mouth, vagina, anus)?

Query about Interest in STD Screening Tests (for patients answering no to all of the above questions):
(10) Would you like to be tested for HIV or any other STDs today? (If yes, clinician can explore which STD and why.)

Source: Adapted from JR Curtis, KK Holmes, in KK Holmes et al (eds): *Sexually Transmitted Diseases*, 3d ed. New York, McGraw-Hill, 1999.

TABLE 115-4 Management of Urethral Discharge in Men

Usual causes	**Usual initial evaluation**
Chlamydia trachomatis	Demonstration of urethral discharge or pyuria
Neisseria gonorrhoeae	Exclusion of local or systemic complications
Ureaplasma urealyticum	Urethral Gram's stain to confirm urethritis, detect gram-negative diplococci
Trichomonas vaginalis	Test for *N. gonorrhoeae*, *C. trachomatis*
Herpes simplex virus	
Mycoplasma genitalium	

INITIAL TREATMENT FOR PATIENT AND PARTNERS

Treat gonorrhea (unless excluded): Cefpodoxime, 400 mg PO; *or* Ceftriaxone, 125 mg IM; *or* Fluoroquinolone (e.g., ciprofloxacin, 500 mg PO)	plus	**Treat chlamydial infection:** Azithromycin, 1 g PO; *or* Doxycycline, 100 mg bid for 7 days

MANAGEMENT OF RECURRENCE

Confirm objective evidence of urethritis. If patient was reexposed to untreated or new partner, repeat treatment of patient and partner.
If patient was not reexposed, consider infection with *T. vaginalis*[a] or doxycycline-resistant *Ureaplasma*, and consider treatment with metronidazole or azithromycin.

[a] In men, the diagnosis of *T. vaginalis* infection requires culture (or nucleic acid amplification test, where available) of early-morning first-voided urine sediment or of a urethral swab specimen obtained before voiding.

guide both the counseling given to the patient and the management of the patient's sexual partner(s).

4. *Treat urethritis.*

Table 115-4 summarizes the steps in management of sexually active men with symptoms of urethral discharge and/or dysuria.

TREATMENT

In practice, if Gram's stain does not reveal gonococci, urethritis is treated with a regimen effective for NGU, such as azithromycin (1.0 g orally in a single dose) or doxycycline (100 mg orally bid for 7 days). If gonococci are demonstrated by Gram's stain or if no diagnostic tests are performed to definitively exclude gonorrhea, treatment should include a single-dose regimen for gonorrhea (Chap. 128) plus azithromycin or doxycycline treatment for *C. trachomatis*. Sexual partners should be tested for gonorrhea and chlamydial infection and should receive the same regimen given to the male index case. Patients with confirmed persistence or recurrence of urethritis after treatment should be re-treated with the initial regimen if they did not comply with the original treatment or were reexposed to an untreated partner. Otherwise, an intraurethral swab specimen and a first-voided urine sample should be cultured for *T. vaginalis*. If compliance with initial treatment is confirmed and reexposure excluded, treatment with metronidazole (2 g orally in a single dose) plus erythromycin base (500 mg orally qid for 7 days) is recommended.

EPIDIDYMITIS Acute epididymitis, almost always unilateral, must be differentiated from testicular torsion, tumor, and trauma. Torsion, a surgical emergency, usually occurs in the second or third decade of life and produces a sudden onset of pain, elevation of the testicle within the scrotal sac, rotation of the epididymis from a posterior to an anterior position, and absence of blood flow on Doppler examination or ^{99m}Tc scan. Persistence of symptoms after a course of therapy for epididymitis suggests the possibility of testicular tumor. In sexually active men under age 35, acute epididymitis is caused most frequently by *C. trachomatis* and less commonly by *N. gonorrhoeae* and is usually associated with overt or subclinical urethritis. Acute epididymitis occurring in older men or following urinary tract instrumentation is usually caused by urinary pathogens. Similarly, epididymitis in men who have practiced insertive rectal intercourse is often caused by Enterobacteriaceae. These men usually have no urethritis but do have bacteriuria.

TREATMENT

Ceftriaxone (250 mg as a single dose IM) followed by doxycycline (100 mg orally bid for 10 days) is effective for epididymitis caused by *N. gonorrhoeae* or *C. trachomatis*. Alternatively, ofloxacin (300 mg orally bid for 10 days) or levofloxacin (500 mg orally once daily for 10 days) is also effective for syndrome-based treatment of epididymitis because of effectiveness against Enterobacteriaceae as well as *N. gonorrhoeae* and *C. trachomatis*; however, emerging gonococcal resistance to fluoroquinolones now limits the use of these drugs in some areas.

URETHRITIS AND THE URETHRAL SYNDROME IN WOMEN *C. trachomatis*, *N. gonorrhoeae*, and occasionally HSV cause symptomatic urethritis—known as the urethral syndrome in women—characterized by "internal" dysuria (usually without urinary urgency or frequency) and pyuria, with *Escherichia coli* or other uropathogens not present in urine at counts of $\geq 10^2$/mL. In contrast, the dysuria associated with vulvar herpes or vulvovaginal candidiasis (and perhaps with trichomoniasis) is often described as "external," being caused by painful contact of urine with the inflamed or ulcerated labia or introitus. Acute onset, association with urinary urgency or frequency, hematuria, or suprapubic bladder tenderness suggests bacterial cystitis. Among women with symptoms of acute bacterial cystitis, costovertebral pain and tenderness or fever suggests acute pyelonephritis. →***The management of bacterial urinary tract infection (UTI) is discussed in Chap. 269.***

Signs of vulvovaginitis, coupled with symptoms of external dysuria, suggest vulvar infection (e.g., with HSV or *Candida albicans*). Among dysuric women without signs of vulvovaginitis, bacterial UTI must be differentiated from the urethral syndrome by assessment of risk, evaluation of the pattern of symptoms and signs, and specific microbiologic testing. An STD etiology of the urethral syndrome is suggested by young age, more than one current sexual partner, a new partner within the past month, a partner with urethritis, or coexisting mucopurulent cervicitis (see below). The finding of a single urinary pathogen, such as *E. coli* or *Staphylococcus saprophyticus*, at a concentration of $\geq 10^2$/mL in a properly collected specimen of midstream urine from a dysuric woman with pyuria indicates probable bacterial UTI, whereas pyuria with $< 10^2$ conventional uropathogens per milliliter of urine ("sterile" pyuria) suggests acute urethral syndrome due to *C. trachomatis* or *N. gonorrhoeae*. Gonorrhea and chlamydial infection should be sought by specific tests (e.g., nucleic acid amplification tests on the first 10 mL of voided urine). Among dysuric women with sterile pyuria caused by infection with *N. gonorrhoeae* or *C. trachomatis*, appropriate treatment alleviates dysuria.

VULVOVAGINAL INFECTIONS ■ Abnormal Vaginal Discharge If directly questioned about vaginal discharge during routine health checkups, many women acknowledge having nonspecific symptoms of vaginal discharge that do not correlate with objective signs of inflammation or with actual infection. However, unsolicited reporting of abnormal vaginal discharge does suggest bacterial vaginosis or trichomoniasis. Specifically, an abnormally increased amount or an abnormal odor of the discharge is associated with one or both of these conditions. Cervical infection with *N. gonorrhoeae* or *C. trachomatis* does not appear to cause an increased amount or abnormal odor of discharge, but cervicitis, like trichomoniasis, can include the production of an increased number of neutrophils in vaginal fluid, resulting in a yellow color. Vulvar conditions such as genital herpes or vulvovaginal candidiasis can cause vulvar pruritus, burning, irritation, or lesions as well as external dysuria (as urine passes over the inflamed vulva) or vulvar dyspareunia.

Certain vulvovaginal infections may have serious sequelae. Tricho-

moniasis, bacterial vaginosis, and vulvovaginal candidiasis have all been associated with increased risk of acquisition of HIV infection. Vaginal trichomoniasis and bacterial vaginosis early in pregnancy independently predict premature onset of labor. Bacterial vaginosis can also lead to anaerobic bacterial infection of the endometrium and salpinges. Vaginitis may be an early and prominent feature of toxic shock syndrome, and recurrent or chronic vulvovaginal candidiasis develops with increased frequency among women with systemic illnesses, such as diabetes mellitus or HIV-related immunosuppression (although only a very small proportion of women with recurrent vulvovaginal candidiasis in the United States actually have a serious predisposing illness).

Thus vulvovaginal symptoms or signs warrant careful evaluation, including pelvic examination, simple rapid diagnostic tests, and appropriate therapy specific for the anatomical site and type of infection. Unfortunately, a recent survey in the United States indicated that clinicians seldom perform the tests required to establish the cause of such symptoms. Further, comparison of telephone and office management of vulvovaginal complaints has documented the inaccuracy of the former, and comparison of evaluations by nurse-midwives with those by physician-practitioners showed that the practitioners' clinical evaluations correlated poorly both with the nurses' evaluations and with diagnostic tests. The diagnosis and treatment of the three most common types of vaginal infection are summarized in Table 115-5.

Inspection of the vulva and perineum may reveal tender genital ulcerations (typically due to HSV infection, occasionally due to chancroid) or fissures (typically due to vulvovaginal candidiasis) or discharge visible at the introitus before insertion of a speculum (suggestive of bacterial vaginosis or trichomoniasis). Speculum examination permits the clinician to discern whether the discharge in fact looks abnormal and whether any abnormal discharge in the vagina emanates from the cervical os (mucoid and, if abnormal, yellow) or from the vagina (not mucoid, since the vaginal epithelium does not produce mucus). Symptoms or signs of abnormal vaginal discharge should prompt testing of vaginal fluid for pH, fishy odor when mixed with 10% KOH, and microscopic features when mixed with saline and with 10% KOH. Additional objective laboratory tests useful for establishing the cause of abnormal vaginal discharge include Gram's staining to

TABLE 115-5 *Diagnostic Features and Management of Vaginal Infection*

Feature	Normal Vaginal Examination	Vulvovaginal Candidiasis	Trichomonal Vaginitis	Bacterial Vaginosis
Etiology	Uninfected; lactobacilli predominant	*Candida albicans*	*Trichomonas vaginalis*	Associated with *Gardnerella vaginalis*, various anaerobic bacteria, and mycoplasmas
Typical symptoms	None	Vulvar itching and/or irritation	Profuse purulent discharge; vulvar itching	Malodorous, slightly increased discharge
Discharge				
Amount	Variable; usually scant	Scant	Often profuse	Moderate
Color[a]	Clear or white	White	White or yellow	White or gray
Consistency	Nonhomogeneous, floccular	Clumped; adherent plaques	Homogeneous	Homogeneous, low viscosity; uniformly coats vaginal walls
Inflammation of vulvar or vaginal epithelium	None	Erythema of vaginal epithelium, introitus; vulvar dermatitis common	Erythema of vaginal and vulvar epithelium; colpitis macularis	None
pH of vaginal fluid[b]	Usually ≤4.5	Usually ≤4.5	Usually ≥5.0	Usually >4.5
Amine (''fishy'') odor with 10% KOH	None	None	May be present	Present
Microscopy[c]	Normal epithelial cells; lactobacilli predominant	Leukocytes, epithelial cells; mycelia or pseudomycelia in up to 80% of *C. albicans* culture-positive persons with typical symptoms	Leukocytes; motile trichomonads seen in 80 to 90% of symptomatic patients, less often in the absence of symptoms	Clue cells; few leukocytes; no lactobacilli or only a few outnumbered by profuse mixed flora, nearly always including *G. vaginalis* plus anaerobic species on Gram's stain
Usual treatment	None	Azole cream, tablet, or suppository—e.g., miconazole 100-mg vaginal suppository or clotrimazole 100-mg vaginal tablet, once daily for 7 days Fluconazole, 150 mg orally (single dose)	Metronidazole, 2 g orally (single dose) Metronidazole, 500 mg PO bid for 7 days	Metronidazole, 500 mg PO bid for 7 days Clindamycin, 2% cream, one full applicator vaginally each night for 7 days Metronidazole gel, 0.75%, one full applicator vaginally twice daily for 5 days Metronidazole, 2 g PO (single dose)[d]
Usual management of sexual partner	None	None; topical treatment if candidal dermatitis of penis is detected	Examination for STD; treatment with metronidazole, 2 g PO (single dose)	Examination for STD; no treatment if normal

[a] Color of discharge is best determined by examination against the white background of a swab.
[b] pH determination is not useful if blood is present.
[c] To detect fungal elements, vaginal fluid is digested with 10% KOH prior to microscopic examination; to examine for other features, fluid is mixed (1:1) with physiologic saline. Gram's stain is also excellent for detecting yeasts and pseudomycelia and for distinguishing normal flora from the mixed flora seen in bacterial vaginosis, but it is less sensitive than the saline preparation for detection of *T. vaginalis*.
[d] Single-dose regimen is less effective than 7-day metronidazole regimen.

detect alterations in the vaginal flora; card tests for bacterial vaginosis, as described below; and a new DNA probe test (the Affirm test) to detect *T. vaginalis* and *C. albicans* as well as the increased concentrations of *Gardnerella vaginalis* associated with bacterial vaginosis.

TREATMENT

Patterns of treatment for vaginal discharge vary widely. In developing countries, where clinics or pharmacies often dispense treatment based on symptoms alone without examination or testing, oral treatment with metronidazole—either as a 2-g single dose or as a 7-day regimen—provides reasonable coverage against both trichomoniasis and bacterial vaginosis, the usual causes of symptoms of vaginal discharge; metronidazole treatment of sex partners prevents reinfection of women with trichomoniasis, even though it does not help prevent the recurrence of bacterial vaginosis. Guidelines promulgated during the 1990s by the World Health Organization suggested treatment for cervical infection and for vulvovaginal candidiasis in women with symptoms of abnormal vaginal discharge; in retrospect, these recommendations were faulty, since these conditions seldom produce such symptoms.

In industrialized countries, clinicians treating symptoms and signs of abnormal vaginal discharge should at least differentiate between bacterial vaginosis and trichomoniasis, because optimal management of patients and partners differs for these two conditions (as discussed briefly below).

Vaginal Trichomoniasis (See also Chap. 199) Symptomatic trichomoniasis characteristically produces a profuse, yellow, purulent, homogeneous vaginal discharge and vulvar irritation, often with visible inflammation of the vaginal and vulvar epithelium and petechial lesions on the cervix (the so-called strawberry cervix, usually evident only by colposcopy). The pH of vaginal fluid usually rises to ≥5.0. In women with typical symptoms and signs of trichomoniasis, microscopic examination of vaginal discharge mixed with saline reveals motile trichomonads in most culture-positive cases. However, in the absence of symptoms or signs, culture is often required for detection of the organism. Polymerase chain reaction (PCR) tests for *T. vaginalis* compare favorably with culture, and PCR testing of urine is now disclosing surprisingly high prevalences of this pathogen among men at several STD clinics in the United States. Treatment of asymptomatic as well as symptomatic cases reduces rates of transmission and prevents later development of symptoms.

TREATMENT

Only nitroimidazoles consistently cure trichomoniasis. Tinidazole and ornidazole have longer half-lives than metronidazole but do not give better results than a single 2-g oral dose of metronidazole, which is much less expensive. Treatment of male sexual partners—often facilitated by dispensing metronidazole to the female patient to give to her partner(s), with a warning about avoiding the concurrent use of alcohol—significantly reduces both the risk of reinfection and the reservoir of infection. Treatment with 0.75% metronidazole gel intravaginally, although moderately effective for bacterial vaginosis, is not reliable for vaginal trichomoniasis. Systemic use of metronidazole is not recommended during the first trimester of pregnancy but is considered safe thereafter. In a large randomized trial, metronidazole treatment of trichomoniasis during pregnancy did not reduce the frequency of perinatal morbidity.

Bacterial Vaginosis This syndrome (formerly termed *nonspecific vaginitis*, *Haemophilus vaginitis*, *anaerobic vaginitis*, or *Gardnerella-associated vaginal discharge*) is characterized by symptoms of vaginal malodor and a slightly to moderately increased white discharge, which appears homogeneous, is low in viscosity, and smoothly coats the vaginal mucosa. An interesting observation is that new genital HPV infection in young women is associated with increased subsequent risk of developing bacterial vaginosis. Other risk factors include multiple sexual partners and recent intercourse with a new partner, but metronidazole treatment of male partners has not reduced the rate of recurrence among affected women.

The vaginal fluid of women with bacterial vaginosis is characterized by markedly increased prevalences and concentrations of *G. vaginalis*, *Mycoplasma hominis*, and several anaerobic bacteria [e.g., *Mobiluncus* spp., *Prevotella* spp. (formerly *Bacteroides* spp.), and some *Peptostreptococcus* spp.]. The vaginal fluid usually lacks hydrogen peroxide–producing *Lactobacillus* spp., which constitute most of the normal vaginal flora and perhaps help protect against certain cervical and vaginal infections. Vaginal douching, use of intravaginal nonoxynol-9 spermicide, and new sexual partners can all result in loss of vaginal colonization by hydrogen peroxide–producing lactobacilli.

Bacterial vaginosis is conventionally diagnosed clinically with the Amsel criteria, which include any three of the following four clinical abnormalities: (1) objective signs of increased white homogeneous vaginal discharge; (2) a vaginal discharge pH of >4.5; (3) liberation of a distinct fishy odor (attributable to volatile amines such as trimethylamine) immediately after vaginal secretions are mixed with a 10% solution of KOH; and (4) microscopic demonstration of "clue cells" (vaginal epithelial cells coated with coccobacillary organisms giving them a granular appearance and indistinct borders; Fig. 115-1) on a wet mount prepared by mixing vaginal secretions with normal saline in a ratio of ~1:1. A diagnostic card test facilitates screening of vaginal fluid for pH > 4.5 and amines, and a dipstick test detects proline aminopeptidase, an enzyme associated with this syndrome.

TREATMENT

The standard dosage of metronidazole for the treatment of bacterial vaginosis is 500 mg orally bid for 7 days. The single 2-g oral dose of metronidazole recommended for trichomoniasis produces somewhat

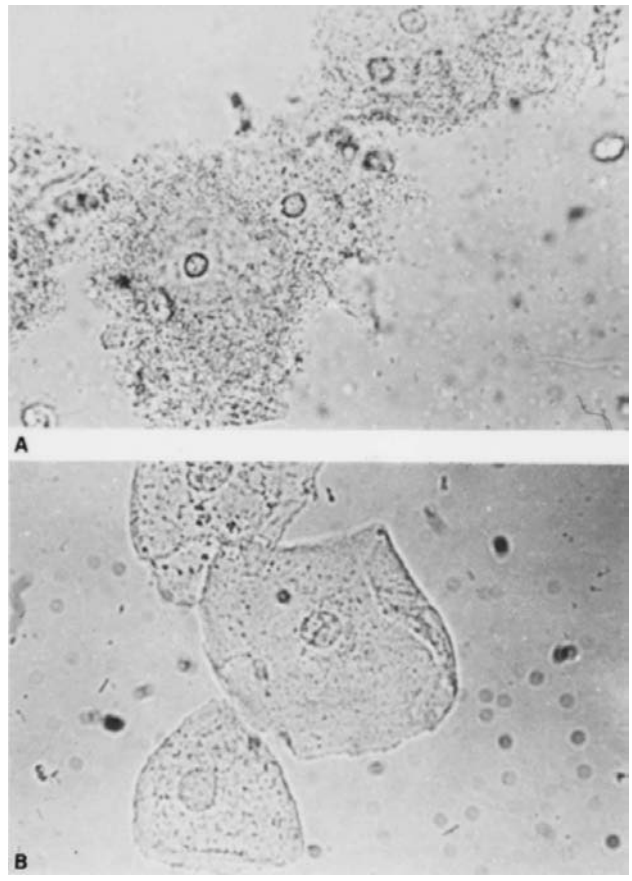

FIGURE 115-1 *A.* Vaginal epithelial "clue cells." Note granular appearance due to adherent *Gardnerella vaginalis* and indistinct cell margins (400×). *B.* Normal vaginal epithelial cells. The cell margins are distinct and lack granularity.

lower short-term cure rates. Intravaginal treatment with 2% clindamycin cream [one full applicator (5 g containing 100 mg of clindamycin phosphate) each night for 7 nights] or with 0.75% metronidazole gel [one full applicator (5 g containing 37.5 mg of metronidazole) twice daily for 5 days] is also approved for use in the United States and does not elicit systemic adverse reactions. Oral clindamycin (300 mg bid for 7 days) and clindamycin ovules (100 g intravaginally once at bedtime for 3 days) have also been approved. Unfortunately, long-term recurrence (i.e., several months later) is distressingly common after either oral or intravaginal treatment. Treatment of male partners with metronidazole does not prevent recurrence of bacterial vaginosis.

No controlled data support the use of currently available vaginal or oral preparations of lactobacilli for the treatment or prevention of recurrence of bacterial vaginosis. In a randomized trial, repeated intravaginal inoculation of a vaginal peroxide-producing *Lactobacillus* species following treatment of bacterial vaginosis with metronidazole did not reduce the frequency of recurrence. A meta-analysis of 18 studies concluded that bacterial vaginosis during pregnancy substantially increased the risk of preterm delivery and of spontaneous abortion. Although intravaginal treatment of bacterial vaginosis during pregnancy has not reduced perinatal morbidity, oral clindamycin treatment of this syndrome early in pregnancy significantly reduced the risk of late miscarriage and of preterm delivery. Oral antimicrobial treatment of bacterial vaginosis for ≥7 days early in pregnancy may reduce the risk of preterm delivery for women with a history of this pregnancy outcome.

Vulvovaginal Pruritus, Burning, or Irritation Vulvovaginal candidiasis produces vulvar pruritus, burning, or irritation, generally without symptoms of increased vaginal discharge or malodor. Genital herpes can produce similar symptoms, with lesions sometimes difficult to distinguish from the fissures caused by candidiasis. Signs of vulvovaginal candidiasis include vulvar erythema, edema, fissures, and tenderness. With candidiasis, a white scanty vaginal discharge sometimes takes the form of white thrush-like plaques or cottage cheese–like curds adhering loosely to the vaginal mucosa. *C. albicans* accounts for nearly all cases of symptomatic vulvovaginal candidiasis, which probably arise from endogenous strains of *C. albicans* that have colonized the vagina or the intestinal tract. Complicated vulvovaginal candidiasis includes cases that recur four or more times per year; are unusually severe; are caused by non-*albicans Candida* spp.; or occur in women with uncontrolled diabetes, debilitation, immunosuppression, or pregnancy.

The diagnosis of vulvovaginal candidiasis usually involves the demonstration of pseudohyphae or hyphae by microscopic examination of vaginal fluid mixed with saline or 10% KOH or subjected to Gram's staining. Microscopic examination is less sensitive than culture but correlates better with symptoms.

Rx TREATMENT

Symptoms and signs of vulvovaginal candidiasis warrant treatment, usually intravaginal administration of any of several imidazole antibiotics (e.g., miconazole or clotrimazole) for 3 to 7 days. Over-the-counter marketing of such preparations has reduced the cost of care and made treatment more convenient for many women with recurrent yeast vulvovaginitis. However, most women who purchase these preparations do not have vulvovaginal candidiasis, while many do have other vaginal infections that require different treatment. Therefore, only women with classic symptoms of vulvar pruritus and a history of previous episodes of yeast vulvovaginitis documented by an experienced clinician should self-treat. Single-dose oral treatment with fluconazole (150 mg) is also effective and is preferred by many patients. Management of complicated cases (see above) and those that do not respond to the usual intravaginal or single-dose oral therapy often involves prolonged or periodic oral therapy; this situation is discussed extensively in the *2002 STD Treatment Guidelines* published by the Centers for Disease Control and Prevention (CDC). Treatment of sexual partners is not routinely indicated.

Other Causes of Vaginal Discharge or Vaginitis In the ulcerative vaginitis associated with staphylococcal toxic shock syndrome, *Staphylococcus aureus* should be promptly identified in vaginal fluid by Gram's stain and by culture. In desquamative inflammatory vaginitis, smears of vaginal fluid reveal neutrophils, massive vaginal epithelial-cell exfoliation with increased numbers of parabasal cells, and gram-positive cocci; this syndrome may respond to treatment with 2% clindamycin cream. Additional causes of vaginitis and vulvovaginal symptoms include retained foreign bodies (e.g., tampons), cervical caps, vaginal spermicides, vaginal antiseptic preparations or douches, vaginal epithelial atrophy (in postmenopausal women or during prolonged breast-feeding in the postpartum period), allergic reactions to latex condoms, vaginal aphthae associated with HIV infection or Behçet's syndrome, and vestibulitis (a poorly understood syndrome).

MUCOPURULENT CERVICITIS Mucopurulent cervicitis (MPC) refers to inflammation of the columnar epithelium and subepithelium of the endocervix and of any contiguous columnar epithelium that lies exposed in an ectopic position on the exocervix. MPC in women represents the "silent partner" of urethritis in men, being equally common and often caused by the same agents (*N. gonorrhoeae*, *C. trachomatis*, or—in a significant association shown by two recent case-control studies—*M. genitalium*); however, MPC is more difficult to recognize. As the most common manifestation of these serious bacterial infections in women, MPC can be a harbinger or sign of upper genital tract infection, also known as pelvic inflammatory disease (PID; see below). In pregnant women, MPC can lead to obstetric complications. More than half of all cases of MPC in the United States today remain idiopathic.

The diagnosis of MPC rests on the detection of yellow mucopurulent discharge from the cervical os or of increased numbers of polymorphonuclear leukocytes (PMNs) in Gram's-stained or Papanicolaou-stained smears of endocervical mucus. MPC due to *C. trachomatis* can also produce edematous cervical ectopy (see below) and endocervical bleeding upon gentle swabbing. Unlike the endocervicitis produced by gonococcal or chlamydial infection, cervicitis caused by HSV produces ulcerative lesions on the stratified squamous epithelium of the exocervix as well as on the columnar epithelium. Yellow cervical mucus on a white swab removed from the endocervix indicates the presence of PMNs. The mucus should be rolled thinly on a slide for Gram's staining. The presence of ≥20 polymorphonuclear cells per 1000× microscopic field within strands of cervical mucus not contaminated by vaginal squamous epithelial cells or vaginal bacteria indicates endocervicitis (Fig. 115-2). Detection of intracellular gram-negative diplococci in carefully collected endocervical mucus is quite specific but ≤50% sensitive for gonorrhea. Therefore, specific and sensitive tests for *N. gonorrhoeae* as well as *C. trachomatis* are also indicated in the evaluation of MPC.

Rx TREATMENT

Although the above criteria for MPC are neither highly specific nor highly predictive of gonococcal or chlamydial infection in many settings, current CDC guidelines call for consideration of empirical treatment for MPC, pending test results, "for a patient who has suspected gonorrhea or chlamydial infection, if (a) the prevalences of these infections are high in the patient population, and (b) the patient might be difficult to locate after treatment." In this situation, therapy should include a single-dose regimen effective for gonorrhea plus treatment for chlamydial infection, as outlined in Table 115-4 for the treatment of urethritis. In settings where gonorrhea is much less common than chlamydial infection, initial therapy for chlamydial infection alone suffices, pending test results for gonorrhea. The etiology and potential benefit of treatment of endocervicitis not associated with gonorrhea or chlamydial infection remain undefined. Although the antimicrobial susceptibility of *M. genitalium* is not yet well defined, it currently seems reasonable to use azithromycin to treat possible *M. genitalium*

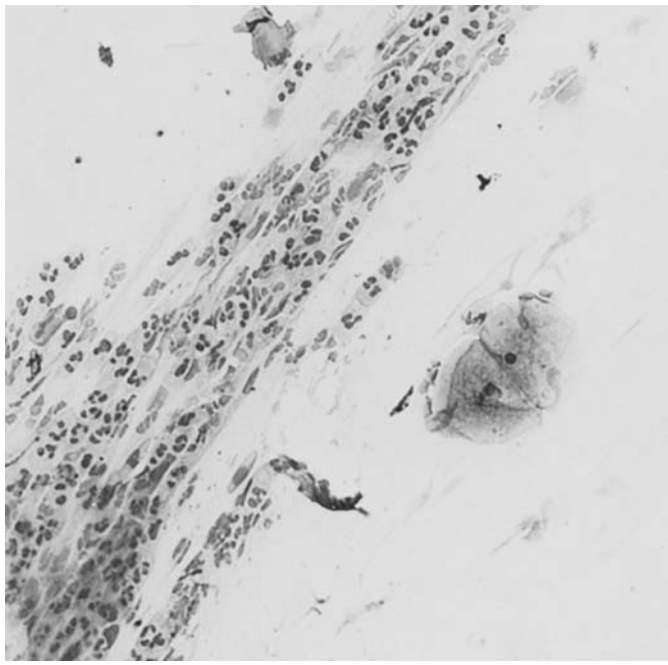

FIGURE 115-2 Gram's stain of cervical mucus, showing a strand of cervical mucus containing many polymorphonuclear leukocytes. This picture is typical of mucopurulent cervicitis. Note that leukocytes are not seen in areas of the slide containing vaginal epithelial cells, adjacent to the mucus strands.

infection in such cases. Sexual partner(s) of a woman with MPC should be examined and given a regimen similar to that chosen for the woman unless results of tests for gonorrhea or chlamydial infection in either partner warrant different therapy or no therapy.

CERVICAL ECTOPY Cervical ectopy, often mislabeled "cervical erosion," is easily confused with infectious endocervicitis. Ectopy represents the presence of the one-cell-thick columnar epithelium extending from the endocervix out onto the visible ectocervix. In ectopy, the cervical os may contain clear or slightly cloudy mucus but usually not yellow mucopus. Colposcopy shows intact epithelium. Normally found during adolescence and early adulthood, ectopy gradually recedes through the second and third decades of life, as squamous metaplasia replaces the ectopic columnar epithelium. Oral contraceptive use favors the persistence or reappearance of ectopy, while smoking apparently accelerates squamous metaplasia. Cauterization of ectopy is not warranted. Ectopy may render the cervix more susceptible to infection with *N. gonorrhoeae*, *C. trachomatis*, or HIV.

PELVIC INFLAMMATORY DISEASE The term *pelvic inflammatory disease* usually refers to infection that ascends from the cervix or vagina to involve the endometrium and/or fallopian tubes. Infection can extend beyond the reproductive tract to cause pelvic peritonitis, generalized peritonitis, perihepatitis, or pelvic abscess. In rare instances, infection extends secondarily to the pelvic organs from adjacent foci of inflammation (e.g., appendicitis, regional ileitis, or diverticulitis), as a result of hematogenous dissemination (e.g., of tuberculosis), or as a rare complication of certain tropical diseases (e.g., schistosomiasis). Intrauterine infection can be primary (spontaneously occurring and usually sexually transmitted) or secondary to invasive intrauterine surgical procedures [e.g., dilatation and curettage, termination of pregnancy, insertion of an intrauterine device (IUD), or hysterosalpingography] or to parturition.

Etiology The agents most often implicated in acute PID include those that are primary causes of endocervicitis (*N. gonorrhoeae* and *C. trachomatis*) and those that can be regarded as components of an altered vaginal flora. In general, PID is most often associated with gonorrhea where there is a high incidence of gonorrhea—e.g., in developing countries and in indigent, inner-city populations in the United States. In recent case-control studies, detection of *M. genitalium* by PCR in endometrial specimens has also been significantly associated with histopathologic diagnoses of endometritis.

Anaerobic and facultative organisms (especially *Prevotella* species, peptostreptococci, *E. coli*, *Haemophilus influenzae*, and group B streptococci) as well as genital mycoplasmas have been isolated from specimens obtained at laparoscopy from the peritoneal fluid or fallopian tubes in a varying proportion (typically one-fourth to one-third) of women with PID studied in the United States. The difficulty of determining the exact microbial etiology of an individual case of PID has implications for the approach to empirical antimicrobial treatment of this infection.

Epidemiology In the United States in 2002, women 15 to 44 years of age made ~200,000 initial visits to physician's offices for PID, and an estimated 66,000 women were hospitalized for acute PID. Important risk factors for acute PID include the presence of endocervical infection or bacterial vaginosis, a history of salpingitis or of recent vaginal douching, and the use of an IUD (especially among nulliparous women, during the first few months after IUD insertion, and among women with multiple sex partners). Certain other iatrogenic factors, such as dilatation and curettage or cesarean section, can increase the risk of PID, especially among women with endocervical gonococcal or chlamydial infection or bacterial vaginosis. The onset of symptoms of *N. gonorrhoeae*–associated and *C. trachomatis*–associated PID often occurs during or soon after the menstrual period; this timing suggests that menstruation is a risk factor in women with endocervical infection. Experimental inoculation of the fallopian tubes of lower primates has shown that repeated exposure to *C. trachomatis* leads to the greatest degree of tissue inflammation and damage; thus, immunopathology probably contributes to the pathogenesis of chlamydial salpingitis. Women using oral contraceptives appear to be at decreased risk of symptomatic PID, and tubal sterilization reduces the risk of salpingitis by preventing intraluminal spread of infection into the tubes.

Clinical Manifestations ■ *ENDOMETRITIS: A CLINICAL PATHOLOGIC SYNDROME* A study of women with clinically suspected PID who were undergoing both endometrial biopsy and laparoscopy showed that those with endometritis alone differed from those who also had salpingitis in that they significantly less often had lower quadrant, adnexal, or cervical motion or abdominal rebound tenderness; fever; or elevated C-reactive protein levels. In addition, women with endometritis alone differed from those with neither endometritis nor salpingitis in that they more often had gonorrhea, chlamydial infection, and risk factors such as douching or IUD use. Thus, women with endometritis alone were intermediate between those with neither endometritis nor salpingitis and those with salpingitis with respect to risk factors, clinical manifestations, cervical infection prevalence, and elevated C-reactive protein.

SALPINGITIS Symptoms of nontuberculous salpingitis classically evolve from a yellow or malodorous vaginal discharge caused by MPC and/or bacterial vaginosis to midline abdominal pain and abnormal vaginal bleeding caused by endometritis and then to bilateral lower abdominal and pelvic pain caused by salpingitis, with nausea, vomiting, and increased abdominal tenderness caused by peritonitis.

The abdominal pain in nontuberculous salpingitis is usually described as dull or aching. In some cases, pain is lacking or is atypical, but active inflammatory changes are found in the course of an unrelated evaluation or procedure, such as a laparoscopic evaluation for infertility. Abnormal uterine bleeding precedes or coincides with the onset of pain in ~40% of women with PID, symptoms of urethritis (dysuria) occur in 20%, and symptoms of proctitis (anorectal pain, tenesmus, and rectal discharge or bleeding) are occasionally seen in women with gonococcal or chlamydial infection.

Speculum examination shows evidence of MPC (yellow endocervical discharge, easily induced endocervical bleeding) in the majority of women with gonococcal or chlamydial PID. Cervical motion ten-

derness is produced by stretching of the adnexal attachments on the side toward which the cervix is pushed. Bimanual examination reveals uterine fundal tenderness due to endometritis and abnormal adnexal tenderness due to salpingitis that is usually, but not necessarily, bilateral. Adnexal swelling is palpable in about one-half of women with acute salpingitis, but evaluation of the adnexae in a patient with marked tenderness is not reliable. The initial temperature is >38°C in only about one-third of patients with acute salpingitis. Laboratory findings include elevation of the erythrocyte sedimentation rate (ESR) in 75% of patients with acute salpingitis and elevation of the peripheral white blood cell count in up to 60%.

Unlike nontuberculous salpingitis, genital tuberculosis often occurs in older women, many of whom are postmenopausal. Presenting symptoms include abnormal vaginal bleeding, pain (including dysmenorrhea), and infertility. About one-quarter of these women have had adnexal masses. Endometrial biopsy shows tuberculous granulomas and provides optimal specimens for culture.

PERIHEPATITIS AND PERIAPPENDICITIS Pleuritic upper abdominal pain and tenderness (usually localized to the right upper quadrant) develop in 3 to 10% of women with acute PID. Symptoms of perihepatitis arise during or after the onset of symptoms of PID and may overshadow lower abdominal symptoms, thereby leading to a mistaken diagnosis of cholecystitis. In perhaps 5% of cases of acute salpingitis, early laparoscopy reveals perihepatic inflammation ranging from edema and erythema of the liver capsule to exudate with fibrinous adhesions between the visceral and parietal peritoneum. When treatment is delayed and laparoscopy is performed late, dense "violin-string" adhesions can be seen over the liver; chronic exertional or positional right upper quadrant pain ensues when traction is placed on the adhesions. Although perihepatitis, also known as the *Fitz-Hugh–Curtis syndrome*, was for many years specifically attributed to gonococcal salpingitis, most cases are now attributed to chlamydial salpingitis. In patients with chlamydial salpingitis, serum titers of microimmunofluorescent antibody to *C. trachomatis* are typically much higher when perihepatitis is present than when it is absent.

Physical findings include right upper quadrant tenderness and usually include adnexal tenderness and cervicitis, even in patients whose symptoms do not suggest salpingitis. Results of liver function tests and right upper quadrant ultrasonography are nearly always normal. The presence of MPC and pelvic tenderness in a young woman with subacute pleuritic right upper quadrant pain and normal ultrasonography of the gallbladder points to a diagnosis of perihepatitis.

Periappendicitis (appendiceal serositis without involvement of the intestinal mucosa) has been found in ~5% of patients undergoing appendectomy for suspected appendicitis and can occur as a complication of gonococcal or chlamydial salpingitis.

Among women with salpingitis, HIV infection is associated with increased severity of salpingitis and with tuboovarian abscess requiring hospitalization and surgical drainage. Nonetheless, among women with HIV infection and salpingitis, the clinical reponse to conventional antimicrobial therapy (coupled with drainage of tuboovarian abscess, when found) has been satisfactory.

Diagnosis Treatment appropriate for PID must not be withheld from patients who have an equivocal diagnosis; it is better to err on the side of overdiagnosis and overtreatment. On the other hand, it is essential to differentiate between salpingitis and other pelvic pathology, particularly surgical emergencies such as appendicitis and ectopic pregnancy.

