The host response to influenza infections involves a complex interplay of humoral antibody, local antibody, cell-mediated immunity, interferon, and other host defenses. Serum antibody responses, which can be detected by the second week after primary infection, are measured by a variety of techniques: hemagglutination inhibition (HI), complement fixation (CF), neutralization, enzyme-linked immunosorbent assay (ELISA), and antineuraminidase antibody assay. Antibodies directed against the hemagglutinin appear to be the most important mediators of immunity; in several studies, HI titers of $\geq$40 have been associated with protection from infection. Secretory antibodies produced in the respiratory tract are predominantly of the IgA class and also play a major role in protection against infection. Secretory antibody neutralization titers of $\geq$4 have also been associated with protection. A variety of cell-mediated immune responses, both antigen-specific and antigen-nonspecific, can be detected early after infection and depend on the prior immune status of the host. These responses include T-cell proliferative, T-cell cytotoxic, and natural killer cell activity. In humans, CD8+, HLA class I–restricted cytotoxic T cells (CTLs) are directed at conserved regions of internal proteins (NP, M, and polymerases) as well as against the surface proteins (H and N). Interferons can be detected in respiratory secretions shortly after the shedding of virus has begun, and rises in interferon titers coincide with decreases in virus shedding.

The host defense factors responsible for cessation of virus shedding and resolution of illness have not been defined specifically. Virus shedding generally stops within 2 to 5 days after symptoms first appear, at a time when serum and local antibody responses often are not detectable by conventional techniques (although antibody rises may be detected earlier by use of highly sensitive techniques, particularly in individuals with previous immunity to the virus). It has been suggested that interferon, cell-mediated immune responses, and/or nonspecific inflammatory responses all contribute to the resolution of illness. CTL responses may be particularly important in that regard.

MANIFESTATIONS Influenza has most frequently been described as an illness characterized by the abrupt onset of systemic symptoms, such as headache, feverishness, chills, myalgia, or malaise, and accompanying respiratory tract signs, particularly cough and sore throat. In many cases, the onset is so abrupt that patients can recall the precise time they became ill. However, the spectrum of clinical presentations is wide, ranging from a mild, afebrile respiratory illness similar to the common cold (with either a gradual or an abrupt onset) to severe prostration with relatively few respiratory signs and symptoms. In most of the cases that come to a physician's attention, the patient has a fever, with temperatures of 38° to 41°C (100.4° to 105.8°F). A rapid temperature rise within the first 24 h of illness is generally followed by a gradual defervescence over a 2- to 3-day period, although, on occasion, fever may last for as long as a week. Patients report a feverish feeling and chilliness, but true rigors are rare. Headache, either generalized or frontal, is often particularly troublesome. Myalgias may involve any part of the body but are most common in the legs and lumbosacral area. Arthralgias may also develop.

Respiratory complaints often become more prominent as systemic symptoms subside. Many patients have a sore throat or persistent cough, which may last for a week or more and which is often accompanied by substernal discomfort. Ocular signs and symptoms include pain on motion of the eyes, photophobia, and burning of the eyes.

Physical findings are usually minimal in cases of uncomplicated influenza. Early in the illness, the patient appears flushed and the skin is hot and dry, although diaphoresis and mottled extremities are sometimes evident, particularly in older patients. Examination of the pharynx may yield surprisingly unremarkable results despite a severe sore throat, but injection of the mucous membranes and postnasal discharge are apparent in some cases. Mild cervical lymphadenopathy may be noted, especially in younger individuals. The results of chest examination are largely negative in uncomplicated influenza, although rhonchi, wheezes, and scattered rales have been reported with variable frequency in different outbreaks. Frank dyspnea, hyperpnea, cyanosis, diffuse rales, and signs of consolidation are indicative of pulmonary complications. Patients with apparently uncomplicated influenza have been reported to have a variety of mild ventilatory defects and increased alveolar-capillary diffusion gradients; thus, subclinical pulmonary involvement may be more frequent than is appreciated.

In uncomplicated influenza, the acute illness generally resolves over a 2- to 5-day period, and most patients have largely recovered in 1 week, although cough may persist for 1 to 2 weeks longer. In a significant minority (particularly the elderly), however, symptoms of weakness or lassitude (postinfluenzal asthenia) may persist for several weeks and may prove troublesome for persons who wish to resume their full level of activity promptly. The pathogenetic basis for this asthenia is unknown, although pulmonary function abnormalities may persist for several weeks after uncomplicated influenza.

COMPLICATIONS Complications of influenza occur most frequently in patients >64 years old and in those with certain chronic disorders, including cardiac or pulmonary diseases, diabetes mellitus, hemoglobinopathies, renal dysfunction, and immunosuppression. Pregnancy in the second or third trimester also predisposes to complications with influenza. The most significant complication of influenza is pneumonia: "primary" influenza viral pneumonia, secondary bacterial pneumonia, or mixed viral and bacterial pneumonia. Primary influenza viral pneumonia is the least common but most severe of the pneumonic complications. It presents as acute influenza that does not resolve but instead progresses relentlessly, with persistent fever, dyspnea, and eventual cyanosis. Sputum production is generally scanty, but the sputum can contain blood. Few physical signs may be evident early in the illness. In more advanced cases, diffuse rales may be noted, and chest x-ray findings consistent with diffuse interstitial infiltrates and/or acute respiratory distress syndrome may be present. In such cases, arterial blood-gas determinations show marked hypoxia. Viral cultures of respiratory secretions and lung parenchyma, especially if samples are taken early in illness, yield high titers of virus. In fatal cases of primary viral pneumonia, histopathologic examination reveals a marked inflammatory reaction in the alveolar septa, with edema and infiltration by lymphocytes, macrophages, occasional plasma cells, and variable numbers of neutrophils. Fibrin thrombi in alveolar capillaries, along with necrosis and hemorrhage, have also been noted. Eosinophilic hyaline membranes can be found lining alveoli and alveolar ducts.

Primary influenza viral pneumonia has a predilection for individuals with cardiac disease, particularly those with mitral stenosis, but has also been reported in otherwise-healthy young adults as well as in older individuals with chronic pulmonary disorders. In some epidemics of influenza (notably those of 1918 and 1957), pregnancy increased the risk of primary influenza pneumonia. Subsequent epidemics of influenza have been associated with increased rates of hospitalization among pregnant women.

Secondary bacterial pneumonia follows acute influenza. Improvement of the patient's condition over 2 to 3 days is followed by a reappearance of fever along with clinical signs and symptoms of bacterial pneumonia, including cough, production of purulent sputum, and physical and x-ray signs of consolidation. The most common bacterial pathogens in this setting are *Streptococcus pneumoniae*, *Staphylococcus aureus*, and *Haemophilus influenzae*—organisms that can colonize the nasopharynx and that cause infection in the wake of changes in bronchopulmonary defenses. The etiology can often be determined by Gram's staining and culture of an appropriately obtained sputum specimen. Secondary bacterial pneumonia occurs most frequently in

high-risk individuals with chronic pulmonary and cardiac disease and in elderly individuals. Patients with secondary bacterial pneumonia often respond to antibiotic therapy when it is instituted promptly.

Perhaps the most common pneumonic complications during outbreaks of influenza have mixed features of viral and bacterial pneumonia. Patients may experience a gradual progression of their acute illness or may show transient improvement followed by clinical exacerbation, with eventual manifestation of the clinical features of bacterial pneumonia. Sputum cultures may contain both influenza A virus and one of the bacterial pathogens described above. Patchy infiltrates or areas of consolidation may be detected by physical examination and chest x-ray. Patients with mixed viral and bacterial pneumonia generally have less widespread involvement of the lung than those with primary viral pneumonia, and their bacterial infections may respond to appropriate antibiotics. Mixed viral and bacterial pneumonia occurs primarily in patients with chronic cardiovascular and pulmonary diseases.

Other pulmonary complications associated with influenza include worsening of chronic obstructive pulmonary disease and exacerbation of chronic bronchitis and asthma. In children, influenza infection may present as croup. Sinusitis as well as otitis media (the latter occurring particularly often in children) may also be associated with influenza.

In addition to the pulmonary complications of influenza, a number of extrapulmonary complications may occur. These include *Reye's syndrome* (Chap. 290), a serious complication in children that is associated with influenza B and to a lesser extent with influenza A virus infection as well as with varicella-zoster virus infection. An epidemiologic association between Reye's syndrome and aspirin therapy for the antecedent viral infection has been noted, and the syndrome's incidence has decreased markedly with widespread warnings regarding aspirin use by children with acute viral respiratory infections.

Myositis, rhabdomyolysis, and myoglobinuria are occasional complications of influenza infection. Although myalgias are exceedingly common in influenza, true myositis is rare. Patients with acute myositis have exquisite tenderness of the affected muscles, most commonly in the legs, and may not be able to tolerate even the slightest pressure, such as the touch of bedsheets. In the most severe cases, there is frank swelling and bogginess of muscles. Serum levels of creatine phosphokinase and aldolase are markedly elevated, and an occasional patient has developed renal failure from myoglobinuria. The pathogenesis of influenza-associated myositis is also unclear, although the presence of influenza virus in affected muscles has been reported.

Myocarditis and pericarditis were reported in association with influenza virus infection during the 1918–1919 pandemic; these reports were based largely on histopathologic findings, and these complications have been reported only infrequently since that time. Electrocardiographic changes during acute influenza are common among patients who have cardiac disease but have been ascribed most often to exacerbations of the underlying cardiac disease rather than to direct involvement of the myocardium with influenza virus.

Central nervous system (CNS) diseases, including encephalitis, transverse myelitis, and Guillain-Barré syndrome, have been reported during influenza. The etiologic relationship of influenza virus to such CNS illnesses remains uncertain. Toxic shock syndrome associated with *S. aureus* or group A streptococcal infection following acute influenza infection has also been reported (Chaps. 120 and 121).

In addition to complications involving the specific organ systems described above, influenza outbreaks include a number of cases in which elderly and other high-risk individuals develop influenza and subsequently experience a gradual deterioration of underlying cardiovascular, pulmonary, or renal function—changes that occasionally are irreversible and lead to death. These fatalities contribute to the overall excess mortality associated with influenza A outbreaks.

LABORATORY FINDINGS AND DIAGNOSIS Influenza virus may be isolated during acute influenza from throat swabs, nasopharyngeal washes, or sputum. Virus is usually detected by use of tissue culture or, less commonly, chick embryos within 48 to 72 h after inoculation. Most commonly, the diagnosis is established by the use of rapid viral tests that detect viral nucleoprotein or neuraminidase with high sensitivity and a specificity of 60 to 90% compared with that of tissue culture. Viral nucleic acids can be detected in clinical samples by reverse transcriptase polymerase chain reaction. The type of influenza virus (A or B) may be determined by either immunofluorescence or HI techniques, and the hemagglutinin subtype of influenza A virus (H1, H2, or H3) may be identified by HI with use of subtype-specific antisera. Serologic methods for diagnosis require comparison of antibody titers in sera obtained during the acute illness with those in sera obtained 10 to 14 days after the onset of illness and are useful primarily in retrospect. Fourfold or greater titer rises as detected by HI or CF or significant rises as measured by ELISA are diagnostic of acute infection. CF tests are generally less sensitive than other serologic techniques, but, as they detect type-specific antigens, they may be particularly useful when subtype-specific reagents are not available.

Other laboratory tests are generally not helpful in making a specific diagnosis of influenza virus infection. Leukocyte counts are variable, frequently being low early in illness and normal or slightly elevated later. Severe leukopenia has been described in overwhelming viral or bacterial infection, while leukocytosis with $>15{,}000$ cells/μL raises the suspicion of secondary bacterial infection.

DIFFERENTIAL DIAGNOSIS During a community-wide outbreak of influenza, a clinical diagnosis of influenza can be made with a high degree of certainty in patients who present to a physician's office with the typical febrile respiratory illness described above. In the absence of an outbreak (i.e., in sporadic or isolated cases), influenza may be difficult to differentiate on clinical grounds alone from an acute respiratory illness caused by any of a variety of respiratory viruses or by *Mycoplasma pneumoniae*. Severe streptococcal pharyngitis or early bacterial pneumonia may mimic acute influenza, although bacterial pneumonias generally do not run a self-limited course. Purulent sputum in which a bacterial pathogen can be detected by Gram's staining is an important diagnostic feature in bacterial pneumonia.

Rx TREATMENT

In uncomplicated cases of influenza, symptom-based therapy with acetaminophen for the relief of headache, myalgia, and fever may be considered, but the use of salicylates should be avoided in children <18 years of age because of the possible association of salicylates with Reye's syndrome. Since cough is ordinarily self-limited, treatment with cough suppressants generally is not indicated, although codeine-containing compounds may be employed if the cough is particularly troublesome. Patients should be advised to rest and maintain hydration during acute illness and to return to full activity only gradually after illness has resolved, especially if it has been severe.

Specific antiviral therapy is available for influenza: amantadine and rimantadine for influenza A and the neuraminidase inhibitors zanamivir and oseltamivir for both influenza A and influenza B. If begun within 48 h of the onset of illness, treatment with amantadine or rimantadine has reduced the duration of systemic and respiratory symptoms of influenza by ~50%. From 5 to 10% of individuals who receive amantadine experience mild CNS side effects, primarily jitteriness, anxiety, insomnia, or difficulty in concentrating. These side effects disappear promptly upon cessation of the drug. Rimantadine appears to be equally efficacious and is associated with less frequent CNS side effects than is amantadine. In adults, the usual dose of amantadine or rimantadine is 200 mg/d for 3 to 7 days. Since both drugs are excreted via the kidney, the dose should be reduced to $\leq$100 mg/d in elderly patients and in patients with renal insufficiency. Zanamivir, inhaled orally at a dose of 10 mg twice a day for 5 days, or oseltamivir, ingested orally at a dose of 75 mg twice a day for 5 days, has reduced the duration of signs and symptoms of influenza by 1 to 1.5 days if treatment is started within 2 days of the onset of illness. Zanamivir may exacerbate bronchospasm in asthmatic patients, and oseltamivir

has been associated with nausea and vomiting, whose frequency can be reduced by drug administration with food. Resistant viruses emerge frequently during treatment with amantadine or rimantadine and can be transmitted among family members. The development of resistance appears to be infrequent with zanamivir or oseltamivir. Treatment of children is approved for amantadine and oseltamivir (≥1 year of age) and for zanamivir (≥7 years of age). Ribavirin is a nucleoside analogue with activity against influenza A and B viruses in vitro. It has been reported to be variably effective against influenza when administered as an aerosol but ineffective when administered orally. Its efficacy in the treatment of influenza A or B is unestablished.

Studies demonstrating the therapeutic efficacy of antiviral compounds in influenza have primarily involved young adults with uncomplicated disease; it is not known whether such compounds are effective in the treatment of influenza pneumonia or of other complications of influenza. Therapy for primary influenza pneumonia is directed at maintaining oxygenation and is most appropriately undertaken in an intensive care unit, with aggressive respiratory and hemodynamic support as needed. Bypass membrane oxygenators have been employed in this setting with variable results. When an acute respiratory distress syndrome develops, fluids must be administered cautiously, with close monitoring of blood gases and hemodynamic function.

Antibacterial drugs should be reserved for the treatment of bacterial complications of acute influenza, such as secondary bacterial pneumonia. The choice of antibiotics should be guided by Gram's staining and culture of appropriate specimens of respiratory secretions, such as sputum or transtracheal aspirates. If the etiology of a case of bacterial pneumonia is unclear from an examination of respiratory secretions, empirical antibiotics effective against the most common bacterial pathogens in this setting (*S. pneumoniae*, *S. aureus*, and *H. influenzae*) should be selected (Chaps. 119, 120, and 130).

PROPHYLAXIS The major public health measure for prevention of influenza has been the use of inactivated influenza vaccines derived from influenza A and B viruses that circulated during the previous influenza season. If the vaccine virus and the currently circulating viruses are closely related, 50 to 80% protection against influenza would be expected. Presently available inactivated vaccines have been highly purified and are associated with few reactions. Up to 5% of individuals experience low-grade fever and mild systemic symptoms 8 to 24 h after vaccination, and up to one-third develop mild redness or tenderness at the vaccination site. Since the vaccine is produced in eggs, individuals with true hypersensitivity to egg products either should be desensitized or should not be vaccinated. Although the 1976 swine influenza vaccine appears to have been associated with an increased frequency of Guillain-Barré syndrome, influenza vaccines administered since 1976 generally have not been. Possible exceptions were noted during the 1992–1993 and 1993–1994 influenza seasons, when there may have been an excess risk of Guillain-Barré syndrome of slightly more than one case per million among vaccine recipients. However, the overall health risk following influenza outweighs the potential risk associated with vaccination.

The U.S. Public Health Service recommends influenza vaccination for any individual >6 months of age who is at an increased risk for complications of influenza, as noted earlier (Table 171-2). Since commercially available vaccines are inactivated ("killed"), they may be administered safely to immunocompromised patients. Influenza vaccination is not associated with exacerbations of chronic nervous-system diseases such as multiple sclerosis. Vaccine should be administered early in the autumn before influenza outbreaks occur and should then be given annually to maintain immunity against the most current influenza virus strains.

Recently, an advisory committee of the U.S. Food and Drug Administration recommended approval of a live attenuated influenza vaccine that is administered by intranasal spray. The vaccine is generated by reassortment of currently circulating strains of influenza A and B virus with a cold-adapted, attenuated master strain. The cold-adapted vaccine is well tolerated and highly efficacious (92% protective) in young children; in one study, it provided protection against a circulating influenza virus that had drifted antigenically away from the vaccine strain. The committee recommended approval of the cold-adapted vaccine for use in healthy children and adults from 5 to 49 years of age.

Chemoprophylaxis with amantadine or rimantadine, at dosages of 100 to 200 mg/d, has efficacy rates of 70 to 100% against illness associated with influenza A infection. Chemoprophylaxis with oseltamivir (75 mg/d by mouth) or zanamivir (10 mg/d inhaled) has resulted in efficacy rates of 84 to 89% against influenza A and B. Chemoprophylaxis is most likely to be used for high-risk individuals who have not received influenza vaccine or in a situation where the vaccines previously administered are relatively ineffective because of antigenic changes in the circulating virus. During an outbreak, antiviral chemoprophylaxis can be administered simultaneously with inactivated vaccine, since the drugs do not interfere with an immune response to the vaccine. In fact, there is evidence that the protective effects of chemoprophylaxis and vaccine may be additive. However, concurrent administration of chemoprophylaxis and the live attenuated vaccine may interfere with the immune response to the latter. Chemoprophylaxis may also be employed to control nosocomial outbreaks of influenza. For prophylaxis, administration should be instituted promptly when influenza activity is detected and must be continued daily for the duration of the outbreak. Amantadine and rimantadine are approved for prophylaxis in adults and in children ≥1 year old; oseltamivir is approved for prophylaxis in adults and in children ≥13 years old.