Nothing short of laparoscopy definitively identifies salpingitis, but routine laparoscopy to confirm suspected salpingitis is generally impractical. Most patients with acute PID have lower abdominal pain of <3 weeks' duration, pelvic tenderness on bimanual pelvic examination, and evidence of lower genital tract infection (e.g., MPC). Approximately 60% of such patients have salpingitis at laparoscopy, and perhaps 10 to 20% have endometritis alone. Among the patients with these findings, a rectal temperature >38°C, a palpable adnexal mass, and elevation of the ESR to >15 mm/h also raise the probability of salpingitis, which has been found at laparoscopy in 68% of patients with one of these additional findings, 90% of patients with two, and 96% of patients with three. However, only 17% of all patients with laparoscopy-confirmed salpingitis have had all three additional findings.

In a woman with pelvic pain and tenderness, increased numbers of PMNs (30 per 1000× microscopic field in strands of cervical mucus) increase the predictive value of a clinical diagnosis of acute PID, as do onset with menses, history of recent abnormal menstrual bleeding, presence of an IUD, history of salpingitis, and sexual exposure to a male with urethritis. Appendicitis or another disorder of the gut is favored by the early onset of anorexia, nausea, or vomiting; the onset of pain later than day 14 of the menstrual cycle; or unilateral pain limited to the right or left lower quadrant. Whenever the diagnosis of PID is being considered, serum assays for human β-chorionic gonadotropin should be performed; these tests are usually positive with ectopic pregnancy. Ultrasonography and magnetic resonance imaging (MRI) can be useful for the identification of tuboovarian or pelvic abscess. MRI of the tubes can also show increased tubal diameter, intratubal fluid, or tubal wall thickening in cases of salpingitis.

The primary and uncontested value of laparoscopy in women with lower abdominal pain is for the exclusion of other surgical problems. Some of the most common or serious problems that may be confused with salpingitis (e.g., acute appendicitis, ectopic pregnancy, corpus luteum bleeding, ovarian tumor) are unilateral. Unilateral pain or pelvic mass, although not incompatible with PID, is a strong indication for laparoscopy unless the clinical picture warrants laparotomy instead. Atypical clinical findings, such as the absence of lower genital tract infection, a missed menstrual period, a positive pregnancy test, or failure to respond to appropriate therapy, are other common indications for laparoscopy. Endometrial biopsy is relatively sensitive and specific for the diagnosis of endometritis, which correlates well with the presence of salpingitis.

Endocervical swab specimens should be examined by Gram's staining for PMNs and gram-negative diplococci and by nucleic acid amplification tests for *N. gonorrhoeae* and *C. trachomatis*. The clinical diagnosis of PID made by expert gynecologists is confirmed by laparoscopy or endometrial biopsy in ~90% of women who also have cultures positive for *N. gonorrhoeae* or *C. trachomatis*. Even among women with no symptoms suggestive of acute PID who were attending an STD clinic or gynecology clinic in Pittsburgh, endometritis was significantly associated with endocervical gonorrhea or chlamydial infection or bacterial vaginosis, being detected in 26, 27, and 15% of women with these conditions, respectively.

Rx TREATMENT

Women with PID can be treated as either outpatients or inpatients. In the multicenter Pelvic Inflammatory Disease Evaluation and Clinical Health (PEACH) trial, 831 women with mild to moderately severe symptoms and signs of PID were randomized to receive either inpatient treatment with intravenous (IV) cefoxitin and doxycycline or outpatient treatment with a single intramuscular (IM) dose of cefoxitin plus oral doxycycline. Short-term clinical and microbiologic outcomes and long-term outcomes were equivalent in the two groups. Nonetheless, hospitalization should be considered when (1) the diagnosis is uncertain and surgical emergencies such as appendicitis and ectopic pregnancy cannot be excluded, (2) pelvic abscess is suspected, (3) severe illness or nausea and vomiting preclude outpatient management, (4) the patient has HIV infection, (5) the patient is assessed as unable to follow or tolerate an outpatient regimen, or (6) the patient has failed to respond to outpatient therapy. Some experts also prefer to hospitalize adolescents with PID for initial therapy.

Recommended combination regimens for ambulatory or parenteral management of PID are presented in Table 115-6. Women managed as outpatients should receive a combined regimen with broad activity,

TABLE 115-6 *Combination Antimicrobial Regimens Recommended for Outpatient Treatment or for Parenteral Treatment of PID*

Outpatient Regimens	Parenteral Regimens
Regimen A Ofloxacin 400 mg PO bid for 14 days *or* Levofloxacin 500 mg PO once daily for 14 days *plus*[a] Metronidazole 500 mg PO bid for 14 days	Initiate parenteral therapy with either of the following regimens; continue parenteral therapy until 48 h after clinical improvement; then change to outpatient therapy, as described in text. **Regimen A** Cefotetan 2 g IV q12h *or* Cefoxitin 2 g IV q6h *plus* Doxycycline 100 mg IV or PO q12h
Regimen B Ceftriaxone 250 mg IM once *plus* Doxycycline 100 mg PO bid for 14 days *plus*[a] Metronidazole 500 mg PO bid for 14 days	**Regimen B** Clindamycin 900 mg IV q8h *plus* Gentamicin, loading dose of 2 mg/kg IV or IM, then maintenance dose of 1.5 mg/kg q8h

[a] The addition of metronidazole is recommended by some experts.
Source: Adapted from Centers for Disease Control and Prevention: MMWR 51(RR-6):1, 2002.

such as ceftriaxone followed by doxycycline. Metronidazole can be added, if tolerated, to enhance activity against anaerobes. Alternatively, oral ofloxacin or levofloxacin, each continued for 14 days and given with or without metronidazole, provides good coverage of the major pathogens. Although few methodologically sound clinical trials (especially with prolonged follow-up) have been conducted, one meta-analysis suggested a benefit of providing good coverage against anaerobes.

The following two parenteral regimens have given nearly identical results in a multicenter randomized trial:

1. Doxycycline (100 mg bid, given IV or by mouth) plus cefotetan (2.0 g IV every 12 h) or cefoxitin (2.0 g IV every 6 h). Administration of these drugs should be continued by the IV route for at least 48 h after the patient's condition improves and then followed with doxycycline (100 mg bid by mouth) to complete 14 days of therapy.
2. Clindamycin (900 mg IV every 8 h) plus gentamicin (2.0 mg/kg IV or IM, followed by 1.5 mg/kg every 8 h) in patients with normal renal function. Once-daily dosing of gentamicin (with combination of the total daily dose into a single daily dose) has not been evaluated in PID but has been efficacious in other serious infections and could be substituted.

Treatment with these drugs should be continued for at least 48 h after the patient's condition improves and then followed with oral doxycycline (100 mg bid by mouth) or clindamycin (450 mg qid by mouth) to complete 14 days of therapy. In cases with tuboovarian abscess, clindamycin rather than doxycycline for continued therapy may provide better coverage for anaerobic infection.

FOLLOW-UP Hospitalized patients should show substantial clinical improvement within 3 to 5 days. Women treated as outpatients should be clinically reevaluated within 72 h. A follow-up telephone survey of women seen in an emergency room and given a prescription for 10 days of oral doxycycline for PID found that 28% never filled the prescription and 41% stopped taking medication early (after an average of 4.1 days), often because of persistent symptoms, lack of symptoms, or side effects. Women not responding favorably to ambulatory therapy should be hospitalized. After completion of treatment, tests for persistent or recurrent infection with *N. gonorrhoeae* or *C. trachomatis* should be performed if symptoms persist or recur or if the patient has not complied with therapy or has been reexposed to an untreated sex partner.

SURGERY Surgery is necessary for the treatment of salpingitis only in the face of life-threatening infection (such as rupture or threatened rupture of a tuboovarian abscess) or for drainage of an abscess. Conservative surgical procedures are usually sufficient. Pelvic abscesses can often be drained by posterior colpotomy, and peritoneal lavage can be used if there is generalized peritonitis.

Prognosis Among 900 women in Sweden who underwent long-term follow-up for a mean period of 8 years after successful treatment of an acute episode of PID with various regimens (that today would often not be considered to provide optimal broad antimicrobial activity), late sequelae included infertility due to bilateral tubal occlusion, ectopic pregnancy due to tubal scarring without occlusion, chronic pelvic pain, and recurrent salpingitis. The postsalpingitis risk of infertility due to tubal occlusion among sexually active women not using contraceptives was 14% at 15 to 24 years of age and 26% at 25 to 34 years of age; the risk for women of all ages combined was 11% after one episode of salpingitis, 23% after two episodes, and 54% after three or more episodes. A study at the University of Washington found a sevenfold increase in the risk of ectopic pregnancy and an eightfold increase in the rate of hysterectomy after PID.

Prevention A randomized controlled trial designed to determine whether selective screening for chlamydial infection reduced the risk of subsequent PID showed that women randomized to undergo screening had a 56% lower rate of PID over the following year than did women receiving the usual care without screening. This report helped to prompt the establishment of U.S. national guidelines for risk-based chlamydial screening of young women as a highly effective way to reduce the incidence of PID and the prevalence of post-PID sequelae, while also reducing sexual transmission of *C. trachomatis*.

ULCERATIVE GENITAL LESIONS Genital ulceration reflects a set of important STIs, most of which sharply increase the risk of sexual acquisition and shedding of HIV. In a 1996 study of genital ulcers in 10 of the U.S. cities with the highest rates of primary syphilis, PCR testing of ulcer specimens demonstrated HSV in 62% of patients, *Treponema pallidum* in 13%, and *Haemophilus ducreyi* in 12 to 20%.

In Asia and Africa, chancroid (Fig. 115-3) was once considered the most common type of genital ulcer, followed in frequency by primary

FIGURE 115-3 Chancroid: multiple, painful, punched-out ulcers with undermined borders on the labia occurring after autoinoculation.

FIGURE 115-4 Lymphogranuloma venereum: striking tender lymphadenopathy occurring at the femoral and inguinal lymph nodes, separated by a groove made by Poupart's ligament.

FIGURE 115-5 Donovanosis, ulcerovegetative type: extensive granulation-tissue formation, ulceration, and scarring of the perineum, scrotum, and penis.

syphilis and then genital herpes. With increased efforts to control chancroid and syphilis, together with more frequent recurrences or persistence of genital herpes attributable to HIV infection, PCR testing of genital ulcers now clearly implicates genital herpes as the most common cause of genital ulceration in many developing countries. Lymphogranuloma venereum (LGV; Fig. 115-4) and donovanosis (granuloma inguinale; Fig. 115-5) continue to cause genital ulceration in developing countries but rarely occur today in North America or Europe. Other causes of genital ulcer include (1) candidiasis and traumatized genital warts—both readily recognized; (2) lesions due to genital involvement of more widespread dermatoses; and (3) cutaneous manifestations of systemic diseases, such as genital mucosal ulceration in Stevens-Johnson syndrome or Behçet's disease.

Diagnosis Although most genital ulcerations cannot be diagnosed confidently on clinical grounds alone, clinical findings plus epidemiologic considerations (Table 115-7) can usually guide initial management (Table 115-8) pending results of further tests. Clinicians should order a rapid serologic test for syphilis in all cases of genital ulcer and a dark-field or direct immunofluorescence test (or PCR test, where available) for *T. pallidum* in all lesions except those highly characteristic of infection with HSV (i.e., those with herpetic vesicles). All patients presenting with genital ulceration should be asked to undergo serologic testing for HIV infection.

Typical vesicles or pustules or a cluster of painful ulcers preceded by vesiculopustular lesions suggests genital herpes. These typical clinical presentations make detection of the virus optional; however, many patients want confirmation of the diagnosis, and differentiation of HSV-1 from HSV-2 has prognostic implications, since the latter causes more frequent genital recurrences.

Painless, nontender, indurated ulcers with firm, nontender inguinal adenopathy suggest primary syphilis. If dark-field examination and a rapid serologic test for syphilis are initially negative and the patient will comply with follow-up and sexual abstinence, the performance of two more dark-field examinations on successive days before treatment is begun will improve the sensitivity of the diagnosis of syphilis. Repeated serologic testing for syphilis 1 or 2 weeks after treatment of seronegative primary syphilis usually demonstrates seroconversion.

TABLE 115-7 *Clinical Features of Genital Ulcers*

Feature	*Syphilis*	*Herpes*	*Chancroid*	*Lymphogranuloma Venereum*	*Donovanosis*
Incubation period	9–90 days	2–7 days	1–14 days	3 days–6 weeks	1–4 weeks (up to 6 months)
Early primary lesions	Papule	Vesicle	Pustule	Papule, pustule, or vesicle	Papule
No. of lesions	Usually one	Multiple, may coalesce	Usually multiple, may coalesce	Usually one	Variable
Diameter	5–15 mm	1–2 mm	Variable	2–10 mm	Variable
Edges	Sharply demarcated, elevated, round, or oval	Erythematous	Undermined, ragged, irregular	Elevated, round, or oval	Elevated, irregular
Depth	Superficial or deep	Superficial	Excavated	Superficial or deep	Elevated
Base	Smooth, nonpurulent, relatively nonvascular	Serous, erythematous, nonvascular	Purulent, bleeds easily	Variable, nonvascular	Red and velvety, bleeds readily
Induration	Firm	None	Soft	Occasionally firm	Firm
Pain	Uncommon	Frequently tender	Usually very tender	Variable	Uncommon
Lymphadenopathy	Firm, nontender, bilateral	Firm, tender, often bilateral with initial episode	Tender, may suppurate, loculated, usually unilateral	Tender, may suppurate, loculated, usually unilateral	None; pseudobuboes

TABLE 115-8 Initial Management of Genital Ulcer

Usual causes
Herpes simplex virus (HSV)
Treponema pallidum (primary syphilis)
Haemophilus ducreyi (chancroid)
Usual initial laboratory evaluation
Dark-field exam, direct FA, or PCR for *T. pallidum*; RPR test (if negative but primary syphilis suspected, repeat RPR in 1 week); culture, direct FA, ELISA, or PCR for HSV. In chancroid-endemic area: PCR or culture for *H. ducreyi*
INITIAL TREATMENT
Herpes confirmed or suspected (history or sign of vesicles):
Treat for genital herpes with acyclovir, valacyclovir, or famciclovir
Syphilis confirmed (dark-field, FA, or PCR showing *T. pallidum*, or RPR reactive):
Benzathine penicillin 2.4 million units IM once to patient, recent (e.g., within 3 months) seronegative partner(s), and every seropositive partner
Chancroid confirmed or suspected (diagnostic test positive, or HSV and syphilis excluded, and lesion persists):
Ciprofloxacin 500 mg PO as single dose *or*
Ceftriaxone 250 mg IM as single dose *or*
Azithromycin 1 g PO as single dose

Note: FA, fluorescent antibody; PCR, polymerase chain reaction; RPR, rapid plasma reagin; ELISA, enzyme-linked immunosorbent assay; HSV, herpes simplex virus.

"Atypical" or clinically trivial ulcers may be more common manifestations of genital herpes than classic vesiculopustular lesions. Specific tests for HSV in such lesions are therefore indicated (Chap. 163). Type-specific serologic tests for serum antibody to HSV-2, now commercially available, may give negative results, especially when patients present early with the initial episode of genital herpes or when HSV-1 is the cause of genital herpes (as is often the case today). Furthermore, a positive test for HSV-2 antibody does not prove that the current lesions are herpetic, since nearly one-fourth of the general population of the United States becomes seropositive for HSV-2 during early adulthood. Nonetheless, a positive HSV-2 serology does enable the clinician to tell the patient that he or she has had genital herpes, should learn to recognize symptoms, should avoid sex during recurrences, and should consider use of condoms or suppressive antiviral therapy, both of which can reduce transmission to a sexual partner.

Demonstration of *H. ducreyi* by culture (or by PCR test, when available) is most useful when ulcers are painful and purulent, especially if inguinal lymphadenopathy with fluctuance or overlying erythema is noted; if chancroid is prevalent in the community; or if the patient has recently had a sexual exposure elsewhere in a chancroid-endemic area (e.g., a developing country). Enlarged, fluctuant lymph nodes should be aspirated for culture or PCR tests to detect *H. ducreyi* as well as for Gram's staining and culture to rule out the presence of other pyogenic bacteria.

When genital ulcers persist beyond the natural history of initial episodes of herpes (2 to 3 weeks) or of chancroid or syphilis (up to 6 weeks) and do not resolve with syndrome-based antimicrobial therapy, then—in addition to the usual tests for herpes, syphilis, and chancroid—biopsy is indicated to exclude donovanosis, carcinoma, and other nonvenereal dermatoses. HIV serology should also be undertaken, since chronic, persistent genital herpes is common in AIDS.

TREATMENT

Immediate syndrome-based treatment for acute genital ulcerations (after collection of all necessary diagnostic specimens) is often appropriate before all test results become available, because patients with typical initial or recurrent episodes of genital or anorectal herpes can benefit from prompt oral antiviral therapy (Chap. 163); because early treatment of sexually transmitted causes of genital ulcers decreases further transmission; and because some patients do not return for test results and treatment. The patient with nonvesicular ulcerative lesions who may not return for follow-up or may continue sexual activity should receive initial treatment for syphilis, together with empirical therapy for chancroid if there has been an exposure in an area where chancroid occurs or if regional lymph node suppuration is evident. In resource-poor settings lacking ready access to diagnostic tests, this approach to syndromic treatment for syphilis and chancroid has helped bring these two diseases under control. Finally, empirical antimicrobial therapy may be indicated if ulcers persist and the diagnosis remains unclear after a week of observation despite attempts to diagnose herpes, syphilis, and chancroid.

PROCTITIS, PROCTOCOLITIS, ENTEROCOLITIS, AND ENTERITIS Sexually acquired *proctitis*, with inflammation limited to the rectal mucosa (the distal 10 to 12 cm), results from direct rectal inoculation of typical STD pathogens. In contrast, inflammation extending from the rectum to the colon (*proctocolitis*), involving both the small and the large bowel (*enterocolitis*), or involving the small bowel alone (*enteritis*) can result from ingestion of typical intestinal pathogens through oral-anal exposure during sexual contact. Anorectal pain and mucopurulent, bloody rectal discharge suggest proctitis or protocolitis. Proctitis commonly produces tenesmus (causing frequent attempts to defecate, but not true diarrhea) and constipation, whereas proctocolitis and enterocolitis more often cause true diarrhea. In all three conditions, anoscopy usually shows mucosal exudate and easily induced mucosal bleeding (i.e., a positive "wipe test"), sometimes with petechiae or mucosal ulcers. Exudate should be sampled for Gram's staining and other microbiologic studies. Sigmoidoscopy or colonoscopy shows inflammation limited to the rectum in proctitis or disease extending at least up into the sigmoid colon in proctocolitis.

The AIDS era brought an extraordinary shift in the clinical and etiologic spectrum of intestinal infections among homosexual men. The number of cases of the acute intestinal STIs described above fell as high-risk sexual behaviors became less common in this group. At the same time, the number of AIDS-related opportunistic intestinal infections increased rapidly, many associated with chronic or recurrent symptoms. The incidence of these infections has since fallen with increasingly effective antiretroviral therapy.

Acquisition of *N. gonorrhoeae*, HSV, or *C. trachomatis* during receptive anorectal intercourse causes most cases of infectious proctitis in women or homosexual men. Primary and secondary syphilis can also produce anal or anorectal lesions, with or without symptoms. Gonococcal or chlamydial proctitis typically involves the most distal rectal mucosa and the anal crypts and is clinically mild, without systemic manifestations. In contrast, primary proctitis due to HSV and proctocolitis due to the strains of *C. trachomatis* that cause LGV usually produce severe anorectal pain and often cause fever. Perianal ulcers and inguinal lymphadenopathy, most commonly due to HSV, can also occur in LGV or syphilis. Sacral nerve root radiculopathies, usually presenting as urinary retention, laxity of the anal sphincter, or constipation, may complicate primary herpetic proctitis. In LGV, rectal biopsy typically shows crypt abscesses, granulomas, and giant cells—findings resembling those in Crohn's disease; such findings should always prompt rectal culture and serology for LGV, which is a curable infection. Syphilis can also produce rectal granulomas, usually in association with infiltration by plasma cells or other mononuclear cells. Syphilis, LGV, and HSV infection involving the rectum can produce perirectal adenopathy that is sometimes mistaken for malignancy; syphilis, LGV, HSV infection, and chancroid involving the anus can produce inguinal adenopathy, because anal lymphatics drain to inguinal lymph nodes.

Diarrhea and abdominal bloating or cramping pain without anorectal symptoms and with normal findings on anoscopy and sigmoidoscopy occur with inflammation of the small intestine (enteritis) or with proximal colitis. In homosexual men without HIV infection, enteritis is often attributable to *Giardia lamblia*. Sexually acquired proctocolitis is most often due to *Campylobacter* or *Shigella* spp.

TREATMENT

Acute proctitis in persons who have practiced receptive intercourse is usually sexually acquired. Such patients should undergo anoscopy to detect rectal ulcers or vesicles and petechiae after swabbing of the rectal mucosa; to examine rectal exudates for PMNs and gram-negative diplococci; and to obtain rectal swab specimens for testing for rectal gonorrhea, chlamydial infection, herpes, and syphilis. Pending test results, patients with proctitis should receive empirical syndromic treatment—e.g., with ceftriaxone (a single IM dose of 125 mg for gonorrhea) plus doxycycline (100 mg bid by mouth for 7 days for possible chlamydial infection) plus treatment for herpes or syphilis if indicated.

PREVENTION AND CONTROL OF STDS

Prevention and control of STDs require (1) reduction of the average rate of sexual exposure through alteration of behaviors and behavioral norms among both susceptible and infected persons in all population groups; (2) reduction of the efficiency of transmission through the promotion of safer sexual practices, the use of condoms during casual or commercial sex, hepatitis B immunization, and many other approaches (e.g., early detection and treatment of other STIs to reduce the efficiency of sexual transmission of HIV); and (3) shortening of the duration of infectivity of STDs through early detection and curative or suppressive treatment of patients and their sexual partners.

Financial and time constraints imposed by managed-care practice patterns often curtail screening and prevention services. As outlined in Fig. 115-6, the success of clinicians' efforts to detect and treat STDs depends in part on societal efforts to teach young people how to recognize symptoms of STDs; to motivate those with symptoms to seek care promptly; and to make such care accessible, affordable, and acceptable, especially to the young indigent patients most likely to acquire an STD.

Since many infected individuals develop no symptoms or fail to recognize and report symptoms, clinicians should routinely perform an STI risk assessment for teenagers and young adults as a guide to selective screening. U.S. Preventive Services Task Force Guidelines recommend screening sexually active female patients ≤25 years of age for *C. trachomatis* whenever they present for health care (at least once a year); older women should be tested if they have more than one sexual partner, have begun a new sexual relationship since the previous test, or have another STD diagnosed. In the United States, widespread selective screening of young women for cervical *C. trachomatis* infection in some regions has been associated with a 50 to 60% drop in prevalence, and such screening also protects the individual woman from PID. Sensitive urine-based genetic amplification tests permit expansion of screening to men, teenage boys, and girls in settings where examination is not planned or is impractical (e.g., during pre-participation sports examinations).

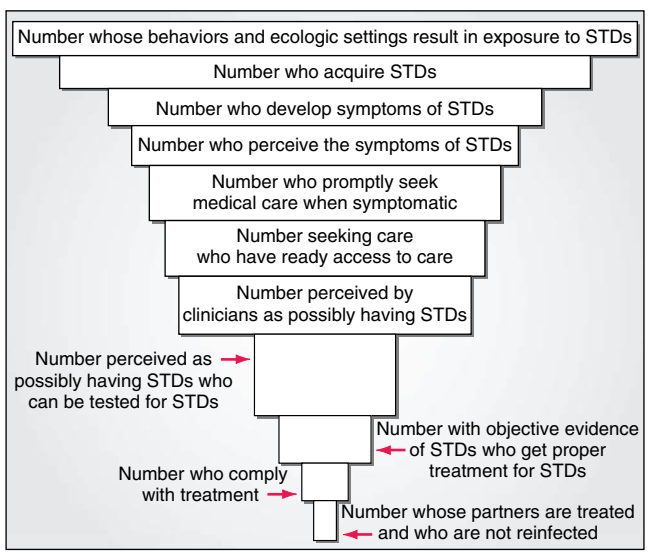

FIGURE 115-6 Critical control points for preventive and clinical interventions against sexually transmitted diseases (STDs). [*Adapted from HT Waller and MA Piot: Bull World Health Organ 41:75, 1969 and 43:1, 1970; and from "Resource allocation model for public health planning—a case study of tuberculosis control," Bull World Health Organ 84(Suppl) 1973.*]

Although gonorrhea is now substantially less common than chlamydial infection in industrialized countries, screening tests for *N. gonorrhoeae* are still appropriate for women and teenage girls attending STD clinics and for sexually active teens and young women from areas of high gonorrhea prevalence. However, multiplex nucleic acid amplification tests that combine screening for *N. gonorrhoeae* and *C. trachomatis* in a single low-cost assay may facilitate the prevention and control of both infections in populations at high risk.

All patients with newly detected STIs or at high risk for STIs according to routine risk assessment as well as all pregnant women should be encouraged to undergo serologic testing for syphilis and HIV infection, with appropriate HIV counseling before and after testing. Randomized trials have shown that risk-reduction counseling of patients with STDs significantly lowers subsequent risk of acquiring an STD; such counseling should now be considered a standard component of STD management. Preimmunization serologic testing for antibody to HBV is indicated for unvaccinated persons who are known to be at high risk, such as homosexually active men and injection drug users. In most young persons, however, it is more cost-effective to vaccinate against HBV without serologic screening.

Partner notification is the process of identifying and informing partners of infected patients of possible exposure to an STI and of examining, testing, and treating partners as appropriate. In a series of 22 reports concerning partner notification during the 1990s, index patients with gonorrhea or chlamydial infection named a mean of 0.75 to 1.6 partners, of whom one-fourth to one-third were infected; those with syphilis named 1.8 to 6.3 partners, with one-third to one-half infected; and those with HIV infection named 0.76 to 5.31 partners, with up to one-fourth infected. Persons who transmit infection or who have recently been infected and are still in the incubation period usually have no symptoms or only mild symptoms and seek medical attention only when notified of their exposure. Therefore, the clinician must encourage patients to participate in partner notification, must ensure that exposed persons are notified, and must guarantee confidentiality to all involved. In the United States, local health departments often offer assistance in partner notification, treatment, and/or counseling. It seems both feasible and most useful to notify those partners exposed within the patient's likely period of infectiousness, which is often considered the preceding 1 month for gonorrhea, 1 to 2 months for chlamydial infection, and up to 3 months for early syphilis.

Persons with a new-onset STD always have a *source* contact who gave them the infection; in addition, they may have a *secondary* (*spread* or *exposed*) contact with whom they had sex after becoming infected. The identification and treatment of these two types of contacts have different objectives. Treatment of the source contact (often a casual contact) benefits the community by preventing further transmission; treatment of the recently exposed secondary contact (typically a spouse or another steady sexual partner) prevents both the development of serious complications (such as PID) in the partner and reinfection of the index patient. A recent survey of a random sample of U.S. physicians found that most instructed patients to abstain from sex during treatment, to use condoms, and to inform their sex partners after being diagnosed with gonorrhea, chlamydial infection, or syphilis; physicians sometimes gave the patients drugs for their partners. However, follow-up of the partners by physicians was infrequent. A recent randomized trial compared patients' delivery of therapy to partners exposed to gonorrhea or chlamydial infection with conventional notification and advice to partners to seek evaluation for STD; patients' delivery of therapy to their partners significantly reduced rates of re-

infection of the index patient. State-by-state variations in regulations on this approach have not been well defined.

In summary, clinicians and public health agencies share responsibility for the prevention and control of STDs. In the managed-care era, the role of primary care clinicians has become increasingly important in prevention as well as in diagnosis and treatment.

Section 3 Clinical Syndromes: Nosocomial Infections

116 HOSPITAL-ACQUIRED INFECTIONS

Robert A. Weinstein

The costs of nosocomial (hospital-acquired) infections are great. It is estimated that nosocomial infections affect more than 2 million patients, cost $4.5 billion, and contribute to 88,000 deaths in U.S. hospitals annually. Efforts to lower infection risks have been challenged by the growing numbers of immunocompromised patients, antibiotic-resistant bacteria, fungal and viral superinfections, and invasive devices and procedures. Nevertheless, evidence-based guidelines for prevention and control are now available (Table 116-1); according to some estimates, the consistent application of these guidelines may reduce the risk of nosocomial infection by more than one-third. This chapter reviews hospital-acquired and device-related infections and the basic surveillance, prevention, and control and treatment activities that have been developed to deal with these problems.

ORGANIZATION AND RESPONSIBILITIES OF INFECTION-CONTROL PROGRAMS The standards of the Joint Commission on Accreditation of Healthcare Organizations require all accredited hospitals to have an active program for surveillance, prevention, and control of nosocomial infections. A multidisciplinary infection-control committee usually oversees the program. The agents of the committee are the chairperson, who is preferably an infectious disease physician, and the infection-control practitioners, who are usually trained in nursing or medical technology and in epidemiology and public health. Education of physicians in infection control and hospital epidemiology is required in infectious disease fellowship programs and is available in courses provided by professional societies, primarily the Society for Healthcare Epidemiology of America.

Diagnosis-related reimbursement has led hospital administrators to place increased emphasis on cost containment and on documentation of the cost-effectiveness of infection control. The quality-improvement movements and the Joint Commission have redirected infection-control attention, in part, beyond the mere writing of policies and procedures to improvement of the actual processes and optimization of outcomes. In many hospitals, epidemiology programs have taken on additional pharmacoepidemiologic and antibiotic-use review responsibilities as well as broader quality-assurance activities under the rubic "patient safety." All programs must respond to governmental regulation of hospital waste and to standards mandated by the Occupational Safety & Health Administration for protecting health care workers from occupational exposure to bloodborne pathogens and tuberculosis.

SURVEILLANCE Traditionally, infection-control practitioners have surveyed inpatients for infections acquired in hospitals (defined as those neither present nor incubating at the time of admission). Surveillance involves a review of microbiology laboratory results, "shoe-leather" epidemiology on the nursing wards, application of standardized defi-

nitions of infection, ongoing dialogue with hospital workers, and common sense. Some innovative infection-control programs have taken advantage of the increased use of computerized pharmacy, microbiology, and other databases in hospitals to create algorithm-driven surveillance.

Most hospitals aim surveillance at infections that (1) are associated with a high level of morbidity [e.g., intensive care unit (ICU)–related infections and nosocomial pneumonia]; (2) are costly (e.g., cardiac surgical wound infections); (3) are difficult to treat (e.g., infections due to antibiotic-resistant bacteria); (4) pose recurrent epidemic problems (e.g., *Clostridium difficile*–related diarrhea); and (5) are potentially preventable (e.g., vascular access–related infections). Quality-assurance activities in infection control have led to increased surveillance of the compliance of personnel with infection-control policies (e.g., monitoring of actual adherence to hand hygiene recommendations).

The results of surveillance are expressed as rates; in general, 5 to 10% of patients develop nosocomial infections. Such overall statistics have little value unless qualified by duration of risk, by site of infection, by patient population, and by exposure to risk factors. Meaningful denominators for infection rates include the number of patients exposed to a specific risk (e.g., rates of pneumonia among patients using mechanical ventilators) and the number of intervention days (e.g., rates of pneumonia per 1000 patient-days on a ventilator).

Temporal trends in rates should be reviewed, and rates should be compared with regional and national norms. However, even comparison rates generated by the ongoing National Nosocomial Infections Surveillance System [a program of the Centers for Disease Control and Prevention (CDC)], which collects data from more than 350 hospitals that use standardized definitions of nosocomial infections, have not been validated independently and represent a nonrandom sample of hospitals. Interhospital comparisons are easily confounded by the wide range in risk factors and in severity of underlying illnesses; unless rates are adjusted for these factors, comparisons may be misleading. Unfortunately, systems for making such adjustments either are rudimentary or have not been well validated.

The ongoing analysis of an individual hospital's infection rates helps to determine whether control efforts are succeeding and where increased education and control measures should be focused. Knowledge of infection rates is also useful in discussions with the hospital administration regarding areas to which additional resources should be directed.

EPIDEMIOLOGIC BASIS AND GENERAL MEASURES FOR PREVENTION AND CONTROL

Nosocomial infections follow basic epidemiologic patterns that can help to direct prevention and control measures. Nosocomial pathogens have reservoirs, are transmitted by predictable routes, and require susceptible hosts. Reservoirs and sources exist in the inanimate environment (e.g., tap water contaminated with *Legionella*) and in the animate environment (e.g., infected or colonized health care workers, patients, and hospital visitors). The mode of transmission most often is either cross-infection (e.g., indirect spread of pathogens from one patient to another on the inadequately cleaned hands of hospital personnel) or autoinoculation (e.g., aspiration of oropharyngeal flora into the lung along an endotracheal tube). Occasionally, pathogens (e.g., group A streptococci and many respiratory viruses) are spread indirectly from person to person via infectious droplets released by coughing or sneezing. Much less common—but often devastating in terms of epidemic risk—is true airborne spread of droplet nuclei (as in nosocomial chickenpox) or common-source spread by contaminated materials (e.g., iodophors contaminated with *Pseudomonas*). Factors that increase host susceptibility include underlying conditions and the many medical-surgical interventions and procedures that bypass or compromise normal host defenses.

Through its program, the hospital's infection-control committee must determine the general and specific measures used to control infections and must review and recommend specific antiseptics and disinfectants for hospital use. Given the prominence of cross-infection, hand hygiene is the single most important preventive measure in hospitals (Table 116-2). Health care workers' rates of adherence to hand-hygiene recommendations are abysmally low (<50%). Reasons cited include inconvenience, time pressures, and skin damage from frequent washing. Sinkless alcohol rubs are quick and highly effective and actually improve hand condition since they contain emollients and allow the retention of natural protective oils that are removed with repeated rinsing. Use of alcohol hand rubs between patient contacts is now recommended for all health care workers except when the hands are visibly soiled, in which case washing with soap and water is still required.

NOSOCOMIAL AND DEVICE-RELATED INFECTIONS The fact that 25 to 50% of nosocomial infections are due to the combined effect of the patient's own flora and invasive devices highlights the importance of improvements in the use and design of such devices. Intensive educational programs can be associated with at least a temporary reduction in infection rates through improved asepsis in handling and earlier removal of invasive devices, but the maintenance of such gains is often difficult. Of particular note, shortages of trained personnel jeopardize safe and effective patient care and have been associated with increased rates of infection and death among patients.

Urinary Tract Infections Urinary tract infections (UTIs) account for as many as 40 to 45% of nosocomial infections; up to 3% of bacteriuric patients develop bacteremia. Although UTIs contribute only 10 to 15% to prolongation of hospital stay and to extra costs, these infections are important reservoirs and sources for spread of antibiotic-resistant bacteria in hospitals. Almost all nosocomial UTIs are associated with preceding instrumentation or indwelling bladder catheters, which create a 3 to 10% risk of infection each day. UTIs generally are caused by pathogens that spread up the periurethral space from the patient's perineum or gastrointestinal tract—the most common pathogenesis in women—or via intraluminal contamination of urinary catheters, usually due to cross-infection by caregivers who are irrigating catheters or emptying drainage bags. Pathogens occasionally come from inadequately disinfected urologic equipment and rarely come from contaminated supplies (e.g., dilute aqueous benzalkonium chloride, an ineffective disinfectant).

The most important measures for preventing nosocomial UTIs are (1) the placement of catheters only when absolutely necessary and not solely for the convenience of caregivers, (2) the use of aseptic technique for catheter insertion and for urinary tract instrumentation, (3) the manipulation and opening of drainage systems as infrequently as possible, and (4) the removal of catheters as soon as feasible. Hospitals

TABLE 116-2 Examples of Ways in which Physicians Can Contribute to Infection-Control Efforts

- Act as role models for other personnel by paying careful attention to hand-hygiene recommendations and barrier precautions during contact with patients and by observing posted isolation precautions.
- Give corrective feedback to caregivers who do not adhere to hand-hygiene recommendations or isolation precautions.
- Place invasive devices based on clinical need (not just on convenience).
- Remove invasive devices promptly when they are no longer needed clinically.
- Limit surgical antimicrobial prophylaxis to the perioperative period.
- Exercise care in initial empirical antibiotic selection (avoid "shotgun" approaches).
- Narrow the spectrum of antibiotic therapy once a pathogen is recovered.
- Discontinue antibiotic therapy in a timely fashion.
- Become familiar with the hospital's bloodborne pathogen and tuberculosis control plans.
- Order appropriate isolation precautions promptly for infected patients.
- During patient rounds, alert nursing staff to lapses in asepsis (e.g., soiled dressings at sites of intravascular catheters) and to infection-predisposing situations (e.g., aspiration-prone positioning of patients).
- Notify infection-control practitioners of potential infection-control problems (e.g., surgical wound infections that manifest after a patient's discharge).

should develop criteria for and closely monitor these four performance measures.

Sealed catheter–drainage tube junctions can help to prevent breaks in the system. Approaches to the prevention of UTIs also have included the use of topical meatal antimicrobials, drainage bag disinfectants, and anti-infective catheters. A meta-analysis and more recent studies suggest that silver alloy–coated catheters may reduce the incidence of bacteriuria, at least during short-term catheterization. However, because of conflicting study results, none of the latter three measures is considered routine.

Systemic antimicrobials given for other purposes decrease the risk of UTI during the first 4 days of catheterization, after which resistant bacteria or yeasts emerge as pathogens. Selective decontamination of the gut is also associated with a reduced risk. Again, however, neither approach is routine.

Irrigation of catheters, with or without antimicrobials, may actually increase the risk of infection. A condom catheter for men without bladder obstruction may be more acceptable than an indwelling catheter, but the infection risks with the two types are similar unless the condom catheter is carefully maintained. The role of suprapubic catheters in preventing infection is not well defined.

Treatment of UTIs is based on the results of quantitative cultures of urine (see Chap. 269); the most common pathogens are *Escherichia coli*, nosocomial gram-negative bacilli, enterococci, and *Candida*. Several caveats apply in the treatment of institutionally acquired infection. First, in patients with chronic indwelling bladder catheters, especially those in long-term-care facilities, the "catheter flora"—microorganisms living in the biofilm or on encrustations within the catheter lumen—may differ from the actual urinary tract pathogens. Therefore, for suspected infection in the setting of chronic catheterization (especially in women), it is useful to replace the bladder catheter and to obtain a freshly voided urine specimen. Second, as in all nosocomial infections, at the time treatment is initiated on the basis of a positive culture, it is useful to repeat the culture to verify the persistence of infection. Third, the frequency with which UTIs occur may lead to the erroneous assumption that this site alone is the source of infection in a febrile hospitalized patient. Thus, in the treatment of nosocomial UTIs, it is important to assess the patient for symptoms, especially of upper-pole infection (e.g., flank pain in conscious patients), and for signs of abnormal urinary sediment. Since nosocomial UTIs usually occur in the setting of catheterization or recent instrumentation, lower-tract symptoms (e.g., dysuria) may not be reliable. Fourth, recovery of *Staphylococcus aureus* from urine cultures may result from hematogenous seeding and may indicate an occult systemic infection. Finally, although *Candida* is now the most common pathogen in nosocomial UTIs in ICU patients, it is not clear that candiduria in the absence of upper-pole invasion, obstruction, neutropenia, or immunosuppression warrants treatment.

Pneumonia Pneumonia accounts for 15 to 20% of nosocomial infections but has been responsible for 24% of extra hospital days and 39% of extra costs—i.e., 6 days and $6000 (based on 1992 dollars) per episode. Almost all cases of bacterial nosocomial pneumonia are caused by aspiration of endogenous or hospital-acquired oropharyngeal (and occasionally gastric) flora. Nosocomial pneumonias are associated with more deaths than are infections at any other body site. However, attributable mortality for ventilator-associated pneumonia—the most common and lethal form of nosocomial pneumonia—is in the 6 to 14% range; this figure suggests that the risk of dying from nosocomial pneumonia is affected greatly by other factors, including comorbidities, inadequate antibiotic treatment, and the involvement of specific pathogens (particularly *Pseudomonas aeruginosa* and *Acinetobacter*). Surveillance and accurate diagnosis of pneumonia are often problematic in hospitals because many patients, especially those in the ICU, have abnormal chest roentgenographs, fever, and leukocytosis potentially attributable to multiple causes. →***Viral pneumonias, which are particularly important in pediatric and immunocompromised patients, are discussed in the virology section and in Chap. 239.***

Risk factors for nosocomial pneumonia, particularly ventilator-associated pneumonia, include those events that increase the risk of colonization by potential pathogens (e.g., prior antimicrobial therapy, contaminated ventilator circuits or equipment, or decreased gastric acidity); those that heighten the possibility of aspiration of oropharyngeal contents into the lower respiratory tract (e.g., intubation, decreased levels of consciousness, or presence of a nasogastric tube); and those that reduce host defense mechanisms in the lung and permit overgrowth of aspirated pathogens (e.g., chronic obstructive pulmonary disease, old age, or upper abdominal surgery).

Control measures for pneumonia are aimed at the remediation of risk factors in general patient care (e.g., minimizing aspiration-prone supine positioning) and at meticulous aseptic care of respirator equipment (e.g., disinfecting or sterilizing all inline reusable components such as nebulizers, replacing tubing circuits at intervals of >48 h—rather than more frequently—to lessen the number of breaks in the system, and teaching aseptic technique for suctioning). In a large multicenter trial, sucralfate, which provides stress-ulcer prophylaxis without altering gastric pH, did not reduce the risk of ventilator-associated pneumonia, despite the theoretical advantage of lessened risk for gastric colonization by gram-negative bacilli. The benefits of selective decontamination of the oropharynx and gut with nonabsorbable antimicrobials and/or use of short-course postintubation systemic antibiotics have been controversial. Among the logical preventive measures that require further investigation are the use of endotracheal tubes that provide channels for subglottic drainage of secretions and the use of noninvasive mechanical ventilation whenever feasible. Of note, even interventions that have reduced the rate of ventilator-associated pneumonia most often have not reduced overall ICU mortality; this fact suggests that this infection is a marker for patients with an otherwise-heightened risk of death.

The most likely pathogens for nosocomial pneumonia and treatment options are discussed in Chap. 239. Several considerations regarding diagnosis and treatment are worth emphasizing. Clinical criteria for diagnosis (e.g., fever, leukocytosis, development of purulent secretions, new or changing radiographic infiltrates, change in oxygen requirement or ventilator settings) have high sensitivity but relatively low specificity. These criteria are most useful for selecting patients for bronchoscopic or nonbronchoscopic procedures that yield lower respiratory tract samples protected from upper-tract contamination; quantitative cultures of such specimens have diagnostic sensitivities in the range of 80%. Early-onset nosocomial pneumonia, which manifests within the first 4 days of hospitalization, is most often caused by community-acquired pathogens, such as *Streptococcus pneumoniae* and *Haemophilus* species. Late-onset pneumonias most commonly are due to *S. aureus*, *P. aeruginosa*, *Enterobacter* species, *Klebsiella pneumoniae*, or *Acinetobacter*—a pathogen of increasing concern in many ICUs. When invasive techniques are used to diagnose ventilator-associated pneumonia, the proportion of isolates accounted for by gram-negative bacilli decreases from 50–70% to 35–45%. Infection is polymicrobial in as many as 20 to 40% of cases. The role of anaerobic bacteria in ventilator-associated pneumonia is not well defined. The appropriate duration of therapy for nosocomial pneumonia, although generally stated to be in the 10- to 21-day range, is not well studied. Finally, in febrile patients (particularly those who have endotracheal and/or nasogastric tubes), more occult sources of respiratory tract infection, especially bacterial sinusitis and otitis media, should be considered.

Surgical Wound Infections Wound infections account for up to 20 to 30% of nosocomial infections but contribute up to 57% of extra hospital days and 42% of extra costs. Because the average wound infection has an incubation period of 5 to 7 days, which is longer than many postoperative stays, and because many procedures now are performed on an outpatient basis, the incidence of wound infections has become difficult to assess. These infections usually are caused by the patient's

endogenous or hospital-acquired skin and mucosal flora and occasionally are due to airborne spread of skin squames that may be shed into the wound from members of the operating-room team. True airborne spread of infection through droplet nuclei is rare in operating rooms unless there is a "disseminator" (e.g., of group A streptococci or staphylococci) among the staff. In general, the most common risks for postoperative wound infection are deficits in the surgeon's technical skill, the patient's underlying diseases (e.g., diabetes mellitus, obesity), and inappropriate timing of antibiotic prophylaxis. Additional risk factors include the presence of drains, prolonged preoperative hospital stays, shaving of the operative site the day before surgery, a long duration of surgery, and infection at remote sites (e.g., untreated UTI).

The substantial literature related to risk factors for surgical-site infections and the recognized morbidity and cost of these infections have led to careful evaluation of a number of interventions. The most important control measures include the use of antimicrobial prophylaxis at the start of high-risk procedures (see Chap. 118), attention to technical surgical issues and operating-room asepsis (e.g., not shaving the operative site until surgery and avoiding open or prophylactic drains), and preoperative therapy for active infection. Reporting of surveillance results to surgeons has been associated with reductions in infection rates. Measures that improve patients' resistance to infection are rare; thus the reductions in postoperative wound-infection rates associated with use of supplemental oxygen, maintenance of normothermia, or improved perioperative glucose control in recent studies are particularly exciting. The increasingly extensive review of infection rates by regulatory agencies and third-party payers emphasizes the importance of stratifying rates by patient-related risk factors and of developing meaningful systems for interhospital comparisons and for wound surveillance after the patient's discharge from the hospital or clinic (when more than 50% of infections first become apparent). The epidemic of mad cow disease, centered in the United Kingdom, and associated cases of variant Creutzfeldt-Jakob disease in humans (Chap. 362) caused by disinfection-resistant prion agents are leading to new recommendations for decontamination of surgical instruments, especially those used for operations on the central nervous system or in patients with a dementing illness of unknown etiology.

The process of diagnosing and treating wound infections begins with a careful assessment of the surgical site in the febrile postoperative patient. Clinical findings range from obvious cellulitis or abscess formation to subtle clues such as a sternal "click" following open heart surgery. Diagnosis of deeper organ-space infections or subphrenic abscesses requires a high index of suspicion and the use of computed tomography or magnetic resonance imaging. Diagnosis of infections of prosthetic devices, such as orthopedic implants, may be particularly difficult and often requires the use of interventional radiographic techniques to obtain periprosthetic specimens for culture. The most common pathogens in postoperative wound infections are *S. aureus*, coagulase-negative staphylococci, and enteric and anaerobic bacteria. In rapidly progressing postoperative infections, which manifest within 24 to 48 h of a surgical procedure, the level of suspicion regarding group A streptococcal or clostridial infection (Chaps. 121 and 126) should be high. Treatment of postoperative wound infections requires drainage or surgical excision of infected or necrotic material and antibiotic therapy aimed at the most likely or laboratory-confirmed pathogens.

Infections Related to Vascular Access and Monitoring Intravascular devices are common causes of local site infection and cause up to 50% of nosocomial bacteremias; central vascular catheters account for 80 to 90% of these infections. National estimates indicate that as many as 250,000 bloodstream infections associated with central vascular catheters occur each year in the United States, with an attributable mortality of 12 to 25% and an estimated cost of $25,000 per episode; one-third to one-half of these episodes occur in ICUs. With increasing care of seriously ill patients in the community, vascular catheter–associated bloodstream infections acquired by outpatients are receiving more attention than in the past. A recent study of bacteremia patients at three hospitals showed that the numbers of patients being treated for device-associated bacteremia acquired in the hospital or in the community setting (e.g., home or clinic intravascular therapy) were similar. This finding emphasizes the need to broaden surveillance activities.

Catheter-related bloodstream infections derive largely from the cutaneous microflora of the insertion site, with pathogens migrating extraluminally to the catheter tip, usually during the first week after insertion. In addition, contamination of hubs of central vascular catheters may lead to intraluminal infection over longer periods, particularly with surgically implanted or cuffed catheters. Intrinsic contamination of infusate, although rare, is the most common cause of epidemic device-related bloodstream infection; extrinsic contamination may cause up to half of endemic bacteremias related to arterial infusions used for hemodynamic monitoring. The most common pathogens isolated from vascular device–associated bacteremias include coagulase-negative staphylococci, *S. aureus* (with up to 50% of isolates potentially resistant to methicillin), enterococci, nosocomial gram-negative bacilli, and *Candida*.

Infections related to vascular catheters and monitoring devices may be the most preventable of nosocomial infections. Evidence-based control measures include implementing educational programs with didactic and interactive components for persons who insert and maintain catheters, using maximal sterile barrier precautions (e.g., gowns, gloves, masks, and large drapes) during catheter placement, using chlorhexidine for skin antisepsis prior to catheter placement, and ensuring that "idle catheters" are removed. Hospitals should periodically monitor adherence to these performance indicators. Use of antimicrobial- or antiseptic-impregnated central venous catheters is a reasonable control measure for adults whose catheters are expected to remain in place for >5 days if, after implementation of the performance measures just listed, the rates of catheter-related bloodstream infection remain above the goals set by individual institutions based on benchmark national rates and local factors. Additional control measures for infections associated with vascular access include avoiding the femoral site for catheterization because of an unusually high risk of infection (most likely related to the density of the skin flora); moving peripheral catheters to a new site at specified intervals (e.g., every 72 to 96 h), which may be facilitated by use of an intravenous therapy team; and applying disposable transducers for pressure monitoring and aseptic technique for accessing transducers or other vascular ports. Improvements in composition of semitransparent access-site dressings and potential nursing benefits (ease of bathing and site inspection, protection of site from secretions) favor the use of such coverings. Unresolved issues include the best frequency for rotation of central vascular catheter sites (given that guidewire-assisted catheter changes at the same site do not lessen infection risk); the appropriate role of mupirocin ointment, a topical antibiotic with excellent antistaphylococcal activity, in site care; the relative degrees of risk posed by peripherally inserted central catheters (PICC lines); and the risk-benefit of prophylactic use of heparin to avoid catheter thrombi, which may be associated with increased risk of infection.

Vascular device–related infection is suspected on the basis of the appearance of the catheter site or the presence of fever or bacteremia without another source in patients with vascular catheters. The diagnosis is confirmed by the recovery of the same species of microorganism from peripheral-blood cultures (preferably two cultures drawn from peripheral veins by separate venipunctures) and from semiquantitative or quantitative cultures of the vascular catheter tip. Less commonly used diagnostic measures include differential time to positivity (>2 h) for blood drawn through the vascular access device compared with a sample from a peripheral vein or differences in quantitative cultures (a 5- to 10-fold or greater "step-up") for blood samples drawn simultaneously from a peripheral vein and from a central vascular catheter. When infusion-related sepsis is considered (e.g., because of the abrupt onset of fever or shock temporally related to infusion therapy), a sample of the infusate or blood product should be retained for culture.

Therapy for vascular access–related infection is directed at the pathogen recovered from the blood and/or infected site. Important considerations in treatment are the need for an echocardiogram (to evaluate the patient for bacterial endocarditis), the duration of therapy, and the need to remove potentially infected catheters. In one report, approximately one-fourth of patients with intravascular catheter–associated *S. aureus* bacteremia studied by transesophageal echocardiography had evidence of endocarditis; the implication is that this test may be useful in determining the appropriate duration of treatment. Detailed consensus guidelines for the management of intravascular catheter–related infections have been published and recommend catheter removal in most cases of bacteremia or fungemia due to nontunneled central venous catheters. When attempting to salvage a potentially infected catheter, some clinicians use the "antibiotic lock" technique (instillation of concentrated antibiotic solution into the catheter lumen) in addition to systemic antimicrobial therapy. In one study of hemodialysis catheters, only about one-third of salvage attempts were successful, although delayed removal did not appear to increase the risk of complications. When feasible, a potentially infected central vascular catheter may be exchanged over a guidewire. If cultures of the removed catheter tip are positive, the replacement catheter will be moved to a new site; if the tip cultures are negative, the replacement catheter can remain in the original site. For patients with track-site infection, successful therapy without catheter removal is unusual. For patients with suppurative venous thrombophlebitis, excision of the affected vein is required. The authors of the consensus guidelines advise that the decision to remove a tunneled catheter or implanted device suspected to be the source of bacteremia or fungemia should be based on the severity of the patient's illness, the strength of the evidence that the device is infected, an assessment of the specific pathogens, and the presence of local or systemic complications.

ISOLATION TECHNIQUES Written policies for the isolation of infectious patients are a standard component of infection-control programs. In 1996, the CDC revised its isolation guidelines to make them simpler; to recognize the importance of all body fluids, secretions, and excretions in the transmission of nosocomial pathogens; and to focus precautions on the major routes of infection transmission.

The revised guidelines contain two tiers of precautions. *Standard precautions* are designed for the care of all patients in hospitals to reduce the risk of transmission of microorganisms from both recognized and unrecognized sources of infection. These precautions include gloving as well as hand cleansing for potential contact with (1) blood; (2) all other body fluids, secretions, and excretions, whether or not they contain visible blood; (3) nonintact skin; and (4) mucous membranes. Depending on exposure risks, standard precautions also include use of masks, eye protection, and gowns.

In the second tier are precautions for the care of patients with suspected or diagnosed colonization or infection with transmissible pathogens. These transmission-based guidelines collapse the older category- and disease-specific isolation guidelines into three sets of precautions based on probable routes of transmission: *airborne precautions*, *droplet precautions*, and *contact precautions*. Sets of precautions may be combined for diseases that have more than one route of transmission (e.g., varicella). Potentially contagious clinical syndromes, such as acute diarrhea, are included in the revised guidelines.

Because some prevalent antibiotic-resistant pathogens, particularly vancomycin-resistant enterococci (VRE), may be present on *intact* skin of patients in hospitals, some experts recommend gloving for all contact with patients who are acutely ill and/or from high-risk units, such as ICUs. In recent trials, wearing gloves did not replace the need for hand hygiene because hands occasionally became contaminated during wearing or removal of gloves. Some studies have suggested that use of gowns and gloves compared with routine care of patients (i.e., using neither of these barriers) decreases the risk of nosocomial infection; however, more recent evaluation suggests that gowning by personnel does not add benefit beyond that conferred by gloving and hand hygiene. Nevertheless, requiring increased precaution levels can improve the compliance of health care workers with isolation recommendations by 30%.

EPIDEMIC AND EMERGING PROBLEMS Outbreaks and emerging pathogens are always big news but probably account for fewer than 5% of nosocomial infections. Concern about emerging pathogens often prompts authorities to require hospitals to develop contingency and response plans. The investigation and control of nosocomial epidemics require that infection-control personnel develop a case definition, confirm that an outbreak really exists (since many apparent epidemics are actually pseudo-outbreaks due to surveillance or laboratory artifacts), review aseptic practices and disinfectant use, determine the extent of the outbreak, perform an epidemiologic investigation to determine modes of transmission, work closely with microbiology personnel to culture for common sources or personnel carriers as appropriate and to type epidemiologically important isolates, and heighten surveillance to judge the effect of control measures. Control measures generally include the early reinforcement of routine aseptic practices and hand hygiene during a search for compliance problems that may have fostered the outbreak, the ensuring of the appropriate isolation of cases (and the institution of cohort isolation and nursing if needed), and the implementation of further controls on the basis of the investigation's findings. Examples of some emerging and potential epidemic problems follow.

Chickenpox When health care workers are exposed to chickenpox in the community or through patients with initially unrecognized infections, or when these employees work during the 24 h before developing chickenpox, infection-control practitioners institute a varicella exposure investigation and control plan. The names of exposed workers and patients are obtained; medical histories are reviewed, and (if necessary) serologic tests for immunity are conducted; physicians are notified of susceptible exposed patients; postexposure prophylaxis with varicella-zoster immune globulin (VZIG) is considered for immunocompromised or pregnant contacts (see Table 164-1); preemptive use of acyclovir is considered as an alternative strategy in some susceptible persons; and susceptible exposed employees are furloughed during the at-risk period for disease (8 to 21 days, or 28 days if VZIG has been administered). Routine varicella vaccination of children and susceptible employees can markedly decrease risk and frequency of exposures.

Tuberculosis The resurgence of pulmonary tuberculosis in the United States since 1987 and a series of nosocomial outbreaks of infection with multidrug-resistant strains—primarily involving patients with AIDS and their caregivers—led to a successful revamping of tuberculosis control. Important control measures include prompt recognition, isolation, and treatment of cases; recognition of atypical presentations (e.g., lower-lobe infiltrates without cavitation); use of negative-pressure, 100% exhaust, private isolation rooms with closed doors and 6 to 12 or more air changes per hour; use of face masks ("respirators" approved by the National Institute for Occupational Safety and Health) by caregivers entering isolation rooms; possible use of high-efficiency particulate air filter units and/or ultraviolet lights for disinfecting air when other engineering controls are not feasible or reliable; and follow-up skin-testing of susceptible personnel who have been exposed to infectious patients before isolation.

Group A Streptococci The potential for a group A streptococcal outbreak should be considered when even a single nosocomial case occurs. Most outbreaks involve surgical wounds and are due to the presence of an asymptomatic carrier in the operating room. Investigation can be confounded by carriage at extrapharyngeal sites such as the rectum and vagina. Health care workers in whom carriage has been linked to nosocomial transmission of group A streptococci are removed from the patient-care setting and are not permitted to return until carriage has been eliminated by antimicrobial therapy.

Aspergillus Fungal spores are common in the environment, particularly on dusty surfaces. When hospital ceiling tiles are removed to provide access for repairs or when dusty areas are disturbed during hospital renovation, the spores become airborne. Inhalation of spores by immunosuppressed (especially neutropenic) patients creates a risk of pulmonary and/or paranasal sinus infection and disseminated aspergillosis. Routine surveillance among neutropenic patients for infections with filamentous fungi, such as *Aspergillus* and *Fusarium*, helps hospitals to determine whether they have unduly large environmental risks. As a matter of routine, hospitals should inspect and clean air-handling equipment, review all planned renovations with infection-control personnel and subsequently construct appropriate barriers, remove immunosuppressed patients from renovation sites, and consider the use of high-efficiency particulate air intake filters for rooms housing immunosuppressed patients.

Legionella Sporadic and epidemic cases of nosocomial *Legionella* pneumonia are most often due to the contamination of potable water and predominantly affect immunosuppressed patients, particularly those receiving glucocorticoid medication. The risk varies greatly within and among geographic regions, depending on the extent of hospital hot-water contamination, on the presence or absence of high-risk patient populations, and on specific hospital practices (e.g., inappropriate use of nonsterile water in respiratory therapy equipment). Laboratory-based surveillance for nosocomial *Legionella* should be performed, and a diagnosis of legionellosis should probably be considered more often than it is. If cases are detected, environmental samples (e.g., tap water) should be cultured. If cultures yield *Legionella* and if typing of clinical and environmental isolates reveals a correlation, eradication measures should be pursued (Chap. 132). An alternative approach is to periodically culture tap water in wards housing high-risk patients. If *Legionella* is found, a concerted effort should be made to culture samples from all patients with nosocomial pneumonia for *Legionella*.

Antibiotic-Resistant Bacteria Outbreaks of antibiotic resistance can depend on any of the following events: Darwinian selection of bacterial chromosomal mutations, spread of plasmid- and/or transposon-borne resistance among bacterial species, and (re)admission to the hospital of patients chronically infected with resistant bacteria. After the introduction of resistant strains, dissemination occurs by cross-infection on contaminated hands of caregivers or, occasionally, via personnel carriage and/or environmental contamination. Outbreak control (Table 116-3) depends on close laboratory surveillance, with early detection of problems; on the reinforcement of routine asepsis (e.g., hand hygiene); on the implementation of barrier precautions for all colonized and/or infected patients; on the use of patient-surveillance cultures to more fully ascertain the extent of patient colonization; and on the timely initiation of an epidemiologic investigation when rates increase. Colonized personnel who are implicated in nosocomial transmission and patients who pose a threat may be decontaminated; for example, colonization with methicillin-resistant *S. aureus* may be controlled with oral antibiotics, including trimethoprim-sulfamethoxazole and rifampin, and with topical agents, including hexachlorophene or chlorhexidine and mupirocin. In a few ICUs, selective decontamination has been used successfully as a temporary emergency control measure for outbreaks of infection due to gram-negative bacilli.

An emerging bacterial-resistance problem to plague hospitals is the presence of VRE. Initially an ICU problem, VRE have now spread onto general wards in many hospitals. VRE are particularly problematic because of a substantial "iceberg" effect (i.e., the fact that, for each individual with a clinical infection, many other patients are colonized); the occurrence of both gastrointestinal and skin colonization (reflecting fecal contamination on the skin of ill, hospitalized patients); and the propensity for these organisms to contaminate the patient's environment, which may increase the risk of cross-infection. Control of VRE requires strict attention to hand hygiene by personnel, concerted use of barrier precautions or cohort nursing for patients known to be colonized or infected, and emphasis on thorough cleaning of the rooms of these patients.

Spread of vancomycin resistance to *S. aureus* is a major concern. Clinical infections with methicillin-resistant *S. aureus* strains that exhibit high-level vancomycin resistance due to VRE-derived plasmids have now been reported in the setting of prolonged or repeated treatment with vancomycin and/or VRE colonization. The detection of these strains appears to be readily accomplished in clinical microbiology laboratories and should trigger an aggressive epidemiologic investigation and infection-control measures.

Because the excessive use of broad-spectrum antibiotics underlies many resistance problems, aggressive antibiotic-control policies must be considered a cornerstone of resistance-control efforts. Although the efficacy of antibiotic-control measures in reducing rates of antimicrobial resistance has not been proved in prospective controlled trials, it seems worthwhile to restrict the use of particular agents to narrowly defined indications or possibly to cycle the use of antibiotic classes to limit selective pressure on the nosocomial flora.

Bioterrorism Preparedness The terrorist attack on the World Trade Center in New York City; other horrific events of September 11, 2001; and the subsequent mailings of anthrax spores in the United States have made bioterrorism a prominent source of concern to hospital

TABLE 116-3 Controlling Antibiotic Resistance: Approaches to Consider

- Conduct surveillance for antibiotic resistance.
- Perform molecular typing (e.g., pulsed-field gel electrophoresis) when rates increase.
- For clonal expansion (e.g., single-strain outbreaks): Stress hand hygiene (alcohol hand rub and universal gloving); monitor adherence and give feedback.
- For polyclonal expansion (e.g., multistrain outbreaks): Stress antibiotic prudence (consider antibiotic rotation for ICUs); monitor adherence and give feedback.
- For continued problems: Obtain patient-surveillance cultures and isolate or provide cohort nursing for colonized/infected patients.
- Control device-related infections.
- Enlist administrative support proactively.

TABLE 116-4 Highlights of Hospital Preparedness for Bioterrorism

Emergency Department: Educate staff regarding bioterrorism diagnoses, case definitions, and appropriate syndrome-based isolation precautions.
Laboratory: Identify protocols and laboratory safety procedures for agents of bioterrorism.
Pharmacy: Develop medication and vaccine par stock, allocation, and delivery plans.
Nursing: Assess bed and isolation surge capacity; help develop contingency plans to free bed space by early discharges and deferred admissions.
Hospital Police: Plan for responsibilities as first responders and providers of risk assessment.
Mailroom: Plan for risk assessment and need/indications-for-use of personal protective equipment as appropriate.
Engineering/Buildings and Grounds: Evaluate air-handling systems and ensure familiarity with shutoffs and controls; educate staff about environmental decontamination.
Outpatient Areas: Develop plans for family and community evaluation and staging for delivery of prophylactic medications and/or vaccines.
Public Health: Ascertain local public health resources and open lines of communication, education, and surveillance.
The Community: Plan for infection-control practitioners to serve as liaisons/links/facilitators for emergency departments, laboratories, and community providers.
Administration: Perform resource assessment for medical supplies, transportation capabilities, potable water, sanitation facilities, provider backup, bed-space backup, etc. Oversee development of an incident command system.
"Morale Officer": Establish this position to help survey and keep staff functioning.

infection-control programs. The essentials for hospital preparedness (Table 116-4) entail education, internal and external communication, and risk assessment. Among the category A agents of bioterrorism (Chap. 205), smallpox is of major concern to the U.S. intelligence community. Consequently, in December 2002, the President of the United States recommended smallpox vaccination of a core group of military and hospital personnel; up-to-date information on a variety of vaccination-related and other bioterrorism-associated issues is available from the CDC (see www.bt.cdc.gov).

EMPLOYEE HEALTH SERVICE ISSUES An institution's employee health service is a critical component of its infection-control efforts. New employees should be processed through the service, where a contagious-disease history can be taken; evidence of immunity to a variety of diseases, such as hepatitis B, chickenpox, measles, and rubella, can be sought; immunizations for hepatitis B, measles, rubella, and varicella can be given as needed and a reminder about the need for yearly influenza immunization can be imparted; baseline and "booster" purified protein derivative of tuberculin skin-testing can be performed; and education about personal responsibility for infection control can be initiated. Evaluations of employees should be codified to meet the requirements of accrediting and regulatory agencies.

The employee health service must have protocols for dealing with workers who have been exposed to contagious diseases, such as those percutaneously or mucosally exposed to the blood of patients infected with HIV or hepatitis B or C virus. For example, postexposure HIV prophylaxis with a combination of two or three antiretroviral agents is recommended; free consultation is available from the CDC PEPLine (1-888-HIV-4911). Protocols are also needed for dealing with caregivers who have common contagious diseases, such as chickenpox, group A streptococcal infections, respiratory infections, and infectious diarrhea, and for those who have less common but high-visibility public health problems, such as chronic hepatitis B or C or HIV infection, for which exposure-control guidelines have been published by the CDC and by the Society for Healthcare Epidemiology of America.

117 INFECTIONS IN TRANSPLANT RECIPIENTS

Robert Finberg, Joyce Fingeroth

The evaluation of infections in transplant recipients involves consideration of both the donor and the recipient of the transplanted organ. Infections following transplantation are complicated by the use of drugs that are necessary to enhance the likelihood of survival of the transplanted organ but that also cause the host to be immunocompromised. Thus what might have been a latent or asymptomatic infection in an immunocompetent donor or in the recipient prior to therapy becomes a life-threatening problem when the recipient becomes immunosuppressed.

A variety of organisms have been transmitted by organ transplantation (Table 117-1). Careful attention to the sterility of the medium used to process the organ combined with meticulous microbiologic evaluation reduces rates of transmission of bacteria that may be present or grow in the organ culture medium. From 2% to >20% of donor kidneys are estimated to be contaminated with bacteria—in most cases, with the organisms that colonize the skin or grow in the tissue culture medium used to bathe the donor kidney while it awaits implantation. The reported rate of bacterial contamination of transplanted bone marrow is as high as 17% but is most commonly ~1%. The use of enrichment columns and monoclonal-antibody depletion procedures results in a higher incidence of contamination. Approximately 2% of cryopreserved marrow and peripheral-blood stem cells transfused as part of treatment for cancer are contaminated. In one series of patients receiving contaminated products, 14% had fever or bacteremia, but none died. Results of cultures performed at the time of cryopreservation and at the time of thawing were helpful in guiding therapy for the recipient.

In many transplantation centers, transmission of infections that may be latent or clinically inapparent in the donor organ has resulted in the development of specific donor-screening protocols. In addition to ordering serologic studies focusing on viruses such as herpes-group viruses [herpes simplex virus (HSV) 1, HSV-2], varicella-zoster virus (VZV), cytomegalovirus (CMV), human herpesvirus (HHV) type 6, Epstein-Barr virus (EBV), HHV-8, hepatitis B and C viruses, HIV, and human T-cell lymphotropic virus (HTLV) type I and on parasites such as *Toxoplasma gondii*, clinicians caring for organ donors should consider assessing stool (for parasites) and should perform skin testing for *Mycobacterium tuberculosis*. An investigation of the patient's dietary habits (e.g., consumption of raw meat or fish or of unpasteurized dairy products), occupations or avocations (e.g., gardening or spelunking), and travel history (e.g., travel to areas with endemic fungi) is mandatory. It is expected that the recipient will have been likewise assessed. This chapter considers aspects of infection unique to various transplantation settings.

INFECTIONS IN BONE MARROW AND HEMATOPOIETIC STEM CELL TRANSPLANT RECIPIENTS

Bone marrow or hematopoietic stem cell transplantation for either immunodeficiency or cancer results in a transient state of complete immune incompetence. Immediately after transplantation, both phagocytes and immune cells (T and B cells) are absent, and the host is extremely susceptible to infection. The reconstitution that follows transplantation has been likened to maturation of the immune system in neonates. The analogy does not entirely predict infections seen in bone marrow transplant (BMT) and hematopoietic stem cell transplant (HSCT) recipients because the new marrow matures in an old host who has several latent infections already. Nevertheless, infections occur in a predictable time frame after transplantation (Table 117-2).

BACTERIAL INFECTIONS In the first month after bone marrow or hematopoietic stem cell transplantation, infectious complications are similar to those in granulocytopenic patients receiving chemotherapy for acute leukemia (Chap. 72). Because of the anticipated 1- to 4-week duration

TABLE 117-1 *Organisms Transmitted by Organ Transplantation and Sites of Reactivation Disease*[a]

	Blood	Lungs	Heart	Brain	Liver	Skin
Viruses						
Cytomegalovirus[b]	+	+	+/−	+	+	+
Epstein-Barr virus[c]	+	+	+	+	+	+

Toxoplasma gondii[f]		+	+	+		
Strongyloides stercoralis[g,h]		+				
Trypanosoma cruzi[h]			+			
Plasmodium falciparum[h]	+					

[a] +, well documented; ±, probably occurs.
[b] Cytomegalovirus reactivation is prone to occur in the transplanted organ. The same may be true for human herpesvirus type 8 (Kaposi's sarcoma–associated herpesvirus).
[c] Epstein-Barr virus reactivation usually presents as an extranodal proliferation of transformed B cells and can be present either as a diffuse disease or as a mass lesion in a single organ.
[d] Bovine spongiform encephalopathy, a prion-mediated disease, can be transmitted with organs.
[e] Rabies has been transmitted through corneal transplants.
[f] *T. gondii* usually causes disease in the brain. In bone marrow transplant recipients, acute pulmonary disease may also occur. Heart transplant recipients develop disease in the allograft.
[g] *Strongyloides* "hyperinfection" may present with pulmonary disease—often associated with gram-negative bacterial pneumonia.
[h] While transmission with organs has been described, it is unusual.

of neutropenia and the high rate of bacterial infection in this population, many centers give prophylactic antibiotics to patients upon initiation of chemotherapy. Levofloxacin decreases the incidence of gram-negative bacteremia among these patients. Bacterial infections are common in the first few days after bone marrow transplantation. The organisms involved are predominantly aerobic bacteria found in the bowels (*Escherichia coli*, *Klebsiella*, *Pseudomonas*) and those found on the skin or in intravenous catheters (*Staphylococcus aureus*, coagulase-negative staphylococci). Beyond the first few days of neutropenia, infections with filamentous bacteria (*Nocardia* and the organisms that cause actinomycosis) become more common. Episodes of bacteremia due to encapsulated organisms mark the late posttransplantation period (>6 months after bone marrow reconstitution).

FUNGAL INFECTIONS Beyond the first week after transplantation, fungal infections become increasingly common. As in most granulocytopenic patients, *Candida* infections are most commonly seen in this setting. With increased use of prophylactic fluconazole, infections with resistant fungi, such as *Candida glabrata* and *Aspergillus*, have become more common. In patients with graft-versus-host disease (GVHD) who require prolonged or indefinite courses of glucocorticoids and other immunosuppressive agents [e.g., cyclosporine, tacrolimus, mycophenolate mofetil, rapamycin, alemtuzumab (an antilymphocyte and antimonocyte antibody)], there is a high risk of fungal infection (usually with *Candida* or *Aspergillus*), even after engraftment and resolution of neutropenia. These patients are also at high risk of reactivation of fungal infection (histoplasmosis, coccidioidomycosis, blastomycosis) in areas where endemic fungi reside and if they are involved in activities such as spelunking or gardening. Because of the high and prolonged risk of *Pneumocystis* pneumonia (especially among patients being treated for hematologic malignancies), most patients should receive maintenance prophylaxis with trimethoprim-sulfamethoxazole (TMP-SMX) starting 1 month after engraftment and continuing for at least 1 year.

PARASITIC INFECTIONS The regimen just described for *Pneumocystis* pneumonia may also protect patients seropositive for *T. gondii*, which may cause pneumonia as well as central nervous system (CNS) lesions. The advantages of maintaining patients on daily TMP-SMX for 1 year after transplantation include protection against *Listeria monocytogenes* and nocardial disease as well as late infections with *Streptococcus pneumoniae* and *Haemophilus influenzae*, which are a consequence of the inability of the immature bone marrow to respond to polysaccharide antigens.

VIRAL INFECTIONS BMT/HSCT recipients are susceptible to infection with a variety of viruses, including reactivation syndromes caused by most HHVs (Table 117-3) and infections caused by viruses that circulate in the community.

Herpes Simplex Virus Within the first 2 weeks after transplantation, most patients who are seropositive for HSV-1 excrete the virus from the oropharynx. The ability to isolate HSV declines with time. Administration of prophylactic acyclovir (or valacyclovir) to seropositive BMT/HSCT recipients has been shown to reduce mucositis and prevent HSV pneumonia (a rare condition reported almost exclusively in BMT recipients). Both esophagitis (usually due to HSV-1) and anogenital disease (commonly induced by HSV-2) may be prevented with acyclovir prophylaxis. →***For further discussion, see Chap. 163.***

Varicella-Zoster Virus Reactivation of herpes zoster may occur within the first month but more commonly occurs several months after transplantation. Reactivation rates are ~40% for allogeneic recipients and 25% for autologous recipients. Localized zoster can spread locally in an immunosuppressed patient. Fortunately, disseminated disease can usually be controlled with high doses of acyclovir. Because of the high incidence of dissem-

TABLE 117-2 *Infections After Bone Marrow Transplantation*

Infection Site	Period after Transplantation		
	Early (<1 Month)	Middle (1–4 Months)	Late (>6 Months)
Disseminated	Bacteria (aerobic gram-negative, gram-positive)	Bacteria (*Nocardia*, agents of actinomycosis) Fungi (*Candida*, *Aspergillus*)	Encapsulated bacteria (*Streptococcus pneumoniae*, *Haemophilus influenzae*, *Neisseria meningitidis*)
Skin and mucous membranes	Herpes simplex virus	Human herpesvirus type 6	Varicella-zoster virus
Lungs	Herpes simplex virus	Viruses (cytomegalovirus, human herpesvirus type 6) Parasites (*Toxoplasma gondii*) Fungi (*Pneumocystis*)	
Kidneys			Viruses (BK)
Brain			Parasites (*T. gondii*) Viruses (JC)

TABLE 117-3 *Herpes-Group Virus Syndromes in Transplant Recipients*

Virus	Reactivation Disease
Herpes simplex virus type 1	Oral lesions, may be associated with pneumonia, described only in BMT recipients
	Hepatitis
Herpes simplex virus type 2	Severe and/or persistent anogenital lesions
	Hepatitis
Varicella-zoster virus	Zoster (potentially disseminated)
Cytomegalovirus	Associated with graft rejection, fever, bone marrow failure, pneumonitis, gastrointestinal disease, other
Epstein-Barr virus	B cell lymphoproliferative disease
	Oral hairy leukoplakia (rare)
Human herpesvirus type 6	Fever, rash,[a] pneumonitis, bone marrow suppression, encephalitis (manifestations controversial)
Human herpesvirus type 7	Undefined
Kaposi's sarcoma–associated herpesvirus/human herpesvirus type 8	Kaposi's sarcoma
	Primary effusion lymphoma (rare)
	Multicentric Castleman's disease (rare)

[a] A rash may be seen with primary infections, but it is difficult to distinguish from other rashes seen in these patients.