TABLE 171-2 Recommendations for Influenza Vaccination[a]

Persons at increased risk for complications
Persons ≥65 years of age
Residents of nursing homes and other chronic-care facilities that house persons of any age who have chronic medical conditions
Adults and children (≥6 months) who have chronic disorders of the pulmonary or cardiovascular systems, including asthma
Adults and children (≥6 months) who have required regular medical follow-up or hospitalization during the preceding year because of chronic metabolic diseases (including diabetes mellitus), renal dysfunction, hemoglobinopathies, or immunosuppression (including immunosuppression caused by medications or by HIV)
Children and adolescents (6 months to 18 years old) who are receiving long-term aspirin therapy and therefore may be at risk for developing Reye's syndrome after influenza infection
Women who will be in the second or third trimester of pregnancy during the influenza season
Persons 50 to 64 years of age
Included because of increased prevalence of high-risk conditions
Persons who can transmit influenza to those at high risk
Physicians, nurses, and other personnel in both hospital and outpatient-care settings, including medical emergency response workers (e.g., paramedics and emergency medical technicians)
Employees of nursing homes and chronic-care facilities who have contact with patients or residents
Employees of assisted-living and other residences for persons in groups at high risk
Persons who provide home care to individuals in groups at high risk
Household members (including children) of persons in groups at high risk

[a] Vaccination of healthy children 6 to 23 months of age is encouraged.

Section 14 Infections Due to Human Immunodeficiency Virus and Other Human Retroviruses

172 THE HUMAN RETROVIRUSES

Dan L. Longo, Anthony S. Fauci

The retroviruses, which make up a large family (Retroviridae), infect mainly vertebrates. They have a unique replication cycle whereby their genetic information is encoded by RNA rather than DNA. Retroviruses contain an RNA-dependent DNA polymerase (a reverse transcriptase) that directs the synthesis of a DNA form of the viral genome after infection of a host cell. The designation *retrovirus* denotes that information in the form of RNA is transcribed into DNA in the host cell—a sequence that overturned a central dogma of molecular biology: that information passes unidirectionally from DNA to RNA to protein. The observation that RNA was the source of genetic information in the causative agents of certain animal tumors led to a number of paradigm-shifting biologic insights regarding not only the direction of genetic-information passage but also the viral etiology of certain cancers and the concept of oncogenes as normal host genes scavenged and altered by a viral vector.

The family Retroviridae includes three subfamilies (Table 172-1): Oncovirinae, of which human T-cell lymphotropic virus (HTLV) type I is the most important in humans; Lentivirinae, of which HIV is the most important in humans; and Spumavirinae, the "foamy" viruses, named for the pathologic appearance of infected cells. A number of spumaviruses have been isolated from humans; however, they are not associated with any known disease and therefore are not discussed further in this chapter.

The wide variety of interactions of a retrovirus with its host range from completely benign events (e.g., silent carriage of endogenous retroviral sequences in the germ-line genome of many animal species) to rapidly fatal infections (e.g., exogenous infection with an oncogenic virus such as Rous sarcoma virus in chickens). The ability of retroviruses to acquire and alter the structure and function of host cell sequences has revolutionized our understanding of molecular carcinogenesis. The viruses can insert into the germ-line genome of the host cell and behave as a transposable or movable genetic element. They can activate or inactivate genes near the site of integration into the genome. They can rapidly alter their own genome by recombination and mutation under selective environmental stimuli.

Most human viral diseases occur as a consequence of either tissue destruction by the virus itself or the host's response to the virus. Although these mechanisms are operative in retroviral infections, retroviruses have additional mechanisms of inducing disease, including the malignant transformation of an infected cell and the induction of an immunodeficiency state that leads to opportunistic diseases (infections and neoplasms; Chap. 173).

STRUCTURE AND LIFE CYCLE Despite the wide range of biologic consequences of retroviral infection, all retroviruses are similar in structure, genome organization, and mode of replication. Retroviruses are 70 to 130 nm in diameter and have a lipid-containing envelope surrounding an icosahedral capsid with a dense inner core. The core contains two identical copies of the single-strand RNA genome. The RNA molecules are 8 to 10 kb long and are complexed with reverse transcriptase and tRNA. Other viral proteins, such as integrase, are also components of the virion particle. The RNA has features usually found in mRNA: a cap site at the 5′ end of the molecule, which is important in the initiation of mRNA translation, and a polyadenylation site at the 3′ end, which influences mRNA turnover (i.e., messages with shorter polyA tails turn over faster than messages with longer polyA tails). However, the retroviral RNA is not translated; instead it is transcribed into DNA. The DNA form of the retroviral genome is called a *provirus*.

The replication cycle of retroviruses proceeds in two phases (Fig. 172-1). In the first phase, the virus enters the cytoplasm after binding to a specific cell-surface receptor (with HIV, a cell-surface co-receptor is also utilized for binding and entry); the viral RNA and reverse transcriptase synthesize a double-strand DNA version of the RNA template; and the provirus moves into the nucleus and integrates into the host cell genome. This proviral integration is permanent. Although some animal retroviruses integrate into a single specific site of the host

TABLE 172-1 *Classification of Retroviruses: the Family Retroviridae*

Subfamily, Group[a]	Example	Feature
Oncovirinae (oncogenic viruses)		
Avian leukosis	Rous sarcoma virus	Contains *src* oncogene
Mammalian C-type	Abelson leukemia virus	Contains *abl* oncogene
B-type	Murine mammary tumor virus	Can be endogenous or exogenous
D-type	Mason-Pfizer monkey virus	—
HTLV-BLV	HTLV-I	Causes T-cell lymphoma and neurologic disease
Lentivirinae (slow viruses)	HIV-1, HIV-2	Causes AIDS
	Visna virus	Causes lung and brain diseases in sheep
	Feline immunodeficiency virus	Causes immunodeficiency in cats
Spumavirinae (foamy viruses)	Simian foamy virus, human foamy virus	Causes no known disease

[a] The Oncovirinae were originally grouped into types A–D on the basis of morphologic features (size, core location, budding) under electron microscopy; however, this system has been replaced by groupings based on relationships of genome structure and sequence.

Note: HTLV, human T-lymphotropic virus; BLV, bovine leukemia virus.

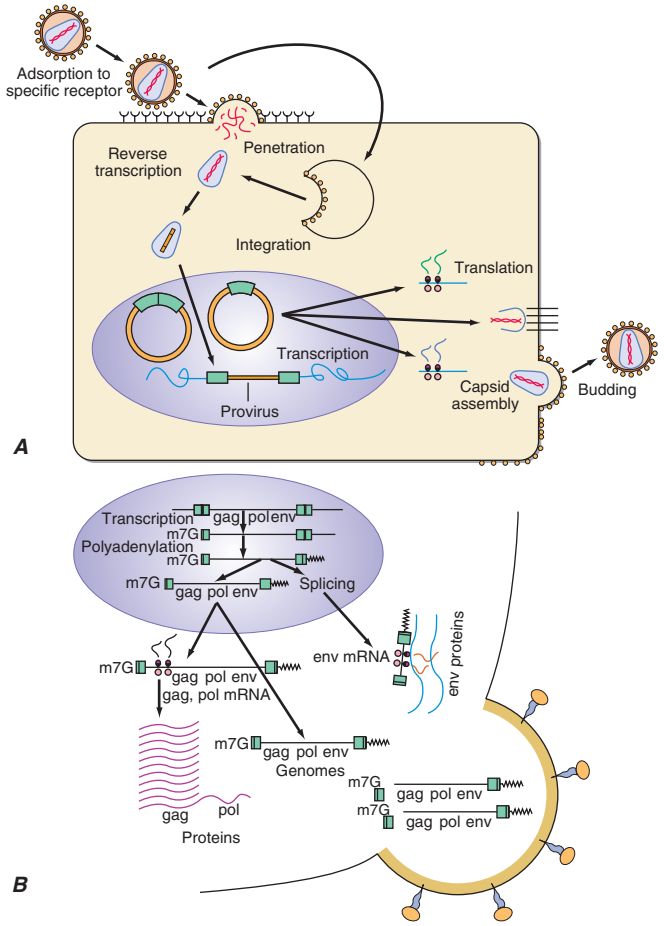

FIGURE 172-1 The life cycle of retroviruses. *A*. Overview of virus replication. The retrovirus enters a target cell by binding to a specific cell-surface receptor; once the virus is internalized, its RNA is released from the nucleocapsid and is reverse-transcribed into proviral DNA. The provirus is inserted into the genome and then transcribed into RNA; the RNA is translated; and virions assemble and are extruded from the cell membrane by budding. *B*. Overview of retroviral gene expression. The provirus is transcribed, capped, and polyadenylated. Viral RNA molecules then have one of three fates: They are exported to the cytoplasm, where they are packaged as the viral RNA in infectious viral particles; they are spliced to form the message for the envelope polyprotein; or they are translated into Gag and Pol proteins. Most of the messages for the Pol protein fail to initiate Pol translation because of a stop codon before its initiation; however, in a fraction of the messages, the stop codon is missed and the Pol proteins are translated. [*Modified from JM Coffin, in BN Fields, DM Knipe (eds): Fields Virology. New York, Raven, 1990, with permission.*]

genome in every infected cell, the four known human retroviruses (HTLV-I, HTLV-II, HIV-1, and HIV-2) integrate randomly. This first phase of replication depends entirely on gene products in the virus. The second phase includes the synthesis and processing of viral genomes, mRNAs, and proteins using host cell machinery, often under the influence of viral gene products. Virions are assembled and released from the cell by budding from the membrane; host cell membrane proteins are frequently incorporated into the envelope of the virus. Proviral integration occurs during the S-phase of the cell cycle; thus, in general, nondividing cells are resistant to retroviral infection. Only the lentiviruses are able to infect nondividing cells. Once a host cell is infected, it is infected for the life of the cell.

Retroviral genomes include both coding and noncoding sequences (Fig. 172-2). In general, noncoding sequences are important recognition signals for DNA or RNA synthesis or processing events and are located in the 5′ and 3′ terminal regions of the genome. All retroviral genomes are terminally redundant, containing identical sequences called *long terminal repeats* (LTRs). The ends of the retroviral RNA genome differ slightly in sequence from the integrated retroviral DNA. In the latter, the LTR sequences are repeated in both the 5′ and the 3′ terminus of the virus. The LTRs contain sequences involved in initiating the expression of the viral proteins, the integration of the provirus, and the polyadenylation of viral RNAs. The primer binding site, which is critical for the initiation of reverse transcription, and the viral packaging sequences are located outside the LTR sequences. The coding regions include the *gag* (group-specific antigen, core protein), *pol* (RNA-dependent DNA polymerase), and *env* (envelope) genes. The *gag* gene encodes a precursor polyprotein that is cleaved to form three to five capsid proteins; a fraction of the Gag precursor proteins also contain a protease responsible for cleaving the Gag and Pol polyproteins. A Gag-Pol polyprotein gives rise to the protease that is responsible for cleaving the Gag-Pol polyprotein. The *pol* gene encodes three proteins: the reverse transcriptase, the integrase, and the protease. The reverse transcriptase functions to copy the viral RNA into the double-strand DNA provirus, which can attach to the host cell DNA via the action of integrase. The protease functions to cleave the Gag-Pol polyprotein into smaller protein products. The *env* gene encodes the envelope glycoproteins: one protein that binds to specific surface receptors and determines what cell types can be infected and a smaller transmembrane protein that anchors the complex to the envelope. The cartoon in Fig. 172-3 shows how the retroviral gene products make up the virus structure.

HTLVs have a region between *env* and the 3′ LTR that encodes at least two proteins in overlapping reading frames: Tax, a 40-kDa protein that does not bind to DNA but induces the expression of host cell transcription factors that alter host cell gene expression; and Rex, a 27-kDa protein that regulates the expression of viral mRNAs. These two proteins are produced from messages that are similar but that are spliced differently from overlapping but distinct exons.

The lentiviruses in general, and HIV-1 and -2 in particular, contain a larger genome than other pathogenic retroviruses. They contain an untranslated region between *pol* and *env* that encodes portions of several proteins, varying with the reading frame into which the mRNA is spliced. Tat is a 14-kDa protein that augments the expression of virus from the LTR. The Rev protein of HIV-1, similar to the Rex protein of HTLV, regulates RNA splicing and/or RNA transport. The Nef protein downregulates CD4, the cellular receptor for HIV; alters host T cell activation pathways; and enhances viral infectivity. The Vif protein is necessary for the proper assembly of the HIV nucleoprotein core in many types of cells; without Vif, proviral DNA is not efficiently produced in these infected cells. Vpr, Vpu (HIV-1 only), and Vpx (HIV-2 only) are viral proteins encoded by translation of the same message in different reading frames. As noted above, oncogenic retroviruses depend on cell proliferation for their replication; lentiviruses can infect nondividing cells, largely owing to effects mediated by Vpr. Vpr facilitates transport of the provirus into the nucleus and can induce other cellular changes, such as G_2 growth arrest and differentiation of some target cells. Vpx is structurally related to Vpr, but its functions are not fully defined. Vpu promotes the degradation of CD4 in the endoplasmic reticulum and stimulates the release of virions from infected cells.

Retroviruses can be either exogenously acquired by infection with a virion capable of replication or transmitted in the germ line as endogenous virus. Endogenous retroviruses are often replication-defective. The human genome contains endogenous retroviral sequences, but there are no known replication-competent endogenous retroviruses in humans.

In general, viruses that contain only the *gag*, *pol*, and *env* genes either are not pathogenic or take a long time to induce disease; these observations indicate the importance of the other regulatory genes in viral disease pathogenesis. The pathogenesis of neoplastic transformation by retroviruses relies on the chance integration of the provirus at a spot in the genome that will result in the expression of a cellular gene (proto-oncogene) that becomes transforming by virtue of its unregulated expression. For example, avian leukosis virus causes B cell leukemia by inducing the expression of *myc*. Some retroviruses possess captured and altered cellular genes near their integration site, and these viral oncogenes are capable of transforming the infected host cell. Viruses that have oncogenes often have lost a portion of their

genome that is required for replication. Such viruses need helper viruses to reproduce, a feature that may explain why these acute transforming retroviruses are rare in nature. All human retroviruses identified to date are exogenous and are not acutely transforming (i.e., they lack a transforming oncogene).

These remarkable properties of retroviruses have led to experimental efforts to use them as vectors to insert specific genes into particular cell types, a process known as *gene therapy* or *gene transfer*. The process could be used to repair a genetic defect or to introduce a new property that could be used therapeutically; for example, a gene (e.g., thymidine kinase) that would make a tumor cell susceptible to killing by a drug (e.g., ganciclovir) could be inserted. One source of concern about the use of retroviral vectors in humans is that replication-competent viruses might rescue endogenous retroviral replication, with unpredictable results. This concern is not merely hypothetical: The detection of proteins encoded by endogenous retroviral sequences on the surface of cancer cells implies that the genetic events leading to the cancer were able to activate the synthesis of these usually silent genes.

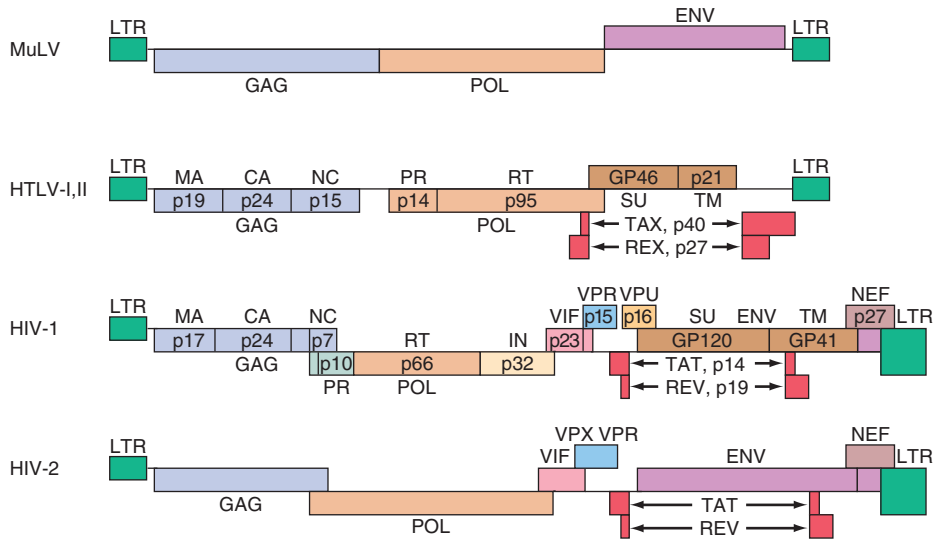

FIGURE 172-2 Genomic structure of retroviruses. The murine leukemia virus MuLV has the typical three structural genes: *gag*, *pol*, and *env*. The *gag* region gives rise to three proteins: matrix (MA), capsid (CA), and nucleic acid–binding (NC) proteins. The *pol* region encodes both a protease (PR) responsible for cleaving the viral polyproteins and a reverse transcriptase (RT). In addition, HIV *pol* encodes an integrase (IN). The *env* region encodes a surface protein (SU) and a small transmembrane protein (TM). The human retroviruses have additional gene products translated in each of the three possible reading frames. HTLV-I and HTLV-II have *tax* and *rex* genes with exons on either side of the *env* gene. HIV-1 and HIV-2 have six accessory gene products: *tat*, *rev*, *vif*, *nef*, *vpr*, and either *vpu* (in HIV-1) or *vpx* (in HIV-2). The genes for these proteins are located mainly between the *pol* and *env* genes.

HUMAN T-CELL LYMPHOTROPIC VIRUS

HTLV-I was isolated in 1980 from a T-cell lymphoma cell line from a patient originally thought to have cutaneous T cell lymphoma. Later it became clear that the patient had a distinct form of lymphoma (originally reported in Japan) called *adult T-cell leukemia/lymphoma* (ATL). Serologic data have determined that HTLV-I is the cause of at least two important diseases: ATL and tropical spastic paraparesis, also called *HTLV-I-associated myelopathy* (HAM). HTLV-I may also play a role in infective dermatitis and uveitis syndromes.

Two years after the isolation of HTLV-I, HTLV-II was isolated from a patient with an unusual form of hairy cell leukemia that affected T cells. Although early epidemiologic studies of HTLV-II failed to reveal a consistent disease association, more recent studies suggest an association of HTLV-II with human disease (see "Associated Diseases" under "Features of HTLV-II Infection," below), particularly among injection drug users.

BIOLOGY AND MOLECULAR BIOLOGY Because the biology of HTLV-I and that of HTLV-II are similar, the following discussion will focus on HTLV-I.

The cellular receptor for HTLV-I has not yet been identified, but it maps to chromosome 17. Generally, only T cells are productively infected, but infection of B cells and other cell types is occasionally detected. The most common outcome of HTLV-I infection is latent carriage of randomly integrated provirus in CD4+ T cells. HTLV-I does not contain an oncogene and does not insert into a unique site in the genome. Indeed, most infected cells express no viral gene products. The only viral gene product that is routinely expressed in tumor cells transformed by HTLV-I in vivo is *tax*, and even *tax* is not expressed in the tumor cells of many ATL patients. Cells transformed in vitro, by contrast, actively transcribe HTLV-I RNA and produce infectious virions. Most HTLV-I-transformed cell lines are the result of the infection of a normal host T cell in vitro. It is difficult to establish cell lines derived from authentic ATL cells.