Note: BMT, bone marrow transplant.

ination of herpes zoster among patients with skin lesions, acyclovir is given prophylactically in some centers to prevent severe disease. Low doses of acyclovir (400 mg orally, three times daily) appear to be effective in preventing reactivation of VZV. However, acyclovir also inhibits the development of VZV-specific immunity. Thus, its administration for only 6 months after transplantation does not prevent zoster from occurring when treatment is stopped. Some data suggest that administration of low doses of acyclovir for an entire year after transplantation is effective and may eliminate most cases of posttransplantation zoster. →***For further discussion, see Chap. 164.***

Cytomegalovirus The onset of CMV disease (interstitial pneumonia, bone marrow suppression, or graft failure) usually comes between 30 and 90 days after transplantation, when the granulocyte count is adequate but immunologic reconstitution has not occurred. CMV disease rarely develops earlier than 14 days after transplantation and may become evident as late as 4 months after the procedure. It is of great concern in the second month after transplantation, particularly in allogeneic BMT/HSCT recipients. In cases in which the donor marrow is depleted of T cells (to prevent GVHD or eliminate a T cell tumor), the disease may be manifested earlier. The use of αCD52 antibody (alemtuzumab) to prevent GVHD in nonmyeloablative transplantation has been associated with an increase in CMV disease. Patients who receive ganciclovir (for prophylaxis, preemptive treatment, or treatment; see below) may develop CMV infection even later than 4 months after transplantation; treatment appears to delay the development of the normal immune response to CMV infection. Although CMV disease may present as isolated fever, granulocytopenia, or gastrointestinal disease, the foremost cause of death from CMV infection in this setting is pneumonia.

With the standard use of CMV-negative or filtered blood products, primary CMV infection should be a risk in allogeneic transplantation only when the donor is CMV-seropositive and the recipient is CMV-seronegative. Reactivation disease or superinfection with another strain from the donor is also common in CMV-positive recipients, and most seropositive patients who undergo bone marrow transplantation excrete CMV, with or without clinical findings. Serious CMV disease is much more common among allogeneic than autologous recipients and is often associated with GVHD. In addition to pneumonia and marrow suppression (and, less often, graft failure), manifestations of CMV disease in BMT/HSCT recipients include fever with or without arthralgias, myalgias, and esophagitis. CMV ulcerations occur in both the lower and the upper gastrointestinal tract, and it may be difficult to distinguish diarrhea due to GVHD from that due to CMV infection. The finding of CMV in the liver of a patient with GVHD does not necessarily mean that CMV is responsible for hepatic enzyme abnormalities.

Management of CMV disease in BMT/HSCT recipients includes strategies directed at prophylaxis, suppression, preemptive therapy, or treatment. Prophylaxis results in a lower incidence of disease at the cost of treating many patients who otherwise would not require therapy. Because of the high fatality rate associated with CMV pneumonia in these patients and the difficulty of early diagnosis of CMV infection, prophylactic intravenous ganciclovir (or oral valganciclovir) has been used in some centers and has been shown to abort CMV disease during the period of maximal vulnerability (from engraftment to day 120 after transplantation). The foremost problem with the administration of ganciclovir relates to adverse effects, which include dose-related bone marrow suppression (thrombocytopenia, leukopenia, anemia, and pancytopenia). Because the frequency of CMV pneumonia is lower among autologous BMT recipients (2 to 7%) than among allogeneic BMT recipients (10 to 40%), prophylaxis in the former group will not become the rule until a less toxic antiviral agent becomes available.

Like prophylaxis, suppressive treatment, which targets patients with polymerase chain reaction evidence of CMV or urine cultures positive for CMV, entails the unnecessary treatment of many individuals (on the basis of a laboratory test that is not highly predictive of disease) with drugs that have adverse effects. Currently, because of the neutropenia associated with ganciclovir in BMT/HSCT recipients, a preemptive approach—treatment of those patients in whose blood CMV is detected by an antigen or DNA test—is used at most centers. This approach is almost as effective as prophylaxis or suppression and causes less toxicity. Quantitative viral load assays, which are not dependent on circulating polymorphonuclear leukocytes, have supplanted antigen-based assays and are used by most centers. A positive test (or increase in titer) prompts the initiation of preemptive therapy.

Treatment of CMV pneumonia in BMT/HSCT recipients requires both intravenous immune globulin (IVIg) and ganciclovir. In patients who cannot tolerate ganciclovir, foscarnet is a useful alternative, although it may produce nephrotoxicity and electrolyte imbalance. Transfusion of CMV-specific T cells from the donor decreased viral load in a small series of patients; this result suggests that immunotherapy may play a role in the treatment of this disease in the future. →***For further discussion, see Chap. 166.***

Human Herpesviruses 6 and 7 HHV-6, the cause of roseola in children, is a ubiquitous herpesvirus that reactivates (as determined by culture of the virus from the blood) in ~50% of transplant recipients between 2 and 4 weeks after surgery. In some cases, reactivation of HHV-6 appears to be associated with neutropenia; since, like CMV, this virus can be found in marrow cells, it is possible that HHV-6 reactivation is responsible for some of the neutropenia that follows bone marrow transplantation. Although encephalitis developing after transplantation has been associated with HHV-6 in cerebrospinal fluid (CSF), the causality of the association is not well defined. HHV-6 DNA is sometimes found in lung samples after transplantation. However, its role in pneumonitis is unclear. While HHV-6 has been shown to be susceptible to foscarnet (and possibly to ganciclovir) in vitro, the efficacy of antiviral treatment has not been well studied. Little is known about the related herpesvirus HHV-7 or its role in posttransplantation infection. →***For further discussion, see Chap. 166.***

Epstein-Barr Virus Primary EBV infection can be fatal to transplant recipients; EBV reactivation can cause EBV–B cell lymphoproliferative disease (LPD), which may also be fatal to patients taking immunosuppressive drugs. The localization of EBV to B cells leads to several interesting phenomena in BMT/HSCT recipients. The marrow ablation that occurs as part of the BMT/HSCT procedure may eliminate latent EBV from the host. Infection can then be reacquired immediately after transplantation by transfer of infected donor B cells.

Rarely, transplantation from a seronegative donor may result in cure. The recipient is then at risk for a second primary infection.

EBV-LPD can develop in the recipient's B cells (if any should survive marrow ablation) but is more likely to be a consequence of outgrowth of infected donor cells. Both lytic and latent EBV replication are more likely during immunosuppression (e.g., they are associated with GVHD and the use of antibodies to T cells). Although less likely in autologous transplantation, reactivation can occur in T cell–depleted autologous recipients (e.g., patients being given antibodies to T cells for the treatment of a T cell lymphoma with marrow depletion). EBV-LPD, which can become apparent as soon as 1 to 3 months after engraftment, causes high fevers and cervical adenopathy resembling the symptoms of infectious mononucleosis but more commonly presents as an extranodal mass. The incidence of 0.6% among allogeneic BMT/HSCT recipients contrasts with figures of ~5% for renal transplant recipients and up to 20% for cardiac transplant patients. In all cases, EBV-LPD is more likely to occur with continued immunosuppression (especially that caused by the use of antibodies to T cells and cyclosporine or other T cell–suppressive agents).

EBV-specific T cells generated from the donor have been used experimentally to prevent and to treat EBV-LPD in the allogeneic recipient. Administration of a monoclonal antibody to CD20 (rituximab) for the treatment of B cell lymphomas that express this surface protein has elicited dramatic responses and currently constitutes first-line therapy for EBV-LPD, although long-term suppression of new antibody responses accompanies therapy. The role of antivirals is uncertain because no available agents have been documented to have activity against latent EBV infection. Ganciclovir has been postulated to have activity on the basis of its ability to inhibit proliferation of B cells, but this activity is associated with toxicity. High-dose zidovudine shows promise for the treatment of EBV-positive CNS lymphomas—another EBV-associated complication of transplantation. Both interferon α and retinoic acid have been used in the treatment of EBV-LPD, as has IVIg, but no large studies have assessed the efficacy of these agents. Chemotherapeutic regimens have been used as a last resort, even though patients' tolerance and long-term results have been disappointing in this setting. →***For further discussion, see Chap. 165.***

Human Herpesvirus 8 The EBV-related gamma herpesvirus HHV-8, which is causally associated with Kaposi's sarcoma, with primary effusion lymphoma, and sometimes with multicentric Castleman's disease, has rarely resulted in disease in BMT/HSCT recipients. The reasons may be a relatively low seroprevalence in the population and the limited duration of profound T cell suppression after bone marrow/hematopoietic stem cell transplantation. →***For further discussion, see Chap. 166.***

Other (Nonherpes) Viruses The diagnosis of pneumonia in BMT/HSCT recipients poses some special problems. Because patients have undergone treatment with multiple chemotherapeutic agents and sometimes radiation, their differential diagnosis should include—in addition to bacterial pneumonia—CMV pneumonitis, pneumonia of other viral or fungal etiology, parasitic pneumonia, diffuse alveolar hemorrhage, and chemical- or radiation-associated pneumonitis. Since fungal disease and viruses such as respiratory syncytial virus (RSV), parainfluenza virus (types 1, 2, and 3), influenza A and B viruses, and adenovirus are also causes of pneumonia in this setting, it is important to diagnose CMV specifically (see above). *M. tuberculosis* has been an uncommon cause of pneumonia among BMT/HSCT recipients in Western countries (<0.1 to 0.2%) but is common in Hong Kong (5.5%) and in countries where the prevalence of tuberculosis is high. The exposure history of the recipient is clearly critical in an assessment of posttransplantation infections.

Both RSV and parainfluenza viruses, particularly type 3, can cause severe or even fatal pneumonia in BMT recipients. Infections with both of these agents sometimes occur as disastrous nosocomial epidemics. Therapy with aerosolized ribavirin as well as RSV immunoglobulin or monoclonal antibody to RSV (palivizumab) has been reported to lessen the severity of RSV disease, but there are no large studies to prove efficacy. Influenza also occurs in BMT recipients and generally mirrors the presence of infection in the community. Several drugs are available for the treatment of influenza (amantadine/rimantadine, ribavirin?) but have limited effects, primarily reducing symptoms and shortening the duration of illness. The neuraminidase inhibitors (oseltamivir and zanamivir) are active against both influenza A virus and influenza B virus and are a reasonable treatment option. Adenovirus can be isolated from BMT recipients at rates varying from 5 to 18%. Although hemorrhagic cystitis, pneumonia, and fatal disseminated infection have been reported, adenovirus infection, which (like CMV infection) usually occurs in the first or second month after transplantation, is often asymptomatic. Cidofovir has proved effective in animal models and in case reports. Infections with parvovirus B19 (presenting as anemia or occasionally as pancytopenia) and enteroviruses (sometimes fatal) can occur. Parvovirus infection can be treated with IVIg (Chap. 168). Pleconaril, a capsid-binding agent, is being studied for the treatment of enterovirus infection. Rotaviruses are a common cause of gastroenteritis in BMT/HSCT recipients. Polyomavirus BK is found at high titers in the urine of patients who are highly immunosuppressed. BK viruria may be associated with hemorrhagic cystitis. Progressive multifocal leukoencephalopathy caused by JC virus is rare among BMT/HSCT recipients compared with the rate among patients with impaired T cell function due to HIV infection. There is no known treatment for this disease. When transmitted by mosquitoes or by blood transfusion, West Nile virus can cause encephalitis and death after bone marrow transplantation.

INFECTIONS IN SOLID ORGAN TRANSPLANT RECIPIENTS

Morbidity and mortality among solid organ transplant recipients have been reduced by the use of more effective antibiotics. The organisms that cause infections in recipients of solid organ transplants are different from those that infect BMT/HSCT recipients because solid organ recipients do not go through a period of neutropenia. As the transplantation procedure involves surgery, however, solid organ recipients are subject to infections at anastomotic sites and to wound infections. Compared with BMT/HSCT recipients, organ transplant patients are immunosuppressed for longer periods (often permanently). Thus they are susceptible to the same organisms as patients with chronically impaired T cell immunity (Chap. 72, especially Table 72-1).

During the early period (<1 month after transplantation), infections are most commonly caused by extracellular bacteria (staphylococci, streptococci, *E. coli*, other gram-negative organisms), which often originate in surgical wound or anastomotic sites. The spectrum of infection is largely determined by the type of transplant.

In subsequent weeks, the consequences of the administration of agents that suppress cell-mediated immunity and of the acquisition or reactivation (from the transplanted organ) of viruses and parasites become apparent. CMV infection is often a problem in the first 6 months after transplantation and may present as severe systemic disease or as infection of the transplanted organ. HHV-6 reactivation (assessed by blood culture) occurs within the first 2 to 4 weeks after transplantation and may be associated with fever and granulocytopenia. Data suggest that HHV-6 and HHV-7 may exacerbate CMV-induced disease. CMV is associated not only with generalized immunosuppression but also with organ-specific, rejection-related syndromes: glomerulopathy in kidney transplant recipients, bronchiolitis obliterans in lung transplant recipients, vasculopathy in heart transplant recipients, and the vanishing bile duct syndrome in liver transplant recipients. A complex interplay between increased CMV replication and enhanced graft rejection is well established: Increasing immunosuppression leads to increased CMV replication, which is associated with graft rejection. For this reason, considerable attention has been focused on the diagnosis, treatment, and prophylaxis of CMV infection in organ transplant recipients. Early transmission of West Nile virus to transplant recipients from an organ donor has been reported.

Beyond 6 months after transplantation, infections characteristic of

patients with defects in cell-mediated immunity—e.g., infections with *Listeria*, *Nocardia*, various fungi, and other intracellular pathogens—may be a problem. Elimination of these late infections will not be possible until specific tolerance to the transplanted organ can be achieved without the administration of drugs that lead to generalized immunosuppression. Meanwhile, vigilance, prophylaxis/preemptive therapy (when indicated), and rapid diagnosis and treatment of infections can be lifesaving in solid organ transplant recipients, who, unlike most BMT recipients, continue to be immunosuppressed.

TABLE 117-4 *Infections After Kidney Transplantation*

Infection Site	Period after Transplantation		
	Early (<1 Month)	Middle (1–4 Months)	Late (>6 Months)
Urinary tract	Bacteria (*Escherichia coli*, *Klebsiella*, Enterobacteriaceae, *Pseudomonas*, *Enterococcus*) associated with bacteremia and pyelonephritis, *Candida*	Cytomegalovirus (CMV; fever alone is common)	Bacteria; late infections usually not associated with bacteremia
Lungs	Bacteria (*Legionella* in endemic settings)	CMV diffuse interstitial pneumonitis, *Pneumocystis*, *Aspergillus*, *Legionella*	*Nocardia*, *Aspergillus*, *Mucor*
Central nervous system		*Listeria* meningitis, CMV encephalitis, *Toxoplasma gondii*	CMV retinitis, *Listeria* meningitis, cryptococcal meningitis, *Aspergillus*, *Nocardia*

Solid organ transplant recipients are susceptible to EBV-LPD from as early as 2 months to many years after transplantation. The prevalence of this complication is increased by potent and prolonged use of T cell–suppressive drugs. The condition may be reversed (in some cases) by decreasing the degree of immunosuppression. Among organ transplant patients, those with heart and lung transplants—who receive the most intensive immunosuppressive regimens—are most likely to develop EBV-LPD, particularly in the lungs. Although the disease usually originates in recipient B cells, several cases of donor origin have been reported. There is a notable tendency for EBV-LPD to develop in the transplanted organ. High organ-specific content of B lymphoid tissues (i.e., bronchial-associated lymphoid tissue in the lung), anatomical factors (i.e., lack of access of host T cells to the transplanted organ because of disturbed lymphatics), and differences in major histocompatibility loci between the host T cells and the organ (i.e., lack of cell migration or lack of effective T cell/macrophage cooperation) may result in defective elimination of EBV-infected B cells. Solid organ transplant recipients are also highly susceptible to the development of Kaposi's sarcoma and to B cell proliferative disorders associated with Kaposi's sarcoma–associated herpesvirus (KSHV) (primary effusion lymphoma, multicentric Castleman's disease). Kaposi's sarcoma can develop very rapidly after transplantation and can occur in the allograft. However, because the seroprevalence of KSHV is very low in Western countries, Kaposi's sarcoma is infrequent in these areas.

KIDNEY TRANSPLANTATION (See Table 117-4) ■ **Early Infections** Infections developing soon after kidney transplantation are often caused by bacteria associated with skin or wound infections. There is a role for perioperative antibiotic prophylaxis, and many centers give cephalosporins to decrease the risk of postoperative complications. Urinary tract infections developing soon after transplantation are usually related to anatomical alterations resulting from surgery. Such early infections may require prolonged treatment (e.g., 6 weeks of antibiotic administration for pyelonephritis). Urinary tract infections that occur >6 months after transplantation do not seem to be associated with the high rate of pyelonephritis or relapse seen with infections that occur in the first 3 months and may be treated for shorter periods.

Prophylaxis with TMP-SMX [1 double-strength tablet (800 mg of sulfamethoxazole, 160 mg of trimethoprim) per day] for the first 4 months after transplantation decreases the incidence of early and middle-period infections (see below and Tables 117-4 and 117-5).

Middle-Period Infections Because of continuing immunosuppression, kidney transplant recipients are predisposed to lung infections characteristic of those in patients with T cell deficiency (i.e., infections with intracellular bacteria, mycobacteria, nocardiae, fungi, viruses, and parasites). The high mortality associated with *Legionella pneumophila* infection (Chap. 132) led to the closing of renal transplant units in hospitals with endemic legionellosis.

About 50% of all renal transplant recipients presenting with fever 1 to 4 months after transplantation have evidence of CMV disease; CMV itself accounts for the fever in more than two-thirds of cases and thus is the predominant pathogen during this period. CMV infection (Chap. 166) may also present as arthralgias or myalgias. During this period, this infection may represent primary disease (in the case of a seronegative recipient of a kidney from a seropositive donor) or may present as reactivation disease or superinfection. Patients may have atypical lymphocytosis. Unlike immunocompetent patients, however, they often do not have lymphadenopathy or splenomegaly. Therefore, clinical suspicion and laboratory confirmation are necessary for diagnosis. The clinical syndrome may be accompanied by bone marrow suppression (particularly leukopenia). CMV also causes glomerulopathy and is associated with an increased incidence of other opportunistic infections. Because of the frequency and severity of CMV disease, a considerable effort has been made to prevent and treat it in renal transplant recipients. Administration of an immune globulin preparation enriched with antibodies to CMV decreases the incidence in the group at highest risk for severe infections (seronegative recipients of

TABLE 117-5 *Prophylaxis of Infections in Transplant Recipients*

Risk Factor	Organism	Prophylactic Antibiotics	Examinations
Travel to or residence in area with known risk of fungal infection	Coccidioidomycosis, histoplasmosis, blastomycosis	Imidazoles (fluconazole, itraconazole, voriconazole)	Chest radiography
Latent viruses	HSV, VZV, EBV, CMV	Acyclovir after bone marrow transplantation for HSV and VZV; ganciclovir in some settings	Serologic test for HSV, VZV, CMV, HHV-6, EBV, HHV-8
Latent parasites	*Pneumocystis*, *Toxoplasma gondii*	Trimethoprim-sulfamethoxazole or dapsone plus pyrimethamine	Serologic test for *Toxoplasma*
History of exposure to tuberculosis or latent tuberculosis	*Mycobacterium tuberculosis*	Isoniazid if recent conversion for positive chest x-ray and no previous treatment	PPD skin test and chest radiography

Note: CMV, cytomegalovirus; EBV, Epstein-Barr virus; HHV, human herpesvirus; HSV, herpes simplex virus; PPD, purified protein derivative; VZV, varicella-zoster virus.

seropositive kidneys). Ganciclovir is useful for prophylaxis and the treatment of serious CMV disease. One study showed a significant (50%) reduction in CMV disease and rejection at 6 months in patients who received prophylactic valacyclovir (an acyclovir congener) for the first 90 days after renal transplantation. The availability of valganciclovir and valacyclovir has allowed most centers to move to oral prophylaxis for transplant recipients.

Infection with the other herpes-group viruses may become evident within 6 months after transplantation or later. Early after transplantation, HSV may cause either oral or anogenital lesions that are usually responsive to acyclovir. Large ulcerating lesions in the anogenital area may lead to bladder and rectal dysfunction as well as predisposing to bacterial infection. VZV may cause fatal disseminated infection in nonimmune kidney transplant recipients, but in immune patients reactivation zoster usually does not disseminate outside the dermatome; thus disseminated VZV infection is a less fearsome complication in kidney transplantation than in bone marrow transplantation. HHV-6 may reactivate and (although usually asymptomatic) may be associated with fever, rash, marrow suppression, or encephalitis.

EBV reactivation disease is more serious; it may present as an extranodal proliferation of B cells that invade the CNS, nasopharynx, liver, small bowel, heart, and transplanted kidney. The disease is diagnosed by the finding of a proliferation of EBV-positive B cells. The incidence of EBV-LPD is higher among patients given high doses of cyclosporine, tacrolimus, or other immunosuppressive agents (including anti–T cell antibodies). Disease may regress once immunocompetence is restored. HHV-8 infection can be transmitted with the donor kidney and is associated with the development of Kaposi's sarcoma in the recipient. Kaposi's sarcoma (primary vs. reactivation of HHV-8) often appears within 1 year after transplantation, although the range of onset times is wide (1 month to ~20 years).

The papovaviruses BK and JC (polyomavirus hominis types 1 and 2) have been cultured from the urine of kidney transplant recipients (as they have from that of BMT recipients). The excretion of BK virus is associated with ureteral strictures, BK nephropathy, and—in rare instances—vasculopathy. JC virus is associated with progressive multifocal leukoencephalopathy (rare). Adenoviruses may persist with continued immunosuppression in these patients.

Kidney transplant recipients are also subject to infections with other intracellular organisms. These patients may develop pulmonary infections with *Nocardia*, *Aspergillus*, and *Mucor* as well as infections with other pathogens in which the T cell/macrophage axis plays an important role. In patients without intravenous catheters, *L. monocytogenes* is a common cause of bacteremia ≥1 month after renal transplantation and should be seriously considered in renal transplant recipients presenting with fever and headache. Kidney transplant recipients may develop *Salmonella* bacteremia, which can lead to endovascular infections and require prolonged therapy. Pulmonary infections with *Pneumocystis* are common unless the patient is maintained on TMP-SMX prophylaxis. *Nocardia* infection (Chap. 146) may present in the skin, bones, and lungs or in the CNS, where it usually takes the form of single or multiple brain abscesses. *Nocardia* infection generally occurs ≥1 month after transplantation and may follow immunosuppressive treatment for an episode of rejection. Pulmonary findings are nonspecific: localized disease with or without cavities is most common, but the disease may disseminate. The diagnosis is made by culture of the organism from sputum or from the involved nodule. As with *Pneumocystis*, prophylaxis with TMP-SMX is often efficacious in the prevention of disease. The occurrence of *Nocardia* infections >2 years after transplantation suggests that a long-term prophylactic regimen may be justified.

Toxoplasmosis can occur in seropositive patients but is less common than in other transplant settings, usually developing in the first few months after kidney transplantation. Again, TMP-SMX is helpful in prevention. In endemic areas, histoplasmosis, coccidioidomycosis, and blastomycosis may cause pulmonary infiltrates or disseminated disease.

Late Infections Late infections (>6 months after kidney transplantation) include CMV retinitis and a variety of CNS complications. Patients (particularly those whose immunosuppression has been increased) are at risk for subacute meningitis due to *Cryptococcus neoformans*. Cryptococcal disease may present in an insidious manner (sometimes as a skin infection before the development of clear CNS findings). *Listeria* meningitis may have an acute presentation and requires prompt therapy to avoid a fatal outcome.

Patients who continue to take glucocorticoids are predisposed to infection. "Transplant elbow" is a recurrent bacterial infection in and around the elbow that is thought to result from a combination of poor tensile strength of the skin of steroid-treated patients and steroid-induced proximal myopathy that requires patients to push themselves up with their elbows to get out of chairs. Bouts of cellulitis (usually caused by *S. aureus*) recur until patients are provided with elbow protection.

Kidney transplant recipients are susceptible to invasive fungal infections—such as those due to *Aspergillus* and *Rhizopus*, which may present as superficial lesions before dissemination. Mycobacterial infection (particularly that with *Mycobacterium marinum*) can be diagnosed by skin examination. Infection with *Prototheca wickerhamii* (an achlorophyllic alga) has been diagnosed by skin biopsy. Warts caused by human papillomaviruses (HPVs) are a late consequence of persistent immunosuppression; imiquimod or other forms of local therapy are usually satisfactory.

HEART TRANSPLANTATION ■ Early Infections Sternal wound infection and mediastinitis are early complications of heart transplantation. An indolent course is common, with fever or a mildly elevated white blood cell count preceding the development of site tenderness or drainage. Clinical suspicion based on evidence of sternal instability and failure to heal may lead to the diagnosis. Although common microbial residents of the skin (e.g., *S. aureus* and *Staphylococcus epidermidis*) as well as gram-negative organisms (e.g., *Pseudomonas aeruginosa*) and fungi (e.g., *Candida*) are often involved, mediastinitis in heart transplant recipients (in rare cases) can also be due to *Mycoplasma hominis* (Chap. 159). Since this organism requires an anaerobic environment for growth and may be difficult to see on conventional medium, the laboratory should be alerted that *M. hominis* infection is suspected. *M. hominis* mediastinitis has been cured with a combination of surgical debridement (sometimes requiring muscle-flap placement) plus clindamycin and tetracycline. Organisms associated with mediastinitis may be cultured from accompanying pericardial fluid.

Middle-Period Infections *T. gondii* (Chap. 198) resident in the heart of a seropositive donor may be transmitted to a seronegative recipient. Thus serologic screening for *T. gondii* infection is important before and in the months after cardiac transplantation. Rarely, active disease can be introduced at the time of transplantation. The overall incidence of toxoplasmosis is so high in this setting that some prophylaxis is always warranted. Although alternatives are available, the most frequently used agent is TMP-SMX, which prevents infection with *Pneumocystis* as well as with *Nocardia* and other bacterial pathogens. CMV has also been transmitted by heart transplantation. CNS infections can be caused by *Toxoplasma*, *Nocardia*, and *Aspergillus*. *L. monocytogenes* meningitis should be considered in heart transplant recipients with fever and headache.

CMV infection is associated with poor outcomes after heart transplantation. The virus is usually cultivable 1 to 2 months after transplantation, causes early signs and laboratory abnormalities (usually fever and atypical lymphocytosis or leukopenia and thrombocytopenia) at 2 to 3 months, and produces severe disease (e.g., pneumonia) at 3 to 4 months. Seropositive recipients usually develop cultivable virus faster than patients whose primary CMV infection is a consequence of transplantation. Between 40 and 70% of patients develop symptomatic CMV disease in the form of (1) CMV pneumonia, the

most likely form of CMV disease to be fatal; (2) CMV esophagitis and gastritis, sometimes accompanied by abdominal pain with or without ulcerations and bleeding; and (3) the CMV syndrome, consisting of CMV in the blood along with fever, leukopenia, thrombocytopenia, and hepatic enzyme abnormalities. Ganciclovir is efficacious in the treatment of CMV infection; prophylaxis with ganciclovir or possibly with other antivirals, as described for renal transplantation, may reduce the incidence of CMV-related disease.

Late Infections EBV infection usually presents as a lymphoma-like proliferation of B cells late after heart transplantation, particularly in patients maintained on heavy immunosuppression. A subset of heart and heart-lung transplant recipients may develop early (within 2 months) fulminant EBV-LPD. Treatment includes the reduction of immunosuppression if possible and the consideration of B cell antibodies (rituximab), immunomodulatory agents, or chemotherapy, as discussed earlier under bone marrow/hematopoietic stem cell transplantation. HHV-8-associated disease, including primary effusion lymphoma, has been reported in heart transplant recipients. Prophylaxis for *Pneumocystis* infection is required for these patients (see below).

LUNG TRANSPLANTATION ■ Early Infections It is not surprising that lung transplant recipients are predisposed to the development of pneumonia. The combination of ischemia and the resulting mucosal damage together with accompanying denervation and lack of lymph drainage probably contributes to the high rate of pneumonia (66% in one series). The prophylactic use of high doses of broad-spectrum antibiotics for the first 3 or 4 days after surgery decreases the incidence of pneumonia. Gram-negative pathogens (Enterobacteriaceae and *Pseudomonas* species) are troublesome in the first 2 weeks after surgery (the period of maximal vulnerability). Pneumonia can also be caused by *Candida* (possibly as a result of colonization of the donor lung), *Aspergillus*, and *Cryptococcus*.

Mediastinitis may occur at an even higher rate among lung transplant recipients than among heart transplant recipients and most commonly develops within 2 weeks of surgery. Pneumonitis due to CMV (which may be transmitted as a consequence of transplantation) usually presents between 2 weeks and 3 months after surgery, with primary disease occurring later than reactivation disease.

Middle-Period Infections The incidence of CMV infection, either reactivated or primary, is between 75 and 100% if either the donor or the recipient is seropositive for CMV. CMV-induced disease appears to be most severe in recipients of lung and heart-lung transplants. Whether this severity relates to the mismatch in lung antigen-presenting and host immune cells or is attributable to other (nonimmune) factors is not known. More than half of lung transplant recipients with symptomatic CMV disease have pneumonia. Difficulty in distinguishing the radiographic picture of CMV infection from organ rejection further complicates therapy. CMV can also cause bronchiolitis obliterans in lung transplants. The development of pneumonitis related to HSV has led to the prophylactic use of acyclovir. Such prophylaxis may also decrease rates of CMV disease, but ganciclovir is more active against CMV and is also active against HSV. Prophylaxis of CMV infection with intravenous ganciclovir (or with valganciclovir, the oral alternative) is recommended for lung transplant recipients.

Late Infections The incidence of *Pneumocystis* infection (which may present with a paucity of findings) is high among lung and heart-lung transplant recipients. Some form of prophylaxis for *Pneumocystis* pneumonia is indicated in all organ transplant situations (Table 117-5). TMP-SMX prophylaxis for 12 months after transplantation may be sufficient to prevent *Pneumocystis* disease in patients whose degree of immunosuppression is not increased.

As in other transplant recipients, infection with EBV may cause either a mononucleosis-like syndrome or LPD. The tendency of the B cell blasts to present in the lung appears to be greater after lung transplantation than after the transplantation of other organs. Reduction of immunosuppression causes remission in some cases, but airway compression can be fatal and more rapid intervention may therefore become necessary. The approach to EBV-LPD is similar to that described in other sections.

LIVER TRANSPLANTATION ■ Early Infections As in other types of transplantation, early bacterial infections are a major problem after liver transplantation. Many centers administer systemic broad-spectrum antibiotics for the first 5 days after surgery, even in the absence of documented infection. However, despite prophylaxis, infectious complications are common and are correlated with the duration of the surgical procedure and the type of biliary drainage. An operation lasting >12 h is associated with an increased likelihood of infection. Patients who have a choledochojejunostomy with drainage of the biliary duct to a Roux-en-Y jejunal bowel loop have more fungal infections than those whose bile is drained via a choledochocholedochostomy with anastomosis of the donor common bile duct to the recipient common bile duct.

Peritonitis and intraabdominal abscesses are common complications of liver transplantation. Bacterial peritonitis may result from biliary leaks and primary or secondary infection after leakage of bile. Peritonitis in liver transplant recipients is often polymicrobial, commonly involving enterococci, aerobic gram-negative bacteria, staphylococci, anaerobes, or *Candida*. Only one-third of patients with intraabdominal abscesses have bacteremia. Abscesses within the first month after surgery may occur not only over the liver but also in the spleen, pericolic area, and pelvis. Treatment includes antibiotic administration and drainage as necessary.

Liver transplant patients have a high incidence of fungal infections, and the occurrence of fungal infection (often candidiasis) correlates with preoperative use of glucocorticoids, a long duration of treatment with antibacterial agents, and posttransplantation use of immunosuppressive agents.

Middle-Period Infections The development of postsurgical biliary stricture predisposes patients to cholangitis. These patients may lack the characteristic signs and symptoms of cholangitis: fever, abdominal pain, and jaundice. Alternatively, these findings may be present but may suggest graft rejection. The diagnosis of cholangitis in liver transplant recipients therefore requires documentation of bacteremia or demonstration of aggregated neutrophils in bile duct biopsy specimens. Unfortunately, invasive studies of the biliary tract (either T-tube cholangiography or endoscopic retrograde cholangiopancreatography) may themselves lead to cholangitis. For this reason, many clinicians recommend prophylaxis with antibiotics covering gram-negative organisms and anaerobes when these procedures are performed in liver transplant recipients.

Viral hepatitis is a common complication of liver transplantation (Chap. 285). Reactivation of hepatitis B and C infections, for which transplantation may be performed, is problematic. To prevent hepatitis B infection, high-dose intravenous hepatitis B immune globulin is administered. The long-term efficacy of lamivudine (3TC) and adefovir in inhibiting hepatitis B viral replication after transplantation is being studied. A combination of interferon α and ribavirin is being tested for treatment/prophylaxis of hepatitis C infection.

As in other transplantation settings, reactivation disease with herpes-group viruses is common (Table 117-3). Herpesviruses can be transmitted in donor organs. Although CMV hepatitis occurs in $\sim$4% of liver transplant recipients, it is usually not so severe as to require retransplantation. CMV disease develops in the majority of seronegative recipients of organs from CMV-positive donors, but fatality rates are lower among liver transplant recipients than among lung or heart-lung transplant recipients. Disease due to CMV is associated with the vanishing bile duct syndrome after liver transplantation. Patients respond to treatment with ganciclovir; prophylaxis with CMV immune globulin and acyclovir or oral ganciclovir may modify disease. A role

for HHV-6 in posttransplantation fever and leukopenia has been proposed. HHV-6 and HHV-7 appear to exacerbate CMV disease in this setting. EBV-LPD after liver transplantation shows a propensity for involvement of the liver, and such disease may be of donor origin.

PANCREAS TRANSPLANTATION Transplantation of the pancreas can be complicated by early abdominal infection. To prevent contamination of the allograft with enteric bacteria and yeasts, some surgeons, instead of draining the pancreas through the bowel, drain secretions into the urinary tract or bladder. A cuff of duodenum is used in the anastomosis between the pancreatic graft and either the bladder or the gut. In addition to bicarbonate loss, bladder drainage causes a high rate of urinary tract infection and sterile cystitis. Prophylactic antimicrobials are commonly used at the time of surgery. An alternative method—the transplantation of islet cells only—may eliminate the problems characteristically posed by wound and urinary tract sepsis in pancreas transplant recipients.

Issues related to the development of CMV infection, EBV-LPD, and infections with opportunistic pathogens in patients receiving a pancreas are similar to those in other solid organ transplant recipients.

MISCELLANEOUS INFECTIONS IN SOLID ORGAN TRANSPLANTATION ■ Indwelling Intravenous Catheter Infections The prolonged use of indwelling intravenous catheters for administration of medications, blood products, and nutrition is common in diverse transplantation settings and poses a risk of local and bloodstream infection. Significant insertion-site infection is most commonly caused by *S. aureus*. Bloodstream infection most frequently develops within a week of catheter placement or in patients who become neutropenic. Coagulase-negative staphylococci are the most common isolates from the blood. ***→For further discussion of differential diagnosis and therapeutic options, see Chap. 72.***

Tuberculosis The incidence of tuberculosis occurring within 12 months after solid organ transplantation ranges broadly worldwide (0.35 to 15%), reflecting prevalences in local populations. Nonrenal transplantation, GVHD within 6 months, and intensity of immunosuppression are predictive of tuberculosis reactivation and development of disseminated disease in a host with latent disease. The use of antibodies to tumor necrosis factor is associated with the development of active tuberculosis. Tuberculosis has rarely been transmitted from the donor organ. In contrast to the low mortality in BMT/HSCT recipients, mortality in solid organ transplant patients is reported to be 29%. Isoniazid toxicity has not been a significant problem except in the liver transplantation setting.

Virus-Associated Malignancies In addition to malignancy associated with gammaherpesvirus infection (EBV, HHV-8) and simple warts (HPV), other tumors that are virus-associated or suspected of being virus-associated are more likely to develop in transplant recipients, particularly those who require long-term immunosuppression, than in the general population. The interval to tumor development is usually >1 year. Transplant recipients develop nonmelanoma skin or lip cancers that, in contrast to de novo skin cancers, have a high ratio of squamous cells to basal cells. HPV appears to play a major role in these lesions. Cervical and vulvar carcinomas, quite clearly associated with HPV, develop with increased frequency in female transplant recipients. Among renal transplant recipients, rates of melanoma are modestly increased and rates of cancers of the kidney and bladder are increased.

VACCINATION OF TRANSPLANT RECIPIENTS

In addition to receiving antibiotic prophylaxis, transplant recipients should be vaccinated against likely pathogens (Table 117-6). In the case of BMT recipients, optimal responses cannot be achieved until after immune reconstitution, despite previous immunization of both donor and recipient. Recipients of allogeneic BMTs must be reimmunized if they are to be protected against pathogens. The situation is less clear-cut in the case of autologous transplantation. T and B cells in the peripheral blood may reconstitute the immune response if they are transferred in adequate numbers. However, cancer patients (particularly those with Hodgkin's disease, in whom vaccination has been extensively studied) who are undergoing chemotherapy do not respond normally to immunization, and titers of antibodies to infectious agents fall more rapidly than in healthy individuals. Therefore, even immunosuppressed patients who have not had marrow transplants may need booster vaccine injections. If memory cells are specifically eliminated as part of a marrow "cleanup" procedure, it will be necessary to reimmunize the recipient with a new primary series. Optimal times for immunizations of different transplant populations are being evaluated. Immunization of household and other contacts (including health care personnel) against influenza every season is likely to benefit the patient by preventing local spread.