Although *tax* does not itself bind to DNA, it does induce the expression of a wide range of host cell gene products, including transcription factors (especially c-*rel*, *ets*-1 and -2, and members of the *fos/jun* family), cytokines [e.g., interleukin (IL) 2, granulocyte-macrophage colony-stimulating factor, and tumor necrosis factor (TNF)], and membrane proteins and receptors [major histocompatibility (MHC) molecules and IL-2 receptor α]. The genes activated by *tax* are generally controlled by transcription factors of the c-*rel* and cyclic AMP response element binding (CREB) protein families. It is unclear how this induction of host gene expression leads to neoplastic transformation; *tax* can interfere with G_1 and mitotic cell-cycle checkpoints, block apoptosis, and promote antigen-independent T cell proliferation. Induction of a cytokine-autocrine loop has been proposed; however, IL-2 is not the crucial cytokine. The involvement of IL-4, IL-7, and IL-15 has been proposed.

In light of the irregular expression of *tax* in ATL cells, it has been suggested that *tax* is important in the early phases of transformation

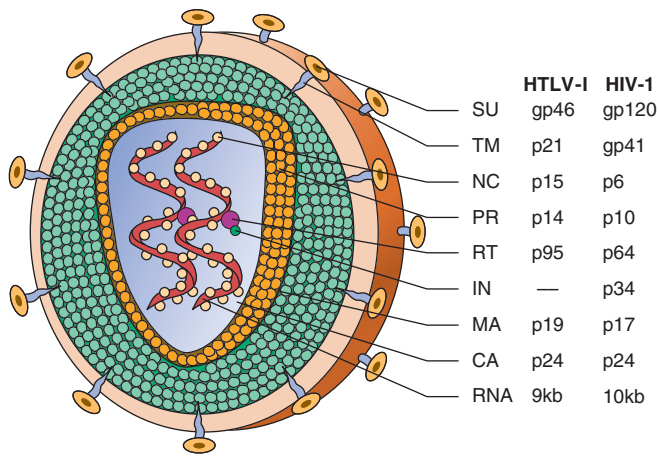

FIGURE 172-3 Schematic structure of human retroviruses. The surface glycoprotein (SU) is responsible for binding to receptors of host cells. The transmembrane protein (TM) anchors SU to the virus. NC is a nucleic acid–binding protein found in association with the viral RNA. A protease (PR) cleaves the polyproteins encoded by the *gag*, *pol*, and *env* genes into their functional components. RT is reverse transcriptase, and IN is an integrase present in some retroviruses (e.g., HIV-1) that facilitates insertion of the provirus into the host genome. MA is a Gag protein closely associated with the lipid of the envelope. The capsid protein (CA) forms the major internal structure of the virus, the core shell.

but is not essential for the maintenance of the transformed state. As is clear from the epidemiology of HTLV-I infection, transformation of an infected cell is a rare event and may depend on heterogeneous second, third, or fourth genetic hits. No consistent chromosomal abnormalities have been described in ATL; however, individual cases with p53 mutations and translocations involving the T cell receptor genes on chromosome 14 have been reported. *Tax* may repress certain DNA repair enzymes, permitting the accumulation of genetic damage that would normally be repaired. However, the molecular pathogenesis of HTLV-I-induced neoplasia is not fully understood.

FEATURES OF HTLV-I INFECTION ■ Epidemiology HTLV-I infection is transmitted in at least three ways: from mother to child, especially in breast milk; through sexual activity, more commonly from men to women; and through the blood—via contaminated transfusions or contaminated needles. The virus is most commonly transmitted perinatally. Compared with HIV, which can be transmitted in cell-free form, HTLV-I is less infectious, and its transmission usually requires cell-to-cell contact.

HTLV-I is endemic in southwestern Japan and Okinawa, where >1 million persons are infected. Antibodies to HTLV-I are present in the serum of up to 35% of Okinawans, 10% of residents of the Japanese island of Kyushu, and <1% of persons in nonendemic regions of Japan. Despite this high prevalence of infection, only ~500 cases of ATL are diagnosed in this area each year. Clusters of infection have been noted in other areas of the Orient, such as Taiwan; in the Caribbean basin, including northeastern South America; in central Africa; in Italy; in Israel; in the Arctic; and in the southeastern part of the United States.

A progressive spastic or ataxic myelopathy that develops in an individual who is HTLV-I positive (i.e., who has serum antibodies to HTLV-I) is likely to be due to direct nervous system infection with the virus; a similar disorder may result from infection with HIV or HTLV-II. In rare instances, patients with HAM are seronegative but have detectable antibody to HTLV-I in the cerebrospinal fluid (CSF).

The cumulative lifetime risk of developing ATL is 3% among HTLV-I-infected patients (the risk is three times greater in men than in women); a similar cumulative risk is projected for HAM. The distribution of the two diseases overlaps the distribution of HTLV-I, with >95% of affected patients showing serologic evidence of HTLV-I infection. The latent period between infection and the emergence of disease is 20 to 30 years for ATL. For HAM, the median latency period is ~3.3 years (range, 4 months to 30 years). The development of ATL is rare among persons infected by blood products; however, ~20% of patients with HAM acquire HTLV-I from contaminated blood.

Associated Diseases ■ *ATL* Four clinical types of HTLV-I-induced neoplasia have been described: acute, lymphomatous, chronic, and smoldering. All of these tumors are monoclonal proliferations of CD4+ post-thymic T cells with clonal proviral integrations and clonal T cell receptor gene rearrangements.

About 60% of patients who develop malignancy have classic acute ATL, which is characterized by a short clinical prodrome (~2 weeks between the first symptoms and the diagnosis) and an aggressive natural history (median survival period, 6 months). The clinical picture is dominated by rapidly progressive skin lesions, pulmonary involvement, hypercalcemia, and lymphocytosis with cells containing lobulated or "flower-shaped" nuclei (see Fig. 97-10). The malignant cells have monoclonal proviral integrations and express CD4, CD3, and CD25 (low-affinity IL-2 receptors) on their surface. Serum levels of CD25 can be used as a tumor marker. Anemia and thrombocytopenia are rare. The skin lesions may be difficult to distinguish from those in mycosis fungoides. Lytic bone lesions, which are common, do not contain tumor cells but rather are composed of osteolytic cells, usually without osteoblastic activity. Despite the leukemic picture, bone marrow involvement is patchy in most cases.

The hypercalcemia of ATL is multifactorial; the tumor cells produce osteoclast-activating factors (TNF-α, IL-1, lymphotoxin) and can also produce a parathyroid hormone–like molecule. Affected patients have an underlying immunodeficiency that makes them susceptible to opportunistic infections similar to those seen in patients with AIDS (Chap. 173). The pathogenesis of the immunodeficiency is unclear. Pulmonary infiltrates in ATL patients reflect leukemic infiltration half the time and opportunistic infections with organisms such as *Pneumocystis* and other fungi the other half. Gastrointestinal symptoms are nearly always related to opportunistic infection. *Strongyloides stercoralis* is a gastrointestinal parasitic infection that has a pattern of endemic distribution similar to that of HTLV-I. HTLV-I-infected persons also infected with the parasite may develop ATL more often or more rapidly than those without *Strongyloides* infections. Serum concentrations of lactate dehydrogenase (LDH) and alkaline phosphatase are often elevated. About 10% of patients have leptomeningeal involvement leading to weakness, altered mental status, paresthesia, and/or headache. Unlike other forms of central nervous system (CNS) lymphoma, ATL may be accompanied by normal CSF protein levels. The diagnosis depends on finding ATL cells in the CSF (Chap. 97).

The lymphomatous type of ATL occurs in ~20% of patients and is similar to the acute form in its natural history and clinical course, except that circulating abnormal cells are rare and lymphadenopathy is evident. The histology of the lymphoma is variable but does not influence the natural history. In general, the diagnosis is suspected on the basis of the patient's birthplace and the presence of skin lesions and hypercalcemia. The diagnosis is confirmed by the detection of antibodies to HTLV-I in serum.

Patients with the chronic form of ATL generally have normal serum levels of calcium and LDH and no involvement of the CNS, bone, or gastrointestinal tract. The median duration of survival for these patients is 2 years. In some cases, chronic ATL progresses to the acute form of the disease.

Fewer than 5% of patients have the smoldering form of ATL. In this form, the malignant cells have monoclonal proviral integration; <5% of peripheral blood cells exhibit typical morphologic abnormalities; hypercalcemia, adenopathy, and hepatosplenomegaly do not develop; the CNS, the bones, and the gastrointestinal tract are not involved; and skin and pulmonary lesions may be present. The median survival period of this small subset of patients appears to be ≥5 years.

HAM (TROPICAL SPASTIC PARAPARESIS) In contrast to ATL, in which there is a slight predominance of male patients, HAM affects females disproportionately. HAM resembles multiple sclerosis in certain ways (Chap. 359). The onset is insidious. Symptoms include weakness or stiffness in one or both legs, back pain, and urinary incontinence. Sensory changes are usually mild, but peripheral neuropathy may develop. The disease generally takes the form of slowly progressive and unremitting thoracic myelopathy; one-third of patients are bedridden within 10 years of diagnosis, and one-half are unable to walk unassisted by this point. Patients display spastic paraparesis or paraplegia with hyperreflexia, ankle clonus, and extensor plantar responses. Cognitive function is usually spared; cranial nerve abnormalities are unusual.

Magnetic resonance imaging (MRI) reveals lesions in both the white matter and the paraventricular regions of the brain as well as in the spinal cord. Pathologic examination of the spinal cord shows symmetric degeneration of the lateral columns, including the corticospinal tracts; some cases involve the posterior columns as well. The spinal meninges and cord parenchyma contain an inflammatory infiltrate with myelin destruction.

HTLV-I is not usually found in cells of the CNS but may be detected in a small population of lymphocytes present in the CSF. In general, HTLV-I replication is greater in HAM than in ATL, and patients with HAM have a stronger immune response to the virus. Antibodies to HTLV-I are present in the serum and appear to be produced

in the CSF of HAM patients, where titers are often higher than in the serum. The pathophysiology of HAM may involve the induction of autoimmune destruction of neural cells by T cells with specificity for viral components such as Tax or Env proteins. One theory is that susceptibility to HAM may be related to the presence of human leukocyte antigen (HLA) alleles capable of presenting viral antigens in a fashion that leads to autoimmunity. Insufficient data are available to confirm an HLA association.

It is unclear what factors influence whether HTLV-I infection will cause disease and, if it does, whether it will induce a neoplasm (ATL) or an autoimmune disorder (HAM). Differences in viral strains, in the susceptibility of particular MHC haplotypes, in the route of HTLV-I infection, in the viral load, and in the nature of the HTLV-I-related immune response are putative factors, but few definitive data are available.

OTHER PUTATIVE HTLV-I-RELATED DISEASES In areas where HTLV-I is endemic, diverse inflammatory and autoimmune diseases have been attributed to the virus, including uveitis, dermatitis, pneumonitis, rheumatoid arthritis, and polymyositis. However, a causal relationship between HTLV-I and these illnesses has not been rigorously established.

Prevention Women in endemic areas should not breast-feed their children, and blood donors should be screened for serum antibodies to HTLV-I. As in the prevention of HIV infection, the practice of safe sex and the avoidance of needle sharing are important.

℞ TREATMENT

For the small number of patients who develop HTLV-I-related disease, therapies are not curative. In patients with the acute and lymphomatous types of ATL, the disease progresses rapidly. Hypercalcemia is generally controlled by glucocorticoid administration and cytotoxic therapy directed against the neoplasm. The tumor is highly responsive to combination chemotherapy that is employed against other forms of lymphoma; however, patients are susceptible to overwhelming bacterial and opportunistic infections, and ATL relapses within 4 to 10 months after remission in most patients. The combination of interferon α and zidovudine may extend survival. Because viral replication is not clearly associated with ATL progression, zidovudine is probably effective through its cytotoxic effects (as a chain-terminating thymidine analogue) rather than its antiviral effects. An experimental approach using an yttrium 90–labeled or toxin-conjugated antibody to the IL-2 receptor appears promising but is not widely available. Patients with the chronic or smoldering form of ATL may be managed with an expectant approach: Treat any infections, and watch and wait for signs of progression to acute disease.

Patients with HAM may obtain some benefit from the use of glucocorticoids to reduce inflammation. Antiretroviral regimens have not been effective. In one study, danazol (200 mg three times daily) produced significant neurologic improvement in five of six treated patients, with resolution of urinary incontinence in two cases, decreased spasticity in three, and restoration of the ability to walk after confinement to a wheelchair in two. Physical therapy and rehabilitation are important components of management.

FEATURES OF HTLV-II INFECTION ■ Epidemiology HTLV-II is endemic in certain Native American tribes and in Africa. It is generally considered to be a New World virus that was brought from Asia to the Americas 10,000 to 40,000 years ago during the migration of infected populations across the Bering land bridge.

The mode of transmission of HTLV-II is probably the same as that of HTLV-I (see above). HTLV-II may be less readily transmitted sexually than HTLV-I.

Studies of large cohorts of injection drug users with serologic assays that reliably distinguish HTLV-I from HTLV-II indicate that the vast majority of HTLV-positive subjects are infected with HTLV-II. The seroprevalence of HTLV in a cohort of 7841 injection drug users from drug treatment centers in Baltimore, Chicago, Los Angeles, New Jersey (Asbury Park and Trenton), New York City (Brooklyn and Harlem), Philadelphia, and San Antonio was 20.9%, with >97% of cases due to HTLV-II. The seroprevalence of HTLV-II was higher in the Southwest and the Midwest than in the Northeast. In contrast, the seroprevalence of HIV-1 was higher in the Northeast than in the Southwest or the Midwest. Approximately 3% of the cohort members were infected with both HTLV-II and HIV-1. The seroprevalence of HTLV-II increased linearly with age. Women were significantly more likely to be infected with HTLV-II than were men; the virus is thought to be more efficiently transmitted from male to female than from female to male.

Associated Diseases Although HTLV-II was isolated from a patient with a T cell variant of hairy cell leukemia, this virus has not been consistently associated with a particular disease and in fact has been thought of as "a virus searching for a disease." However, evidence is accumulating that HTLV-II may play a role in certain neurologic, hematologic, and dermatologic diseases. These data require confirmation, particularly in light of the previous confusion regarding the relative prevalences of HTLV-I and HTLV-II among injection drug users.

Prevention Avoidance of needle sharing, safe-sex practices, screening of blood (by assays for HTLV-I, which also detect HTLV-II), and avoidance of breast-feeding by infected women are important principles in the prevention of spread of HTLV-II.

HUMAN IMMUNODEFICIENCY VIRUS

HIV-1 and HIV-2 are members of the lentivirus subfamily of Retroviridae and are the only lentiviruses known to infect humans. The lentiviruses are slow-acting by comparison with viruses that cause acute infection (e.g., influenza virus) but not by comparison with other retroviruses. The features of acute primary infection with HIV resemble those of more classic acute infections. The characteristic chronicity of HIV disease is consistent with the designation lentivirus. →***For a detailed discussion of HIV, see Chap. 173.***

173 HUMAN IMMUNODEFICIENCY VIRUS DISEASE: AIDS AND RELATED DISORDERS

Anthony S. Fauci, H. Clifford Lane

AIDS was first recognized in the United States in the summer of 1981, when the U.S. Centers for Disease Control and Prevention (CDC) reported the unexplained occurrence of *Pneumocystis carinii* pneumonia in five previously healthy homosexual men in Los Angeles and of Kaposi's sarcoma (KS) in 26 previously healthy homosexual men in New York and Los Angeles. Within months, the disease became recognized in male and female injection drug users (IDUs) and soon thereafter in recipients of blood transfusions and in hemophiliacs. As the epidemiologic pattern of the disease unfolded, it became clear that a microbe transmissible by sexual (homosexual and heterosexual) contact and blood or blood products was the most likely etiologic agent of the epidemic.

In 1983, human immunodeficiency virus (HIV) was isolated from a patient with lymphadenopathy, and by 1984 it was demonstrated clearly to be the causative agent of AIDS. In 1985, a sensitive enzyme-linked immunosorbent assay (ELISA) was developed, which led to an appreciation of the scope and evolution of the HIV epidemic at first in the United States and other developed nations and ultimately among developing nations throughout the world (see below). The staggering worldwide growth of the HIV pandemic has been matched by an explosion of information in the areas of HIV virology, pathogenesis (both immunologic and virologic) and treatment of HIV disease, treatment and prophylaxis of the opportunistic diseases associated with HIV infection, and vaccine development. The information flow related to HIV disease is enormous and continues to expand, and it has become almost impossible for the health care generalist to stay abreast of the literature. The purpose of this chapter is to present the most current information available on the scope of the epidemic; on its pathogenesis, treatment, and prevention; and on prospects for vaccine development. Above all, the aim is to provide a solid scientific basis and practical clinical guidelines for a state-of-the-art approach to the HIV-infected patient.

DEFINITION With the identification of HIV in 1983 and its proof as the etiologic agent of AIDS in 1984, and with the availability of sensitive and specific diagnostic tests for HIV infection, the case definition of AIDS has undergone several revisions over the years. The current CDC classification system for HIV-infected adolescents and adults categorizes persons on the basis of clinical conditions associated with HIV infection and CD4+ T lymphocyte counts. The system is based on three ranges of CD4+ T lymphocyte counts and three clinical categories and is represented by a matrix of nine mutually exclusive categories (Tables 173-1 and 173-2). Using this system, any HIV-infected individual with a CD4+ T cell count of $<200/\mu L$ has AIDS by definition, regardless of the presence of symptoms or opportunistic diseases (Table 173-1). Once individuals have had a clinical condition in category B, their disease cannot again be classified as category A, even if the condition resolves; the same holds true for category C in relation to category B.

TABLE 173-1 *1993 Revised Classification System for HIV Infection and Expanded AIDS Surveillance Case Definition for Adolescents and Adults*[a]

CD4+ T Cell Categories	Clinical Categories		
	A Asymptomatic, Acute (Primary) HIV or PGL[b]	B Symptomatic, Not A or C Conditions	C AIDS-Indicator Conditions
>500/μL	A1	B1	C1
200–499/μL	A2	B2	C2
<200/μL	A3	B3	C3

[a] The shaded areas indicate the expanded AIDS surveillance case definition.
[b] PGL, progressive generalized lymphadenopathy.
Source: MMWR 42(No. RR-17), December 18, 1992.

The definition of AIDS is indeed complex and comprehensive; however, the clinician should not focus on whether AIDS is present but should view HIV disease as a spectrum ranging from primary infection, with or without the acute syndrome, to the asymptomatic stage, to advanced disease (see below). The definition of AIDS was established not for the practical care of patients but for surveillance purposes.

TABLE 173-2 *Clinical Categories of HIV Infection*

Category A: Consists of one or more of the conditions listed below in an adolescent or adult (>13 years) with documented HIV infection. Conditions listed in categories B and C must not have occurred.
- Asymptomatic HIV infection
- Persistent generalized lymphadenopathy
- Acute (primary) HIV infection with accompanying illness or history of acute HIV infection

Category B: Consists of symptomatic conditions in an HIV-infected adolescent or adult that are not included among conditions listed in clinical category C and that meet at least one of the following criteria: (1) The conditions are attributed to HIV infection or are indicative of a defect in cell-mediated immunity; or (2) the conditions are considered by physicians to have a clinical course or to require management that is complicated by HIV infection. Examples include, but are not limited to, the following:
- Bacillary angiomatosis
- Candidiasis, oropharyngeal (thrush)
- Candidiasis, vulvovaginal; persistent, frequent, or poorly responsive to therapy
- Cervical dysplasia (moderate or severe)/cervical carcinoma in situ
- Constitutional symptoms, such as fever (38.5°C) or diarrhea lasting >1 month
- Hairy leukoplakia, oral
- Herpes zoster (shingles), involving at least two distinct episodes or more than one dermatome
- Idiopathic thrombocytopenic purpura
- Listeriosis
- Pelvic inflammatory disease, particularly if complicated by tuboovarian abscess
- Peripheral neuropathy

Category C: Conditions listed in the AIDS surveillance case definition.
- Candidiasis of bronchi, trachea, or lungs
- Candidiasis, esophageal
- Cervical cancer, invasive[a]
- Coccidioidomycosis, disseminated or extrapulmonary
- Cryptococcosis, extrapulmonary
- Cryptosporidiosis, chronic intestinal (>1 month's duration)
- Cytomegalovirus disease (other than liver, spleen, or nodes)
- Cytomegalovirus retinitis (with loss of vision)
- Encephalopathy, HIV-related
- Herpes simplex: chronic ulcer(s) (>1 month's duration); or bronchitis, pneumonia, or esophagitis
- Histoplasmosis, disseminated or extrapulmonary
- Isosporiasis, chronic intestinal (>1 month's duration)
- Kaposi's sarcoma
- Lymphoma, Burkitt's (or equivalent term)
- Lymphoma, primary, of brain
- *Mycobacterium avium* complex or *M. kansasii*, disseminated or extrapulmonary
- *Mycobacterium tuberculosis*, any site (pulmonary[a] or extrapulmonary)
- *Mycobacterium*, other species or unidentified species, disseminated or extrapulmonary
- *Pneumocystis carinii* pneumonia
- Pneumonia, recurrent[a]
- Progressive multifocal leukoencephalopathy
- *Salmonella* septicemia, recurrent
- Toxoplasmosis of brain
- Wasting syndrome due to HIV

[a] Added in the 1993 expansion of the AIDS surveillance case definition.

ETIOLOGIC AGENT

The etiologic agent of AIDS is HIV, which belongs to the family of human retroviruses (Retroviridae) and the subfamily of lentiviruses (Chap. 172). Nononcogenic lentiviruses cause disease in other animal species, including sheep, horses, goats, cattle, cats, and monkeys. The four recognized human retroviruses belong to two distinct groups: the human T lymphotropic viruses (HTLV) I and HTLV-II, which are transforming retroviruses; and the human immunodeficiency viruses, HIV-1 and HIV-2, which are cytopathic viruses (Chap. 172). The most common cause of HIV disease throughout the world, and certainly in the United States, is HIV-1, which comprises several subtypes with different geographic distributions (see below). HIV-2 was first identified in 1986 in West African patients and was originally confined to West Africa. However, a number of cases that can be traced to West Africa or to sexual contacts with West Africans have been identified throughout the world. Both HIV-1 and HIV-2 are zoonotic infections. HIV-2 is more closely related phylogenetically to the simian immunodeficiency virus (SIV) found in sooty mangabeys than it is to HIV-1. HIV-1 likely originated from the *Pan troglodytes troglodytes* species of chimpanzees in whom the virus had co-evolved over centuries. The taxonomic relationship among primate lentiviruses is shown in Fig. 173-1.

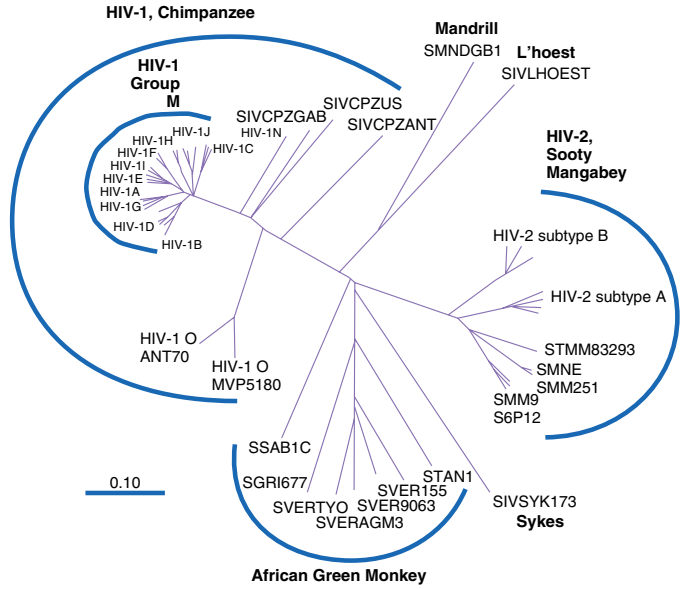

FIGURE 173-1 A phylogenetic tree, based on the complete genomes of primate immunodeficiency viruses. The scale at the bottom (0.10) indicates a 10% difference at the nucleotide level. (*Prepared by Brian Foley, PhD, of the HIV Sequence Database, Theoretical Biology and Biophysics Group, Los Alamos National Laboratory.*)

MORPHOLOGY OF HIV Electron microscopy shows that the HIV virion is an icosahedral structure (Fig. 173-2*A*) containing numerous external spikes formed by the two major envelope proteins, the external gp120 and the transmembrane gp41. The virion buds from the surface of the infected cell and incorporates a variety of host proteins, including major histocompatibility complex (MHC) class I and II antigens (Chap. 296), into its lipid bilayer. The structure of HIV-1 is schematically diagrammed in Fig. 173-2*B* (Chap. 172).

REPLICATION CYCLE OF HIV HIV is an RNA virus whose hallmark is the reverse transcription of its genomic RNA to DNA by the enzyme *reverse transcriptase*. The replication cycle of HIV begins with the high-affinity binding of the gp120 protein via a portion of its V1 region near the N terminus to its receptor on the host cell surface, the CD4 molecule (Fig. 173-3). The CD4 molecule is a 55-kDa protein found predominantly on a subset of T lymphocytes that are responsible for helper or inducer function in the immune sys tem (Chap. 295). It is also expressed on the surface of monocytes/macrophages and dendritic/Langerhans cells. Once gp120 binds to CD4, the gp120 undergoes a conformational change that facilitates binding to one of a group of co-receptors. The two major co-receptors for HIV-1 are CCR5 and CXCR4. Both receptors belong to the family of seven-transmembrane-domain G protein–coupled cellular receptors, and the use of one or the other or both receptors by the virus for entry into the cell is an important determinant of the cellular tropism of the virus (see below for details). Certain dendritic cells express a diversity of C-type lectin receptors on their surface, one of which is called *DC-SIGN*, that bind with high affinity to the HIV gp120 envelope protein, allowing the dendritic cell to facilitate the binding of virus to the CD4+ T cell upon engagement of dendritic cells with CD4+ T cells. Following binding of the envelope protein to the CD4 molecule, the conformation of the viral envelope changes dramatically, and fusion with the host cell membrane occurs via the newly exposed gp41 molecule penetrating the plasma membrane of the target cell and then coiling upon itself to bring the virion and target cell together. Following fusion (Fig. 173-4), the HIV genomic RNA is uncoated and internalized into the target cell (Fig. 173-3). The reverse transcriptase enzyme, which is contained in the infecting virion, then catalyzes the reverse transcription of the genomic RNA into double-strand DNA. The DNA translocates to the nucleus, where it is integrated in a somewhat, but not completely, random fashion into the host cell chromosomes through the action of another virally encoded enzyme, *integrase*. Sites of HIV integration into the nuclear DNA are preferential for active genes and regional hotspots. This provirus may remain transcriptionally inactive (latent) or it may manifest varying levels of gene expression, up to active production of virus.

Cellular activation plays an important role in the life cycle of HIV and is critical to the pathogenesis of HIV disease (see below). Following initial binding and internalization of virions into the target cell, incompletely reverse-transcribed DNA intermediates are labile in quiescent cells and will not integrate efficiently into the host cell genome

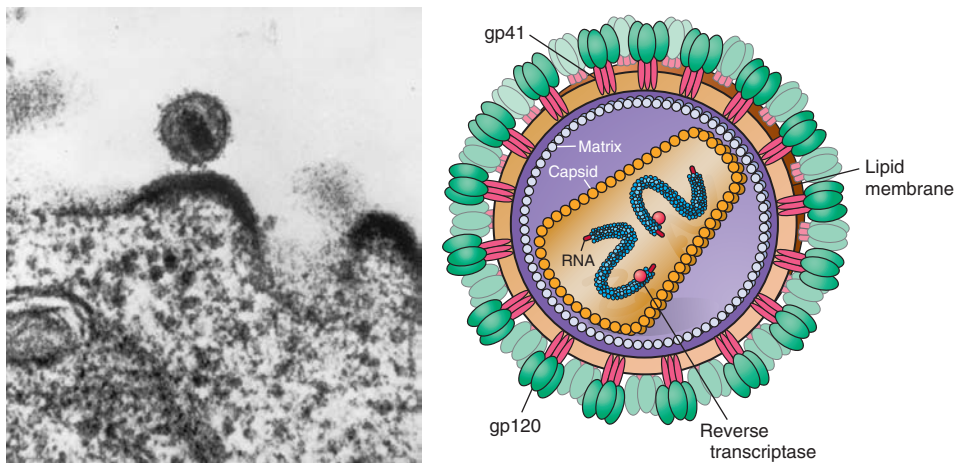

FIGURE 173-2 *A*. Electron micrograph of HIV. Figure illustrates a typical virion following budding from the surface of a CD4+ T lymphocyte, together with two additional incomplete virions in the process of budding from the cell membrane. *B*. Structure of HIV-1, including the gp120 outer membrane, gp41 transmembrane components of the envelope, genomic RNA, enzyme reverse transcriptase, p18(17) inner membrane (matrix), and p24 core protein (capsid) (copyright by George V. Kelvin). (*Adapted from RC Gallo: Sci Am 256:46, 1987.*)

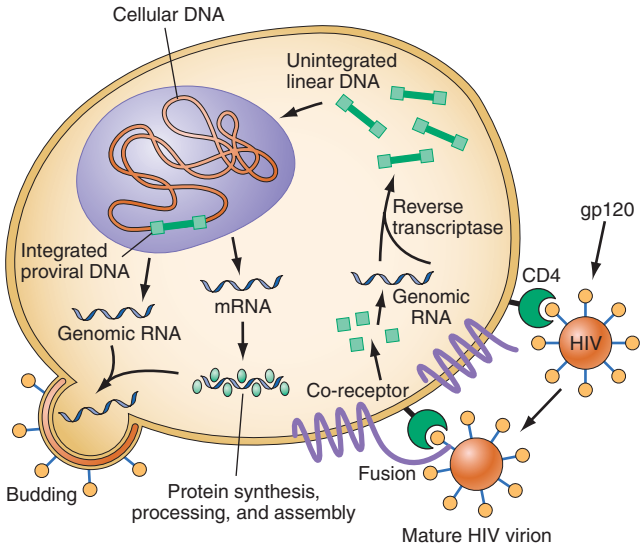

FIGURE 173-3 The replication cycle of HIV. See text for description. (*Adapted from Fauci, 1996.*)

unless cellular activation occurs shortly after infection. Furthermore, some degree of activation of the host cell is required for the initiation of transcription of the integrated proviral DNA into either genomic RNA or mRNA. This latter process may not necessarily be associated with the obvious expression of the classic cell surface markers of activation. In this regard, activation of HIV expression from the latent state depends on the interaction of a number of cellular and viral factors. Following transcription, HIV mRNA is translated into proteins that undergo modification through glycosylation, myristylation, phosphorylation, and cleavage. The viral particle is formed by the assembly of HIV proteins, enzymes, and genomic RNA at the plasma membrane of the cells. Budding of the progeny virion occurs through specialized regions in the lipid bilayer of the host cell membrane known as *lipid rafts*, where the core acquires its external envelope (Chap. 172). The virally encoded protease then catalyzes the cleavage of the gag-pol precursor (see below) to yield the mature virion. Progression through the virus replication cycle is profoundly influenced by a variety of viral regulatory gene products. Likewise, each point in the replication cycle of HIV is a real or potential target for therapeutic intervention (see below). Thus far, the reverse transcriptase and protease enzymes have proven clinically to be susceptible to pharmacologic disruption (see below). Recently, inhibitors of virus–target cell fusion have shown therapeutic promise, and inhibitors of the viral enzyme integrase are in clinical trials.

HIV GENOME Figure 173-5 illustrates the arrangement of the HIV genome schematically. Like other retroviruses, HIV-1 has genes that encode the structural proteins of the virus: *gag* encodes the proteins that form the core of the virion (including p24 antigen); *pol* encodes the enzymes responsible for reverse transcription and integration; and *env* encodes the envelope glycoproteins. However, HIV-1 is more complex than other retroviruses, particularly those of the nonprimate group, in that it also contains at least six other genes (*tat*, *rev*, *nef*, *vif*, *vpr*, and *vpu*), which code for proteins involved in the regulation of gene expression (Chap. 172). Several of these proteins are felt to play a role in the pathogenesis of HIV disease; their various functions are listed in Fig. 173-5. Flanking these genes are the long terminal repeats (LTRs), which contain regulatory elements involved in gene expression (Fig. 173-5). The major difference between the genomes of HIV-1 and HIV-2 is the fact that HIV-2 lacks the *vpu* gene and has a *vpx* gene not contained in HIV-1.

MOLECULAR HETEROGENEITY OF HIV-1 Molecular analyses of various HIV isolates reveal sequence variations over many parts of the viral genome. For example, in different isolates, the degree of difference in the coding sequences of the viral envelope protein ranges from a few percent (very close) to 50%. These changes tend to cluster in hypervariable regions. HIV can evolve by several means, including simple base substitution, insertions and deletions, recombination, and gain and loss of glycosylation sites. The balance of immune pressure and functional constraints on proteins influences the regional level of variation within proteins. For example, Envelope, which is exposed on the surface of the virion and is under immune selective pressure from both antibodies and cytolytic T lymphocytes, is extremely variable, with clusters of mutations in hypervariable domains. In contrast, Reverse Transcriptase, with important enzymatic functions, is relatively conserved, particularly around the active site. The extraordinary variability of HIV-1 is in marked contrast to the relative stability of HTLV-I and -II.

There are three groups of HIV-1: group M (major), which is responsible for most of the infections in the world; group O (outlier), a relatively rare viral form found originally in Cameroon, Gabon, and France; and group N first identified in a Cameroonian woman with AIDS; only a few cases of the latter have been identified. Among primate lentiviruses, HIV-1 is most closely related to viruses isolated from chimpanzees. The M group comprises nine subtypes, or *clades*, designated A, B, C, D, F, G, H, J, and K, as well as a growing number of major circulating recombinant forms (CRFs). These CRFs range from highly prelavent forms such as the AE virus, CRF 01, which is predominant in southeast Asia and often referred to simply as E, despite the fact that the parental E virus has never been found, and AG from west and central Africa, to a large number of CRFs that are more or less rare. The subtypes and CRFs create the major lineages of the M group of HIV-1. The picture has been complicated somewhat when it was found that some subtypes are not equidistant from one another, while others contained sequences so diverse that they could not properly be considered to be the same subtype. Thus, the sub-subtype was introduced, and subtypes A and F are now subdivided into A1 and A2, F1 and F2. It has also been argued that subtypes B and D are really too close to be separate subtypes and should be considered sub-subtypes; it was decided, however, not to increase the confusion by renaming the clades (Fig. 173-6).

The global patterns of HIV-1 variation likely result from accidents of viral trafficking. Subtype B viruses, which now differ by up to 17% in their *env* coding sequences, are the overwhelmingly predominant viruses seen in the United States, Canada, certain countries in South America, western Europe, and Australia. Other subtypes are also present in these countries to varying degrees. It is thought that, purely by chance, subtype B was seeded into the United States in the late 1970s, thereby establishing an overwhelming founder effect. Subtype C viruses (of the M group) are the most common form worldwide; many countries have cocirculating viral subtypes that are giving rise

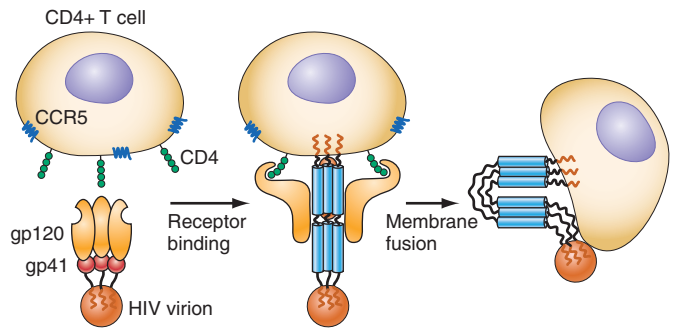

FIGURE 173-4 Binding and fusion of HIV-1 with its target cell. HIV-1 binds to its target cell via the CD4 molecule, leading to a conformational change in the gp120 molecule that allows it to bind to the co-receptor CCR5 (for R5-using viruses). The virus then firmly attaches to the host cell membrane in a coiled-spring fashion via the newly exposed gp41 molecule. Virus-cell fusion occurs as the transitional intermediate of gp41 undergoes further changes to form a hairpin structure that draws the two membranes into close proximity (see text for details). to CRFs. Figure 173-7 schematically diagrams the worldwide distribution of HIV-1 subtypes by region. The predominant subtype in Europe and the Americas is subtype B. In Africa, >75% of strains recovered to date have been of subtypes A, C, and D, with C being the most common. In Asia, HIV-1 isolates of the CRF01 (AE) lineage and subtypes C and B predominate. CRF01 (AE) accounts for most infections in southeast Asia, while subtype C is prevalent in India (see "HIV Infection and AIDS Worldwide," below). Sequence analyses of HIV-1 isolates from infected individuals indicate that recombination among viruses of different clades likely occurs as a result of infection of an individual with viruses of more than one subtype, particularly in geographic areas where subtypes overlap.

TRANSMISSION

HIV is transmitted by both homosexual and heterosexual contact; by blood and blood products; and by infected mothers to infants either intrapartum, perinatally, or via breast milk. After >20 years of scrutiny, there is no evidence that HIV is transmitted by casual contact or that the virus can be spread by insects, such as by a mosquito bite.

SEXUAL TRANSMISSION HIV infection is predominantly a sexually transmitted disease (STD) worldwide. Although in the United States ~42% of new HIV infections are among men who have sex with men and ~33% of new HIV infections are by heterosexual transmission, the most common mode of infection worldwide, particularly in developing countries, is clearly heterosexual transmission. Furthermore, the yearly incidence of new cases of AIDS attributed to heterosexual transmission of HIV is steadily increasing in the United States, mainly among minorities, particularly women in minority groups (Fig. 173-8).