TABLE 117-6 *Vaccination for Bone Marrow or Solid Organ Transplant Recipients*

Vaccine	Type of Transplantation	
	Bone Marrow	Solid Organ
Streptococcus pneumoniae, *Haemophilus influenzae*, *Neisseria meningitidis*	Immunize after transplantation (optimal timing not established); preimmunize graft[a]	Immunize before transplantation and every 5 years for Pneumovax (others not established)
Seasonal influenza	Vaccinate in the fall; vaccinate close contacts	Vaccinate in the fall
Poliomyelitis	Administer inactivated vaccine	Administer inactivated vaccine
Measles/mumps/rubella	Immunize 24 months after transplantation if patient does not have graft-versus-host disease	Immunize before transplantation
Tetanus, diphtheria	Reimmunize after transplantation	Immunize before transplantation; give boosters at 10 years or as required; a new primary series is not required

[a] Studies indicate that it is possible to "immunize the graft" before transplantation.

In the absence of compelling data as to optimal timing, it is reasonable to administer the pneumococcal and *H. influenzae* type b conjugate vaccines to both autologous and allogeneic BMT recipients 12 months after transplantation and again 12 months later (since the response to the initial vaccine dose is weak in the early posttransplantation period). Recent studies indicate that the use of the pneumococcal conjugate vaccines will be more effective than previous products. The pneumococcal and *H. influenzae* type b vaccines are particularly important for patients who have undergone splenectomy. In addition, *Neisseria meningitidis* polysaccharide vaccine, diphtheria vaccine, tetanus vaccine, and inactivated polio vaccine can all be given at these same intervals (12 and 24 months after transplantation). Some authorities recommend a new primary series for tetanus/diphtheria and inactivated polio vaccine (vaccination 12, 14, and 16 months after transplantation). Because of the risk of spread, household contacts of BMT recipients (or of patients immunosuppressed as a result of chemotherapy) should receive only inactivated polio vaccine. Live-virus measles/mumps/rubella (MMR) vaccine can be given to autologous BMT recipients 24 months after transplantation and to most allogeneic BMT recipients at the same point if they are not receiving maintenance therapy with immunosuppressive drugs and do not have ongoing GVHD. The risk of spread from a household contact is lower for MMR vaccine than for polio vaccine. Neither patients nor household contacts of patients should be vaccinated with vaccinia unless they have been exposed to the smallpox virus. In patients who have active GVHD and/or are taking high maintenance doses of glucocorticoids, it may be prudent to avoid all live-virus vaccines. In the absence of detectable antibody titers, vaccination to prevent hepatitis B and hepatitis A also seems advisable.

In the case of solid organ transplant recipients, administration of all the usual vaccines and of the indicated booster doses should be completed before immunosuppression, if possible, to maximize responses. For patients taking immunosuppressive agents, the administration of pneumococcal vaccine should be repeated every 5 years. No data are available for meningococcal polysaccharide vaccine, but it is probably reasonable to administer it along with the pneumococcal vaccine or more frequently (every 3 years for persons with significant exposure risk). *H. influenzae* conjugate vaccine is safe and should be efficacious in this population; therefore, its administration before transplantation is recommended. Booster doses of this vaccine are not recommended for adults. Solid organ transplant recipients who continue to receive immunosuppressive drugs (glucocorticoids, cyclosporine) should not receive live-virus vaccines. A person in this group exposed to measles should be given immune globulin. Similarly, an immunocompromised patient who is seronegative for varicella and who comes into contact with a person who has chickenpox should be given varicella-zoster immune globulin as soon as possible (and certainly within 96 h) or, if this is not possible, should be started immediately on a 10- to 14-day course of acyclovir therapy. Susceptible household contacts of transplant recipients should receive live attenuated VZV vaccine, but vaccinees should avoid direct contact with the patient if a rash develops.

Immunocompromised patients who travel may benefit from some but not all vaccines. In general, they should receive any killed or inactivated vaccine preparation appropriate to the area they are visiting; this recommendation includes the vaccines for Japanese encephalitis, hepatitis A and B, poliomyelitis, meningococcal infection, and typhoid. The live typhoid vaccines are not recommended for use in most immunocompromised patients, but inactivated typhoid or the purified polysaccharide vaccine can be used. Live yellow fever vaccine should not be administered. Phenol-inactivated cholera vaccine is probably of little use in this setting. On the other hand, immunization with the purified-protein hepatitis B vaccine is indicated if patients are likely to be exposed. Patients who will reside for >6 months in areas where hepatitis B is common (Africa, Southeast Asia, the Middle East, Eastern Europe, parts of South America, and the Caribbean) should receive hepatitis B vaccine. Inactivated hepatitis A vaccine should be used in the appropriate setting (Chap. 107). If hepatitis A vaccine is not administered, travelers should consider receiving passive protection with immune globulin (the dose depending on the duration of travel in the high-risk area).

Section 4 Approach to Therapy for Bacterial Diseases

118 TREATMENT AND PROPHYLAXIS OF BACTERIAL INFECTIONS

Gordon L. Archer, Ronald E. Polk

The development of vaccines and drugs that prevent and cure bacterial infections was one of the twentieth century's major contributions to human longevity and quality of life. Antibacterial agents are among the most commonly prescribed drugs of any kind worldwide. Used appropriately, these drugs are lifesaving. However, their indiscriminate use drives up the cost of health care, leads to a plethora of side effects and drug interactions, and fosters the emergence of bacterial resistance, rendering previously valuable drugs useless. The rational use of antibacterial agents depends on an understanding of their mechanisms of action, pharmacokinetics, pharmacodynamics, toxicities, and interactions; bacterial strategies for resistance; and bacterial susceptibility in vitro. In addition, patient-associated parameters, such as the site of infection and the immune and excretory status of the host, are critically important to appropriate therapeutic decisions. This chapter provides specific data required for making an informed choice of antibacterial agent.

MECHANISMS OF ACTION

Antibacterial agents, like all antimicrobial drugs, are directed against unique targets not present in mammalian cells. The goal is to limit toxicity to the host and maximize chemotherapeutic activity affecting invading microbes only. *Bactericidal drugs* kill the bacteria that are within their spectrum of activity; *bacteriostatic drugs* only inhibit bacterial growth. While bacteriostatic activity is adequate for the treatment of most infections, bactericidal activity may be necessary for cure in patients with altered immune systems (e.g., neutropenia), protected infectious foci (e.g., endocarditis or meningitis), or specific infections (e.g., complicated *Staphylococcus aureus* bacteremia). The mechanisms of action of the antibacterial agents to be discussed in this section are summarized in Table 118-1 and are depicted in Fig. 118-1.

INHIBITION OF CELL-WALL SYNTHESIS One major difference between bacterial and mammalian cells is the presence in bacteria of a rigid wall external to the cell membrane. The wall protects bacterial cells from osmotic rupture, which would result from the cell's usual marked hyperosmolarity (by up to 20 atm) relative to the host environment. The structure conferring cell-wall rigidity and resistance to osmotic lysis in both gram-positive and gram-negative bacteria is peptidoglycan, a large, covalently linked sacculus that surrounds the bacterium. In gram-positive bacteria, peptidoglycan is the only layered structure external to the cell membrane and is thick (20 to 80 nm); in gram-negative bacteria, there is an outer membrane external to a very thin (1-nm) peptidoglycan layer.

Chemotherapeutic agents directed at any stage of the synthesis, export, assembly, or cross-linking of peptidoglycan lead to inhibition of bacterial cell growth and, in most cases, to cell death. Peptidoglycan is composed of (1) a backbone of two alternating sugars, *N*-acetylglucosamine and *N*-acetylmuramic acid; (2) a chain of four amino acids that extends down from the backbone (stem peptides); and (3) a peptide bridge that cross-links the peptide chains. Peptidoglycan is formed by the addition of subunits (a sugar with its five attached amino acids) that are assembled in the cytoplasm and transported through the cytoplasmic membrane to the cell surface. Subsequent cross-linking is

TABLE 118-1 *Mechanisms of Action of and Resistance to Major Classes of Antibacterial Agents*

Letter for Fig. 118-1	Antibacterial Agent[a]	Major Cellular Target	Mechanism of Action	Major Mechanisms of Resistance
A	β-Lactams (penicillins and cephalosporins)	Cell wall	Inhibit cell-wall cross-linking	1. Drug inactivation (β-lactamase) 2. Insensitivity of target (altered penicillin-binding proteins) 3. Decreased permeability (altered gram-negative outer-membrane porins) 4. Active efflux
B	Vancomycin	Cell wall	Interferes with addition of new cell-wall subunits (muramyl pentapeptides)	Alteration of target (substitution of terminal amino acid of peptidoglycan subunit)
	Bacitracin	Cell wall	Prevents addition of cell-wall subunits by inhibiting recycling of membrane lipid carrier	Not defined
C	Macrolides (erythromycin)	Protein synthesis	Bind to 50S ribosomal subunit	1. Alteration of target (ribosomal methylation and mutation of 23S rRNA) 2. Active efflux
	Lincosamides (clindamycin)	Protein synthesis	Bind to 50S ribosomal subunit	Alteration of target (ribosomal methylation)
D	Chloramphenicol	Protein synthesis	Binds to 50S ribosomal subunit	1. Drug inactivation (chloramphenicol acetyltransferase) 2. Active efflux
E	Tetracycline	Protein synthesis	Binds to 30S ribosomal subunit	1. Decreased intracellular drug accumulation (active efflux) 2. Insensitivity of target
F	Aminoglycosides (gentamicin)	Protein synthesis	Bind to 30S ribosomal subunit	1. Drug inactivation (aminoglycoside-modifying enzyme) 2. Decreased permeability through gram-negative outer membrane 3. Active efflux
G	Mupirocin	Protein synthesis	Inhibits isoleucine tRNA synthetase	Mutation of gene for target protein or acquisition of new gene for drug-insensitive target
H	Quinupristin/dalfopristin (Synercid)	Protein synthesis	Bind to 50S ribosomal subunit	1. Alteration of target (ribosomal methylation: dalfopristin) 2. Active efflux (quinupristin) 3. Drug inactivation (quinupristin and dalfopristin)
I	Linezolid	Protein synthesis	Bind to 50S ribosomal subunit	Alteration of target (mutation of 23S rRNA)
J	Sulfonamides and trimethoprim	Cell metabolism	Competitively inhibit enzymes involved in two steps of folic acid biosynthesis	Production of insensitive targets [dihydropteroate synthetase (sulfonamides) and dihydrofolate reductase (trimethoprim)] that bypass metabolic block
K	Rifampin	Nucleic acid synthesis	Inhibits DNA-dependent RNA polymerase	Insensitivity of target (mutation of polymerase gene)
L	Metronidazole	Nucleic acid synthesis	Intracellularly generates short-lived reactive intermediates that damage DNA by electron transfer system	Not defined
M	Quinolones (ciprofloxacin)	DNA synthesis	Inhibit DNA gyrase (A subunit) and topoisomerase IV	1. Insensitivity of target (mutation of gyrase genes) 2. Decreased intracellular drug accumulation (active efflux)
	Novobiocin	DNA synthesis	Inhibits DNA gyrase (B subunit)	Not defined
N	Polymyxins (polymyxin B)	Cell membrane	Disrupt membrane permeability by charge alteration	Not defined
	Gramicidin	Cell membrane	Forms pores	Not defined

[a] Compounds in parentheses are major representatives for the class.

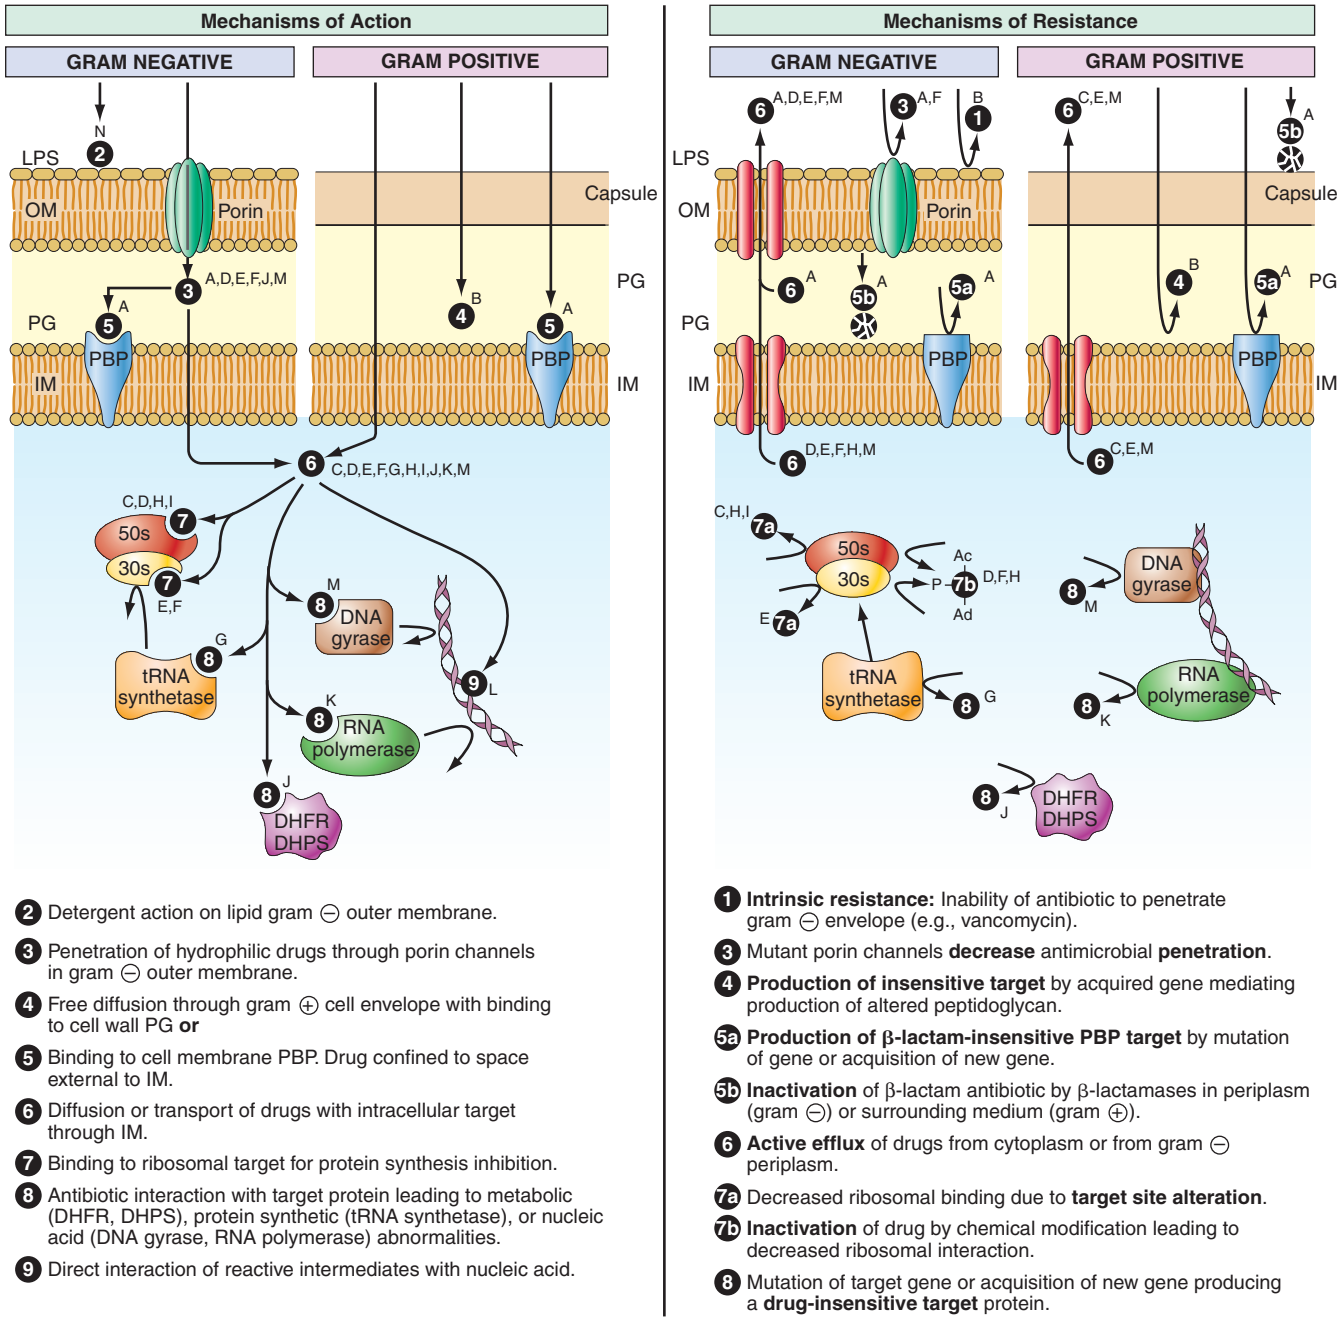
driven by cleavage of the terminal stem-peptide amino acid. Antibacterial agents act to inhibit cell-wall synthesis in several ways, as described below.

Bacitracin Bacitracin, a cyclic peptide antibiotic, inhibits the conversion to its active form of the lipid carrier that moves the water-soluble cytoplasmic peptidoglycan subunits through the cell membrane to the cell exterior. Cell-wall subunits accumulate in the cytoplasm and cannot be added to the growing peptidoglycan chain.

Glycopeptides Glycopeptides (vancomycin and teicoplanin) are high-molecular-weight antibiotics that bind to the terminal D-alanine–D-alanine component of the stem peptide while the subunits are external to the cell membrane but still linked to the lipid carrier. This binding sterically inhibits the addition of subunits to the peptidoglycan backbone.

β-Lactam Antibiotics β-Lactam antibiotics (penicillins, cephalosporins, carbapenems, and monobactams; Table 118-2) are characterized by a four-membered β-lactam ring and prevent the cross-linking reaction called *transpeptidation*. The energy for attaching a peptide cross-bridge from the stem peptide of one peptidoglycan subunit to another is derived from the cleavage of a terminal D-alanine residue from the subunit stem peptide. The cross-bridge amino acid is then attached to the penultimate D-alanine by transpeptidase enzymes. The β-lactam ring of the antibiotic forms an irreversible covalent acyl bond with the transpeptidase enzyme (probably because of the antibiotic's steric similarity to the enzyme's D-alanine–D-alanine target), preventing the cross-linking reaction. Transpeptidases and similar enzymes involved in cross-linking are called *penicillin-binding proteins* (PBPs) because they all have active sites that bind β-lactam antibiotics.

Virtually all the antibiotics that inhibit bacterial cell-wall synthesis are bactericidal. That is, they eventually result in the cell's death due to osmotic lysis. However, much of the loss of cell-wall integrity following treatment with cell wall–active agents is due to the bacteria's own cell-wall remodeling enzymes (autolysins) that cleave peptido-



2 Detergent action on lipid gram ⊖ outer membrane.

3 Penetration of hydrophilic drugs through porin channels in gram ⊖ outer membrane.

4 Free diffusion through gram ⊕ cell envelope with binding to cell wall PG **or**

5 Binding to cell membrane PBP. Drug confined to space external to IM.

6 Diffusion or transport of drugs with intracellular target through IM.

7 Binding to ribosomal target for protein synthesis inhibition.

8 Antibiotic interaction with target protein leading to metabolic (DHFR, DHPS), protein synthetic (tRNA synthetase), or nucleic acid (DNA gyrase, RNA polymerase) abnormalities.

9 Direct interaction of reactive intermediates with nucleic acid.

1 **Intrinsic resistance:** Inability of antibiotic to penetrate gram ⊖ envelope (e.g., vancomycin).

3 Mutant porin channels **decrease** antimicrobial **penetration**.

4 **Production of insensitive target** by acquired gene mediating production of altered peptidoglycan.

5a **Production of β-lactam-insensitive PBP target** by mutation of gene or acquisition of new gene.

5b **Inactivation** of β-lactam antibiotic by β-lactamases in periplasm (gram ⊖) or surrounding medium (gram ⊕).

6 **Active efflux** of drugs from cytoplasm or from gram ⊖ periplasm.

7a Decreased ribosomal binding due to **target site alteration**.

7b **Inactivation** of drug by chemical modification leading to decreased ribosomal interaction.

8 Mutation of target gene or acquisition of new gene producing a **drug-insensitive target** protein.

FIGURE 118-1 Mechanisms of action of and resistance to antibacterial agents. Black lines trace the routes of drug interaction with bacterial cells, from entry to target site. The letters in each figure indicate specific antibacterial agents or classes of agents, as shown in Table 118-1. The numbers correspond to mechanisms listed beneath each panel. Abbreviations: LPS, lipopolysaccharide; OM, outer membrane; PG, peptidoglycan; PBP, penicillin-binding protein; IM, inner (cytoplasmic) membrane; 50s and 30s, large and small ribosome subunits; DHFR, dihydrofolate reductase; DHPS, dihydropteroate synthetase; Ac, acetylation; Ad, adenylation; P, phosphorylation.

glycan bonds in the normal course of cell growth. In the presence of antibacterial agents that inhibit cell-wall growth, autolysis proceeds without normal cell-wall repair; weakness and eventual cellular lysis occur.

INHIBITION OF PROTEIN SYNTHESIS Most of the antibacterial agents that inhibit protein synthesis interact with the bacterial ribosome. The difference between the composition of bacterial and mammalian ribosomes gives these compounds their selectivity.

Aminoglycosides Aminoglycosides (gentamicin, kanamycin, tobramycin, streptomycin, netilmicin, neomycin, and amikacin) are a group of structurally related compounds containing three linked hexose sugars. They exert a bactericidal effect by binding irreversibly to the 30S subunit of the bacterial ribosome and blocking initiation of protein synthesis. The reason for the lethal effect of aminoglycosides, as opposed to the largely bacteriostatic effect of other protein synthesis–inhibiting antibacterial drugs, is not completely understood. Uptake of aminoglycosides and their penetration through the cell membrane constitute an aerobic, energy-dependent process. Thus, aminoglycoside activity is markedly reduced in an anaerobic environment. *Spectinomycin*, an aminocyclitol antibiotic, also acts on the 30S ribosomal subunit but has a different mechanism of action from the aminoglycosides and is bacteriostatic rather than bactericidal.

Macrolide Antibiotics Macrolide antibiotics (erythromycin, clarithromycin, and azithromycin) consist of a large lactone ring to which sugars are attached. *Ketolide antibiotics*, including telithromycin, replace the cladinose sugar on the macrolactone ring with a ketone group. These drugs bind specifically to the 50S portion of the bacterial ribosome. After attachment of mRNA to the initiation site of the 30S ribosomal subunit (the process blocked by aminoglycosides), the 50S subunit becomes bound to the 30S component to form the 70S ribosomal com-

TABLE 118-2 *Classification of β-Lactam Antibiotics*

Class	Route of Administration	
	Parenteral	Oral
Penicillins		
β-Lactamase–susceptible		
Narrow-spectrum	Penicillin G	Penicillin V
Enteric-active	Ampicillin	Amoxicillin, ampicillin
Enteric-active and antipseudomonal	Ticarcillin	None
β-Lactamase–resistant		
Antistaphylococcal	Methicillin, oxacillin, nafcillin	Cloxacillin, dicloxacillin
Combined with β-lactamase inhibitors	Ticarcillin plus clavulanic acid, ampicillin plus sulbactam, piperacillin plus tazobactam	Amoxicillin plus clavulanic acid
Cephalosporins		
First-generation	Cefazolin, cephalothin, cephapirin	Cephalexin, cephradine, cefadroxil
Second-generation		
Haemophilus-active	Cefamandole, cefuroxime, cefonicid, ceforanide	Cefaclor, cefuroxime axetil, ceftibuten, cefdinir, cefprozil, cefpodoxime,[a] loracarbef
Bacteroides-active	Cefoxitin, cefotetan, cefmetazole	None
Third-generation		
Extended-spectrum	Ceftriaxone, cefotaxime, ceftizoxime	None
Extended-spectrum and antipseudomonal	Ceftazidime, cefepime	None
Carbapenems	Imipenem-cilastatin, meropenem, ertapenem	None
Monobactams	Aztreonam	None

[a] Some sources classify cefpodoxime as a third-generation oral agent because of a marginally broader spectrum.

plex, and protein chain elongation proceeds. When these drugs bind to the 50S ribosomal subunit, protein chain elongation is inhibited.

Although structurally unrelated to the macrolides, *lincosamides* (clindamycin and lincomycin) bind to a site on the 50S ribosome nearly identical to the binding site for macrolides. Although the mechanism and site of action of macrolides and lincosamides are similar, the number and types of bacteria against which these two groups of agents are active differ.

Streptogramins Streptogramins [quinupristin (streptogramin B) and dalfopristin (streptogramin A)], which are supplied as a combination in Synercid, are peptide macrolactones that also bind to the 50S ribosomal subunit and block protein synthesis. Streptogramin B binds to a ribosomal site similar to the binding site for macrolides and lincosamides, whereas streptogramin A binds to a different ribosomal site, blocking the late phase of protein synthesis. The two streptogramins act synergistically to kill bacteria if the strain is susceptible to both components.

Chloramphenicol *Chloramphenicol* consists of a single aromatic ring and a short side chain. This antibiotic binds reversibly to the 50S portion of the bacterial ribosome at a site close to but not identical with the binding sites for the macrolides and lincosamides. The ribosomal binding of chloramphenicol inhibits peptide bond formation.

Linezolid Linezolid is the first drug in a new, completely synthetic class of antimicrobial agents, the oxazolidinones. Linezolid binds to the 50S ribosomal subunit and blocks the initiation of protein synthesis.

Tetracyclines Tetracyclines (tetracycline, doxycycline, and minocycline) consist of four aromatic rings with various substituent groups. They interact reversibly with the bacterial 30S ribosomal subunit, blocking the binding of aminoacyl tRNA to the mRNA-ribosome complex. This mechanism is markedly different from that of the aminoglycosides, which also bind to the 30S subunit. The specificity of tetracyclines for bacteria depends both on their selectivity for bacterial ribosomes and on their requirement for active, energy-dependent transport into the bacterial cell by a system not found in mammalian cell membranes.

Mupirocin Mupirocin (pseudomonic acid) is produced by the bacterium *Pseudomonas fluorescens*. Its mechanism of action is unique: the drug inhibits isoleucine tRNA synthetase by competing with bacterial isoleucine for its binding site on the enzyme. Inhibition of this enzyme depletes cellular stores of isoleucine-charged tRNA and therefore leads to a cessation of protein synthesis. Mupirocin is selective for bacteria because mammalian isoleucine tRNA synthetase lacks affinity for the compound.

INHIBITION OF BACTERIAL METABOLISM The *antimetabolites* are all synthetic compounds that interfere with bacterial synthesis of folic acid. Products of the folic acid synthesis pathway function as coenzymes for the one-carbon transfer reactions that are essential for the synthesis of thymidine, all purines, and several amino acids. Inhibition of folate synthesis leads to cessation of bacterial cell growth and, in some cases, to bacterial cell death. The principal antibacterial antimetabolites are sulfonamides (sulfisoxazole, sulfadiazine, and sulfamethoxazole) and trimethoprim.

Sulfonamides Sulfonamides are structural analogues of *p*-aminobenzoic acid (PABA), one of the three structural components of folic acid (the other two being pteridine and glutamate). The first step in the synthesis of folic acid is the addition of PABA to pteridine by the enzyme dihydropteroic acid synthetase. Sulfonamides compete with PABA as substrates for the enzyme. The selective effect of sulfonamides is due to the fact that bacteria synthesize folic acid, while mammalian cells cannot synthesize the cofactor and must have exogenous supplies. However, the activity of sulfonamides can be greatly reduced by the presence of excess PABA or by the exogenous addition of end products of one-carbon transfer reactions (e.g., thymidine and purines). High concentrations of the latter substances may be present in some infections as a result of tissue and white cell breakdown, compromising sulfonamide activity.

Trimethoprim Trimethoprim is a diaminopyrimidine, a structural analogue of the pteridine moiety of folic acid. Trimethoprim is a competitive inhibitor of dihydrofolate reductase; this enzyme is responsible for reduction of dihydrofolic acid to tetrahydrofolic acid—the essential final component in the folic acid synthesis pathway that is necessary for all one-carbon transfer reactions. Like the sulfonamides, trimethoprim is bactericidal in the absence of thymine but is only bacteriostatic when this pyrimidine is present in high concentration. The selective antibacterial activity of trimethoprim is based on the much (~50,000-fold) greater sensitivity of bacterial dihydrofolate reductase than of the mammalian enzyme to inhibition by this drug.

INHIBITION OF NUCLEIC ACID SYNTHESIS OR ACTIVITY Numerous antibacterial compounds have disparate effects on nucleic acids. The *quinolones*, including nalidixic acid and its fluorinated derivatives (ciprofloxacin, levofloxacin, gatifloxacin, and moxifloxacin), are synthetic compounds that inhibit the activity of the A subunit of the bacterial enzyme DNA gyrase as well as topoisomerase IV. DNA gyrase and topoisomerases are responsible for negative supercoiling of DNA—an essential conformation for DNA replication in the intact cell. Inhibition of the activity of DNA gyrase and topoisomerase IV is lethal to bacterial cells. The antibiotic *novobiocin* also interferes with the activity of DNA gyrase, but it interferes with the B subunit.

Rifampin Rifampin, used primarily against *Mycobacterium tuberculosis*, is also active against a variety of other bacteria. Rifampin binds tightly to the B subunit of bacterial DNA-dependent RNA polymerase, thus inhibiting transcription of DNA into RNA. Mammalian-cell RNA polymerase is not sensitive to this compound.

Nitrofurantoin Nitrofurantoin, a synthetic compound, causes DNA damage. The nitrofurans, compounds containing a single five-membered ring, are reduced by a bacterial enzyme to highly reactive, short-lived intermediates that are thought to cause DNA strand breakage, either directly or indirectly.

Metronidazole Metronidazole, a synthetic imidazole, is active against a wide range of anaerobic bacteria and protozoa. Its activity is totally dependent on its anaerobic electron-transport system for energy production. In the presence of this system, the nitro group of metronidazole is reduced to a series of transiently produced, reactive intermediates that are thought to cause DNA damage. The unique redox system of anaerobes accounts for the selective antibacterial activity of metronidazole. This compound is also a mutagen and a radiosensitizer of hypoxic mammalian cells.

ALTERATION OF CELL-MEMBRANE PERMEABILITY The *polymyxins* (polymyxin B and colistin, or polymyxin E) are cyclic, basic polypeptides. They behave as cationic, surface-active compounds that disrupt the permeability of both the outer and the cytoplasmic membranes of gram-negative bacteria.

Gramicidin A is a polypeptide of 15 amino acids that acts as an ionophore, forming pores or channels in lipid bilayers.

MECHANISMS OF RESISTANCE

Some bacteria exhibit *intrinsic resistance* to certain classes of antibacterial agents (e.g., obligate anaerobic bacteria to aminoglycosides and gram-negative bacteria to vancomycin). In addition, bacteria that are ordinarily susceptible to antibacterial agents can acquire resistance. *Acquired resistance* is one of the major limitations to effective antibacterial chemotherapy. Resistance can develop by mutation of resident genes or by acquisition of new genes. New genes mediating resistance are usually spread from cell to cell by way of mobile genetic elements such as plasmids, transposons, and bacteriophages. The resistant bacterial populations flourish in areas of high antimicrobial use, where they enjoy a selective advantage over susceptible populations.

The major mechanisms used by bacteria to resist the action of antimicrobial agents are inactivation of the compound, alteration or overproduction of the antibacterial target through mutation of the target protein's gene, acquisition of a new gene that encodes a drug-insensitive target, decreased permeability of the cell envelope to the agent, and active efflux of the compound from the periplasm or interior of the cell. Specific mechanisms of bacterial resistance to the major antibacterial agents are outlined below, summarized in Table 118-1, and depicted in Fig. 118-1.

β-LACTAMS Bacteria develop resistance to β-lactam antibiotics by a variety of mechanisms. Most common is the destruction of the drug by β-lactamases. The β-lactamases of gram-negative bacteria are confined to the periplasm, between the inner and outer membranes, while gram-positive bacteria secrete their β-lactamases into the surrounding medium. These enzymes have a higher affinity for the antibiotic than the antibiotic has for its target. Binding results in hydrolysis of the β-lactam ring. Genes encoding β-lactamases have been found in both chromosomal and extrachromosomal locations and in both gram-positive and gram-negative bacteria; these genes are often on mobile genetic elements. Many "advanced-generation" β-lactam antibiotics, such as ceftriaxone and ceftazidime, are stable in the presence of plasmid-mediated β-lactamases and are active against bacteria resistant to earlier-generation β-lactam antibiotics. However, some β-lactamases either acquired by gram-negative bacteria (e.g., *Klebsiella pneumoniae* and *Escherichia coli*) on mobile genetic elements or present as stable chromosomal genes in other gram-negative species (e.g., *Enterobacter* spp.) have a broad substrate specificity, hydrolyzing virtually all penicillins and cephalosporins. One strategy that has been devised for circumventing resistance mediated by β-lactamases is to combine the β-lactam agent with an inhibitor that avidly binds the inactivating enzyme, preventing its attack on the antibiotic. Unfortunately, the inhibitors (e.g., clavulanic acid, sulbactam, and tazobactam) do not bind all chromosomal β-lactamases (e.g., *Enterobacter* chromosomal β-lactamase) and thus cannot be depended on to prevent the inactivation of β-lactam antibiotics by such enzymes. No β-lactam antibiotic or inhibitor has been produced that can resist all of the many β-lactamases that have been identified.

A second mechanism of bacterial resistance to β-lactam antibiotics is an alteration in PBP targets so that the PBPs have a markedly reduced affinity for the drug. While this alteration may occur by mutation of existing genes, the acquisition of new PBP genes (as in staphylococcal resistance to methicillin) or of new pieces of PBP genes (as in streptococcal, gonococcal, and meningococcal resistance to penicillin) is more important.

A final resistance mechanism is the coupling, in gram-negative bacteria, of a decrease in outer-membrane permeability with rapid efflux of the antibiotic from the periplasm to the cell exterior. Mutations of genes encoding outer-membrane protein channels called *porins* decrease the entry of β-lactam antibiotics into the cell, while additional proteins form channels that actively pump β-lactams out of the cell. Resistance of Enterobacteriaceae to some cephalosporins and resistance of *Pseudomonas* spp. to cephalosporins and ureidopenicillins are the best examples of this mechanism.

VANCOMYCIN Clinically important resistance to vancomycin was first described among enterococci in France in 1988. Vancomycin-resistant enterococci have subsequently become disseminated worldwide. The genes encoding resistance are carried on plasmids that can transfer themselves from cell to cell and on transposons that can jump from plasmids to chromosomes. Resistance is mediated by enzymes that substitute D-lactate for D-alanine on the peptidoglycan stem peptide so that there is no longer an appropriate target for vancomycin binding. This alteration does not appear to affect cell-wall integrity, however. This type of acquired vancomycin resistance was confined for 14 years to enterococci—more specifically, to *Enterococcus faecium* rather than the more common pathogen *E. faecalis*. However, in 2002, *S. aureus* isolates that were highly resistant to vancomycin were recovered from two patients in the United States. Both isolates contained the gene that mediated vancomycin resistance in enterococci. In addition, since 1996, a few isolates of both *S. aureus* and *S. epidermidis* that display a four- to eightfold reduction in susceptibility to vancomycin have been found worldwide, and many more isolates may contain subpopulations with reduced vancomycin susceptibility. These isolates have not acquired the genes that mediate vancomycin resistance in enterococci but are mutant bacteria with markedly thickened cell walls. These mutants were apparently selected in patients who were undergoing prolonged vancomycin therapy. The failure of vancomycin therapy in some patients infected with *S. aureus* or *S. epidermidis* strains exhibiting only intermediate susceptibility to this drug is thought to have been a result of this resistance.

AMINOGLYCOSIDES The most common aminoglycoside resistance mechanism is inactivation of the antibiotic. Aminoglycoside-modifying enzymes, usually encoded on plasmids, transfer phosphate, adenyl, or acetyl residues from intracellular molecules to hydroxyl or amino side groups on the antibiotic. The modified antibiotic is less active because of diminished binding to its ribosomal target. Modifying enzymes that can inactivate any of the available aminoglycosides have been found in both gram-positive and gram-negative bacteria.

A second aminoglycoside resistance mechanism, which has been identified predominantly in clinical isolates of *Pseudomonas aeruginosa*, is decreased antibiotic uptake, presumably due to alterations in the bacterial outer membrane.

MACROLIDES, KETOLIDES, LINCOSAMIDES, AND STREPTOGRAMINS Resistance in gram-positive bacteria, which are the usual target organisms for macrolides, lincosamides, and streptogramins, can be due to the production of an enzyme—most commonly plasmid-encoded—that methylates ribosomal RNA, interfering with binding of the antibiotics to their target. Methylation mediates resistance to erythromycin, clarithromycin, azithromycin, clindamycin, and streptogramin B. Resistance to streptogramin B converts quinupristin/dalfopristin from a bactericidal to a bacteriostatic antibiotic. Streptococci can also actively cause the efflux of macrolides, and staphylococci can cause the efflux of clindamycin and streptogramin A. In addition, staphylococci can inactivate streptogramin A by acetylation and streptogramin B by either acetylation or hydrolysis. Finally, mutations in 23S ribosomal RNA that alter macrolide binding to their targets have been found in both staphylococci and streptococci. Ketolides retain activity against most isolates of *Streptococcus pneumoniae* resistant to macrolides.

CHLORAMPHENICOL Most bacteria resistant to chloramphenicol produce a plasmid-encoded enzyme, chloramphenicol acetyltransferase, that inactivates the compound by acetylation.