HIV has been demonstrated in seminal fluid both within infected mononuclear cells and in the cell-free state. The virus appears to concentrate in the seminal fluid, particularly in situations where there are increased numbers of lymphocytes and monocytes in the fluid, as in genital inflammatory states such as urethritis and epididymitis, conditions closely associated with other STDs (see below). The virus has also been demonstrated in cervical smears and vaginal fluid. There is a strong association of transmission of HIV with receptive anal intercourse, probably because only a thin, fragile rectal mucosal membrane separates the deposited semen from potentially susceptible cells in and beneath the mucosa and trauma may be associated with anal intercourse. Anal douching and sexual practices that traumatize the rectal mucosa also increase the likelihood of infection. It is likely that anal intercourse provides at least two modalities of infection: (1) direct inoculation into blood in cases of traumatic tears in the mucosa; and (2) infection of susceptible target cells, such as Langerhans cells, in the mucosal layer in the absence of trauma (see below). Although the vaginal mucosa is several layers thicker than the rectal mucosa and less likely to be traumatized during intercourse, it is clear that the virus can be transmitted to either partner through vaginal intercourse. In a 10-year prospective study in the United States of heterosexual transmission of HIV, male-to-female transmission was approximately eight times more efficient than female-to-male transmission. This difference may be due in part to the prolonged exposure to infected seminal fluid of the vaginal and cervical mucosa, as well as the endometrium (when

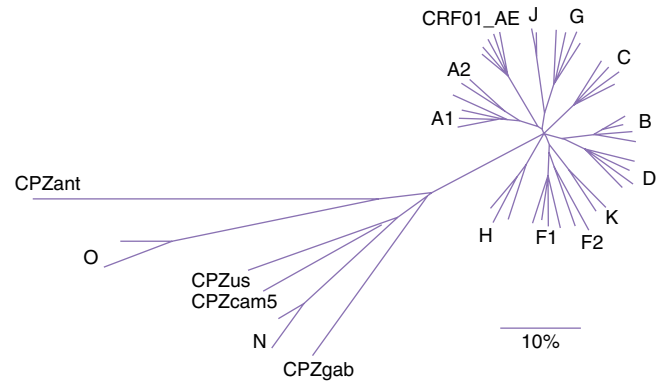

FIGURE 173-6 Phylogenetic tree constructed from representative viral envelope sequences of the subtypes and circulating recombinant forms (CRFs) in group M and some isolates from groups N and O (human) and CPZ (chimpanzee). The scale bar at the bottom indicates the genetic distances between the sequences. A1 and A2, F1 and F2 are subtypes; CRF01_AE is unique in the envelope gene, but similar to subtype A in the rest of the genome. FIGURE 173-7 Geographic distribution of HIV-1 subtypes, 2001. The prevalence of HIV-1 genetic subtypes varies by geographic region. The proportions of subtypes in different regions are indicated by pie charts. (*From S Osmanov et al: J Acquir Imm Def Syndr 29:184, 2002.*)

semen enters through the cervical os). By comparison, the penis and urethral orifice are exposed relatively briefly to infected vaginal fluid. Among various cofactors examined in this study, a history of STDs (see below) was most strongly associated with HIV transmission. In this regard, there is a close association between genital ulcerations and transmission, from the standpoints of both susceptibility to infection and infectivity. Infections with microorganisms such as *Treponema pallidum* (Chap. 153), *Haemophilus ducreyi* (Chap. 130), and herpes simplex virus (HSV; Chap. 163) are important causes of genital ulcerations linked to transmission of HIV. In addition, pathogens responsible for nonulcerative inflammatory STDs such as those caused by *Chlamydia trachomatis* (Chap. 160), *Neisseria gonorrhoeae* (Chap. 128), and *Trichomonas vaginalis* (Chap. 199) are also associated with an increased risk of transmission of HIV infection. Bacterial vaginosis, an infection related to sexual behavior, but not strictly an STD, may also be linked to an increased risk of transmission of HIV infection. Several studies suggest that treating other STDs and genital tract syndromes may help prevent transmission of HIV. This effect is most prominent in populations in which the prevelance of HIV infection is relatively low. In studies conducted in Uganda, the chief predictor of heterosexual transmission of HIV was the level of plasma viremia. In a cohort of couples in which one partner was HIV-infected and one was initially uninfected, the mean serum HIV RNA level was significantly higher among HIV-infected subjects whose partners seroconverted than among those whose partners did not seroconvert. In fact transmission was rare when the infected partner had a plasma level of <1500 copies of HIV RNA per milliliter. Of note, in that study, there were no seroconversions among 50 circumcised male partners. Furthermore, in a number of other studies, lack of circumcision has been strongly associated with a higher risk of HIV infection. This difference may be due to increased susceptibility of uncircumcised men to ulcerative STDs, as well as other factors such as microtrauma. In addition, the highly vascularized inner foreskin tissue contains a high density of Langerhans cells as well as increased numbers of CD4+ T cells, macrophages, and other cellular targets for HIV. Finally, the moist environment under the foreskin may promote the presence or persistence of microbial flora which, via inflammatory changes, may lead to even higher concentrations of target cells for HIV in the foreskin. In some studies the use of oral contraceptives was associated with an increase in incidence of HIV infection over and above that which might be expected by not using a condom for birth control.

Oral sex is a much less efficient mode of transmission of HIV than is receptive anal intercourse. A number of studies have reported that the incidence of transmission of infection by oral sex among couples discordant for HIV was extremely low; indeed, one study reported no cases among 239 men whose only risk was receptive oral intercourse where 28% knew that their partner was HIV-infected. However, there have been several reports of documented HIV transmission resulting solely from receptive fellatio and insertive cunnilingus. There are probably many more cases that go unreported because of the frequent practice of both oral sex and receptive anal intercourse by the same person. Therefore, the assumption that receptive oral sex is com-

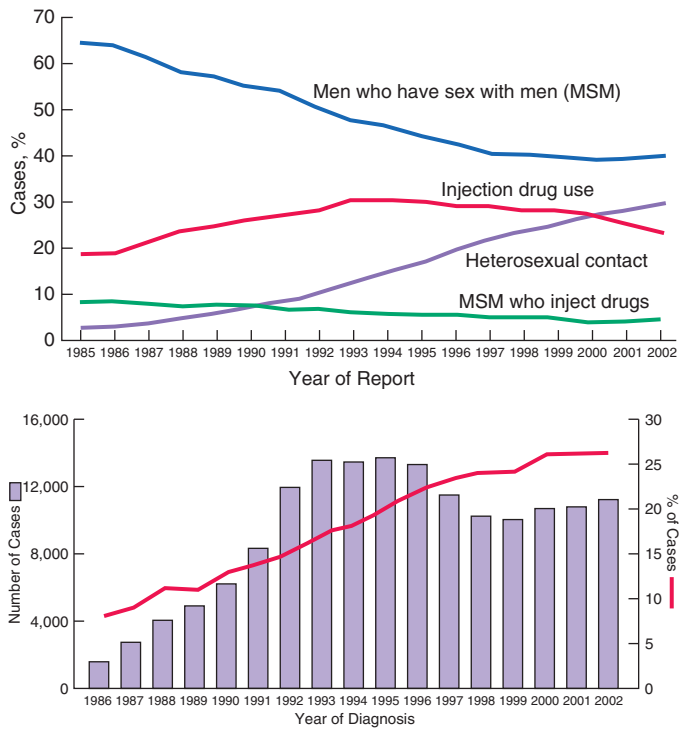

FIGURE 173-8 The changing face of the HIV/AIDS epidemic in the United States *Upper.* Proportion of AIDS cases among U.S. adults and adolescents, by exposure category and year of diagnosis. *Lower.* The proportion of AIDS cases among women and adolescent girls (aged >13 years) increased from 8% in 1986 to 26% in 2002. (*From the Centers for Disease Control and Prevention, 2003.*)

pletely safe is not warranted. The association of alcohol consumption and illicit drug use with unsafe sexual behavior, both homosexual and heterosexual, leads to an increased risk of sexual transmission of HIV.

TRANSMISSION BY BLOOD AND BLOOD PRODUCTS HIV can be transmitted to individuals who receive HIV-tainted blood transfusions, blood products, or transplanted tissue as well as to IDUs who are exposed to HIV while sharing injection paraphernalia such as needles, syringes, the water in which drugs are mixed, or the cotton through which drugs are filtered. Parenteral transmission of HIV during injection drug use does not require intravenous puncture; subcutaneous ("skin popping") or intramuscular ("muscling") injections can transmit HIV as well, even though these behaviors are sometimes erroneously perceived as low-risk. Among IDUs, the risk of HIV infection increases with the duration of injection drug use; the frequency of needle sharing; the number of partners with whom paraphernalia are shared, particularly in the setting of "shooting galleries" where drugs are sold and large numbers of IDUs may share a limited number of "works"; comorbid psychiatric conditions such as antisocial personality disorder; the use of cocaine in injectable form or smoked as "crack"; and the use of injection drugs in a geographic location with a high prevalence of HIV infection, such as certain inner-city areas in the United States.

From the late 1970s until the spring of 1985, when mandatory testing of donated blood for HIV-1 was initiated, it has been estimated that >10,000 individuals in the United States were infected through transfusions of blood or blood products (Chap. 99). Approximately 9300 individuals in the United States who survived the illness for which they received HIV-contaminated blood transfusions, blood components, or transplanted tissue have developed AIDS. It is estimated that 90 to 100% of individuals who were exposed to such HIV-contaminated products became infected. Transfusions of whole blood, packed red blood cells, platelets, leukocytes, and plasma are all capable of transmitting HIV infection. In contrast, hyperimmune γ globulin, hepatitis B immune globulin, plasma-derived hepatitis B vaccine, and Rh_o immune globulin have not been associated with transmission of HIV infection. The procedures involved in processing these products either inactivate or remove the virus.

In addition to the above, several thousand individuals in the United States with hemophilia or other clotting disorders were infected with HIV by receipt of HIV-contaminated fresh-frozen plasma or concentrates of clotting factors; ~5470 of these individuals have developed AIDS. Currently, in the United States and in most developed countries, the following measures have made the risk of transmission of HIV infection by transfused blood or blood products extremely small: (1) the screening of all blood for HIV nucleic acid, p24 antigen, and/or anti-HIV antibodies; (2) the self-deferral of donors on the basis of risk behavior; (3) the screening out of HIV-negative individuals with positive surrogate laboratory parameters of HIV infection, such as hepatitis B and C; and (4) serologic testing for syphilis. It is currently estimated that the risk of infection with HIV in the United States via transfused screened blood is approximately 1 in 725,000 to 1 in 835,000 donations. Therefore, among the 12 million donations collected in the United States each year, an estimated 16 infectious donations are available for transfusion. Thus, despite the best efforts of science, one cannot completely eliminate the risk of tranfusion-related transmission of HIV since current technology cannot detect HIV RNA for the first 1 to 2 weeks following infection due to the low levels of viremia. In this regard, two individuals in Florida recently contracted HIV from a single donor who had recently become infected; the blood collection system in question had used nucleic acid amplification testing to screen the blood. There have been several reports of sporadic breakdowns in routinely available screening procedures in certain countries, where contaminated blood was allowed to be transfused, resulting in small clusters of patients becoming infected. In China, a disturbingly large number of people have become infected by selling blood in situations where the collectors reused needles that were contaminated and in some instances mixed blood products from a number of people, separated the plasma, and re-infused red blood cells back into individual donors. It is estimated that >6% of China's HIV-infected population were infected while selling blood. There have been no reported cases of transmission of HIV-2 in the United States via donated blood, and, currently, donated blood is screened for both HIV-1 and HIV-2 antibodies. The chance of infection of a hemophiliac via clotting factor concentrates has essentially been eliminated because of the added layer of safety resulting from heat treatment of the concentrates.

Prior to the screening of donors, a small number of cases of transmission of HIV via semen used in artificial insemination and tissues used in organ transplantation were well documented. At present, donors of such tissues are prescreened for HIV infection.

OCCUPATIONAL TRANSMISSION OF HIV: HEALTH CARE WORKERS AND LABORATORY WORKERS There is a small, but definite, occupational risk of HIV transmission to health care workers and laboratory personnel and potentially others who work with HIV-containing materials, particularly when sharp objects are used. An estimated 600,000 to 800,000 health care workers are stuck with needles or other sharp medical instruments in the United States each year. Large, multi-institutional studies have indicated that the risk of HIV transmission following skin puncture from a needle or a sharp object that was contaminated with blood from a person with documented HIV infection is ~0.3% and after a mucous membrane exposure it is 0.09% (see "HIV and the Health Care Worker," p. 1136). HIV transmission after non-intact skin exposure has been documented, but the average risk for transmission by this route has not been precisely determined; however, it is estimated to be less than the risk for mucous membrane exposure. Transmission of HIV through intact skin has not been documented. An increased risk for HIV infection following percutaneous exposures to HIV-infected blood is associated with exposures involving a relatively large quantity of blood, as in the case of a device visibly contaminated with the patient's blood, a procedure that involves a needle placed directly in a vein or artery, or a deep injury. Factors that might be associated with mucocutaneous transmission of HIV include exposure to an unusually large volume of blood, prolonged contact, and a potential portal of entry. In addition, the risk increases for exposures to blood from patients with advanced-stage disease, probably owing to the higher titer of HIV in the blood as well as to other factors, such as the presence of more virulent strains of virus. The use of antiretroviral drugs as postexposure prophylaxis decreases the risk of infection compared to historic controls in occupationally exposed health care workers (see "HIV and the Health Care Worker"). The risk of hepatitis B virus (HBV) infection following a similar type of exposure is 6 to 30% in nonimmune individuals; if a susceptible worker is exposed to HBV, postexposure prophylaxis with hepatitis B immune globulin and initiation of HBV vaccine is >90% effective in preventing HBV infection. The risk of hepatitis C virus (HCV) infection following percutaneous injury is ~1.8% (Chap. 285).

Since the beginning of the HIV epidemic, there have been at least three reported instances in which transmission of infection from a health care worker to patients seemed highly probable. The first involved a dentist in Florida who apparently infected six of his patients, most likely through contaminated instruments. Another case involved an orthopedic surgeon in France who apparently infected a patient during placement of a total hip prosthesis. A third case involved the apparent transmission of HIV from a nurse to a surgical patient in France. An additional situation involved the apparent infection of four patients by an HIV-negative general surgeon in Australia during routine outpatient surgery. The cause of the transmission was felt to be a failure on the part of the surgeon to sterilize instruments properly between procedures following prior surgery on an infected patient. Despite these few cases, the risk of transmission from an infected health care worker to patients is extremely low; in fact, too low to be mea-

sured accurately. Indeed several epidemiologic studies have been performed tracing thousands of patients of HIV-infected dentists, physicians, surgeons, obstetricians, and gynecologists, and no other cases of HIV infection that could be linked to the health care providers were identified. The very occurrence of transmission of HIV as well as HBV and HCV to and from health care workers in the workplace underscores the importance of the use of universal precautions when caring for all patients (see below and Chap. 116).

MATERNAL-FETAL/INFANT TRANSMISSION HIV infection can be transmitted from an infected mother to her fetus during pregnancy, during delivery, or by breast-feeding. This is an extremely important form of transmission of HIV infection in developing countries, where the proportion of infected women to infected men is ~1:1. Virologic analysis of aborted fetuses indicate that HIV can be transmitted to the fetus as early as the first and second trimester of pregnancy. However, maternal transmission to the fetus occurs most commonly in the perinatal period. This conclusion is based on a number of considerations, including the time frame of identification of infection by the sequential appearance of classes of antibodies to HIV (i.e., the appearance of HIV-specific IgA antibody within 3 to 6 months after birth); a positive viral culture; the appearance of p24 antigenemia weeks to months after delivery, but not at the time of delivery; a polymerase chain reaction (PCR) assay of infant blood following delivery that is negative at birth and positive several months later; the demonstration that the firstborn twin of an infected mother is more commonly infected than is the second twin; and the evidence that cesarean section results in decreased transmission to the infant. Two studies performed in Rwanda and the former Zaire indicated that the relative proportions of mother-to-child transmissions were 23 to 30% before birth, 50 to 65% during birth, and 12 to 20% via breast-feeding.

In the absence of prophylactic antiretroviral therapy to the mother during pregnancy, labor, and delivery, and to the fetus following birth (see below), the probability of transmission of HIV from mother to infant/fetus ranges from 15 to 25% in industrialized countries and from 25 to 35% in developing countries. These differences may relate to the adequacy of prenatal care as well as to the stage of HIV disease and the general health of the mother during pregnancy. Higher rates of transmission have been reported to be associated with many factors; some of these are well proven by a number of studies, while others are considered to be potential factors since various studies may have given divergent results. The best-documented factor that is associated with higher rates of transmission is the presence of high maternal levels of plasma viremia. Low maternal CD4+ T cell counts have also been associated with higher rates of transmission; however, since low CD4+ T cell counts are often associated with high levels of plasma viremia, in one study using multivariate analysis including plasma viral load and CD4+ T cell count, only the level of plasma HIV RNA was significant. A prolonged interval between membrane rupture and delivery is another well-documented risk factor for transmission. Other conditions that are potential risk factors, but which have not been consistently demonstrated, are the presence of chorioamnionitis at delivery; STDs during pregnancy; hard drug use during pregnancy; cigarette smoking; preterm delivery; and obstetric procedures such as amniocentesis, amnioscopy, fetal scalp electrodes, and episeotomy. Vitamin A deficiency had been reported to be associated with higher transmission rates; however, vitamin A supplementation during pregnancy resulted in improved birth weight and neonatal growth and reduced anemia but did not affect perinatal transmission of HIV. With regard to levels of viremia, several studies indicate that the risk of transmission increases with the maternal plasma HIV RNA level. In one series of 552 singleton pregnancies in the United States, the rate of mother-to-baby transmission was 0% among women with <1000 copies of HIV RNA per milliliter of blood, 16.6% among women with 1000 to 10,000/mL, 21.3% among women with 10,001 to 50,000/mL, 30.9% among women with 50,001 to 100,000/mL, and 40.6% among women with >100,000/mL. However, there may be no lower "threshold" below which transmission never occurs, since other studies have reported transmission by women with viral RNA levels <50 copies per milliliter. Finally, it has been speculated that if the mother experiences acute primary infection during pregnancy, there is a higher rate of transmission to the fetus, owing to the high levels of viremia that occur during primary infection. However, a study from Thailand reported no increased risk of transmission of HIV from mother-to-child in women who seroconverted during pregnancy. In that study, maternal viral loads at delivery were no different among women who seroconverted during pregnancy and those who were seropositive when first tested. In a study conducted in the United States, zidovudine treatment of HIV-infected pregnant women from the beginning of the second trimester through delivery and of the infant for 6 weeks following birth dramatically decreased the rate of intrapartum and perinatal transmission of HIV infection from 22.6% in the untreated group to <5%. The rate of mother-to-child transmission is approaching 1% or less in pregnant women who are receiving combination antiretroviral therapy for their HIV infection. Such treatment, combined with cesarean section delivery, has rendered mother-to-child transmission of HIV an unusual event in the United States and other developed nations. In developed countries, current recommendations to reduce perinatal transmission of HIV include universal voluntary HIV testing and counseling of pregnant women, antiretroviral prophylaxis with one or more drugs in cases in which the mother does not require therapy for her HIV infection, combination therapy for women who do require therapy, obstetric management that attempts to minimize exposure of the infant to maternal blood and genital secretions, and avoidance of breast-feeding. It is recommended that the choice of antiretroviral therapy for pregnant women should be based on the same considerations used for women who are not pregnant, with discussion of the recognized and unknown risks and benefits of such therapy during pregnancy. The cost and logistics of the above protocol are not currently feasible for developing countries, particularly those in sub-Saharan Africa where the per capita health care delivery allocation is often only a few dollars per year. Studies have demonstrated that truncated regimens of zidovudine alone or in combination with lamivudine given to the mother during the last few weeks of pregnancy or even only during labor and delivery, and to the infant for a week or less, reduced transmission to the infant by 50% compared to placebo. One important study in Uganda demonstrated that a single dose of nevirapine given to the mother at the onset of labor followed by a single dose to the newborn within 72 h of birth decreased transmission by 50% compared with a regimen of zidovudine to the mother that began at the onset of labor and continued throughout labor and to the infant for 1 week following birth. The cost of the nevirapine for the mother and infant was $4.00, thus making this regimen more affordable. Indeed, short-course nevirapine regimens increasingly are being utilized in developing nations for the prevention of mother-to-child transmission. It is estimated that the successful implementation of such regimens could potentially save 1000 babies per day from becoming infected with HIV, the vast majority of whom are in sub-Saharan Africa.

Breast-feeding is an important modality of transmission of HIV infection in developing countries, particularly where mothers continue to breast feed for prolonged periods. The risk factors for mother-to-child transmission of HIV via breast-feeding are not fully understood; factors that increase the likelihood of transmission include detectable levels of HIV in breast milk, the presence of mastitis, low maternal CD4+ T cell counts, and maternal vitamin A deficiency. The risk of HIV infection via breast-feeding is highest in the early months of breast-feeding. In addition, exclusive breast-feeding has been reported to carry a lower risk of HIV transmission than mixed feeding. Certainly, in developed countries breast-feeding by an infected mother should be avoided. However, there is disagreement regarding recommendations for breast-feeding in certain developing countries, where breast milk is the only source of adequate nutrition as well as immunity against potentially serious infections for the infant. Studies are being conducted to determine whether intermittent administration of nevi-

rapine, which has a relatively long half-life, to uninfected babies born of infected mothers decreases the incidence of infection via breast-feeding. The optimal approach to prevent transmission by infected mothers who choose to breast-feed would be to provide continual treatment to the infected mother where feasible.

TRANSMISSION BY OTHER BODY FLUIDS Although HIV can be isolated typically in low titers from saliva of a small proportion of infected individuals, there is no convincing evidence that saliva can transmit HIV infection, either through kissing or through other exposures, such as occupationally to health care workers. Saliva contains endogenous antiviral factors; among these factors, HIV-specific immunoglobulins of IgA, IgG, and IgM isotypes are detected readily in salivary secretions of infected individuals. It has been suggested that large glycoproteins such as mucins and thrombospondin-1 sequester HIV into aggregates for clearance by the host. In addition, a number of soluble salivary factors inhibit HIV to various degrees in vitro, probably by targeting host cell receptors rather than the virus itself. Perhaps the best-studied of these, secretory leukocyte protease inhibitor (SLPI), blocks HIV infection in several cell culture systems, and it is found in saliva at levels that approximate those required for inhibition of HIV in vitro. In this regard, higher salivary levels of SLPI in breast-fed infants were associated with a decreased risk of HIV transmission through breast milk. It has also been suggested that submandibular saliva reduces HIV infectivity by stripping gp120 from the surface of virions, and that saliva-mediated disruption and lysis of HIV-infected cells occurs because of the hypotonicity of oral secretions. There have been outlier cases of suspected transmission by saliva, but these have probably been blood-to-blood transmissions. Transmission of HIV by a human bite can occur but is a rare event; at least four cases of such transmission have been reported. In addition, a most unusual form of HIV transmission from infected children to mothers in the former Soviet Union has been identified. In those cases, the children (infected through transfusion) were said to have bleeding sores in the mouth, and the mothers were said to have lacerations and abrasions on and around the nipples of the breast resulting from trauma from the children's teeth. Breast-feeding had been continued until the children were older than is usual in other developed countries.

Although virus can be identified, if not isolated, from virtually any body fluid, there is no evidence that HIV transmission can occur as a result of exposure to tears, sweat, and urine. However, there have been isolated cases of transmission of HIV infection by body fluids that may or may not have been contaminated with blood. Most of these situations occurred in the setting of a close relative providing intensive nursing care for an HIV-infected person without observing universal precautions. These cases underscore the importance of observing universal precautions in the handling of body fluids and wastes from HIV-infected individuals (see below).

EPIDEMIOLOGY

HIV INFECTION AND AIDS WORLDWIDE HIV infection/AIDS is a global pandemic, with cases reported from virtually every country. The current estimate of the number of cases of HIV infection among adults worldwide is ~37 million, two-thirds of whom are in sub-Saharan Africa; 50% of cases are women. In addition, an estimated 2.5 million children younger than age 15 are living with HIV/AIDS. The global distribution of these cases is illustrated in Fig. 173-9. According to the Joint United Nations Programme on HIV/AIDS (UNAIDS), in 2003 alone there were an estimated 5 million new cases of infection worldwide (>14,000 new infections each day) and 3 million deaths from AIDS, making it the fourth leading cause of mortality worldwide. The cumulative number of AIDS-related deaths worldwide through the year 2003 exceeds 20 million. The HIV epidemic has occurred in "waves" in different regions of the world, each wave having somewhat different characteristics depending on the demographics of the country and region in question and the timing of the introduction of HIV into the population. As noted above, different subtypes, or clades, of HIV-1 are prevalent in different regions of the world (see above and Fig. 173-7), increasing the difficulty in the development of vaccines and perhaps accounting for different degrees of virulence. It is unlikely that a single vaccine will be applicable to all regions of the world. In this regard, in addition to HIV-1 subtype B, the predominant subtype in the United States, HIV-1 subtypes A, AE, AG, C, D, and O have been detected in individuals in the United States, as might be expected given the degree of international travel that occurs.

Table 173-3 provides the statistics and demographic features of HIV/AIDS in different regions of the world. Although the epidemic was first recognized in the United States and shortly thereafter in western Europe, it very likely began in sub-Saharan Africa (see above), which has been particularly devastated by the epidemic, with the prevalance of infection in many cities in the double digits. In certain sub-Saharan African countries, such as Zimbabwe and Botswana, available seroprevalence data indicate >30% of the adult population aged 15 to 49 is HIV-infected. In addition, among high-risk individuals (e.g., commercial sex workers, patients attending STD clinics) who live in urban areas of sub-Saharan Africa, seroprevalence is now >50% in many countries. According to projections of the United Nations Pop-

ulation Division, by the year 2015 life expectancy at birth in the seven countries in Africa with adult HIV prevalence rates >20% will be 32 years lower on average than the projected life expectancy in the absence of AIDS (Table 173-4). The epidemic in Asian countries, particularly India and China, has lagged temporally behind that in Africa; however, the number of new cases in this region is accelerating rapidly, and the magnitude of the epidemic is projected to exceed that of sub-Saharan Africa in the early part of the twenty-first century. The epidemic is also expanding rapidly in the Baltic States, the Russian Federation, and several Central Asian Republics. The major mode of transmission of HIV worldwide is unquestionably heterosexual sex; this is particularly true and has been so since the beginning of the epidemic in developing countries, where the numbers of infected men and women are approximately equal. The epidemic in most developed countries was first introduced among homosexual men and, to a greater or lesser degree (depending on the individual country), among IDUs. In this regard, the total numbers of AIDS cases in those countries still reflect a high proportion of cases among these high-risk groups. However, in most developed countries, including the United States (see below), there has been a gradual shift such that among new cases of AIDS, there is a greater total prevalence among heterosexuals and IDUs than among homosexual men.

AIDS IN THE UNITED STATES AIDS has had and will continue to have an extraordinary public health impact in the United States. As of January 1, 2003, an estimated 886,575 cumulative cases of AIDS had been diagnosed in adults and adolescents in the United States (Table 173-5) and ~502,000 AIDS-related deaths had occurred. In 2002, AIDS was the sixth leading cause of death among Americans aged 25 to 44, having dropped from first within the past few years. The annual number of AIDS-related deaths in the United States fell ~70% from 1995 to 2002 (Fig. 173-10). This trend is due to several factors including the improved prophylaxis and treatment of opportunistic infections, the growing experience among the health professions in caring for HIV-infected individuals, improved access to health care, and a decrease in new infections due to saturational effects and prevention efforts. However, the most influential factor clearly has been the increased use of potent antiretroviral drugs, generally administered in a combination of three or four agents (see below). When one looks at the totality of data collected from the beginning of the epidemic, ~47% of all cases are among men who have had sex with men. However, since the mid-1980s the proportion of newly reported cases of AIDS in this population has declined from 65% of cases diagnosed in 1985 to 40% of cases diagnosed in 2002. Meanwhile, the proportion of new AIDS cases attributed to heterosexual contact has increased dramatically, from 3% in 1985 to 29% in 2002 (Fig. 173-8). Women are increasingly affected; the proportion of AIDS cases in the United States reported among adult and adolescent females has increased from <5% to 26% from 1985 to 2002 (Fig. 173-8). Most cases of transmission by injection drug use and heterosexual contact are reported from the northeast and southeast regions of the country, particularly among minorities. HIV infection and AIDS have disproportionately affected minority populations in the United States. The estimated rates of AIDS diagnoses per 100,000 population among adults and adolescents in 2002 were 76.4 for African Americans, 26.0 for Hispanics, 7.0 for whites, 11.2 for American Indians/Alaska Natives, and 4.9 for Asian/Pacific Islanders (Fig. 173-11).

As of January 1, 2003, an estimated 9,300 cases of AIDS in children ≤13 years old had been diagnosed, and ~55% of these children have died. Approximately 90% of these children were born to mothers who were HIV-infected or who were at risk for HIV infection and, in ~60% of those cases, the mother was either an IDU or the heterosexual partner of an IDU. The estimated number of AIDS cases diagnosed among children perinatally exposed to HIV peaked in 1992 and has decreased in recent years (Fig. 173-12). The decline of these cases is likely associated with the implementation of guidelines for the universal counseling and voluntary HIV testing of pregnant women and the use of antiretroviral therapy for pregnant women and newborn infants in order to prevent infection. Another contributing factor is the effective treatment of HIV infection in children who have become infected.

About 43% of women with AIDS have become infected through injection drug use, compared to 24% of men with AIDS; 53% of women have become infected by heterosexual contact, compared to 7% of men with AIDS. Only 1% of AIDS cases are among hemophiliacs, and 1% are among recipients of blood transfusions, blood products, or transplanted tissue. The relative contribution of the latter groups will gradually decrease, even though individuals infected pre-

viously through this mode of transmission will continue to develop AIDS. The risk of additional infections via this mode of transmission in the United States is extremely small (see above). In recent years, the incidence of AIDS has decreased considerably, with ~42,000 new cases in 2002 compared to ~60,000 in 1996 (Fig. 173-10). This trend likely reflects both reduced infection rates since the mid-1980s; more widespread use of prophylactic therapies, which delay the onset of AIDS; and the use of highly effective antiretroviral therapy early in the course of HIV infection (see below). Also, the demography of newly infected individuals has changed considerably since the mid-1980s (see below).

HIV PREVALENCE AND INCIDENCE IN THE UNITED STATES It is estimated that between 850,000 and 950,000 adults and adolescents in the United States are living with HIV infection, one-quarter of whom are unaware of their infection. This estimate results in an overall nationwide prevalence of HIV infection of ~0.3%. Prevalence is highest among young adults in their late twenties and thirties and among minorities. An estimated 3% of black men and 1% of black women in their thirties are living with HIV infection. The number of new infections per year is estimated to be ~40,000, and this number has remained stable for more than a decade. The estimated proportion of HIV infections has declined among white males, especially those >30, while the proportion of new HIV infections appears to have increased among young homosexual men and heterosexual women, especially in minority groups. Among newly infected persons in the United States, ~70% are men and ~30% are women (Fig. 173-13). Of these newly infected individuals, half are <25 years. Of new infections among men, the CDC estimates that ~60% were infected through homosexual sex, 25% through injection drug use, and 15% through heterosexual sex. Of new infections among women, ~75% were infected through heterosexual sex and 25% through injection drug use.

HIV infection and AIDS are widespread in the United States; although the epidemic on the whole is plateauing, it is spreading rapidly among certain populations, stabilizing in others, and decreasing in others. Similar to other STDs, HIV infection will not spread homogeneously throughout the population of the United States. However, it is clear that anyone who practices high-risk behavior is at risk for HIV infection. In addition, the increase in infections and AIDS cases among young homosexual men, heterosexuals (particularly sexual partners of IDUs, women, and adolescents) as well as the spread in

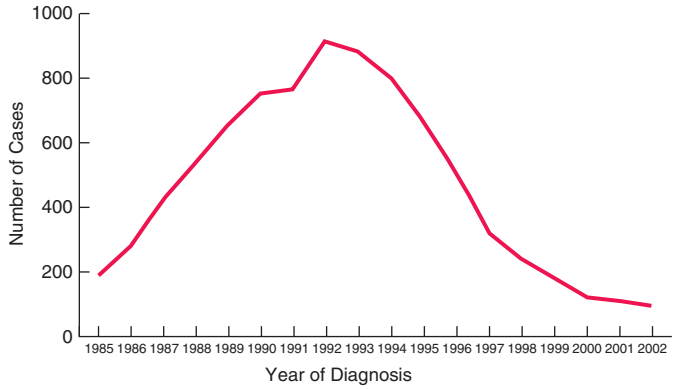

FIGURE 173-12 Perinatally acquired AIDS cases by year of diagnosis, 1985–2002, United States. (*From the Centers for Disease Control and Prevention, 2003.*)

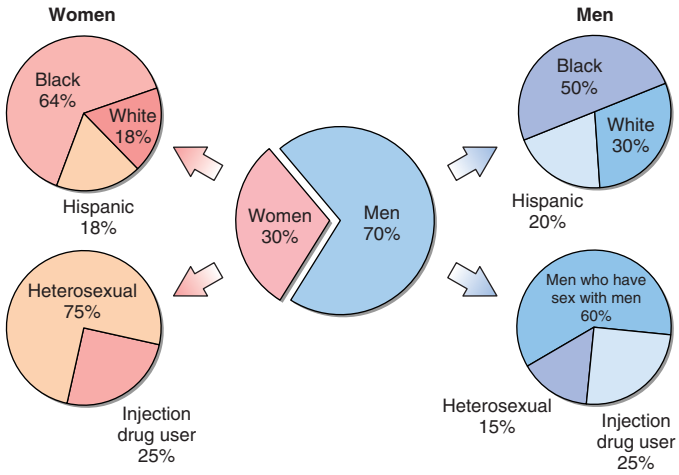

FIGURE 173-13 Estimated new HIV infections annually by race and risk in the United States. (*From the Centers for Disease Control and Prevention.*)

pockets of poverty in both urban and rural regions (particularly among underserved minority populations with inadequate access to health care) testifies to the fact that the epidemic of HIV infection in the United States is a public health problem of major proportions.

PATHOPHYSIOLOGY AND PATHOGENESIS

The hallmark of HIV disease is a profound immunodeficiency resulting primarily from a progressive quantitative and qualitative deficiency of the subset of T lymphocytes referred to as *helper T cells*, or *inducer T cells*. This subset of T cells is defined phenotypically by the presence on its surface of the CD4 molecule (Chap. 295), which serves as the primary cellular receptor for HIV. A co-receptor must also be present together with CD4 for efficient fusion and entry of HIV-1 into its target cells (Figs. 173-3 and 173-4). HIV uses two major co-receptors for fusion and entry; these co-receptors are also the primary receptors for certain chemoattractive cytokines termed *chemokines* and belong to the seven-transmembrane-domain G protein–coupled family of receptors. CCR5 and CXCR4 are the major co-receptors used by HIV (see above and below). Although a number of mechanisms responsible for cytopathicity and immune dysfunction of CD4+ T cells have been demonstrated in vitro, particularly direct infection and destruction of these cells by HIV and activation-induced cell death (see below), it remains unclear which mechanisms or combination of mechanisms are primarily responsible for their progressive depletion and functional impairment in vivo. When the number of CD4+ T cells declines below a certain level (see below), the patient is at high risk of developing a variety of opportunistic diseases, particularly the infections and neoplasms that are AIDS-defining illnesses. Some features of AIDS, such as KS and neurologic abnormalities (see below), cannot be explained completely by the immunosuppressive effects of HIV, since these complications may occur prior to the development of severe immunologic impairment.

The combination of viral pathogenic and immunopathogenic events that occurs during the course of HIV disease from the moment of initial (primary) infection through the development of advanced-stage disease is complex and varied. It is important to appreciate that the pathogenic mechanisms of HIV disease are multifactorial and multiphasic and are different at different stages of the disease. Therefore, it is essential to consider the typical clinical course of an untreated HIV-infected individual in order to more fully appreciate these pathogenic events (Fig. 173-14).

PRIMARY HIV INFECTION, INITIAL VIREMIA, AND DISSEMINATION OF VIRUS

The events associated with primary HIV infection are likely critical determinants of the subsequent course of HIV disease. In particular, the dissemination of virus to lymphoid organs is a major factor in the establishment of a chronic and persisent infection (see below). The initial infection of susceptible cells may vary somewhat with the route of infection. Virus that enters directly into the bloodstream via infected blood or blood products (i.e., transfusions, use of contaminated needles for injecting drugs, sharp-object injuries, maternal-to-fetal transmission either intrapartum or perinatally, or sexual intercourse where there is enough trauma to cause bleeding) is likely cleared from the circulation to the spleen and other lymphoid organs, where it replicates to a critical level and then leads to a burst of viremia that disseminates virus throughout the body. Dendritic cells play an important role in the initiation of HIV infection. These cells express a diversity of C-type lectin receptors on their surface, one of which is called *DC-SIGN* (see above). DC-SIGN binds with high affinity to the HIV envelope gp120 and can retain infectious particles for days in vitro. Certain studies have demonstrated that following binding to DC-SIGN, HIV is internalized into a low pH nonlysosomal compartment that allows for the retention of infectivity. Upon encountering a susceptible CD4+ T cell target, the dendritic cell markedly enhances the infectivity of the virus for the target cell. This mechanism likely operates in humans when HIV enters "locally" (as opposed to directly into the blood) and encounters mucosal dendritic cells via the vagina, rectum, or urethra during intercourse or via the upper gastrointestinal tract from swallowed infected semen, vaginal fluid, or breast milk. In primary HIV infection, virus replication in CD4+ T cells intensifies prior to the initiation of an HIV-specific immune response (see below), leading to a burst of viremia (Fig. 173-14) and then to a rapid dissemination of virus to other lymphoid organs, the brain, and other tissues. Individuals who experience the "acute HIV syndrome," which occurs to varying degrees in ~50% of individuals with primary infection, have high levels of viremia measured in millions of copies of HIV RNA per milliliter that last for several weeks (see below). The acute mononucleosis-like symptoms are well correlated with the presence of viremia. Virtually all patients appear to develop some degree of viremia during primary infection, which contributes to virus dissemination throughout the lymphoid tissue, even though they may remain asymptomatic or not recall experiencing symptoms. A more detailed description of the role of lymphoid tissue in the immunopathogenesis of HIV disease is given below. It appears that the initial level of plasma viremia in primary HIV infection does not necessarily determine the rate of disease progression; however, the set point of the level of steady-state plasma viremia after ~1 year does seem to correlate with the rapidity of disease progression (see below).