TETRACYCLINES The most common mechanism of tetracycline resistance in gram-negative bacteria is a plasmid-encoded active-efflux pump that is inserted into the cytoplasmic membrane and extrudes antibiotic from the cell. Resistance in gram-positive bacteria is due either to active efflux or to ribosomal alterations that diminish binding of the antibiotic to its target. Genes involved in ribosomal protection are found on mobile genetic elements.

MUPIROCIN Although the topical compound mupirocin was introduced into clinical use relatively recently, resistance is already becoming widespread in some areas. The mechanism appears to be either mutation of the target isoleucine tRNA synthetase so that it is no longer inhibited by the antibiotic or plasmid-encoded production of a form of the target enzyme that binds mupirocin poorly.

TRIMETHOPRIM AND SULFONAMIDES The most prevalent mechanism of resistance to trimethoprim and the sulfonamides in both gram-positive and gram-negative bacteria is the acquisition of plasmid-encoded genes that produce a new, drug-insensitive target—specifically, an insensitive dihydrofolate reductase for trimethoprim and an altered dihydropteroate synthetase for sulfonamides.

QUINOLONES Resistance to the newer fluoroquinolones emerged rapidly among *Staphylococcus* and *Pseudomonas* spp. after the introduction of these agents. Widespread use of fluoroquinolones in the community has resulted in increasing rates of resistance in *S. pneumoniae*. The most common mechanism is the development of one or more mutations in target DNA gyrases and topoisomerase IV that prevent the antibacterial agent from interfering with the activity of the enzyme. Some gram-negative bacteria develop mutations that both decrease outer-membrane porin permeability and cause active drug efflux from the cytoplasm. Mutations that result in active quinolone efflux are also found in gram-positive bacteria.

RIFAMPIN Bacteria rapidly become resistant to rifampin by developing mutations in the B subunit of RNA polymerase that render the enzyme unable to bind the antibiotic. The rapid selection of resistant mutants is the major limitation to the use of this antibiotic against otherwise-susceptible staphylococci and requires that the drug be used in combination with another antistaphylococcal agent.

LINEZOLID Enterococci, streptococci, and staphylococci become resistant to linezolid in vitro by mutation of the 23S rRNA binding site. Clinical isolates of *E. faecium* and *E. faecalis* acquire resistance to linezolid readily by this mechanism, often during therapy, but linezolid-resistant staphylococcal and streptococcal isolates are rare.

MULTIPLE ANTIBIOTIC RESISTANCE The acquisition by one bacterium of resistance to multiple antibacterial agents is becoming increasingly common. The two major mechanisms are the acquisition of multiple unrelated resistance genes and the development of mutations in a single gene or gene complex that mediate resistance to a series of unrelated compounds. The construction of multiresistant strains by acquisition of multiple genes occurs by sequential steps of gene transfer and environmental selection in areas of high-level antimicrobial use. In contrast, mutations in a single gene can conceivably be selected in a single step. Bacteria that are multiresistant by virtue of the acquisition of new genes include hospital-associated gram-negative bacteria, enterococci, and staphylococci and community-acquired strains of salmonellae, gonococci, and pneumococci. Mutations that confer resistance to multiple unrelated antimicrobial agents occur in the genes encoding outer-membrane porins and efflux proteins of gram-negative bacteria. These mutations decrease bacterial intracellular and periplasmic accumulation of β-lactams, quinolones, tetracyclines, chloramphenicol, and aminoglycosides. Multiresistant bacterial isolates pose increasing problems in U.S. hospitals; strains resistant to all available antibacterial chemotherapy have already been identified.

PHARMACOKINETICS OF ANTIBIOTICS

The *pharmacokinetic profile* of an antibacterial agent refers to concentrations in serum and tissue versus time and reflects the processes of absorption, distribution, metabolism, and excretion. Important characteristics include peak and trough serum concentrations and mathematically derived parameters such as half-life, clearance, and distribution volume. Pharmacokinetic information is useful for estimating the appropriate antibacterial dose and frequency of administration, for adjusting dosages in patients with impaired excretory capacity, and for comparing one drug with another. In contrast, the *pharmacodynamic profile* of an antibiotic refers to the relationship between serum and tissue concentrations of the antibiotic and its minimal inhibitory concentrations (MICs) for bacteria. →***For further discussion of basic pharmacokinetic principles, see Chap. 3.***

ABSORPTION Antibiotic *absorption* refers to the rate and extent of a drug's systemic bioavailability after oral, intramuscular, or intravenous administration.

Oral Administration Most patients with infection are treated with oral antibacterial agents in the outpatient setting. Advantages of oral therapy over parenteral therapy include lower cost, generally fewer adverse effects (including complications of indwelling lines), and greater acceptance by patients. The percentage of an orally administered antibacterial agent that is absorbed (i.e., its *bioavailability*) ranges from as little as 10 to 20% (erythromycin and penicillin G) to nearly 100% [amoxicillin, clindamycin, metronidazole, doxycycline, trimethoprim-sulfamethoxazole (TMP-SMX), linezolid, and most fluoroquinolones]. These differences in bioavailability are not clinically important as long as drug concentrations at the site of infection are sufficient to inhibit or kill the pathogen. However, therapeutic efficacy may be compromised when absorption is reduced as a result of physiologic or pathologic conditions (such as the presence of food for some drugs or the shunting of blood away from the gastrointestinal tract in patients with hypotension), drug interactions (such as that of quinolones and metal cations), or noncompliance. The oral route is usually used for patients with relatively mild infections in whom absorption is not thought to be compromised by the preceding conditions. In addition, the oral route can often be used in more severely ill patients after they have responded to parenteral therapy ("switch" therapy).

Intramuscular Administration Although the intramuscular route of administration usually results in 100% bioavailability, it is not as widely used in the United States as the oral and intravenous routes, in part because of the pain often associated with intramuscular injections and the relative ease of intravenous access in the hospitalized patient. Intramuscular injection may be suitable for specific indications requiring an "immediate" and reliable effect (e.g., with long-acting forms of penicillin, including benzathine and procaine, and with single doses of ceftriaxone for acute otitis media or uncomplicated gonococcal infection).

Intravenous Administration The intravenous route is appropriate when oral antibacterial agents are not effective against a particular pathogen, when bioavailability is uncertain, or when larger doses are required than are feasible with the oral route. After intravenous administration, bioavailability is 100%; serum concentrations are maximal at the end of the infusion. For many patients in whom long-term antimicrobial therapy is required and oral therapy is not feasible, outpatient parenteral antibiotic therapy, including the use of convenient portable pumps, may be cost-effective and safe. Alternatively, some oral antibacterial drugs (e.g., fluoroquinolones) are sufficiently active against Enterobacteriaceae to provide potency equal to that of parenteral therapy; their use may allow the patient to return home from the hospital earlier or to avoid hospitalization entirely.

DISTRIBUTION To be effective, an antibacterial agent must exceed the pathogen's MIC. Serum concentrations usually exceed the MIC for susceptible bacteria, but since most infections are extravascular, the antibiotic must also distribute to the site of the infection. Concentrations of most antibacterial agents in interstitial fluid are similar to free-drug concentrations in serum. However, when the infection is located in a "protected" site where penetration is poor, such as cerebrospinal fluid (CSF), the eye, the prostate, or infected cardiac vegetations, high parenteral doses or local administration for prolonged periods may be required for cure. In addition, even though an antibacterial agent may penetrate to the site of infection, its activity may be antagonized by factors in the local environment, such as an unfavorable pH or inactivation by cellular degradation products. For example, since the activity of aminoglycosides is reduced at acidic pH, the acidic environment in many infected tissues may be partly responsible for the relatively poor efficacy of aminoglycoside monotherapy. In addition, the abscess milieu reduces the penetration and local activity of many antibacterial compounds, so that surgical drainage may be required for cure.

Most bacteria that cause human infections are located extracellularly. Intracellular pathogens such as *Legionella*, *Chlamydia*, *Brucella*, and *Salmonella* may persist or cause relapse if the antibacterial agent does not enter the cell. In general, β-lactams, vancomycin, and aminoglycosides penetrate cells poorly, whereas macrolides, ketolides, tetracyclines, metronidazole, chloramphenicol, rifampin, TMP-SMX, and quinolones penetrate cells well.

METABOLISM AND ELIMINATION Like other drugs, antibacterial agents are disposed of by hepatic elimination (metabolism or biliary elimination), by renal excretion of the unchanged or metabolized form, or by a combination of the two processes. For most antibacterial drugs, metabolism leads to loss of in vitro activity, although some agents, such as cefotaxime, rifampin, rifabutin, and clarithromycin, have bioactive metabolites that may contribute to their overall efficacy.

The most practical application of knowing the mode of excretion of an antibacterial agent is adjustment of the dosage when elimination capability is impaired (Table 118-3). Direct, nonidiosyncratic toxicity from antibacterial drugs may result from failure to reduce the dosage in a patient with impaired elimination. For agents that are primarily cleared intact by glomerular filtration, drug clearance is linearly correlated with creatinine clearance. Unfortunately, for drugs whose elimination is primarily hepatic, no simple marker (such as serum creatinine) is useful for dosage adjustment in patients with liver disease. Even in patients with severe hepatic disease, residual metabolic capability is usually sufficient to preclude accumulation and toxic effects.

TABLE 118-3 *Antibacterial Drug Dose Adjustments in Patients with Renal Impairment*

Antibiotic	Major Route of Excretion	Dosage Adjustment with Renal Impairment
Aminoglycosides	Renal	Yes
Azithromycin	Biliary	No
Cefazolin	Renal	Yes
Cefepime	Renal	Yes
Ceftazidime	Renal	Yes
Ceftriaxone	Renal/biliary	Modest reduction in severe renal impairment
Ciprofloxacin	Renal/biliary	Only in severe renal insufficiency
Clarithromycin	Renal/biliary	Only in severe renal insufficiency
Erythromycin	Biliary	Only when given in high IV doses
Levofloxacin	Renal	Yes
Linezolid	Metabolism	No
Metronidazole	Biliary	No
Nafcillin	Biliary	No
Penicillin G	Renal	Yes (when given in high IV doses)
Piperacillin	Renal	Only with Cl_{cr} of <40 mL/min
Quinupristin/dalfopristin	Metabolism	No
Ticarcillin	Renal	Yes
TMP-SMX	Renal/biliary	Only in severe renal insufficiency
Vancomycin	Renal	Yes

Abbreviations: Cl_{cr}, creatinine clearance rate; TMP-SMX, trimethoprim-sulfamethoxazole.

PRINCIPLES OF ANTIBACTERIAL CHEMOTHERAPY

The choice of an antibacterial compound for a particular patient and a specific infection involves more than just a knowledge of the agent's pharmacokinetic profile and in vitro activity. The basic tenets of chemotherapy, to be elaborated below, include the following: When appropriate, material containing the infecting organism(s) should be obtained before the start of treatment so that presumptive identification can be made by microscopic examination of stained specimens and the organism can be grown for definitive identification and susceptibility testing. Awareness of local susceptibility patterns is useful when the patient is treated empirically. Once the organism is identified and its susceptibility to antibacterial agents is determined, the regimen with the narrowest effective spectrum should be chosen. The choice of antibacterial agent is guided by the pharmacokinetic and adverse-reaction profile of active compounds, the site of infection, the immune status of the host, and evidence of efficacy from well-performed clinical trials. If all other factors are equal, the least expensive antibacterial regimen should be chosen.

SUSCEPTIBILITY OF BACTERIA TO ANTIBACTERIAL DRUGS IN VITRO Determination of the susceptibility of the patient's infecting organism to a panel of appropriate antibacterial agents is an essential first step in devising a chemotherapeutic regimen. Standard susceptibility testing is designed to estimate the susceptibility of a bacterial isolate to an antibacterial drug under standardized conditions. These conditions favor rapidly growing aerobic or facultative organisms and assess bacteriostasis only. Specialized testing is required for the assessment of bactericidal antimicrobial activity; for the detection of resistance among such fastidious organisms as obligate anaerobes, *Haemophilus* spp., and pneumococci; and for the determination of resistance phenotypes with variable expression, such as resistance to methicillin or oxacillin among staphylococci. Antimicrobial susceptibility testing is important when susceptibility is unpredictable, most often as a result of increasing acquired resistance among hospitalized patients.

PHARMACODYNAMICS: RELATIONSHIP OF PHARMACOKINETICS AND IN VITRO SUSCEPTIBILITY TO CLINICAL RESPONSE Bacteria are often considered to be *susceptible* to a drug if the achievable peak serum concentration exceeds the MIC by approximately fourfold. The *breakpoint* is the concentration of the antibiotic that separates susceptible from resistant bacteria (Fig. 118-2). When a majority of the isolates of a given bacterial species are inhibited at concentrations below the breakpoint, the species is considered to be within the spectrum of the antibiotic (see "Choice of Antibacterial Therapy," below).

The pharmacodynamic profile of an antibiotic refers to the quantitative relationships between the time course of antibiotic concentrations in serum and tissue, in vitro susceptibility, and microbial response (inhibition of growth or rate of killing). Three pharmacodynamic parameters quantify these relationships: the ratio of the area

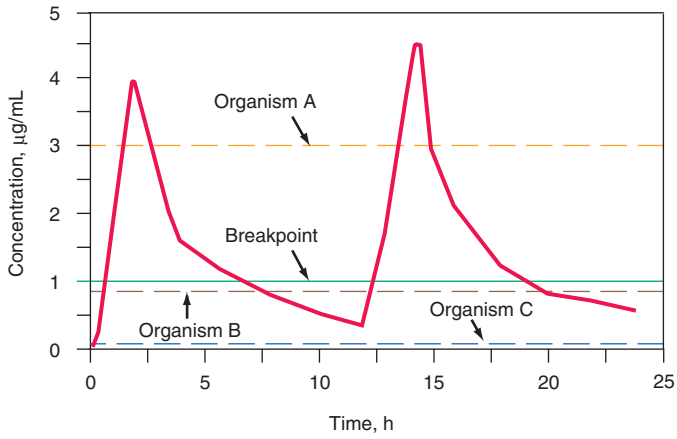


FIGURE 118-2 Relationship between pharmacokinetics of an antibiotic and susceptibility. Organism A is resistant, organism B is moderately susceptible, and organism C is very susceptible.

under the curve for the plasma concentration vs. time curve to MIC (AUC/MIC), the ratio of the maximal serum concentration to the MIC (C_{max}/MIC), and the time during a dosing interval that plasma concentrations exceed the MIC ($t >$ MIC). The pharmacodynamic profile of an antibiotic class is characterized as either *concentration dependent* (fluoroquinolones, aminoglycosides), such that the increase in antibiotic concentration leads to a more rapid rate of bacterial death, or *time dependent* (β-lactams), such that the reduction in bacterial density is proportional to the time that concentrations exceed the MIC. For concentration-dependent antibiotics, the C_{max}/MIC or AUC/MIC ratio correlates best with the reduction in microbial density in vitro and in animal investigations. Dosing strategies attempt to maximize these ratios by the administration of a large dose relative to the MIC for anticipated pathogens, often at long intervals (relative to the serum half-life). Once-daily dosing of aminoglycoside antibiotics is the most practical consequence of these relationships. In contrast, dosage strategies for time-dependent antibiotics emphasize the administration of doses sufficient to maintain serum concentrations above the MIC for a critical portion of the dose interval. Response to β-lactam antibiotics, measured as the decline in bacterial density at the site of infection, appears to be maximal when serum and tissue concentrations are maintained above the MIC for 30 to 50% of the dose interval. For example, the use of high-dose amoxicillin (90 to 100 mg/kg per day) in the treatment of acute otitis media increases not only the penetration of amoxicillin into the inner ear but also the duration of time that concentrations exceed the MIC for pneumococci. This approach provides effective therapy in most patients, including those whose pneumococcal isolates are penicillin resistant. The clinical implications of these pharmacodynamic relationships are in the early stages of investigation; their elucidation should eventually result in more rational antibacterial dosage regimens. Table 118-4 summarizes the pharmacodynamic properties of the major antibiotic classes.

STATUS OF THE HOST Various host factors must be considered in the devising of antibacterial chemotherapy. The host's antibacterial *immune function* is of importance, particularly as it relates to opsonophagocytic function. Since the major host defense against acute, overwhelming bacterial infection is the polymorphonuclear leukocyte, patients with neutropenia must be treated aggressively and empirically with bactericidal drugs for suspected infection (Chap. 72). Likewise, patients who have deficient humoral immunity (e.g., those with chronic lymphocytic leukemia and multiple myeloma) and individuals with surgical or functional asplenia (e.g., those with sickle cell disease) should be treated empirically for infections with encapsulated organisms, especially the pneumococcus.

Pregnancy increases the risk of toxicity of certain antibacterial drugs for the mother (e.g., hepatic toxicity of tetracycline), affects drug disposition and pharmacokinetics, and—because of the risk of fetal toxicity—severely limits the choice of agents for treating infections. Certain antibacterial agents are contraindicated in pregnancy either because their safety has not been established or because they are known to be toxic. These agents include all fluoroquinolones, clarithromycin, erythromycin estolate (but not erythromycin base), and tetracyclines (Table 118-5). Data on the safety of many other antibacterial drugs are limited, but these drugs may be used cautiously when there is no suitable alternative and the perceived benefit outweighs the risk. These agents include the aminoglycosides, azithromycin, clindamycin, imipenem, metronidazole, trimethoprim, and vancomycin. Nitrofurantoin and the sulfonamides are contraindicated in the third trimester but can be used cautiously in the first two trimesters.

In patients with *concomitant viral infections*, the incidence of adverse reactions to antibacterial drugs may be unusually high. For example, persons with infectious mononucleosis and those infected with HIV react more often to ampicillin and folic acid synthesis inhibitors, respectively.

In addition, the patient's age, sex, racial heritage, genetic background, and excretory status all determine the incidence and type of side effects that can be expected with certain antibacterial agents.

SITE OF INFECTION The location of the infected site may play a major role in the choice and dose of antimicrobial drug. Patients with suspected *meningitis* should receive drugs that can cross the blood-CSF barrier; in addition, because of the relative paucity of phagocytes and opsonins at the site of infection, the agents should be bactericidal. Chloramphenicol, an older drug but occasionally useful in the treatment of meningitis, is bactericidal for common organisms causing meningitis (i.e., meningococci, pneumococci, and *Haemophilus influenzae*, but *not* enteric gram-negative bacilli), is highly lipid-soluble, and enters the CSF well. However, β-lactam drugs, the mainstay of therapy for most of these infections, do not normally reach high levels in CSF. Their efficacy is based on the increased permeability of the blood-brain and blood-CSF barriers to hydrophilic molecules during inflammation and the extreme susceptibility of most infectious organisms to even small amounts of β-lactam drug.

The vegetation, which is the major site of infection in *bacterial endocarditis*, is also a focus that is protected from normal host-defense mechanisms. Antibacterial therapy needs to be bactericidal, with the selected agent administered parenterally over a long period and at a dose that produces serum levels at least eight times higher than the minimal bactericidal concentration (MBC) for the infecting organism. Likewise, *osteomyelitis* involves a site that is somewhat resistant to opsonophagocytic removal of infecting bacteria; furthermore, avascular bone (sequestrum) represents a foreign body that thwarts normal host-defense mechanisms. *Chronic prostatitis* is exceedingly difficult to cure because most antibiotics do not penetrate through the capillaries serving the prostate, especially when acute inflammation is absent. *Intraocular infections*, especially endophthalmitis, are difficult to treat because retinal capillaries lacking fenestration hinder drug penetration into the vitreous from blood. Inflammation does little to disrupt this barrier. Thus, direct injection into the vitreous is necessary in many cases. Antibiotic penetration into *abscesses* is usually poor, and local conditions (e.g., low pH or the presence of enzymes that hydrolyze the drug) may further antagonize antibacterial activity.

TABLE 118-4 *Pharmacodynamic Parameters of Major Antimicrobial Classes*

Parameter Predicting Response	Drug or Drug Class
Time above the MIC	Penicillins, cephalosporins, carbapenems, aztreonam
24-h AUC/MIC	Aminoglycosides, fluoroquinolones, tetracyclines, vancomycin, macrolides, clindamycin, quinupristin/dalfopristin
Peak to MIC	Aminoglycosides, fluoroquinolones

Abbreviations: MIC, minimal inhibitory concentration: AUC, area under the concentration curve.

In contrast, *urinary tract infections*, when confined to the bladder, are relatively easy to cure, in part because of the higher concentration of most antibiotics in urine than in blood. Since blood is the usual reference fluid in defining susceptibility (Fig. 118-2), even organisms found to be resistant to achievable serum concentrations may be susceptible to achievable urine concentrations. For drugs that are used only for the treatment of urinary tract infections, such as nitrofurantoin and methenamine salts, achievable urine concentrations are used to determine susceptibility.

TABLE 118-5 *Antibacterial Drugs in Pregnancy*

Antibacterial Drug	Toxicity in Pregnancy	Recommendation
Aminoglycosides	Possible 8th nerve toxicity	Caution[a]
Chloramphenicol	Gray syndrome in newborn	Caution at term
Fluoroquinolones	Arthropathy in immature animals	Caution
Clarithromycin	Teratogenicity in animals	Contraindicated
Ertapenem	Decreased weight in animals	Caution
Erythromycin estolate	Cholestatic hepatitis	Contraindicated
Imipenem/cilastatin	Toxicity in some pregnant animals	Caution
Linezolid	Embryonic and fetal toxicity in rats	Caution
Meropenem	Unknown	Caution
Metronidazole	None known, but carcinogenic in rats	Caution
Nitrofurantoin	Hemolytic anemia in newborns	Caution; contraindicated at term
Quinupristin/dalfopristin	Unknown	Caution
Sulfonamides	Hemolysis in newborn with G6PD[b] deficiency; kernicterus in newborn	Caution; contraindicated at term
Tetracyclines	Tooth discoloration, inhibition of bone growth in fetus; hepatotoxicity	Contraindicated
Vancomycin	Unknown	Caution

[a] Use only for strong clinical indication in the absence of a suitable alternative.
[b] G6PD, glucose-6-phosphate dehydrogenase.

COMBINATION CHEMOTHERAPY One of the tenets of antibacterial chemotherapy is that if the infecting bacterium has been identified, the most specific chemotherapy possible should be used. The use of a single agent with a narrow spectrum of activity against the pathogen diminishes the alteration of normal flora and thus limits the overgrowth of resistant nosocomial organisms (e.g., *Candida albicans*, enterococci, *Clostridium difficile*, or methicillin-resistant staphylococci), avoids the potential toxicity of multiple-drug regimens, and reduces cost. However, certain circumstances call for the use of more than one antibacterial agent. These are summarized below.

1. *Prevention of the emergence of resistant mutants*. Spontaneous mutations occur at a detectable frequency in certain genes encoding the target proteins for some antibacterial agents. The use of these agents can eliminate the susceptible population, select out resistant mutants at the site of infection, and result in the failure of chemotherapy. Resistant mutants are usually selected when the MIC of the antibacterial agent for the infecting bacterium is close to achievable levels in serum or tissues and/or when the site of infection limits the access or activity of the agent. Among the most common examples are rifampin for staphylococci, imipenem for *Pseudomonas*, and fluoroquinolones for staphylococci and *Pseudomonas*. Small-colony variants of staphylococci resistant to aminoglycosides also emerge during monotherapy with these antibiotics. A second antibacterial agent with a mechanism of action different from that of the first is added to prevent the emergence of these resistant mutants (e.g., imipenem plus an aminoglycoside for systemic *Pseudomonas* infections). However, since resistant mutants have emerged following combination chemotherapy, this approach clearly is not uniformly successful.

2. *Synergistic or additive activity*. Synergistic or additive activity involves a lowering of the MIC or MBC of each or all of the drugs tested in combination against a specific bacterium. In *synergy*, each agent is more active when combined with a second drug than it would be alone, and the drugs' combined activity is therefore greater than the sum of the individual activities of each drug. In an *additive relationship*, the combined activity of the drugs is equal to the sum of their individual activities. Among the best examples of a synergistic or additive effect, confirmed both in vitro and by animal studies, are the enhanced bactericidal activities of certain β-lactam/aminoglycoside combinations against enterococci, viridans streptococci, and *P. aeruginosa*. The synergistic or additive activity of these combinations has also been demonstrated against selected isolates of enteric gram-negative bacteria and staphylococci. The combination of trimethoprim and sulfamethoxazole has synergistic or additive activity against many enteric gram-negative bacteria. Most other antimicrobial combinations display indifferent activity (i.e., the combination is *no better* than the more active of the two agents alone), and some combinations (e.g., penicillin plus tetracycline against pneumococci) may be antagonistic (i.e., the combination is *worse* than either drug alone).

3. *Therapy directed against multiple potential pathogens*. For certain infections, either a mixture of pathogens is suspected or the patient is desperately ill with an as-yet-unidentified infection (see "Empirical Therapy," below). In these situations, the most important of the likely infecting bacteria must be covered by therapy until culture and susceptibility results become available. Examples of the former infections are intraabdominal or brain abscesses and infections of limbs in diabetic patients with microvascular disease. The latter situations include fevers in neutropenic patients, acute pneumonia from aspiration of oral flora by hospitalized patients, and septic shock or sepsis syndrome.

EMPIRICAL THERAPY In many situations, antibacterial therapy is begun before a specific bacterial pathogen has been identified. The choice of agent is guided by the results of studies identifying the usual pathogens at that site or in that clinical setting, by pharmacodynamic considerations, and by the resistance profile of the expected pathogens in a particular hospital or geographic area. Situations in which empirical therapy is appropriate include the following:

1. *Life-threatening infection*. Any suspected bacterial infection in a patient with a life-threatening illness should be treated presumptively. Therapy is usually begun with more than one agent and is later tailored to a specific pathogen if one is eventually identified.

2. *Treatment of community-acquired infections*. In many situations, it is appropriate to treat non-life-threatening infections without obtaining cultures. These situations include outpatient infections such as community-acquired upper and lower respiratory tract infections, cystitis, cellulitis or local wound infection, urethritis, and prostatitis. However, if any of these infections recurs or fails to respond to initial therapy, every effort should be made to obtain cultures to guide retreatment.

CHOICE OF ANTIBACTERIAL THERAPY

The antibacterial spectrum of specific agents and the infections for which they represent the treatment of choice are detailed below. No attempt has been made to include all the potential situations in which antibacterial agents may be used. A more detailed discussion of specific bacteria and infections that they cause can be found elsewhere in this volume.

β-LACTAMS (Table 118-2) All *penicillins* (except for the semisynthetic, penicillinase-resistant antistaphylococcal agents) are hydrolyzed by β-lactamases and are ineffective against isolates that produce these enzymes. Penicillin G has a spectrum that includes spirochetes

(*Treponema pallidum*, *Borrelia*, and *Leptospira*), streptococci (groups A and B, viridans, and many strains of *S. pneumoniae*), *E. faecalis*, most *Neisseria* spp., a few staphylococci, many fastidious oral bacteria (including many *Porphyromonas* and *Prevotella* spp., streptococci, *Actinomyces*, and *Fusobacterium*), *Clostridium* spp. (except *C. difficile*), *Pasteurella multocida*, *Erysipelothrix rhusiopathiae*, and *Streptobacillus moniliformis*. However, penicillin G resistance is widespread among staphylococci; is increasing rapidly among gonococci and pneumococci; and is emerging among meningococci, viridans streptococci, and oral anaerobes such as *Porphyromonas* and *Prevotella*. Penicillin G is the *drug of choice* for syphilis, yaws, leptospirosis, group A and B streptococcal infections, actinomycosis, oral and periodontal infections, meningococcal meningitis and meningococcemia, viridans streptococcal endocarditis, clostridial myonecrosis, tetanus, anthrax, rat-bite fever, *P. multocida* infections, and erysipeloid (*E. rhusiopathiae*).

Ampicillin extends the spectrum of penicillin G to some gram-negative rods. It is active against some isolates of *Escherichia coli*, *Proteus mirabilis*, *Salmonella*, *Shigella*, and *H. influenzae* and is one of the *drugs of choice* for susceptible organisms causing salmonellosis, acute otitis media, *H. influenzae* meningitis and epiglottitis, and *Listeria monocytogenes* meningitis. *E. faecalis* is usually susceptible, and amoxicillin is the *drug of choice* for urinary tract infections caused by this organism. High rates of resistance have lessened the value of ampicillin and amoxicillin as empirical therapy in some situations. For example, >80% of isolates of *E. coli* and *P. mirabilis* are resistant in many hospitals, as are ~30% of isolates of *H. influenzae*; moreover, in some outbreaks of infection due to salmonellae, all isolates are resistant to ampicillin.

The *penicillinase-resistant penicillins* are used solely for the treatment of staphylococcal infections and are the *drugs of choice* for systemic or deep staphylococcal infections caused by susceptible organisms. Unfortunately, on average, ~40% of *S. aureus* isolates and >70% of coagulase-negative staphylococcal isolates acquired in U.S. hospitals are resistant to these agents (i.e., methicillin-resistant). The spectrum of these agents also includes most of the same gram-positive bacteria that are susceptible to penicillin G.

The spectrum of the *antipseudomonal penicillins* includes the bacteria covered by ampicillin as well as some nonpseudomonal enteric gram-negative bacilli. For example, piperacillin is active against many indole-positive *Proteus*, *Enterobacter*, *Klebsiella*, *Providencia*, and *Serratia* spp. However, the susceptibility of these penicillins to β-lactamase markedly limits their utility as empirical therapy when infections caused by gram-negative enteric organisms are suspected. The "antipseudomonal penicillins" are no longer commercially available or have been formulated in combination with *β-lactamase inhibitors*. The addition of a β-lactamase inhibitor (clavulanic acid, sulbactam, or tazobactam) to ampicillin, amoxicillin, ticarcillin, or piperacillin extends the spectrum of the β-lactam agent to include many organisms that are resistant by virtue of β-lactamase production. These organisms include many strains of *E. coli*, *Klebsiella* spp., all *Proteus* spp., *H. influenzae*, *Moraxella catarrhalis*, *Providencia* spp., and anaerobes (including *Bacteroides* spp.). Such combinations are also active against staphylococci that produce β-lactamase but are not resistant to methicillin. However, the efficacy of these combinations in serious staphylococcal infections has not been adequately proven. Furthermore, *Serratia*, indole-positive *Proteus*, *Citrobacter*, *Enterobacter*, *Pseudomonas*, *Acinetobacter*, and various enteric gram-negative isolates either produce chromosomal β-lactamases that are not inhibited by these compounds or develop resistance attributable to non-β-lactamase-mediated mechanisms.

The *first-generation cephalosporins* have a spectrum that includes penicillinase-producing, methicillin-susceptible staphylococci and penicillin-susceptible streptococci. While these drugs may be used when infections with gram-positive bacteria are suspected, they are *not* the drugs of choice for such infections. They have excellent activity against many isolates of *E. coli*, *Klebsiella pneumoniae*, and *P. mirabilis* and are among the *drugs of choice* in presumptive therapy for community-acquired urinary tract infections. They have no activity against *Bacteroides fragilis*, enterococci, methicillin-resistant staphylococci, *Pseudomonas*, *Acinetobacter*, *Enterobacter*, indole-positive *Proteus*, and *Serratia* and only poor activity against *H. influenzae*.

The *parenteral second-generation cephalosporins* extend the gram-negative spectrum of first-generation compounds. The various second-generation agents have differing activities. Cefuroxime retains activity against gram-positive cocci and is also active against *H. influenzae*, *Neisseria*, and indole-positive *Proteus* but exhibits poor activity against *B. fragilis*. Cefoxitin and cefotetan have reasonably good activity against *B. fragilis*, but cefotetan is less effective against some other *Bacteroides* spp. (Chaps. 112 and 148). Both of the latter drugs display poor activity against gram-positive cocci and *Enterobacter*. No second-generation cephalosporin is active against *Pseudomonas* or *Acinetobacter*.

Oral second- and third-generation cephalosporins have fair activity against gram-positive cocci and *H. influenzae* and are widely used in outpatient therapy for otitis media, sinusitis, and lower respiratory tract infections, although cheaper agents that are equally effective are preferable. Cefditoren, cefdinir, and cefpodoxime have good activity against most respiratory pathogens and methicillin-susceptible *S. aureus*.

Third-generation parenteral cephalosporins all have a broad spectrum of activity against enteric gram-negative rods and are especially useful for treating hospital-acquired infections caused by multiresistant organisms. In addition, ceftazidime and cefepime have good antipseudomonal activity; the other drugs have poor activity. Since resistance to third-generation cephalosporins is increasing among all nosocomial gram-negative rods, the use of these agents should be guided by susceptibility testing. The gram-positive spectrum of the third-generation cephalosporins is variable. All are less active than first-generation cephalosporins against methicillin-susceptible staphylococci; ceftazidime has the least antistaphylococcal activity of this group. However, ceftriaxone and cefotaxime have excellent activity against streptococci, especially *S. pneumoniae*. Ceftazidime is not recommended for treatment of streptococcal infections.

Ceftriaxone has an excellent gram-negative spectrum; is active against *Haemophilus*, most *S. pneumoniae* strains, and penicillin-resistant *Neisseria*; has a long serum half-life; and reaches high serum and CSF levels (with inflammation). Thus it has become one of the *drugs of choice* for empirical therapy for bacterial meningitis (except that caused by *Listeria* and by highly penicillin-resistant pneumococcal strains), all gonococcal infections, salmonellosis, and typhoid fever. The third-generation cephalosporins are among the *drugs of choice* for nonpseudomonal hospital-acquired pneumonia. Cefepime is more resistant to chromosomal β-lactamase produced by *Enterobacter* spp. than are other third-generation cephalosporins and is more active against methicillin-susceptible *S. aureus*. Third-generation cephalosporins have poor activity against *Bacteroides* and no activity against methicillin-resistant staphylococci, *Enterococcus*, *Acinetobacter*, or *Stenotrophomonas*.

The *carbapenems* currently available in the United States are imipenem, meropenem, and ertapenem. Imipenem is marketed in combination with the renal dipeptidase inhibitor cilastatin, which enables imipenem to escape renal inactivation and thus to reach higher urinary levels. Imipenem and meropenem have excellent activity in vitro against virtually all bacterial pathogens except *Stenotrophomonas*, methicillin-resistant staphylococci, and *E. faecium*. Imipenem has dose-related central nervous system side effects that are less frequent with meropenem. Resistance to imipenem and meropenem is a problem among nosocomial isolates of *P. aeruginosa*, ~20% of which are resistant. Ertapenem has poor activity against enterococci, *P. aeruginosa*, and *Acinetobacter* but exhibits activity similar to that of meropenem against Enterobacteriaceae. Because of their broad spectrum, imipenem and meropenem can be used as empirical therapy for serious nosocomial infections thought to be caused by multiple bacterial spe-

cies or multiresistant organisms. Imipenem and meropenem are often used to treat hospital-acquired infections caused by *Enterobacter* spp. because these organisms produce inducible β-lactamases that inactivate third-generation cephalosporins but not the carbapenems. The latter antibiotics are often held in reserve as therapy for nosocomial infections due to gram-negative pathogens that are resistant to third-generation cephalosporins.

The only *monobactam* currently available is aztreonam. This antibiotic has a spectrum limited to gram-negative enteric bacilli. It has no activity against any gram-positive or anaerobic bacterium. Its gram-negative spectrum is similar to that of ceftazidime, with equally good activity against *Pseudomonas*. Aztreonam's primary advantages are its theoretical ability to preserve the normal gram-positive and anaerobic flora and the lack of cross-reactive immediate hypersensitivity in patients who have had this type of reaction to other β-lactam antibiotics.

VANCOMYCIN The spectrum of vancomycin is limited to gram-positive cocci, especially enterococci, streptococci, and staphylococci. Vancomycin serves as second-line therapy for most gram-positive bacterial infections but is the *drug of choice* for infections caused by methicillin-resistant staphylococci or *Corynebacterium jeikeium* and for serious infections in penicillin-allergic patients. Given orally (a route by which it is not absorbed), vancomycin can be used to treat antibiotic-associated pseudomembranous colitis caused by *C. difficile* in patients who have failed to respond to metronidazole—the *drug of choice*. Vancomycin has also been recommended as initial empirical therapy for presumed pneumococcal meningitis because of increasing pneumococcal resistance to penicillins and cephalosporins. Resistance to vancomycin is increasing rapidly among isolates of *E. faecium* in large hospitals, particularly in areas of high vancomycin use. In addition, *S. aureus* isolates with both high-level resistance and reduced susceptibility to vancomycin have now been detected. Because of the growing threat of vancomycin-resistant enterococci and the potential for increasing resistance among staphylococci, a national advisory committee has established guidelines for appropriate and limited use of this antibiotic (Table 118-6).

AMINOGLYCOSIDES The aminoglycosides are rapidly bactericidal in vitro at low concentrations, with activity limited to gram-negative bacteria and staphylococci. They have no activity against anaerobic bacteria and are not effective in environments that are acidic or have a low oxygen tension. However, their spectrum includes virtually all gram-negative bacteria that are not strict anaerobes, and they are among the *drugs of choice* for any suspected gram-negative bacteremic infection, particularly in neutropenic patients. Aminoglycosides are synergistically bactericidal in combination with a penicillin for the treatment of staphylococcal, enterococcal, or viridans streptococcal endocarditis and are usually combined with a β-lactam antibiotic for the treatment of gram-negative bacteremia. Aminoglycosides are also among the *drugs of choice* for severe infections of the upper urinary tract. The major limitations to use of aminoglycosides are their renal and otic toxicity, their diminished activity at certain sites of infection (e.g., abscesses and the central nervous system), and the resistance of target bacteria. Among the available agents, gentamicin and tobramycin are generally preferred because of their low cost. Tobramycin has slightly greater activity against *P. aeruginosa*, and amikacin retains activity against many tobramycin- and gentamicin-resistant gram-negative bacteria because it is inactivated by fewer aminoglycoside-modifying enzymes. Streptomycin is still one of the *drugs of choice* in initial therapy for tularemia, plague, glanders, and brucellosis and is a second-line agent for the treatment of *tuberculosis*.