ESTABLISHMENT OF CHRONIC AND PERSISTENT INFECTION ■ Persistent Virus Replication HIV infection is unique among human viral infections. Despite the robust cellular and humoral immune responses that are mounted following primary infection (see below), once infection has been established the virus succeeds in escaping immune-mediated

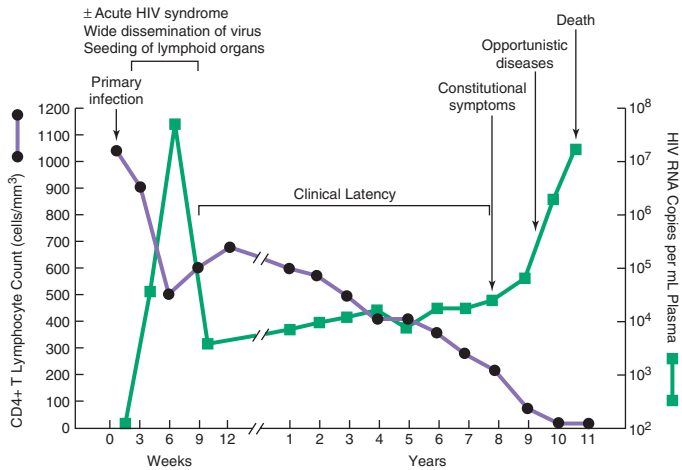

FIGURE 173-14 Typical course of an HIV-infected individual. See text for detailed description. (*From A Fauci et al: Ann Intern Med 124:654, 1996.*)

clearance (see below) and is virtually never eliminated completely from the body. Rather, a chronic infection develops that persists with varying degrees of virus replication in the untreated patient for a median of ~10 years before the patient becomes clinically ill (see below). It is this establishment of a chronic, persistent infection that is the hallmark of HIV disease. Throughout the often protracted course of chronic infection, virus replication can almost invariably be detected in untreated patients, both by highly sensitive assays for plasma viremia as well as by demonstration of cell-associated HIV RNA in immunocompetent cells (predominantly CD4+ T cells and macrophages) in the circulation and in lymphoid tissue. In other human viral infections, with very few exceptions, if the host survives, the virus is completely cleared from the body and a state of immunity against subsequent infection develops. HIV infection very rarely kills the host during primary infection. Certain viruses, such as HSV (Chap. 163), are not completely cleared from the body after infection but instead enter a latent state; in these cases, clinical latency is accompanied by microbiologic latency. This is not the case with HIV infection, in which some degree of virus replication invariably occurs during the period of clinical latency (see below). Chronicity associated with persistent virus replication can also be seen in certain cases of HBV and HCV infections (Chap. 287); however, in these infections the immune system is not a target of the virus.

Evasion of Immune System Control Inherent to the establishment of chronicity of HIV infection is the ability of the virus to evade elimination and control by the immune system. There are a number of mechanisms whereby the virus accomplishes this evasion. Paramount among these is the ability of the virus to mutate, which becomes particularly relevant after the establishment of chronic infection and which contributes to the maintenance of chronicity. The evolution of mutants that escape control by CD8+ cytolytic T lymphocytes (CTLs) is critical to the propagation and progression of HIV infection. The high rate of virus replication and the continual mutation of virus also contribute to the inability of neutralizing antibody to contain the virus quasispecies present in an individual at any given time. Molecular analysis of clonotypes has demonstrated that clones of CD8+ CTLs that expand greatly during primary HIV infection, and likely represent the high-affinity clones that would be expected to be most efficient in eliminating virus-infected cells, are no longer detectable after their initial burst of expansion. It is thought that the initially expanded clones may have been deleted owing to the overwhelming exposure to viral antigens during the initial burst of viremia, similar to the exhaustion of CD8+ CTLs that has been reported in the murine model of lymphocytic choriomeningitis virus (LCMV) infection. To compound this phenomenon, virus replication and thus saturation of antigen-presenting cells with viral antigen take place in the lymphoid tissue (see below), which is also the site of generation of HIV-specific CTLs. Another mechanism of evasion by HIV of immune system control is the downregulation of HLA class I molecules on the surface of HIV-infected cells by the Nef protein of HIV, resulting in the lack of ability of the CD8+ CTL to recognize and kill the infected target cell. Although this downregulation of HLA class I molecules would favor elimination of HIV-infected cells by natural killer (NK) cells, this latter mechanism does not seem to effectively remove HIV-infected cells (see below). An important mechanism of evasion of the humoral immune response is the avoidance by the virus of antibody-mediated neutralization through its conformational masking of receptor-binding sites.

CD4+ T cell help is critical for the integrity of antigen-specific immune responses, both humoral and cell-mediated. HIV preferentially infects HIV-specific CD4+ T cells, and so this loss of viral-specific helper T cell responses has potentially profound negative consequences for the immunologic control of HIV replication. Other means of escape of HIV-infected cells from elimination by CD8+ CTLs are the sequestration of infected cells in immunologically privileged sites such as the central nervous system (CNS) as well as the segregation of HIV-specific CTLs and CTL precursors in the peripheral blood where relatively little active virus replication takes place, rather than in the lymphoid tissue, which is the major site of virus replication and spread.

Finally, the escape of HIV from elimination during primary infection allows the formation of a large pool of latently infected cells that cannot be eliminated by virus-specific CTLs (see below). Thus, despite a potent immune response and the marked downregulation of virus replication following primary HIV infection, HIV succeeds in establishing a state of chronic infection with a variable degree of persistent virus replication. In most cases, during this period the patient makes the clinical transition from acute primary infection to a relatively prolonged state of clinical latency (see below).

Latent Reservoir of HIV-Infected Cells: Obstacle to the Eradication of Virus There exists in virtually all HIV-infected individuals a pool of latently infected, resting CD4+ T cells that serves as at least one component of the persistent reservoir of virus. Such cells manifest postintegration latency in that the HIV provirus integrates into the genome of the cell and can remain in this state until an activation signal drives the expression of HIV transcripts and ultimately replication-competent virus. This form of latency is to be distinguished from preintegration latency, in which HIV enters a resting CD4+ T cell and, in the absence of an activation signal, only a limited degree of reverse transcription of the HIV genome occurs. This period of preintegration latency may last hours to days, and if no activation signal is delivered to the cell, the proviral DNA loses its capacity to initiate a productive infection. If these cells do become activated, reverse transcription proceeds to completion and the virus continues along its replication cycle (see above and Fig. 173-15). The pool of cells that are in the postintegration state of latency is established early during the course of primary HIV infection. Despite the suppression of plasma viremia to <50 copies of

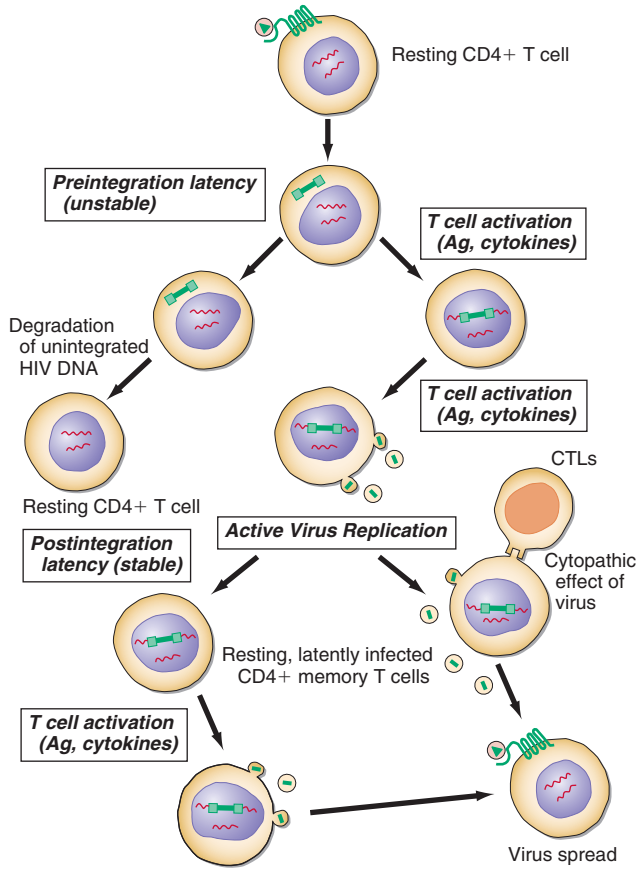

FIGURE 173-15 Generation of latently infected, resting CD4+ T cells in HIV-infected individuals. See text for details. Ag, antigen; CTLs, cytolytic T lymphocytes. (*Courtesy of TW Chun.*)

HIV RNA per milliliter by potent combinations of several antiretroviral drugs for as long as 5 years, this pool of latently infected cells persists and can give rise to replication-competent virus. Modeling studies built on projections of decay curves (see below) have estimated that in a setting of prolonged suppression of plasma viremia to <50 copies of HIV RNA per milliliter by antiretroviral therapy (a goal that is difficult to maintain consistently over years), it would require from 7 to 70 years for the pool of latently infected cells to be completely eliminated. Furthermore, the reservoir of latently infected cells is replenished during minor rebounds of virus replication that may occur intermittently, even in patients who for the most part are treated successfully, and certainly during major rebounds of viremia in patients whose therapy is interrupted for a period of weeks or longer. Thus, this persistent pool of latently infected cells is a major obstacle to any goal of eradication of virus from infected individuals, despite the favorable clinical outcomes that have resulted from antiretroviral therapy (see below).

Viral Dynamics The dynamics of viral production and turnover have been quantified using mathematical modeling in the setting of the administration of reverse transcriptase and protease inhibitors to HIV-infected individuals in clinical studies. Treatment with these drugs resulted in a precipitous decline in the level of plasma viremia, which typically fell by well over 90% within 2 weeks. The number of CD4+ T cells in the blood increased concurrently, which suggested that the killing of CD4+ T cells was linked directly to the levels of replicating virus. However, it is generally agreed that a significant component of the early rise in CD4+ T cell numbers following the initiation of therapy is due to the redistribution of cells into the peripheral blood from other body compartments as a consequence of alterations in immune system activation. It was determined on the basis of modeling the kinetics of viral decline and the emergence of resistant mutants during therapy that 93 to 99% of the circulating virus originated from recently infected, rapidly turning over CD4+ T cells and that ~1 to 7% of circulating virus originated from longer-lived cells, likely monocyte/macrophages. A negligible amount of circulating virus originated from the pool of latently infected cells (see above) (Fig. 173-16). It was also determined that the half-life of a circulating virion was approximately 30 to 60 min and that of productively infected cells was 1 day. Given the relatively steady level of plasma viremia and of infected cells, it appears that extremely large amounts of virus (~10^{10} to 10^{11} virions) are produced and cleared from the circulation each day. In addition, data suggest that the minimum duration of the HIV-1 replication cycle in vivo is ~2 days. Other studies have demonstrated that the decrease in plasma viremia that results from antiretroviral therapy correlates closely with a decrease in virus replication in lymph nodes, further confirming that lymphoid tissue is the main site of HIV replication and the main source of plasma viremia.

The level of steady-state viremia, called the viral *set point*, at ~1 year has important prognostic implications for the progression of HIV disease. It has been demonstrated that HIV-infected individuals who have a low set point at 6 months to 1 year progress to AIDS much more slowly than individuals whose set point is very high at that time (Fig. 173-17). Levels of viremia generally increase as disease progresses. Measurement of the level of viremia is critical in guiding therapeutic decisions in HIV-infected individuals (see below).

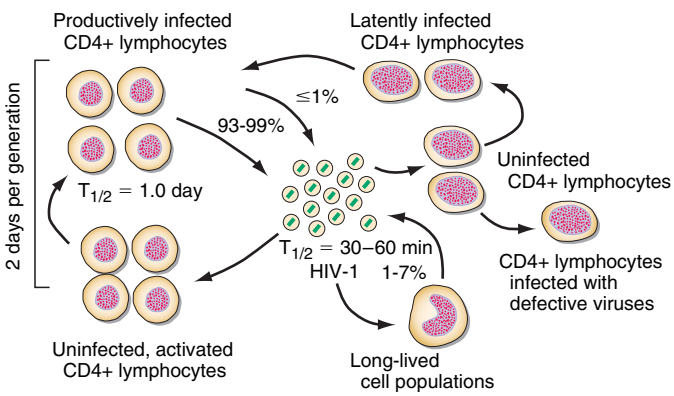

FIGURE 173-16 Dynamics of HIV infection in vivo. See text for detailed description. (*From AS Perelson et al: Science 271:1582, 1996.*)

Clinical Latency versus Microbiologic Latency With the exception of long-term nonprogressors (see below), the level of CD4+ T cells in the blood decreases progressively in HIV-infected individuals. The slope of this decline is usually a good predictor of the pattern of the clinical course and the development of advanced disease. The decline in CD4+ T cells may be gradual or abrupt, the latter usually reflecting a significant spike in the level of plasma viremia. Most patients are entirely asymptomatic while this progressive decline is taking place (see below) and are often described as being in a state of *clinical latency*. However, this term is misleading; it does not mean disease latency, since progression is generally relentless during this period. Furthermore, clinical latency should not be confused with microbiologic latency, since virus replication manifested by low-level viremia is present in the vast majority of patients during the period of clinical latency. Even in those rare patients who have <50 copies of HIV RNA per milliliter in the absence of therapy, there is virtually always some degree of ongoing virus replication, as determined by sensitive molecular methods such as PCR techniques that detect cell-associated viral RNA or that concentrate virus from large volumes of blood.

ADVANCED HIV DISEASE In untreated patients or in patients in whom therapy has not adequately controlled virus replication (see below), after a variable period, usually measured in years, the CD4+ T cell count falls below a critical level (<200/μL) and the patient becomes highly susceptible to opportunistic disease (Fig. 173-14). For this reason, the CDC case definition of AIDS includes all HIV-infected individuals with CD4+ T cell counts below this level (Table 173-1). Patients may experience constitutional signs and symptoms or may develop an opportunistic disease abruptly without any prior symptoms, although the latter scenario is unusual. The depletion of CD4+ T cells continues to be progressive and unrelenting in this phase. It is not uncommon for CD4+ T cell counts to drop as low as 10/μL or even to zero, yet such patients may survive for months or even years. This situation has become increasingly common as patients are treated more aggressively and are given prophylaxis against the common life-threatening opportunistic infections (see below). In this regard, control of plasma viremia by antiretroviral therapy, even in individuals with extremely low CD4+ T cell counts, has increased survival in these patients despite the fact that their CD4+ T cell counts may not significantly increase as a result of therapy. Ultimately, patients who

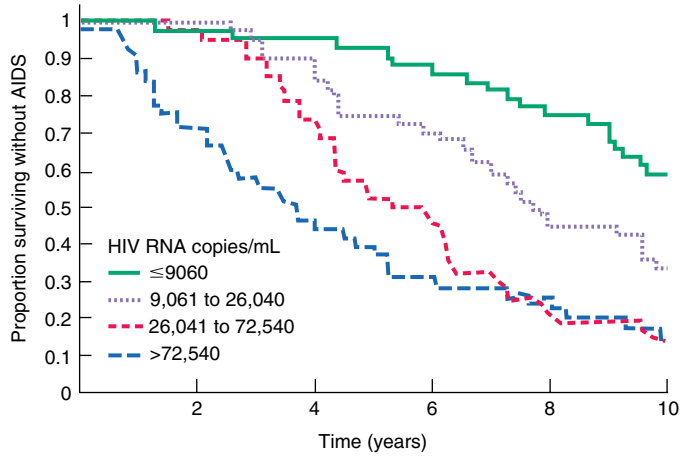

FIGURE 173-17 Relationship between levels of virus and rates of disease progression. Kaplan-Meier curves for AIDS-free survival stratified by baseline HIV-1 RNA categories (copies per milliliter). (*From Mellors et al.*)

progress to this severest form of immunodeficiency usually succumb to opportunistic infections or neoplasms (see below).

LONG-TERM SURVIVORS AND LONG-TERM NONPROGRESSORS The prognosis for HIV-infected individuals who have access to health care and antiretroviral therapy has improved greatly since the beginning of the epidemic. The median time from primary HIV infection to the development of AIDS in untreated individuals in the developed world is ~10 years. This period has been markedly extended by the wide availability of combinations of antiretroviral drugs in the developed world; the full extent of this benefit has yet to be realized. It is important to distinguish between the terms *long-term survivor* and *long-term nonprogressor*. Long-term nonprogressors are by definition long-term survivors; however, the reverse is not always true. The definitions of these categories are empirical and continue to change as more data are collected from prospective cohort studies. Predictions from one study that antedated the availability of effective antiretroviral therapy estimated that ~13% of homosexual/bisexual men who were infected at an early age may remain free of clinical AIDS for >20 years. Originally, individuals were considered to be long-term survivors if they remained alive for 10 to 15 years after initial infection. Currently, individuals are considered to be long-term survivors if they remain alive for ≥20 years after initial infection. In most such individuals the disease has progressed, in that they have significant immunodeficiency, and many have experienced opportunistic diseases. Some of these individuals have CD4+ T cell counts that have decreased to ≤200/μL but have remained stable at that level for years. The mechanisms of this stabilization are not entirely clear but may relate to the beneficial effects of antiretroviral therapy and prophylaxis against opportunistic infections. In addition, a number of viral and/or host determinants likely contribute to the long-term survival of these individuals. Quantitative and qualitative aspects of the HIV-specific immune response, as well as recognized and unrecognized genetic factors (see below), may also contribute to the long-term survival of these individuals.

Definitions of long-term nonprogressors have varied considerably over the years, and so such individuals constitute a heterogeneous group. Originally, individuals considered to be long-term nonprogressors were those who had been infected with HIV for a long period (≥10 years), whose CD4+ T cell counts were in the normal range and remained stable over years, and who had not received antiretroviral therapy. Such patients had low, but usually detectable, levels of plasma viremia, generally normal immune function according to commonly measured parameters (skin tests, in vitro lymphocyte responses to various mitogens and antigens), and normal-appearing lymphoid tissue architecture as determined on lymph node biopsy. The definition rested more on the status of the immune system than on the absolute control of plasma viremia. In general, long-term nonprogressors manifested robust HIV-specific immune responses, both humoral (neutralizing antibodies) and cell-mediated (HIV-specific CTLs). However, this may also be true of some individuals early in the course of disease who ultimately progress to advanced disease. No qualitative abnormalities in the virus were detected in most of these patients. However, a small subset of patients did have defective virus; in particular, in one cohort of five long-term nonprogressors, the virus had a defect in the *nef* gene. In another report, a blood donor in Australia who was HIV-infected and a group of seven individuals who were infected by blood or blood products from that donor remained free of HIV-related disease and maintained normal and stable CD4+ T cell counts for several years after infection. Sequence analysis of viruses isolated from the donor and recipients revealed similar deletions in the *nef* gene and the region of overlap of *nef* and the U3 region of the HIV LTR (Fig. 173-5). The vast majority of these originally reported long-term nonprogressors have now gone on to progressive disease. More recently, cohorts of rare long-term nonprogressors have been described who have been infected for 20 years with normal CD4+ T cell counts and who typically maintain plasma viral RNA <50 copies per milliliter without antiretroviral therapy. When these more stringent definitions based predominantly on levels of plasma viremia are applied, very strong associations with HLA B*5701 or HLA B*2705 alleles have been found. In addition, the HIV-specific CD8+ T cell response in these patients is highly focused on B5701-restricted peptides, suggesting that the B5701 molecule plays a direct role in restriction of virus replication in these individuals, although the precise mechanisms of this effect remain unclear.