TABLE 118-6 *Guidelines for Appropriate and Limited Use of Vancomycin*

Acceptable Use	*Discourage Use*
Infection with methicillin-resistant *Staphylococcus aureus*	When culture reveals a β-lactam-susceptible organism
Infection with gram-positive bacteria in penicillin-allergic patient (where vancomycin is one of the drugs of choice)	Continued empirical use without indication (e.g., no evidence of infection)
Antibiotic-associated colitis unresponsive to metronidazole	Coagulase-negative staphylococcal bacteremia, single positive culture
Endocarditis prophylaxis during dental procedures for patients allergic to β-lactam antibiotics	Routine empirical therapy
Cardiovascular surgical prophylaxis (with unusually high rates of postoperative infection with β-lactam-resistant organisms)	Routine surgical prophylaxis or prophylaxis in the dialysis patient

MACROLIDES AND KETOLIDES Erythromycin has broad-spectrum activity against gram-positive bacteria, with additional activity against *Legionella*, *Mycoplasma*, *Campylobacter*, *Bordetella pertussis*, and some *Chlamydia* isolates. It is the *drug of choice* for infections due to *Legionella*, *Campylobacter*, and *Mycoplasma* and is among the *drugs of choice* for community-acquired pneumococcal pneumonia and group A streptococcal pharyngitis in penicillin-allergic patients. However, resistance to erythromycin among group A streptococci and especially pneumococci is increasing dramatically in some areas. Erythromycin also appears to be one of the *drugs of choice* for infections caused by the agent of bacillary angiomatosis (*Bartonella henselae*) in immunocompromised patients. Clarithromycin and azithromycin have an antibacterial spectrum similar to that of erythromycin in vitro. However, azithromycin has greater activity against *Chlamydia*. Clarithromycin, in combination with a proton pump inhibitor, has been designated a *drug of choice* for the treatment of gastric infections due to *Helicobacter pylori* (gastritis, gastric and duodenal ulcers). Both azithromycin and clarithromycin are active against nontuberculous mycobacteria, and both appear to have fewer gastrointestinal side effects than does erythromycin. Bacteria that are resistant to erythromycin are also resistant to clarithromycin and azithromycin. Telithromycin is a ketolide antibiotic that is similar to erythromycin in structure, spectrum of activity, and mechanism of action. However, telithromycin is active against most macrolide-resistant strains of *S. pneumoniae*.

LINCOSAMIDES The only lincosamide used in the United States is clindamycin. It shares the gram-positive coccal spectrum of erythromycin but is more active (in some cases showing bactericidal activity) against susceptible staphylococci. However, resistance among staphylococci and some streptococci, mediated by the same genes responsible for macrolide resistance, limits clindamycin's usefulness against gram-positive cocci. In general, all staphylococci resistant to erythromycin should be considered resistant to clindamycin regardless of the results of in vitro susceptibility testing. However, at least half of the streptococci resistant to erythromycin are truly susceptible to clindamycin. In these bacteria, resistance is mediated by a drug-efflux pump that removes macrolides but not lincosamides. Despite increasing resistance, clindamycin remains useful for most anaerobic infections because of its broad spectrum of activity against most gram-positive and gram-negative strict anaerobes. It is also a *drug of choice* for the treatment of severe, invasive group A streptococcal infections. In contrast, clindamycin, like erythromycin, has no clinically significant activity against facultative gram-negative enteric bacilli. The appropriate use of clindamycin is limited only by resistance or the development of pseudomembranous colitis, the major serious side effect of this drug.

CHLORAMPHENICOL Chloramphenicol has a broad spectrum of activity against gram-positive and gram-negative bacteria, although plasmid-mediated resistance has diminished its effective spectrum. This antibiotic is rarely used in adult infections because of the rare idiosyncratic side effect of irreversible bone-marrow aplasia and the availability of other agents with similar activity. It remains one of the *drugs of choice* for the treatment of typhoid fever and plague and is still useful for the treatment of brucellosis and both pneumococcal and meningococcal meningitis in patients with severe penicillin allergy.

TETRACYCLINES Tetracyclines have a broad spectrum of bacteriostatic activity against gram-positive and gram-negative bacteria and are widely used in a variety of community-acquired infections. These agents are among the *drugs of choice* for acute bacterial exacerbations of chronic bronchitis, granuloma inguinale, brucellosis (with streptomycin), tularemia, glanders, melioidosis, spirochetal infections caused by *Borrelia* (Lyme disease and relapsing fever; doxycycline), infections caused by *Vibrio vulnificus*, some *Aeromonas* infections, infections due to *Stenotrophomonas* (minocycline), plague, ehrlichiosis, chlamydial infections (doxycycline), and granulomatous skin infections due to *Mycobacterium marinum* (minocycline). The tetracyclines are also used in penicillin-allergic patients for the treatment of leptospirosis, syphilis, actinomycosis, and skin and soft tissue infections caused by gram-positive cocci. Doxycycline is also among the drugs recommended for the treatment of community-acquired pneumonia, although clinical data are few and resistance in *S. pneumoniae* is increasing.

SULFONAMIDES AND TRIMETHOPRIM The folic acid synthesis inhibitors have a broad spectrum of bacteriostatic activity individually; in combination, they can be bactericidal against facultative gram-negative bacteria and staphylococci. The fixed combination of sulfamethoxazole and trimethoprim, the major folic acid synthesis inhibitors used in therapy for bacterial infections, has modest activity against some streptococci and no activity against strict anaerobes. However, resistance to TMP-SMX is common among methicillin-resistant staphylococci and penicillin-resistant pneumococci and is increasing among *E. coli* strains that cause urinary tract infections. The individual sulfonamides are rarely used in the treatment of bacterial infections but are among the *drugs of choice* for the treatment of nocardial infections, leprosy (dapsone, a sulfone), and toxoplasmosis (sulfadiazine). Although increasing resistance has been reported among gram-negative organisms, TMP-SMX remains one of the *drugs of choice* for the treatment of uncomplicated urinary tract infections (except for those caused by enterococci) and had been used in the treatment of otitis media. It can be used in therapy for upper respiratory tract infections in which *S. pneumoniae*, *H. influenzae*, or *M. catarrhalis* is suspected (although resistance in *S. pneumoniae* is now common in some areas); for gonococcal and meningococcal infections; for chancroid; and for infections thought to be caused by *Aeromonas*, *Stenotrophomonas*, *Burkholderia cepacia*, *Acinetobacter*, and *Yersinia enterocolitica*. For nosocomial infections due to *Stenotrophomonas*, TMP-SMX is the *drug of choice*.

FLUOROQUINOLONES The fluoroquinolones have excellent activity against most facultative gram-negative rods and variable activity against gram-positive cocci. The quinolones are the oral agents with greatest activity against *P. aeruginosa*; ciprofloxacin is the most active against this species, although a high rate of acquired resistance limits its utility in many hospitals. All the quinolones except norfloxacin are well absorbed orally; ciprofloxacin, levofloxacin, moxifloxacin, and gatifloxacin are also administered as intravenous formulations. The quinolones are among the *drugs of choice* for urinary tract infections, bacterial gastroenteritis, community-acquired pneumonia, and enteric fever and are useful for serious hospital-acquired infections caused by gram-negative organisms. While older quinolones (such as ciprofloxacin) have limited activity against gram-positive bacteria, the newer quinolones have an expanded spectrum of activity against gram-positive cocci, including staphylococci (methicillin-susceptible) and streptococci (especially *S. pneumoniae*). Quinolones can also be used as prophylaxis for persons at risk for meningococcal meningitis. However, use of quinolones should be coupled with the realization that, in conjunction with rapidly expanding usage, resistance is being reported increasingly among all bacteria targeted by these drugs, including *S. pneumoniae*, *Neisseria gonorrhoeae*, *E. coli*, and *P. aeruginosa*.

RIFAMPIN Rifampin has been used in combinations for the treatment of serious infections due to methicillin-resistant staphylococci (e.g., coagulase-negative staphylococcal foreign-body infections). Because the spontaneous selection of rifampin-resistant mutants occurs rapidly, rifampin should never be used alone in the treatment of staphylococcal infections. Rifampin is also used for chemoprophylaxis in persons at risk of meningococcal meningitis and for the treatment of *Legionella* pneumonia.

METRONIDAZOLE Metronidazole has a spectrum limited to anaerobic bacteria, especially gram-negative species (e.g., *Bacteroides* spp.). It is less active against anaerobic gram-positive cocci (e.g., *Peptostreptococcus* and *Peptococcus* spp.). Because of its spectrum and its ability to penetrate into the area of infection, metronidazole is one of the *drugs of choice* for the treatment of any abscess in which the involvement of obligate anaerobes is suspected (e.g., lung, brain, or intraabdominal abscesses). Other antibacterial agents should be used in combination with metronidazole if facultative and aerobic pathogens are also thought to be involved. Metronidazole is the *drug of choice* for the treatment of bacterial vaginosis and antibiotic-associated pseudomembranous colitis.

LINEZOLID This antibacterial agent has a spectrum limited to gram-positive bacteria and is indicated for the treatment of infections caused by streptococci, staphylococci, and enterococci. Because there is very little preexisting resistance to linezolid, the drug is active against gram-positive bacteria that are resistant to other antibacterial agents. In particular, it is active against vancomycin-resistant enterococci (both *E. faecium* and *E. faecalis*) and is one of the *drugs of choice* for treating infections due to these organisms. However, since this drug has only bacteriostatic activity, it has limited utility in treating complicated *S. aureus* infections.

POLYMYXINS Polymyxins B and E have a broad spectrum of activity that includes virtually all gram-negative bacteria. However, while polymyxin B is still used as a component of topical preparations (see "Topical Antibacterial Agents," below), polymyxin E (colistin) has been used little since the early 1980s because of the high incidence of severe renal toxicity associated with its systemic use. The occurrence in recent years of nosocomial infections caused by strains of bacteria such as *P. aeruginosa*, *Acinetobacter baumanii*, and *Stenotrophomonas maltophilia* that are resistant to all available therapy but susceptible to colistin has prompted a reexamination of its use in certain patients for whom there are no other options. Recent data suggest that colistin is reasonably safe and effective when used with caution.

STREPTOGRAMINS The combination of streptogramin B (quinupristin) and streptogramin A (dalfopristin) has a spectrum that is limited to gram-positive bacteria and is indicated for the treatment of infections caused by staphylococci, streptococci, and *E. faecium*. It is not active against *E. faecalis*. Quinupristin/dalfopristin is used primarily as therapy for infections caused by vancomycin-resistant *E. faecium*. The agent has bactericidal activity against isolates of *S. aureus* and *S. epidermidis* that are susceptible to both components. However, since ~80% of oxacillin (methicillin)-resistant *S. aureus* and *S. epidermidis* and 20 to 40% of oxacillin-susceptible staphylococci are resistant to streptogramin A (dalfopristin) as a result of ribosomal methylation, quinupristin/dalfopristin has only bacteriostatic activity against most hospital-acquired staphylococci. It is *not*, therefore, a drug of choice for serious nosocomial staphylococcal infections and should be used for complicated *S. aureus* infections only when complete susceptibility to both components can be demonstrated.

URINARY TRACT ANTISEPTICS Urinary tract antiseptics are active only in the lower urinary tract and cannot be used for the treatment of upper urinary tract or systemic infections. The available agents in this category include nitrofurantoin and methenamine salts, which are most active against susceptible gram-negative enteric bacteria. Nitrofurantoin is often active against vancomycin-resistant enterococci and is a less expensive alternative to linezolid for the treatment of lower urinary tract infections.

TOPICAL ANTIBACTERIAL AGENTS Mupirocin is available only as a topical preparation for use against staphylococci and streptococci. Its major

applications are for impetigo and eradication of the staphylococcal carrier state. It is the *drug of choice* for the elimination of nasal carriage of both methicillin-susceptible and methicillin-resistant staphylococci. Unfortunately, the emergence of resistance is limiting its usefulness in some hospitals.

Although their efficacy has never been well documented, topical preparations that include sulfonamides, polymyxin B, neomycin, bacitracin, gramicidin, and novobiocin in a variety of combinations are widely used as eyedrops, irrigation solutions, and ointments for superficial skin infections.

ADVERSE REACTIONS

Adverse drug reactions are frequently classified by mechanism as either dose-related ("toxic") effects or unpredictable reactions. Unpredictable reactions are either idiosyncratic or allergic. Dose-related reactions include aminoglycoside-induced nephrotoxicity, linezolid-induced thrombocytopenia, penicillin-induced seizures, and vancomycin-induced anaphylactoid reactions. Many of these reactions can be avoided by reducing dosage, limiting the duration of therapy, or reducing the frequency or rate of administration. Adverse reactions to antibacterial agents are a common cause of morbidity, requiring alteration in therapy and additional expense, and they occasionally result in death. The elderly, often those with the more severe infections, may be especially prone to certain adverse reactions. →***For further discussion of adverse drug reactions, see Chap. 3.***

β-LACTAMS The therapeutic index for β-lactam antibiotics is broad, and dose-related adverse reactions are uncommon and largely preventable. The greatest concern is allergic reactions. All types can occur, including anaphylaxis (type 1, immediate-hypersensitivity reactions), nephritis and Coombs-positive hemolytic anemia (type 2, cytotoxic reactions), drug fever and serum sickness (type 3, immune-complex formation), contact dermatitis (type 4, cell-mediated effects), and maculopapular eruption (type 5, idiopathic reactions). Approximately 1 to 4% of treatment courses result in an allergic reaction, and ~0.004 to 0.015% of treatment courses result in anaphylaxis. Only 10 to 20% of the patients who claim an allergy to penicillin react to skin testing with the major and minor determinants (penicilloyl-polylysine and benzylpenicillin degradation products, respectively); those with negative skin tests only rarely react adversely to subsequent therapeutic doses. Generally, a suitable alternative to β-lactams is available for patients who have a severe allergy, and penicillin desensitization can be carefully undertaken if there is no suitable alternative. A small proportion (<2%) of persons who are allergic to penicillin react similarly when a cephalosporin is administered; thus, cephalosporins are contraindicated in patients with a history of an immediate reaction to penicillin, although they are often used in patients with a history of mild reactions. The same precaution applies to carbapenems, but aztreonam is antigenically distinct and can be administered safely to the penicillin-allergic patient.

Other reactions thought to have an allergic basis include nephritis (associated with methicillin and occasionally nafcillin), hepatitis (related to oxacillin), leukopenia (following high doses of most β-lactams administered for prolonged periods), and severe skin rashes (toxic epidermal necrolysis and Stevens-Johnson syndrome). These reactions are not IgE-mediated, and skin testing is not predictive of their occurrence. For unclear reasons, most patients who have infectious mononucleosis or cytomegalovirus infection develop a rash when given ampicillin or amoxicillin.

Miscellaneous reactions to β-lactams include gastrointestinal side effects ranging in severity from mild diarrhea (5 to 10%) to pseudomembranous colitis (<1%). Although the probability of antibiotic-associated colitis is low, a large number of cases occur because β-lactams are so commonly prescribed. Drugs excreted to a large extent through the bile, such as ampicillin and ceftriaxone, may be especially prone to cause diarrhea. The addition of clavulanic acid to amoxicillin further increases the frequency of diarrhea. Ceftriaxone, because of extremely high concentrations in bile, can cause "sludging" in the gallbladder and occasionally produces symptoms compatible with acute cholecystitis.

In high doses—and most often in patients with renal impairment who receive an excessive dose—penicillins (especially ticarcillin and penicillin G) can cause bleeding from impaired platelet aggregation. Seizures are occasionally observed with β-lactams, especially penicillin G and imipenem. This reaction is most common when excessive doses relative to renal function are administered or when the patient has a history of seizures.

VANCOMYCIN When vancomycin was first used clinically in 1956, local intolerance at the infusion site was common, as were systemic reactions, including ototoxicity and nephrotoxicity. Current formulations are of higher purity and, when proper dosage guidelines are followed, are very safe, although phlebitis can still be troublesome. The most common adverse reaction is called *red man syndrome* and is characterized by pruritus, flushing, and erythema of the head and upper torso. This anaphylactoid reaction usually follows the first dose, is dependent on dose size and infusion time, and results from vancomycin-induced release of histamine. The reaction is usually mild in adult patients who receive 1 g over 60 min and diminishes with repeated doses. If vancomycin is mistakenly given as a bolus, severe hypotension may result. In unusually sensitive patients, extending the infusion time or administering H_1 receptor antagonists is usually effective in preventing this reaction or reducing its severity. Patients with this reaction must not be mislabeled as having an allergy to vancomycin, since vancomycin may be the only effective treatment for certain infections (e.g., those due to methicillin-resistant staphylococci).

Nephrotoxicity from vancomycin is mild and uncommon. Although some data suggest that aminoglycosides and vancomycin are synergistically nephrotoxic, this point is difficult to prove, and the simultaneous use of these agents should not be avoided if clinically indicated, as in the treatment of enterococcal endocarditis in penicillin-allergic patients.

Ototoxicity from vancomycin is rare as long as doses are appropriately reduced in patients with renal insufficiency. Other uncommon adverse reactions include leukopenia, skin rashes, and true allergy. Serum concentrations of vancomycin are of little use in predicting toxicity but may be of value in selecting dosages for patients with unstable renal function.

AMINOGLYCOSIDES Aminoglycoside antibiotics have a narrow therapeutic index. The two most common adverse reactions are nephrotoxicity and ototoxicity. Rarely, respiratory depression is observed. Nephrotoxicity results from accumulation of the aminoglycoside in the peritubular space, with damage to the proximal tubule and a corresponding reduction in the glomerular filtration rate. The incidence of nephrotoxicity, defined as an increase of >0.5 mg/dL over baseline in the serum creatinine level, is ~5 to 10% among adult patients who receive therapy for 10 to 14 days. However, many cofactors also influence the frequency of toxicity, such as extremes of age (toxicity is uncommon among children, more common among the elderly), concomitant drug therapy, and hydration status. Nephrotoxicity is manifested clinically by a gradual rise in serum creatinine levels after a few days of therapy and is reversible if the dosage is reduced or treatment is discontinued. Serum creatinine levels should be monitored every 3 to 5 days or more often if changes are seen. There is not an important difference among the most useful agents (gentamicin, tobramycin, and amikacin) in terms of the frequency of nephrotoxicity; streptomycin is a rare cause of nephrotoxicity. Some data suggest that once-daily administration of aminoglycosides may cause less nephrotoxicity than more frequent administration.

Ototoxicity from aminoglycoside therapy presents as either auditory or vestibular damage. Since the aminoglycosides can destroy hair cells in the inner ear, ototoxicity may be permanent. The risk of ototoxicity increases with prolonged therapy, higher serum concentrations (especially in patients with renal impairment), hypovolemia, and con-

current treatment with other ototoxins, especially ethacrynic acid. There is evidence of a genetic predisposition to ototoxicity in some persons. Clinically apparent ototoxicity, manifested by diminished acuity or vestibular imbalance, is uncommon (probably occurring in <1% of cases) when the duration of therapy is kept to a minimum. With more sensitive monitoring (e.g., audiograms), asymptomatic high-tone hearing loss is more commonly noted. There are no clinically important differences among the aminoglycosides in the overall frequency of ototoxicity.

Neuromuscular depression from aminoglycosides is caused by reduced acetylcholine activity at postsynaptic membranes and can result in rare but severe respiratory depression. Risk factors include hypocalcemia, peritoneal administration, use of neuromuscular blockers, and preexisting respiratory depression. This complication can be largely avoided if the aminoglycoside is administered intravenously over 30 min or by intramuscular injection; if respiratory depression occurs, it is reversed by the administration of calcium.

Fear of toxicity should not prevent the use of aminoglycosides for a legitimate indication, since toxicity is usually mild and reversible. The value of measuring serum concentrations is controversial; these measurements are usually unnecessary when the patient is receiving once-daily therapy, especially when the duration is <7 to 10 days.

MACROLIDES Serious adverse reactions to the macrolide antibiotics are very rare. Gastrointestinal effects, such as burning, nausea, and vomiting, are the most common adverse reactions to the macrolides; depending on dosage, these reactions may occur in up to 50% of patients, occasionally requiring early discontinuation of therapy. The mechanism is thought to be the binding of erythromycin to motilin receptors, with a consequent increase in gastrointestinal motility. Gastrointestinal side effects appear equally common for all the oral formulations and also occur with intravenous administration. Clarithromycin and azithromycin are better tolerated than erythromycin, although gastrointestinal distress is still their most common adverse effect.

Less common reactions include hepatotoxicity and ototoxicity. Hepatotoxicity is a rare, nonfatal complication that is usually associated with erythromycin estolate and presents as an allergic cholestatic jaundice. Ototoxicity is rare after oral administration but may occur in a dose-dependent pattern in up to 20% of adults who receive intravenous erythromycin (4 g/d) and have audiograms performed. Ototoxicity is usually reversible and mild. Allergic cutaneous reactions are observed in rare cases. Macrolides are among the many drugs that can prolong the QT_c interval in some patients. The clinical significance of this effect continues to be investigated. The limited data suggest that the ketolide telithromycin has adverse effects similar to those of erythromycin.

LINCOSAMIDES The most common adverse effect of clindamycin is gastrointestinal distress. Diarrhea has been reported in up to 20% of patients and pseudomembranous colitis in 0.01 to 10%. The mechanism of pseudomembranous colitis is production of a toxin by *C. difficile* (Chap. 114). *C. difficile* colonizes the gastrointestinal tract and may produce a toxin when the normal flora is suppressed by clindamycin and other antibiotics, especially β-lactams. This toxin causes mucosal damage that results in cramps, pain, and diarrhea that may be bloody. Pseudomembranous colitis may follow both intravenous and oral administration and may not become manifest until after completion of therapy. Oral metronidazole or oral vancomycin is effective in treating symptomatic patients with toxin-positive stools, but some spores may survive, and relapse is frequent. Metronidazole is the *drug of choice* since oral treatment with vancomycin can select for vancomycin-resistant enterococci. Although diarrhea and pseudomembranous colitis can be caused by most antibacterial agents, the incidence in relation to the amount used may be highest for clindamycin. Allergic reactions (such as rashes and fever), hepatotoxicity, and neutropenia are observed only rarely.

CHLORAMPHENICOL Chloramphenicol causes two types of bone marrow suppression: a dose-related, reversible suppression of all elements, which occurs commonly during therapy at the maximal recommended doses (4 g/d in adults), and an idiosyncratic, irreversible aplastic anemia, which occurs in ~1 of every 25,000 to 40,000 exposures. The irreversible form has been reported to follow all types of chloramphenicol treatment, including ocular administration, and often develops months after therapy is discontinued.

In premature neonates and infants, chloramphenicol can cause a dose-related "gray syndrome" that is characterized by cyanosis, hypotension, and death and that results from an inability of the newborn to metabolize the drug. These potentially serious toxicities and the availability of newer drugs have substantially reduced the indications for chloramphenicol use.

TETRACYCLINES Gastrointestinal effects are the most common adverse reactions to the tetracyclines. These problems may be related to a direct irritant effect, since tetracyclines can also cause esophageal ulceration when they dissolve before reaching the stomach. It is important that nighttime doses be taken with sufficient fluid. Concurrent food intake may improve tolerance, but absorption of tetracycline HCl is impaired when the drug is taken with food.

Hepatotoxicity has been reported after administration of >2 g of tetracycline intravenously and at lower doses during pregnancy. There are currently no indications for intravenous tetracycline treatment in pregnancy. All tetracyclines can cause phototoxic skin reactions; these reactions are most common with doxycycline. Other dermal reactions, including rash, are uncommon. Tetracyclines are contraindicated in children <8 years of age because of mottling of the permanent teeth; doxycycline may be less likely than the other tetracyclines to cause this problem. Worsening of renal function in patients with preexisting renal dysfunction has been reported with use of tetracycline. Doxycycline and perhaps minocycline appear to be free from these renal side effects. Alternative effective agents are nearly always available for use in patients with renal dysfunction. Minocycline can cause vertigo in up to 70% of women receiving therapeutic doses and in a lower percentage of men.

SULFONAMIDES AND TRIMETHOPRIM The sulfonamides are generally safe, but the list of possible adverse reactions is very long. These compounds occasionally cause a number of allergic reactions, from relatively minor skin rashes (including maculopapular rashes and urticarial reactions typically appearing after a week of therapy) to severe or even life-threatening reactions such as erythema multiforme, Stevens-Johnson syndrome, and toxic epidermal necrolysis. The severe hypersensitivity reactions have occurred most commonly after treatment with the long-acting sulfonamides, such as sulfamethoxypyridazine, which are no longer used. Pyrimethamine plus sulfadoxine (Fansidar), used for malaria prophylaxis, may cause severe allergic reactions, including hepatic and hematologic toxicities, in addition to dermatologic toxicity. Photosensitivity reactions are also relatively common with sulfonamides.

Many patients infected with HIV who receive TMP-SMX have adverse dermatologic reactions. These reactions are usually not life-threatening and appear to regress in many cases despite continuation of therapy. In high doses, trimethoprim interferes with the renal secretion of potassium. Hyperkalemia is relatively common among HIV-positive patients and is most often found after 7 days of TMP-SMX therapy for pneumonia caused by *Pneumocystis*.

Sulfonamides and trimethoprim may also cause severe hematologic complications, including agranulocytosis, hemolytic and megaloblastic anemia, and thrombocytopenia. These dose-related side effects may be more frequent and more severe in patients with renal insufficiency. Hemolytic anemia is most common in patients with glucose-6-phosphate dehydrogenase deficiency who take long-acting compounds; TMP-SMX rarely causes hemolysis in such subjects. Granulocytopenia from TMP-SMX is especially common among HIV-infected patients, occurring in 10 to 50% of this group.

Renal insufficiency, caused by crystals of the relatively insoluble

acetyl metabolite, is observed primarily with the long-acting sulfonamides. Many cases of crystalluria in HIV-infected patients taking sulfadiazine for toxoplasmosis have been reported. A high level of fluid intake may prevent this complication.

It is recommended that sulfonamides not be administered to newborns because of concerns that bilirubin may be displaced from protein-binding sites, with subsequent jaundice and kernicterus.

In addition to the preceding problems, sulfonamides may occasionally cause drug fever with serum sickness, hepatic toxicity (including necrosis), and systemic lupus erythematosus.

FLUOROQUINOLONES Fluoroquinolones are relatively safe; adverse reactions rarely require discontinuation of therapy. The most common reactions include gastrointestinal distress, such as nausea or diarrhea (<5%), and central nervous system effects, including insomnia and dizziness (<5%). Phototoxicity is occasionally severe. Rarely, hepatic and renal dysfunction and anaphylactoid and allergic reactions are observed. Quinolones can cause tendon rupture in rare instances. The use of these drugs is currently contraindicated in patients <18 years of age because of evidence in animals of cartilage damage in developing joints. In carefully selected situations in which the perceived benefits outweigh the risks (e.g., in adolescent patients with cystic fibrosis who have pulmonary exacerbations), fluoroquinolones may be useful for short-term therapy. They are contraindicated in pregnancy because of concern for the developing fetus. Quinolones can also increase the QT_c interval; it is unclear whether the currently available quinolones differ in a clinically important way in this respect. Hypo- and hyperglycemia have been reported and may be more common with gatifloxacin. As of 2003, a number of fluoroquinolones—including temafloxacin, sparfloxacin, grepafloxacin, and trovafloxacin—have been removed from the U.S. market because of rare but severe adverse effects. It may be prudent to limit the use of the newest drugs in this class until their safety has been fully established.

TABLE 118-7 *Interactions of Antibacterial Agents with Other Drugs*

Antibiotic	Interacts with	Potential Consequence (Clinical Significance[a])
Erythromycin/clarithromycin/ telithromycin	Theophylline	Theophylline toxicity (1)
	Carbamazepine	CNS depression (1)
	Digoxin	Digoxin toxicity (2)
	Triazolam/midazolam	CNS depression (2)
	Ergotamine	Ergotism (1)
	Warfarin	Bleeding (2)
	Cyclosporine/tacrolimus	Nephrotoxicity (1)
	Cisapride	Cardiac arrhythmias (1)
	Statins[b]	Rhabdomyolysis (2)
	Valproate	Valproate toxicity (2)
	Vincristine/vinblastine	Excess neurotoxicity (2)
Quinupristin/dalfopristin	Similar to erythromycin[c]	
Fluoroquinolones[d]	Theophylline	Theophylline toxicity (2)
	Antacids/sucralfate/iron	Subtherapeutic antibiotic levels (1)
Tetracycline	Antacids/sucralfate/iron	Subtherapeutic antibiotic levels (1)
Trimethoprim-sulfamethoxazole	Phenytoin	Phenytoin toxicity (2)
	Oral hypoglycemics	Hypoglycemia (2)
	Warfarin	Bleeding (1)
	Digoxin	Digoxin toxicity (2)
Metronidazole	Ethanol	Disulfiram-like reactions (2)
	Fluorouracil	Bone marrow suppression (1)
	Warfarin	Bleeding (2)
Rifampin	Warfarin	Clot formation (1)
	Oral contraceptives	Pregnancy (1)
	Cyclosporine/tacrolimus	Rejection (1)
	HIV-1 protease inhibitors	Increased viral load, resistance (1)
	Nonnucleoside reverse-transcriptase inhibitors	Increased viral load, resistance (1)
	Glucocorticoids	Loss of steroid effect (1)
	Methadone	Narcotic withdrawal symptoms (1)
	Digoxin	Subtherapeutic digoxin levels (1)
	Itraconazole	Subtherapeutic itraconazole levels (1)
	Phenytoin	Loss of seizure control (1)
	Statins	Hypercholesterolemia (1)
	Diltiazem	Subtherapeutic diltiazem levels (1)
	Verapamil	Subtherapeutic verapamil levels (1)

[a] 1 = a well-documented interaction with clinically important consequences; 2 = an interaction of uncertain frequency but of potential clinical importance.
[b] Lovastatin and simvastatin are most affected; pravastatin and atorvastatin are less prone to clinically important effects.
[c] The macrolide antibiotics and quinupristin/dalfopristin inhibit the same human metabolic enzyme, CYP3A4, and similar interactions are anticipated.
[d] Ciprofloxacin only. Levofloxacin, moxifloxacin, and gatifloxacin do not inhibit theophylline metabolism.
Note: New interactions are commonly reported after marketing. Consult the most recent prescribing information for updates.
Abbreviation: CNS, central nervous system.

RIFAMPIN Rifampin is generally well tolerated but has several important side effects. Some patients have transient rises in hepatic aminotransferases, but these levels usually return to normal without discontinuation of the drug. Although hepatitis from rifampin itself develops only rarely, the drug is thought by some investigators to potentiate the hepatic toxicity of concomitantly administered isoniazid. Intermittent administration of rifampin (usually fewer than three times per week) has been associated with signs and symptoms that seem to have an immunologic basis. These include flulike symptoms and (rarely) hemolysis, thrombocytopenia, shock, and renal failure. Minor gastrointestinal side effects, skin rashes, and interstitial nephritis have also been reported. Patients should be warned that rifampin and its metabolites cause secretions such as urine, tears, sweat, and saliva to turn orange and that contact lenses may be stained.

METRONIDAZOLE Serious adverse reactions to metronidazole are uncommon. Gastrointestinal side effects such as nausea are most frequent but rarely necessitate discontinuation of therapy. Pseudomembranous colitis in association with metronidazole has been reported but is very rare. A metallic taste is relatively common, and stomatitis and glossitis are occasionally reported. Peripheral neuropathy develops in some patients, and seizures and encephalopathy have been reported after high doses and in patients with hepatic failure.

Concerns about mutagenicity and carcinogenicity from metronidazole have led to recommendations that it not be used in pregnancy (especially during the first trimester) when alternative agents are available. Although retrospective studies have found no association between metronidazole and carcinogenesis, long-term administration of high doses should be avoided when therapeutic alternatives exist.

LINEZOLID The most common adverse events accompanying linezolid therapy include gastrointestinal upset (nausea, vomiting, and diarrhea) and headache. Of most concern is a reversible myelosuppression that is directly related to the duration of therapy. Thrombocytopenia is the most likely hematologic abnormality, although anemia and leukopenia are also observed. If the duration of therapy is expected to exceed 1 week, then weekly complete blood counts are recommended.

QUINUPRISTIN/DALFOPRISTIN Quinupristin/dalfopristin is not well tolerated. In particular, venous irritation is a frequent and potentially serious adverse effect when the drug is given by peripheral intravenous infusion. Administration via a central line is often required to complete a course of therapy. In addition, arthralgia and myalgia are substan-

TABLE 118-8 *Prophylaxis of Bacterial Infections in Adults*

Condition	Antibacterial Agent	Timing or Duration of Prophylaxis
Nonsurgical		
Cardiac lesions susceptible to bacterial endocarditis	Amoxicillin[a]	Before and after procedures causing bacteremia
Recurrent *S. aureus* infections	Mupirocin	5 days (intranasal)
Contact with patient with meningococcal meningitis	Rifampin Fluoroquinolone	2 days Single dose
Bite wounds[b]	Penicillin V or amoxicillin/clavulanic acid	3–5 days
Recurrent cystitis	Trimethoprim-sulfamethoxazole or a fluoroquinolone or nitrofurantoin	3 times per week for up to 1 year or after sexual intercourse
Surgical		
Clean (cardiac, vascular, neurologic, or orthopedic surgery)	Cefazolin (vancomycin)[c]	Before and during procedure
Ocular	Topical combinations and subconjunctival cefazolin	During and at end of procedure
Clean-contaminated (head and neck, high-risk gastroduodenal or biliary tract surgery; high-risk cesarean section; hysterectomy)	Cefazolin (or clindamycin for head and neck)	Before and during procedure
Clean-contaminated (vaginal or abdominal hysterectomy)	Cefazolin or cefoxitin or cefotetan	Before and during procedure
Clean-contaminated (high-risk genitourinary surgery)	Fluoroquinolone	Before and during procedure
Clean-contaminated (colorectal surgery or appendectomy)	Cefoxitin or cefotetan (add oral neomycin + erythromycin for colorectal)	Before and during procedure
Dirty[b] (ruptured viscus)	Cefoxitin or cefotetan ± gentamicin (clindamycin + gentamicin) or another appropriate regimen directed at anaerobes and gram-negative aerobes	Before and for 3–5 days after procedure
Dirty[b] (traumatic wound)	Cefazolin	Before and for 3–5 days after trauma

[a] Gentamicin should be added to the amoxicillin regimen for high-risk gastrointestinal and genitourinary procedures; vancomycin should be used in penicillin-allergic patients.
[b] In these cases, use of antibacterial agents actually constitutes treatment of infection rather than prophylaxis.
[c] Vancomycin is recommended only in institutions that have a high incidence of infection with methicillin-resistant staphylococci.

tially more common among patients treated with quinupristin/dalfopristin than among those receiving other antimicrobial agents. Other side effects include rash, elevated serum bilirubin levels, and gastrointestinal distress.

DRUG INTERACTIONS

Antimicrobial drugs are a common cause of drug-drug interactions. Table 118-7 lists the most common and best-documented interactions of antibacterial agents with other drugs and characterizes the clinical relevance of these interactions. Coadministration of drugs paired in the tables does not necessarily result in clinically important adverse consequences. Recognition of the potential for an interaction before the administration of an antibacterial agent is crucial to the rational use of these drugs, since adverse consequences can often be prevented if the interaction is anticipated. Table 118-7 is intended only to heighten awareness of the potential for an interaction. Additional sources should be consulted to identify appropriate options. →***For further discussion of drug interactions, see Chap. 3.***

MACROLIDES AND KETOLIDES Erythromycin, clarithromycin, and telithromycin inhibit the P450 enzyme CYP3A4 and thus the metabolism of many other drugs, including cyclosporine, certain statins (lovastatin, simvastatin), theophylline, carbamazepine, warfarin, certain antineoplastic agents (e.g., vincristine, irinotecan), and ergot alkaloids. When erythromycin and other inhibitors of CYP3A4 are given to patients receiving terfenadine, astemizole, cisapride, and pimozide, cardiac arrhythmias (including torsades de pointes) can occur; the availability of the latter drugs has been severely restricted or they have been removed from the U.S. market. Azithromycin has little effect on the metabolism of other drugs. In ~10% of patients receiving digoxin, concentrations increase when these drugs are given.

QUINUPRISTIN/DALFOPRISTIN Quinupristin/dalfopristin is an inhibitor of CYP3A4. Its interactions with other drugs should be similar to those of erythromycin.

LINEZOLID Linezolid is a monoamine oxidase inhibitor. Its concomitant administration with sympathomimetics such as phenylpropanolamine, with selective serotonin reuptake inhibitors, and with foods with high concentrations of tyramine should be avoided.

TETRACYCLINES The most important interaction involving tetracyclines is the reduction in absorption when these drugs are coadministered with divalent and trivalent cations, such as antacids, iron compounds, or dairy products. Food also adversely affects absorption of most tetracyclines. Inducers of hepatic isoenzymes, such as phenytoin and rifampin, increase the clearance of doxycycline; although the clinical significance of this effect is unknown, use of an alternative antibiotic may be appropriate.

SULFONAMIDES Sulfonamides, including sulfamethoxazole, increase the hypoprothrombinemic effect of warfarin by inhibition of its metabolism and possibly by protein-binding displacement. Sulfonamides may also potentiate the effects of oral hypoglycemic agents and phenytoin through reduction in metabolism or displacement from serum protein.

FLUOROQUINOLONES There are two clinically important drug interactions involving fluoroquinolones. First, like tetracyclines, all fluoroquinolones are chelated by divalent and trivalent cations, which prevent most of the dose from being absorbed. Second, certain fluoroquinolones, including ciprofloxacin, inhibit hepatic enzymes that metabolize theophylline, with consequent theophylline toxicity. The same mechanism accounts for increases in serum caffeine concentrations, but the clinical significance of this interaction is unknown. Scattered case reports suggest that quinolones can also potentiate the effects of warfarin, but this effect has not been observed in most controlled trials.

RIFAMPIN Rifampin is an excellent inducer of many cytochrome P450 enzymes and increases the hepatic clearance of a number of drugs, including the following (with the indicated predictable outcomes): HIV-1 protease inhibitors (loss of viral suppression), oral contraceptives (pregnancy), warfarin (decreased prothrombin times), cyclosporine and prednisone (organ rejection or exacerbations of any underlying inflammatory condition), and verapamil and diltiazem (increased dosage requirements). Before rifampin is prescribed for any patient, a review of concomitant drug therapy is essential.

METRONIDAZOLE Metronidazole can cause a disulfiram-like syndrome when alcohol is ingested; thus, patients taking metronidazole should be instructed to avoid alcohol. Inhibition of the metabolism of warfarin by metronidazole leads to significant rises in prothrombin times.

PROPHYLAXIS OF BACTERIAL INFECTIONS

Antibacterial agents are occasionally indicated for use in patients who have no evidence of infection but who have been or are expected to be exposed to bacterial pathogens under circumstances that constitute a major risk of infection. The basic tenets of antimicrobial prophylaxis are as follows: (1) the risk or potential severity of infection should be greater than the risk of side effects from the antibacterial agent, (2) the antibacterial agent should be given for the shortest period necessary to prevent target infections, and (3) the antibacterial agent should be given before the expected period of risk (e.g., surgical prophylaxis) or as soon as possible after contact with an infected individual (e.g., prophylaxis for meningococcal meningitis).

Table 118-8 lists the major indications for antibacterial prophylaxis in adults. (The use of antibacterial agents in children to prevent rheumatic fever and otitis media under certain circumstances is also common practice.) The table includes only those indications that are widely accepted, supported by well-designed studies, or recommended by expert panels. Prophylaxis is also used but is less widely accepted for recurrent cellulitis in conjunction with lymphedema, recurrent pneumococcal meningitis in conjunction with deficiencies in humoral immunity or CSF leaks, traveler's diarrhea, gram-negative sepsis in conjunction with neutropenia, and spontaneous bacterial peritonitis in conjunction with ascites.

The major use of antibacterial prophylaxis in the United States is for infections following surgical procedures. Antibacterial agents are administered just before the surgical procedure—and, for long operations, during the procedure as well—to ensure high levels in serum and tissues during surgery. The objective is to eradicate bacteria originating from the air of the operating suite, the skin of the surgical team, or the patient's own flora that may contaminate the wound. In all but colorectal surgical procedures, prophylaxis is predominantly directed against staphylococci. Prophylaxis is intended to prevent wound infection or infection of implanted devices, not all infections that may occur during the postoperative period (e.g., urinary tract infections or pneumonia). Prolonged prophylaxis merely alters the normal flora and favors infections with organisms resistant to the antibacterial agents used.

DURATION OF THERAPY AND TREATMENT FAILURE

It is often difficult to determine the proper duration of therapy for bacterial infections. There are few infections for which trials have established the appropriate treatment duration. Table 118-9 lists those common bacterial infections for which guidelines have been established or for which there is sufficient clinical experience to establish treatment durations. The ultimate test of cure for a bacterial infection is the absence of relapse when therapy is discontinued. *Relapse* is defined as a recurrence of infection with the identical organism that caused the first infection. In general, therefore, the duration of therapy should be long enough to prevent relapse yet not excessive. Therapy extended beyond the limit of effectiveness will increase side effects of medication and encourage the selection of resistant bacteria. The art of treating bacterial infections lies in the ability to determine the appropriate duration of therapy for infections that are not covered by established guidelines. Re-treatment of infections for which therapy has failed usually requires a prolonged course (>4 weeks) with combinations of antibacterial agents.

ANTIBACTERIAL COSTS AND INAPPROPRIATE USE

Use of antibacterial agents in U.S. hospitals can represent the largest expenditure for any single pharmacologic class. It is not unusual for the purchase cost of a newer parenteral antibiotic (in 2003 dollars) to be $1000 to $2000 for a 10- to 14-day course of treatment. Therapy for 5 to 10 days with a new oral antibiotic can easily cost $60 to $100, compared with a few dollars for older drugs such as doxycycline and amoxicillin. Administration costs, monitoring costs, and pharmacy charges must be added to these figures. While some newer antibacterial agents undeniably represent important advances in therapy, many newer drugs offer no advantage over older, less expensive agents. With rare exceptions, newer drugs are usually found to be no more effective than the comparison antibiotic in controlled trials, despite the "high prevalence of resistance" often touted to market the advantage of the new antibiotic over older therapies.

Clinicians are understandably confused by the bewildering array of available drugs and their competing claims of superiority. Numerous surveys have reported that ~50% of antibiotic use is in some way "inappropriate." Aside from the monetary cost of unnecessary antibiotics, there are the costs of excess morbidity from adverse effects and drug interactions and the eventual costs of treating more resistant organisms. The following suggestions are intended to provide guidance through the antibiotic maze.

First, objective evidence regarding the merits of newer drugs is available through publications such as *The Medical Letter* (including periodic updates of the *Drugs of Choice*) and through online references such as those on the Johns Hopkins website (http://hopkins-abxguide.org), which offers much current information. Second, clinicians should become comfortable using a few drugs recommended by independent experts and professional organizations and should resist the temptation to use a new drug unless the merits are clear. A new antibacterial agent with a "broader spectrum and greater potency," a "longer half-life and higher tissue levels," or a "higher serum concentration-to-MIC ratio" does not necessarily translate into greater clinical efficacy. Third, clinicians should become familiar with local bacterial susceptibility profiles. It may not be necessary to use a new drug with "improved activity against *P. aeruginosa*" if that pathogen is rarely encountered or if it retains full susceptibility to older drugs. Finally, with regard to inpatient use of antibacterial drugs, appropriate empirical treatment with one or more broad-spectrum agents may often be simplified, with use of a narrower-spectrum agent or even an oral drug, once the results of cultures and susceptibility tests become available. While there is an understandable temptation not to alter effective therapy, switching to a more specific agent once the patient has improved clinically does not compromise outcome. A promising and active area of research includes shorter durations of antimicrobial therapy. Many antibiotics that once were given for 7 to 14 days can probably be given for 3 to 7 days. As these clinical trials of shorter duration and equal efficacy are published, prompt adoption of the shorter courses by the clinical community may be an effective counter to the problems of

TABLE 118-9 *Duration of Therapy for Bacterial Infections*

Duration of Therapy	*Infections*
Single dose	Gonococcal urethritis, streptococcal pharyngitis (penicillin G benzathine), primary and secondary syphilis (penicillin G benzathine)
3 days	Cystitis in young women, community- or travel-acquired diarrhea
7–10 days	Community-acquired pneumonia, community-acquired meningitis (pneumococcal or meningococcal), antibiotic-associated diarrhea (10 days), *Giardia* enteritis, cellulitis, epididymitis
2 weeks	*Helicobacter pylori*–associated peptic ulcer, neurosyphilis (penicillin IV), penicillin-susceptible viridans streptococcal endocarditis (penicillin plus aminoglycoside), disseminated gonococcal infection with arthritis, acute pyelonephritis, uncomplicated *S. aureus* catheter-associated bacteremia
3 weeks	Lyme disease, septic arthritis (nongonococcal)
4 weeks	Acute and chronic prostatitis, infective endocarditis (penicillin-resistant streptococcal)
>4 weeks	Acute and chronic osteomyelitis, *S. aureus* endocarditis, foreign-body infections (prosthetic-valve and joint infections), relapsing pseudomembranous colitis

increasing resistance. Adoption of these guidelines will not undermine the care of patients, many unnecessary complications and expenses will be avoided, and the useful life of valuable drugs will be extended.

Section 5 Diseases Caused by Gram-Positive Bacteria

119 PNEUMOCOCCAL INFECTIONS

Daniel M. Musher

Streptococcus pneumoniae (the pneumococcus) was recognized as the major cause of pneumonia in the 1880s and has been a central focus of study leading to the modern understanding of humoral immunity. The name *Diplococcus pneumoniae* was assigned to the organism in 1926 because of its appearance in Gram-stained sputum. In 1974, the organism was renamed *Streptococcus pneumoniae* because it grows in chains in liquid medium. Around 1900, pneumococcal serotypes were recognized when the injection of killed organisms into a rabbit stimulated the production of serum antibody that agglutinated the immunizing strain and protected rabbits against challenge with that strain and with some but not all other pneumococcal isolates. Ninety serotypes have now been identified, each possessing a unique polysaccharide capsule.

MICROBIOLOGY Pneumococci are identified in the clinical laboratory as gram-positive cocci that grow in chains and are catalase-negative. They produce pneumolysin, a toxin that breaks down hemoglobin into a greenish degradation product, thereby causing α-hemolysis on blood agar. More than 98% of pneumococcal isolates are susceptible to ethylhydrocupreine (optochin), and virtually all pneumococcal colonies are dissolved by bile salts; these reactions are the basis for laboratory identification.

Peptidoglycan and teichoic acid are the principal constituents of the pneumococcal cell wall. The cell wall's integrity depends on the presence of numerous peptide side chains cross-linked by the activity of enzymes such as trans- and carboxypeptidases. β-Lactam antibiotics inactivate these enzymes by covalently binding their active site. Unique to *S. pneumoniae* and present in all strains is C (for "cell-wall") substance, a polysaccharide consisting of teichoic acid with a phosphorylcholine residue. Surface-exposed choline residues serve as a site of attachment for potential virulence factors, such as pneumococcal surface protein A (PspA), which may prevent phagocytosis. Except for strains that cause conjunctivitis, nearly every clinical isolate of *S. pneumoniae* has a polysaccharide capsule.

There are two systems for numbering the 90 known distinct capsules of *S. pneumoniae*. In the American system, serotypes are numbered in the order in which they were identified. The strains that most frequently cause human disease were generally the earliest to be identified and thus tend to have lower numbers. The more widely accepted Danish system places serotypes into groups based on antigenic similarities; for example, Danish group 19 includes types 19F ("first recognized"), 19A, 19B, and 19C, which in the American system would be types 19, 57, 58, and 59, respectively. Serotyping was clinically relevant in the 1930s, when type-specific antisera were administered as therapy, and again in the 1990s, when it was used to track the spread of antibiotic-resistant isolates (although this method has largely been replaced by molecular biologic techniques such as pulsed-field gel electrophoresis and multilocus sequence typing). Capsule switching has been documented and further limits the epidemiologic reliability of serotyping.

EPIDEMIOLOGY *S. pneumoniae* colonizes the nasopharynx and, on any single occasion, can be isolated from 5 to 10% of healthy adults and from 20 to 40% of healthy children. Once the organisms have colonized an adult, they are likely to persist for 4 to 6 weeks but may persist for as long as 6 months. Pneumococci spread from one individual to another by direct or droplet transmission as a result of close contact; transmission may be enhanced by crowding or poor ventilation. Day-care centers have been a site of spread, especially of penicillin-resistant strains of serotypes 6B, 14, 19F, and 23F. Outbreaks occur among adults in crowded living conditions—e.g., in military barracks, prisons, and shelters for the homeless—as well as among susceptible populations in settings such as nursing homes. The risk of pneumococcal pneumonia is not increased by contact in schools or workplaces (including hospitals).

The incidence of bacteremic pneumococcal infection is relatively high among infants up to 2 years of age and low among teenagers and young adults; rates increase with increasing age beginning at around age 55. A surveillance study in South Carolina showed the incidences of pneumococcal bacteremia among infants, young adults, and persons $\geq$70 years of age to be 160, 5, and 70 cases per 100,000 population, respectively. (These results antecede implementation of vaccination for infants and young children.) Most cases of pneumococcal bacteremia in adults are due to pneumonia, and there are three to four cases of nonbacteremic pneumonia for every bacteremic case. Thus an estimated 20 cases of pneumococcal pneumonia per 100,000 young adults and 280 cases per 100,000 persons over the age of 70 occur annually. The incidence of pneumococcal bacteremia among adults exhibits a distinct midwinter peak and a striking dip in summer. In children, the incidence of bacteremia is relatively constant throughout the year except for a marked dip in midsummer. For reasons that are unclear but probably are multifactorial, Native Americans, Native Alaskans, and African Americans are unusually susceptible to invasive pneumococcal disease. This enhanced susceptibility is thought to have a genetic basis that thus far remains unelucidated.

PATHOGENETIC MECHANISMS *S. pneumoniae* attaches to human nasopharyngeal cells through the specific interaction of bacterial surface adhesins, such as pneumococcal surface antigen A or choline-binding proteins (including PspA), with epithelial cell receptors. Epithelial cell glycoconjugates containing the disaccharide GlcNAcβ1-4Gal or asialo-GM1 glycolipid are possible binding sites. Pneumococcal phase variation, in which organisms may form transparent or opaque colonies, may also play a role in adherence. Organisms from opaque colonies have relatively little peptidoglycan and large capsules; those from transparent colonies have much more phosphorylcholine (which contributes to their capacity to adhere to mammalian cells) and less capsular polysaccharide. When pneumococci are inoculated intranasally into an experimental animal, organisms that form transparent colonies persist; in contrast, after intraperitoneal inoculation, organisms

that yield transparent colonies are rapidly cleared from the blood, whereas those that make opaque colonies resist clearance.

Once the nasopharynx has been colonized, infection results if the organisms are carried into anatomically contiguous areas such as the eustachian tubes or the nasal sinuses and if their clearance is hindered, for example, by mucosal edema due to allergy or viral infection. Similarly, pneumonia ensues if organisms are inhaled or aspirated into the bronchioles or alveoli and then are not cleared—especially, for example, if viral infection or cigarette smoke or other toxic substances have increased mucus production and/or damaged ciliary action. A mechanism by which pneumococci may bind to pneumocytes after viral infection has been suggested. Pneumocytes activated by cytokines express the receptor for platelet-activating factor, which binds the phosphorylcholine residue of pneumococcal C substance, enhancing the adherence of pneumococci. Pneumococci may invade tissues by penetrating mucosal layers; the clinical significance of this finding remains to be determined.

Once pneumococci reach an area where they do not naturally belong, they activate complement by classic and alternative pathways and stimulate cytokine production, which leads to the attraction of polymorphonuclear leukocytes (PMNs). The polysaccharide capsule, however, renders the organisms resistant to phagocytosis. In the absence of anticapsular antibody, phagocytic cells such as alveolar macrophages have a limited capacity to ingest and kill pneumococci; a large bacterial inoculum and/or a compromise of phagocytic function allows the initiation of lung infection. Infection of the meninges, joints, bones, and peritoneal cavity may result from the spread of pneumococci through the bloodstream, usually but not always from a respiratory tract focus of infection.

The capacity to cause disease reflects the capacities of pneumococci to escape ingestion and killing by host phagocytic cells, on the one hand, and to stimulate an inflammatory response and damage tissues, on the other. Encapsulated pneumococci are poorly ingested and killed in vivo in the immunologically naïve host or in vitro by mammalian phagocytic cells in the absence of anticapsular antibody and complement. Unencapsulated pneumococci virtually never cause invasive disease (although they can cause conjunctivitis), and mutants lacking a capsule are essentially avirulent in mice. Symptoms of disease are largely attributable to the generation of an inflammatory response that may cause pain by increasing pressure (as in sinusitis or otitis media) or may interfere with vital bodily functions by preventing oxygenation of blood (as in pneumonia) or by inhibiting blood flow (as in vasculitis due to meningitis). Cell-wall constituents of *S. pneumoniae*, including teichoic acid, C substance, and (in particular) peptidoglycan, activate complement by the alternative pathway; the reaction between cell-wall structures and antibody that is present in all humans also activates the classic complement pathway. The result is the release of C5a, a potent attractant for PMNs, into the surrounding medium. Peptidoglycan can also directly stimulate the release of proinflammatory cytokines such as interleukin (IL) 1β, tumor necrosis factor (TNF) α, and IL-6 that activate a cascade of inflammation mediators. These cytokines increase expression of selectins on endothelial cells and integrins on leukocytes, thereby enhancing PMN migration. Pneumolysin, a thiol-activated toxin, exerts a variety of effects on ciliary cells and PMNs and also activates the classic complement pathway by direct binding of Clq. Injection of pneumolysin into the lungs of experimental animals produces the histologic features of pneumonia; in mice, immunization with this substance or challenge with genetically engineered mutants that do not produce it is associated with a significant reduction in virulence. Autolysin may contribute to the pathogenesis of pneumococcal disease by lysing bacteria, thereby releasing their constituents and heightening the reaction with human tissues. Inflammation in the central nervous system (CNS) during meningitis is a major contributor to neuronal cell injury. The release of matrix metalloproteinases, reactive oxygen species, and reactive nitrogen intermediates in neuronal tissue also contributes to damage caused by meningitis.

HOST DEFENSE MECHANISMS Mechanisms of host defense may be immunologically nonspecific or specific. Nonspecific mechanisms that protect against pneumonia include laminar airflow across mucous layers that filter inspired air, the glottal reflex, laryngeal closure, the cough reflex, clearance of organisms from the lower airways by ciliated cells, and ingestion by pulmonary macrophages and PMNs of small bacterial inocula that manage to reach alveolar spaces. Respiratory virus infection, chronic pulmonary disease, or heart failure compromises these mechanisms, predisposing to the development of pneumococcal pneumonia.

Anticapsular antibody provides the best specific protection against pneumococcal infection. Most healthy adults lack IgG antibody to the majority of pneumococcal capsular polysaccharides. Antibody appears after colonization, infection, or vaccination. In the first few weeks after colonization, nonspecific mechanisms probably protect the host from infection. Thereafter, newly developed anticapsular antibody provides a high degree of specific protection. Adults who are at risk of aspirating pharyngeal contents and/or who have diminished mechanisms of lower airway clearance are at risk of developing pneumonia before antibody is produced. Similarly, children whose nasal mucosal membranes become acutely congested around the time of colonization are at risk of developing otitis media. Persons with a diminished capacity to form antibody remain susceptible for as long as they are colonized. Antibody to PspA and other pneumococcal constituents, such as pneumolysin, is prevalent in the population and may contribute to immunity that is immunologically specific but not type specific.

The risk of serious pneumococcal infection is greatly increased in persons with conditions that compromise IgG synthesis and/or the phagocytic function of PMNs and macrophages; this risk is also elevated in the presence of conditions associated with debilitation or malnutrition. Nearly all adults who are hospitalized for pneumococcal pneumonia have at least one predisposing condition and/or fall into a group known to be at high risk epidemiologically (Table 119-1). Prior hospitalization either predisposes to or serves as a strong marker for subsequent pneumococcal infection. The susceptibility of elderly individuals to pneumococcal pneumonia is multifactorial, reflecting diminished clearance mechanisms as well as debilitation, malnutrition, and the presence of comorbid diseases. Although IgG responses to

TABLE 119-1 Conditions That Commonly Predispose to Pneumococcal Infection

- Increased risk of exposure
  - Day-care centers
  - Military training camps
  - Prisons
  - Shelters for the homeless
- Respiratory infection, inflammation
  - Influenza, other viral respiratory infections
  - Air pollution
  - Allergies
  - Cigarette smoking
  - Chronic obstructive pulmonary disease
  - Other causes of chronic pulmonary inflammation or obstruction
- Anatomical disruption of meninges (dural tear)
- Defective antibody formation
  - Common variable hypogammaglobulinemia
  - Selective IgG subclass deficiency
  - Multiple myeloma
  - Chronic lymphocytic leukemia
  - Lymphoma
- Defective complement function
- Defective clearance of pneumococcal bacteremia[a]
  - Congenital asplenia, hyposplenia
  - Splenectomy
  - Sickle cell disease
- Multifactorial conditions
  - Infancy and aging
  - Chronic disease, hospitalization
  - Alcoholism
  - Malnutrition
  - HIV infection
  - Chronic lung disease
  - Glucocorticoid treatment
  - Cirrhosis of the liver
  - Renal insufficiency
  - Diabetes mellitus
  - Anemia
  - Coronary artery disease
  - Fatigue, stress, and/or exposure to cold

[a] The absence of a spleen predisposes to more fulminant infection (see text).

some capsular polysaccharides, as measured by enzyme-linked immunosorbent assay (ELISA), are more or less normal in elderly persons, postvaccination levels of antibody to others are reduced, and the functional capacity of the antibody appears to be decreased. A remarkably high incidence of pneumococcal infection—perhaps 100-fold above baseline—among persons with AIDS is largely related to poor formation of antibody to capsular polysaccharides.

Once a pneumococcal infection has been initiated, the absence of a spleen predisposes to fulminant disease. The liver is able to remove opsonized (antibody-coated) pneumococci from the circulation; in the absence of antibody, however, only the slow passage of blood through the splenic sinuses and prolonged contact with reticuloendothelial cells in the cords of Billroth allow time for bacterial clearance. Patients without spleens may die of pneumococcal pneumonia and sepsis at such an early stage of the illness that pulmonary consolidation is not evident on x-ray but rather is found only at autopsy.

SPECIFIC INFECTIONS CAUSED BY *S. PNEUMONIAE* *S. pneumoniae* causes infections of the middle ear, sinuses, trachea, bronchi, and lungs (Table 119-2) by direct spread from the nasopharyngeal site of colonization. Infections of the CNS, heart valves, bones, joints, and peritoneal cavity usually arise by hematogenous spread; peritoneal infection also results from ascent via the fallopian tubes. The CNS may also be infected by contiguous spread of organisms, as in patients who have a tear in the dura. Primary pneumococcal bacteremia—i.e., the presence of pneumococci in the blood with no apparent source—occurs commonly in children <2 years of age and as a small percentage of all pneumococcal bacteremias in adults; if no therapy is given, a source and/or a secondary site of infection may become apparent. Pleural infection results either from direct extension of pneumonia to the visceral pleura or from hematogenous spread of bacteria from a pulmonary or extrapulmonary focus to the pleural space; the route cannot be determined in any individual case. Infections listed after meningitis in Table 119-2 are uncommon or rare.

Otitis Media and Sinusitis When fluid from the middle ear is cultured during acute otitis media or fluid from a paranasal sinus is cultured during acute sinusitis, *S. pneumoniae* is the most common isolate or is second only to nontypable *Haemophilus influenzae*. Whether in adults or in children, pneumococci are identified in ~40 to 50% of cases of otitis in which an etiologic agent is isolated. Prior infection by a respiratory virus or allergy is thought to contribute significantly to these pneumococcal infections by causing congestion of the openings to the eustachian tubes or the paranasal sinuses. Prospective studies of young children have shown that colonization precedes infection in most cases. For reasons that are unclear, serotypes 6B, 14, 19F, and 23F predominate both as colonizing and as infecting organisms of children.

Pneumonia The distinctive symptoms and signs of pneumonia, whether due to the pneumococcus or to other bacteria, are (1) cough and sputum production, which reflect the proliferation of bacteria and the resulting inflammatory response in the alveoli; (2) fever; and (3) radiographic detection of an infiltrate.

TABLE 119-2 *Most Common Infections Caused by Streptococcus pneumoniae in Adults*

Acute sinusitis	Septic arthritis
Pneumonia	Peritonitis
Acute purulent tracheobronchitis	Endocarditis
Otitis media	Pericarditis
Empyema	Endometritis
Meningitis	Cellulitis
Primary bacteremia	Brain abscess
Osteomyelitis	

Note: The order of the list very roughly approximates the order of frequency among adults, from most to least common.

PREDISPOSING CONDITIONS Pneumococcal pneumonia is most common at the extremes of age. Despite the undisputed role of *S. pneumoniae* as a major pathogenic bacterium for humans, the great majority of adults with pneumococcal pneumonia have underlying diseases that predispose them to infection. Otherwise-healthy military recruits involved in outbreaks of infection may be an exception to this rule; however, many of those affected have an exposure to stress and/or an antecedent viral-type illness that may reduce normal host resistance. In addition to prior viral respiratory illness, the most common predisposing conditions are alcoholism, malnutrition, chronic pulmonary disease of any kind, cigarette smoking, infection with HIV, diabetes mellitus, cirrhosis of the liver, anemia, prior hospitalization for any reason, renal insufficiency, and coronary artery disease (with or without recognized congestive heart failure). HIV infection is such an important predisposing factor that some authorities recommend that any young adult with pneumococcal pneumonia be tested for antibody to HIV.

PRESENTING SYMPTOMS Patients often present with a preexisting respiratory condition that has distinctly deteriorated. If a viral respiratory illness is the predisposing factor, the patient may have felt unwell for several days, with coryza or a nonproductive cough and low-grade fever. At the time of onset of pneumonia, the patient feels distinctly worse. The temperature may rise to 38.9 to 39.4°C (102 to 103°F); however, one series of cases documented temperatures from 33.3 to 40.5°C (92 to 104.9°F), with only one-third of bacteremic patients having a temperature of ≥37.5°C (≥99.5°F) at admission. Sputum production may become prominent; in a patient who has chronic bronchitis, the sputum may increase in volume and may become yellow or green and thicker than usual. In a small proportion of cases, the onset of disease follows a hyperacute pattern in which the patient suddenly has a single episode of shaking chills followed by sustained fever and a cough productive of blood-tinged sputum. This clinical picture is unfortunately called "classic," a vague term that is best avoided because many physicians believe that it means "most common," which is clearly not the case. In elderly subjects, the onset of disease may be especially insidious and may not suggest pneumonia at all. Elderly patients may have minimal cough, no sputum production, and no fever, instead appearing tired or confused. Nausea and vomiting or diarrhea, sometimes quite prominent, occur in up to 20% of cases of pneumococcal pneumonia. Symptoms of myocardial ischemia or an actual infarction may be present in 5% of cases. The most abrupt progression of pneumococcal disease is seen in patients who have undergone splenectomy; given their defective clearance of pneumococci from the bloodstream, these individuals may go from apparent good health to death in as little as 24 h. An inapparent pulmonary focus is often responsible. In pneumonia, pleuritic chest pain may result from extension of the inflammatory process to the visceral pleura; persistence of this pain, especially after the first day or two of treatment, raises concern about empyema (see "Complications," below). Clearly, the range of symptoms is sufficiently broad that no characteristic presentation distinguishes pneumococcal from other types of bacterial pneumonia (or from some types of nonbacterial pneumonia).

PHYSICAL FINDINGS Patients with pneumococcal pneumonia usually appear ill and have a grayish, anxious appearance that differs from that of persons with viral or mycoplasmal pneumonia. Temperature, pulse, and respiratory rate are typically elevated. Elderly patients may have only a slight temperature elevation or may be afebrile. Hypothermia is associated with increased morbidity and mortality. Herpes labialis appears in a small percentage of cases. Pain may cause diminished respiratory excursion (splinting) on the affected side. Dullness to percussion is noted in about half of cases, and vocal fremitus is increased. Breath sounds may be bronchial or tubular, and crackles are heard in most cases if enough air is being moved to generate them. Flatness to percussion at the lung base, absent fremitus, and lack of the expected degree of diaphragmatic motion suggest the presence of pleural fluid, which raises the possibility that empyema is present. The finding of a heart murmur, certainly if new, raises concern about endocarditis, a rare but serious complication. Hypoxia or the generalized response to

pneumonia may cause the patient to be confused, but the appearance of confusion should also raise concern about meningitis. Obtundation or neck stiffness should lead to an immediate consideration of this complication.

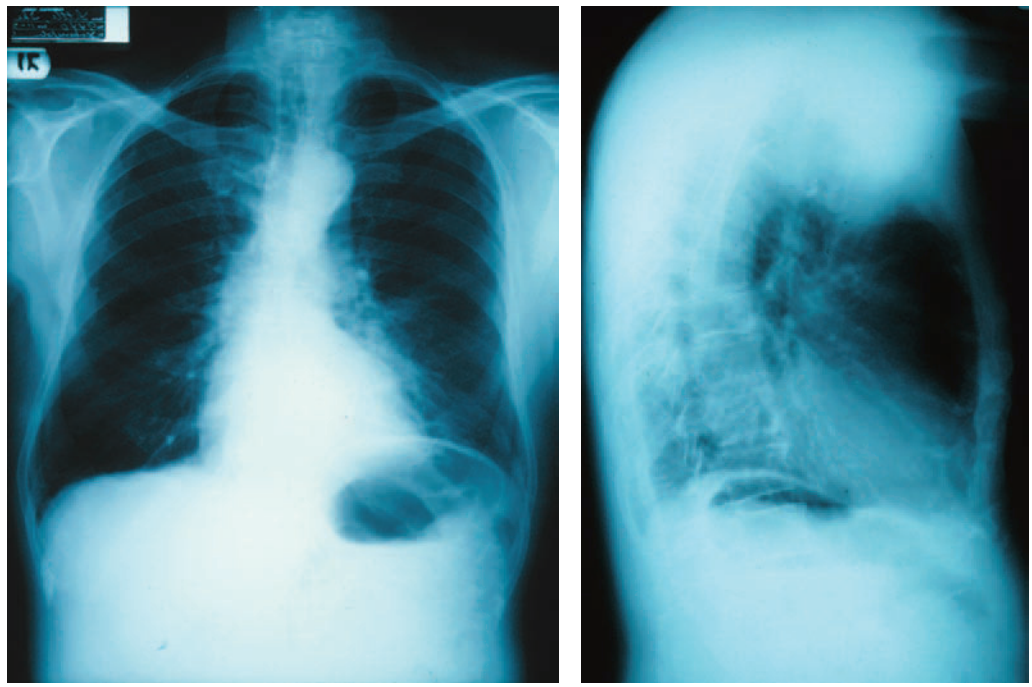

FIGURE 119-1 A retrocardiac infiltrate in a patient with pneumococcal pneumonia. Consolidation is apparent on posterior-anterior view (left) but is better visualized on lateral view of the chest (right).

RADIOGRAPHIC FINDINGS Pneumococcal pneumonia involves only one lung segment or a portion thereof in one-fourth of cases; it involves more than one segment but only one lobe or a portion thereof in another one-fourth of instances. Thus multilobar disease is seen in half of cases. Air-space consolidation is the predominant finding and is detected in 80% of cases (Fig. 119-1). Air bronchogram (visualization of the air-filled bronchus against a background of consolidation in the alveoli) is evident in fewer than half of cases and is more common in bacteremic than in nonbacteremic disease. In rare instances, pneumococcal pneumonia leads to a lung abscess; an underlying malignancy may be present, and co-infection with a mixture of anaerobic and microaerophilic organisms may be documented as well. Although some pleural fluid may actually be present in half of cases, no more than 20% of patients have a sufficient volume of fluid to allow aspiration, and in only a minority of these patients is empyema documented.

GENERAL LABORATORY FINDINGS Anemia (a hemoglobin level of <10 g/dL) is present in 25% of cases. The peripheral-blood white blood cell (WBC) count exceeds 12,000/μL in the great majority of patients with pneumococcal pneumonia. However, the count is $<6000/\mu$L in 5 to 10% of persons hospitalized for pneumococcal pneumonia. Such a low count is strongly associated with lethal disease and is often but not always associated with bone marrow suppression due to alcohol ingestion. The serum bilirubin level is modestly elevated in one-third of cases; hypoxia, inflammatory changes in the liver, and breakdown of red blood cells in the lung are all thought to contribute to this increase. A serum albumin level of <2.5 g/dL in 30% of cases may indicate predisposing malnutrition or may be secondary to sepsis. About 20% of patients have serum sodium concentrations of ≤ 130 meq/L, and another 20% have serum creatinine concentrations of ≥ 2 mg/dL. ***→Abnormalities of pleural fluid in empyema are reviewed in Chap. 239.***

DIFFERENTIAL DIAGNOSIS Patients who present with community-acquired pneumonia may actually have infection due to one of many organisms. The extensive list includes the following: *H. influenzae* or *Moraxella catarrhalis* in persons with little to predispose them other than chronic or acute inflammation of the airways; *Staphylococcus aureus* in persons who take glucocorticoids or who have major anatomical disruption of the airways; *Streptococcus pyogenes*; *Neisseria meningitidis*; anaerobic species in persons who have seizures or who may have aspirated oropharyngeal contents for some other reason; *Legionella*; *Pasteurella multocida* in dog or cat owners; gram-negative bacilli, especially in persons with severely damaged lungs who are taking glucocorticoids; viruses, especially influenza virus (in season), adenovirus, or respiratory syncytial virus; *Mycobacterium tuberculosis*; fungi, including *Pneumocystis* (depending on epidemiologic factors and the possible presence of HIV infection); *Mycoplasma*; *Chlamydia pneumoniae*, especially in older adults; and *Chlamydia psittaci* in bird owners. Many older men with lung cancer present with pneumonia, as do persons who have acute-onset inflammatory pulmonary conditions of uncertain etiology or those with pulmonary embolus and infarction. The breadth of this list vividly illustrates the deficiency of empirical therapy for community-acquired pneumonia (Table 119-3). Many of these diseases require evaluation, and specific therapy is available for an increasing number. Moreover, pneumococci—perhaps the most common cause of community-acquired pneumonia—are increasingly resistant to available antibiotics. Taken together, these factors favor precise determination of the etiology of a pneumonia syndrome whenever possible.

DIAGNOSTIC MICROBIOLOGY An etiologic role for the pneumococcus in pneumonia is strongly suggested by the microscopic demonstration of large numbers of PMNs and slightly elongated gram-positive cocci in pairs and chains in the sputum (Fig. 119-2). Capsules may be seen surrounding the bacterial forms. Examined areas of the slide must be free of buccal epithelial cells, which indicate the admixture of saliva with sputum; saliva may contain viridans streptococci at counts of $>10^7$/mL. When characteristic microscopic findings are noted, the identification of *S. pneumoniae* in sputum culture strongly indicates pneumococcal infection of the lower respiratory tract. In the absence of such microscopic findings, the identification of pneumococci by culture may be nonspecific, reflecting colonization of the upper airways. Culture is, however, more sensitive than microscopic exami-

TABLE 119-3 *Causes of a Pneumonia Syndrome Leading to Hospitalization of Adults in Houston, Texas*[a]

Common	Less Common
Streptococcus pneumoniae	*Moraxella catarrhalis*
Haemophilus influenzae	*Staphylococcus aureus*
Lung cancer	*Legionella* species
Mycobacterium tuberculosis	Pulmonary infarction
Pneumocystis	*Klebsiella pneumoniae*
Influenza (seasonal)	Respiratory syncytial virus
	Microaerophilic and anaerobic mouth flora
	Pseudomonas aeruginosa
	Chlamydia pneumoniae
	Cryptococcus, *Histoplasma*
	Hamman-Rich syndrome, others

[a] Pneumonia was defined as a syndrome consisting of fever, increased cough, sputum production, and an abnormal pulmonary shadow on chest x-ray.

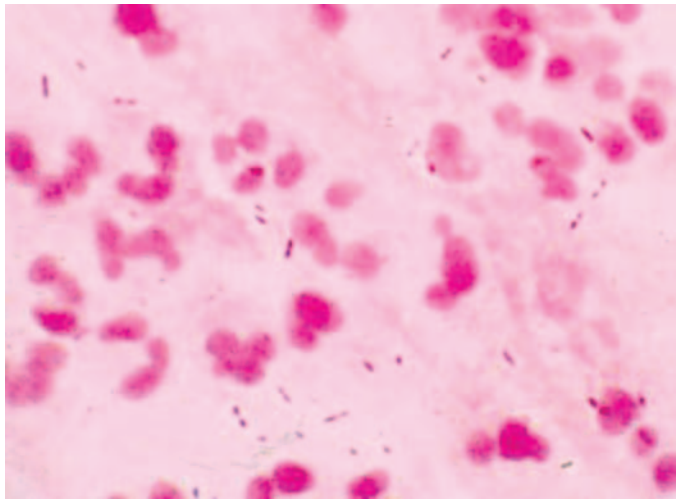

FIGURE 119-2 Gram-stained sputum from a patient with pneumococcal pneumonia shows polymorphonuclear cells with no epithelial cells, indicating the origin of the sample in inflammatory exudate without contamination. Slightly pleomorphic gram-positive coccobacilli appear, generally in pairs. Displacement of stained proteinaceous background material outlines a capsule surrounding some of the organisms. When obtained from a patient with pneumonia, a sample like this one is highly specific in identifying the pneumococcus as the etiologic agent.

nation for identifying pneumococci. Since most pneumococci do not produce distinctively mucoid colonies, their identification in the laboratory depends on the ability to select putative pneumococcal colonies for further study from among α-hemolytic streptococci of the mouth. In short, laboratory diagnosis by sputum culture depends on the quality of the specimen provided, the care with which the relevant purulent component is separated for study, and the assiduity with which α-hemolytic colonies are studied. Prior treatment with antibiotics can also rapidly clear pneumococci from sputum. These factors need to be considered when sputum cultures from patients who appear to have pneumococcal pneumonia are said to yield only "normal mouth flora" and when the medical literature describes what appear to be poor results of sputum culture. Because of the central role of microscopic examination in diagnosis, physicians may wish to view the slides with the microbiologist. Blood cultures yield *S. pneumoniae* in ~25% of cases of pneumococcal pneumonia, often within 12 h after the sample is obtained.

COMPLICATIONS Empyema is the most common complication of pneumococcal pneumonia, occurring in ~2% of cases. Some fluid appears in the pleural space in a substantial proportion of cases of pneumococcal pneumonia, but this parapneumonic effusion usually reflects an inflammatory response to infection that has been contained within the lung, and its presence is self-limited. When bacteria reach the pleural space—either hematogenously or as a result of contiguous spread, possibly across lymphatics of the visceral pleura—empyema results. The finding of frank pus, a positive result on Gram's staining, or the presence of fluid with a pH of ≤7.1 indicates the need for aggressive and complete drainage, preferably by prompt insertion of a chest tube, with verification by computed tomography (CT) that fluid has been removed. Failure to drain most or all of the fluid usually indicates the need for thoracotomy. Persistence of fever (even if low-grade) and leukocytosis after 4 or 5 days of appropriate antibiotic treatment for pneumococcal pneumonia suggests empyema. In this setting, the diagnosis is exceedingly likely if the x-ray shows pleural fluid; at this stage, thoracotomy is often needed for cure. Aggressive drainage is likely to reduce morbidity and mortality from empyema (Chap. 245).