A number of other host genetic factors exert more modest effects on restriction of HIV replication, yet they also may be associated with slower progression of disease (see "Genetic Factors in HIV Pathogenesis," below). The precise role of host factors in long-term nonprogression remains unclear. There is no obvious and consistent genetic determinant for nonprogression. However, several genetic mutations have been demonstrated to result in a delay in the progression of HIV disease. These include heterozygosity for the *CCR5*-Δ32 deletion, heterozygosity for the *CCR2*-64I mutation, homozygosity for the *SDF1*-3′A mutation, and heterozygosity for the *RANTES*-28G mutation (see "Genetic Factors in HIV Pathogenesis," below). Since CCR5 is the major co-receptor for R5 or macrophage-tropic strains of HIV and since individuals who are homozygous for the *CCR5*-Δ32 deletion are, with rare exceptions, protected against HIV infection, the potential mechanism for slow progression in heterozygotes is clear. In addition, certain single nucleotide polymorphisms in the *CCR5* promoter have been shown to be associated with slower progression of disease. The reason for the slowing of progression of HIV disease in individuals who are heterozygous for the *CCR2*-64I mutation is less clear; however, it has been demonstrated that CXCR4 can dimerize with the CCR2-64I mutant but not with wild-type CCR2. This dimerization may reduce the amount of CXCR4 on the cell surface and as a result inhibit infection with X4 viruses. Homozygosity for the *SDF1*-3′A mutation may upregulate the *SDF1* gene enabling SDF-1, which is the natural ligand for CXCR4, to compete more effectively with X4 or T cell tropic virus for the CXCR4 coreceptor. The *RANTES*-28G mutation increases RANTES expression, which is the natural ligand for CCR5 and may thus inhibit infection with R5 viruses. Finally, maximal HLA heterozygosity of class I loci (A, B, and C) has been shown to be associated with delayed progression of HIV disease. Although long-term nonprogressors have robust HIV-specific immune responses as well as competent CD8+ T cell suppressors of HIV replication, it is unclear whether these factors are directly responsible for the state of nonprogression. A substantial proportion of HIV-infected individuals manifest comparable immune responses early in the course of their disease and still experience disease progression. As noted above, long-term nonprogressors likely represent a heterogeneous group. The lack of disease progression may be explained in some by a defect in the virus; in others by any of a variety of host factors, including recognized and as yet unrecognized genetic factors; and in others by a combination of both.

LYMPHOID ORGANS AND HIV PATHOGENESIS Regardless of the portal of entry of HIV, lymphoid tissues are the major anatomic sites for the establishment and propagation of HIV infection (see above) Despite the use of measurements of plasma viremia to determine the level of disease activity, virus replication occurs mainly in lymphoid tissue and not in blood; indeed, the level of plasma viremia directly reflects virus production in lymphoid tissue.

Some patients experience progressive generalized lymphadenopathy (see below) early in the course of the infection; others experience varying degrees of transient lymphadenopathy. Lymphadenopathy reflects the cellular activation and immune response to the virus in the lymphoid tissue, which is generally characterized by follicular or germinal center hyperplasia. Lymphoid tissue involvement is a common denominator of virtually all patients with HIV infection, even those without easily detectable lymphadenopathy.

Simultaneous examinations of lymph tissue and peripheral blood in patients and monkeys during various stages of HIV and SIV infec-

tion, respectively, have led to substantial insight into the pathogenesis of HIV disease. Using a combination of PCR techniques for HIV DNA and HIV RNA in tissue and HIV RNA in plasma, in situ hybridization for HIV RNA, and light and electron microscopy, the following picture has emerged. During acute HIV infection, a high level of viral replication in individual cells is demonstrated in lymphoid tissue and is associated with a burst of plasma viremia. A profound degree of cellular activation occurs (see below) and is reflected in follicular or germinal center hyperplasia. At this time copious amounts of extracellular virions are trapped on the processes of the follicular dendritic cells (FDCs) in the germinal centers of the lymph nodes (Fig. 173-18*A*). Virions that have bound complement components on their surfaces attach to the surface of FDCs via interactions with complement receptors and likely via Fc receptors that bind to antibodies that are attached to the virions. In situ hybridization reveals expression of virus in individual cells of the paracortical area and, to a lesser extent, the germinal center (Fig. 173-18*B*). The persistence of trapped virus after the transition from acute to chronic infection likely reflects a steady state whereby trapped virus turns over and is replaced by fresh virions, which are continually produced to a greater or lesser degree in individual patients.

During early-stage HIV disease, the architecture of the germinal centers is generally preserved and may even be hyperplastic owing to in situ proliferation of cells (mostly B lymphocytes) and recruitment to the lymph nodes of a number of cell types (B cells, CD4+ and CD8+ T cells). Electron microscopy demonstrates a fine network of FDCs with many long, finger-like processes that envelop virtually every lymphocyte in the germinal center (Fig. 173-18*C*). Extracellular virions can be seen attached to the processes, yet the FDCs appear to be relatively healthy. The trapping of antigen is a physiologically normal function for the FDCs, which present antigen to B cells and contribute to the generation of B cell memory. However, in the case of HIV, the trapped virions serve as a persistent source of cellular activation, resulting in the secretion of proinflammatory cytokines such as interleukin (IL) 1β, tumor necrosis factor (TNF) α, and IL-6, which can upregulate virus replication in infected cells (see below). Furthermore, although trapped virus is coated by neutralizing antibodies, it has been demonstrated that these virions remain infectious for CD4+ T cells while attached to the processes of the FDCs. CD4+ T cells that migrate into the germinal center to provide help to B cells in the generation of an HIV-specific immune response are susceptible to infection by these trapped virions. Thus, in HIV infection, a normal physiologic function of the immune system, which contributes to the clearance of virus as well as to the generation of a specific immune response, can also have deleterious consequences. It is difficult to demonstrate infection of the FDCs at this point, or even in advanced disease; however, rare examples of virus budding off FDCs have been reported.

As the disease progresses, the architecture of the germinal centers begins to show disruption, and the trapping efficiency of the lymph node diminishes. Electron microscopy reveals swollen organelles, and the FDCs begin to undergo cell death. The mechanisms of FDC death remain unclear; there is no indication by electron microscopy of copious virus replication or budding of virions off the cell in great quantities. As the disease progresses to an advanced stage, there is complete disruption of the architecture of the germinal centers, accompanied by

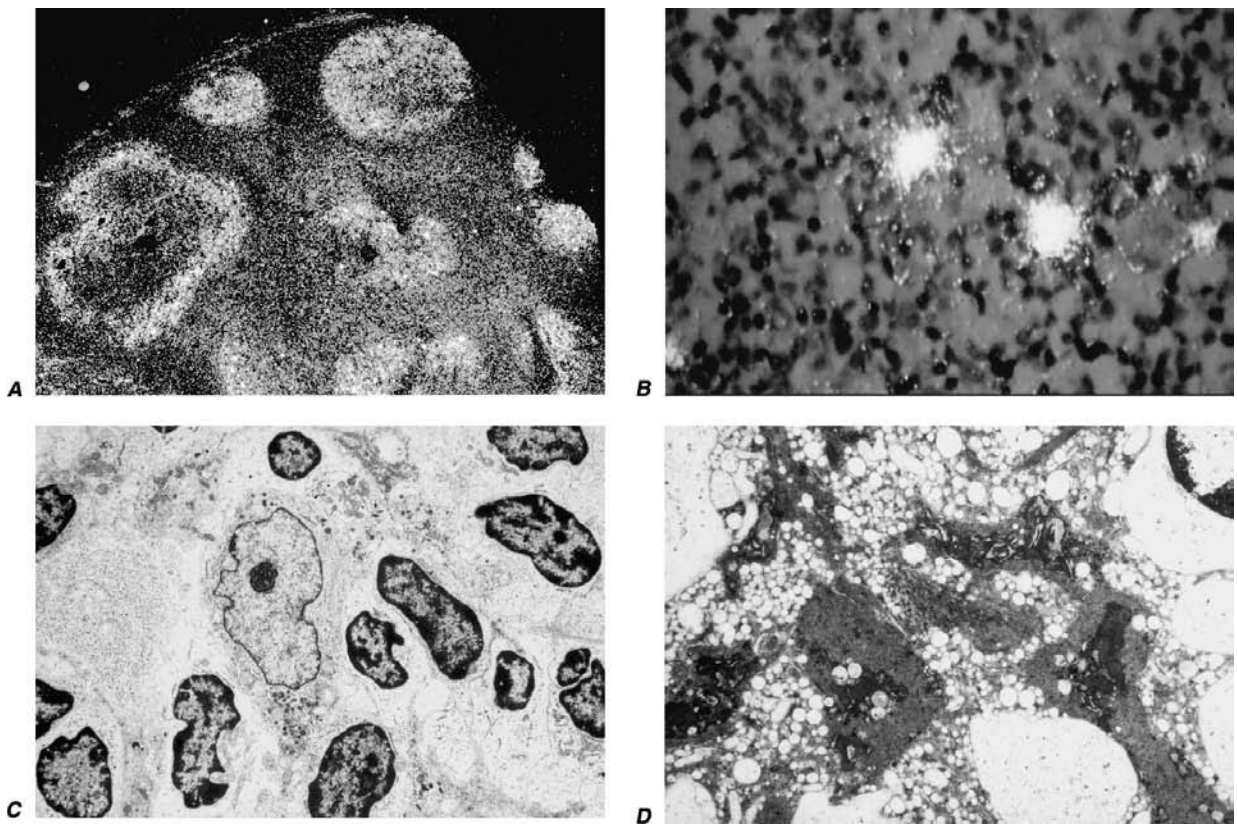

FIGURE 173-18 HIV in the lymph nodes of HIV-infected individuals. *A*. Cervical lymph node from an asymptomatic individual with very low levels of plasma viremia. In situ hybridization using a molecular probe for HIV RNA reveals copious virus demarcating the numerous germinal centers (bright areas) of the node. The virus was extracellular and bound to the processes of the follicular dendritic cells (FDCs), which form a matrix within the confines of the germinal centers. Original ×25. *B*. Individual cells infected with HIV. Two cells in the paracortical area of the lymph node are shown expressing HIV RNA by in situ hybridization using a radiolabeled molecular probe. Original ×250. *C*. FDCs in cervical node of an asymptomatic HIV-infected individual. Electron microscopy reveals an FDC with a prominent nucleolus surrounded by several lymphocytes within the germinal center of the node. Higher magnification of several fields indicates that multiple processes of the FDCs are in contact with several lymphocytes. Original ×1920. *D*. Dissolution of FDCs in the germinal center of a cervical lymph node from a patient with advanced HIV disease. Widespread death of FDCs is associated with a loss of ability of the lymph node to trap virus late in the course of HIV disease. Original ×3744. (*A and B courtesy of Dr. Cecil Fox; C and D courtesy of Dr. Jan Orenstein. Adapted from G Pantaleo et al: N Engl J Med 328:327, 1993.*)

dissolution of the FDC network and massive dropout of FDCs (Fig. 173-18*D*). At this point, the lymph nodes are "burnt out." This destruction of lymphoid tissue compounds the immunodeficiency of HIV disease and contributes both to the inability to control HIV replication (leading usually to high levels of plasma viremia in the untreated or inadequately treated patient) and to the inability to mount adequate immune responses against opportunistic pathogens. The events from primary infection to the ultimate destruction of the immune system are illustrated in Fig. 173-19.

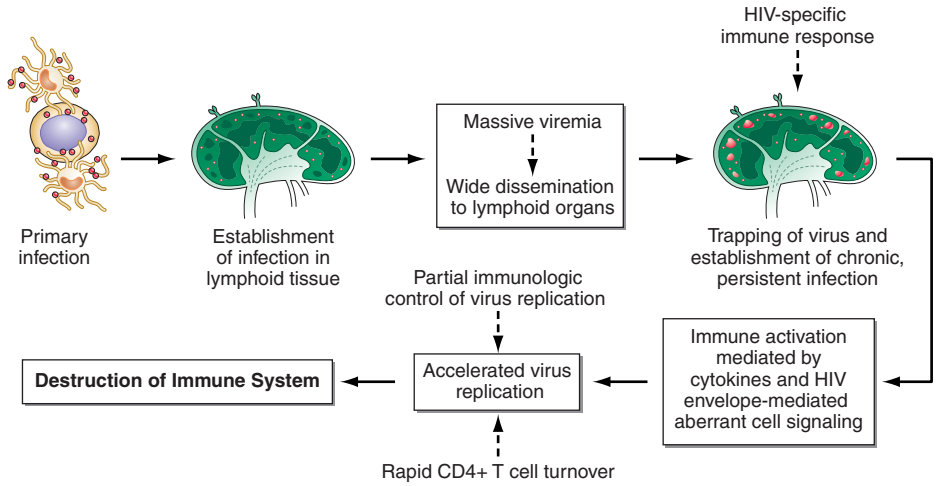

FIGURE 173-19 Events that transpire from primary HIV infection through the establishment of chronic persistent infection to the ultimate destruction of the immune system. See text for details; CTLs, cytolytic T lymphocytes.

CELLULAR ACTIVATION AND HIV PATHOGENESIS

Activation of the immune system is an essential component of an appropriate immune response to a foreign antigen. The immune system is normally in a state of homeostasis, awaiting perturbation by foreign antigenic stimuli. Once the immune response deals with and clears the antigen, the system returns to relative quiescence (Chap. 295). In HIV infection, however, the immune system is chronically activated owing to the persistence of virus replication throughout the course of HIV disease, particularly in the untreated patient (see above) and to variable degrees even in certain patients receiving antiretroviral therapy whose level of plasma viremia is suppressed to below the level of detection by standard assays (see below). Aberrant immune activation is the hallmark of HIV infection and is a critical component of the pathogenesis of HIV disease. This activated state is reflected by hyperactivation of B cells leading to hypergammaglobulinemia; spontaneous lymphocyte proliferation; activation of monocytes; expression of activation markers on CD4+ and CD8+ T cells; lymph node hyperplasia, particularly early in the course of disease (see above); increased secretion of proinflammatory cytokines (see below); elevated levels of neopterin, β_2-microglobulin, acid-labile interferon, and soluble IL-2 receptors; and autoimmune phenomena (see below). Even in the absence of direct infection of a target cell, HIV envelope proteins can interact with cellular receptors (CD4 molecules and chemokine receptors) to deliver potent activation signals resulting in calcium flux, the phosphorylation of certain proteins involved in signal transduction, co-localization of cytoplasmic proteins including those involved in cell trafficking, immune dysfunction, and under certain circumstances, apoptosis (see below). The secretion of certain proinflammatory and immunoregulatory cytokines is both a consequence of the aberrant immune activation associated with HIV infection and a mechanism of propagation of the process of aberrant cellular activation (see below).

In addition to endogenous factors such as cytokines, a number of exogenous factors such as other microbes that are associated with heightened cellular activation can enhance HIV replication and thus may have important effects on HIV pathogenesis. Co-infection or simultaneous cotransfection of cells with HIV and other viruses or viral genes has demonstrated that certain viruses, such as HSV type 1, cytomegalovirus (CMV), human herpesvirus (HHV) 6, Epstein-Barr virus (EBV), HBV, adenovirus, pseudorabies virus, and HTLV-I can upregulate HIV expression. Other microbes, such as *Mycoplasma*, have been reported to contribute to the induction of HIV expression. In addition, infestation with nematodes has been shown to be associated with a heightened state of immune activaton that facilitates HIV replication; de-worming of the infected host results in a decrease in plasma viremia. *Mycobacterium tuberculosis* is a common opportunistic infection in HIV-infected individuals (see below and Chap. 150). In addition to the fact that HIV-infected individuals are more likely to develop active tuberculosis (TB) after exposure, it has been demonstrated that active TB can accelerate the course of HIV infection. It has also been shown that levels of plasma viremia are greatly elevated in HIV-infected individuals with active TB, compared to pre-TB levels and levels of viremia after successful treatment of the active TB. In vitro studies demonstrated that virus replication was markedly enhanced in lymphocytes of HIV-infected individuals who were skin test–positive for purified protein derivative (PPD) when PPD antigen was added to culture, resulting in cellular activation. Confirmatory evidence that antigen-induced activation was a major contributor to the accelerated viremia in HIV-infected individuals with active TB was provided by studies in which HIV-infected individuals were immunized with common recall antigens such as tetanus toxoid, influenza, or pneumococcal polysaccharide. Under these circumstances, a transient elevation of plasma viremia accompanied the cellular activation induced by the immunization. A greater degree of induction of virus was seen in those individuals with early-stage as opposed to advanced stage HIV disease, and the degree of virus induction correlated with the level of immune system activation.

Persistent immune activation may have several deleterious consequences. From a virologic standpoint, although quiescent CD4+ T cells can be infected with HIV, reverse transcription, integration, and virus spread are much more efficient in activated cells. Furthermore, cellular activation induces expression of virus in cells latently infected with HIV (see above). From an immunologic standpoint, chronic exposure of the immune system to a particular antigen over an extended period may ultimately lead to an inability to sustain an adequate immune response to the antigen in question. Furthermore, the ability of the immune system to respond to a broad spectrum of antigens may be compromised if immunocompetent cells are maintained in a state of chronic activation. In addition, activation of the immune system may favor the elimination of cells via programmed cell death (apoptosis) (see below) as well as the secretion of certain cytokines that can induce HIV expression (see below).

Apoptosis *Apoptosis* is a form of programmed cell death that is a normal mechanism for the elimination of effete cells in organogenesis as well as in the cellular proliferation that occurs during a normal immune response (Chap. 295). Apoptosis is strictly dependent on cellular activation, and the aberrant cellular activation associated with HIV disease (see above) is correlated with a heightened state of apoptosis. It has been hypothesized that, in HIV infection, sequential activation signals delivered to CD4+ T cells induce apoptosis. Cross-linking of the CD4 molecule by gp120 or gp120/anti-gp120 complexes delivers the first of two signals required for apoptosis. The second signal supposedly leading to cell death is delivered via the T cell receptor by antigen. According to this hypothesis, direct infection of CD4+ T cells is not required for apoptosis to occur, although it has been demonstrated that alterations in tyrosine kinase activity of HIV-infected cells may induce the cell to undergo apoptosis. HIV can trigger both Fas-dependent and Fas-independent pathways of apoptosis. Mechanisms involved in this process include upregulation of Fas and Fas ligand,

upregulation of caspase-1 and caspase-6, downregulation of the anti-apoptotic Bcl-2 protein, and activation of cyclin-dependent kinases. Certain viral gene products have been associated with enhanced susceptibility to apoptosis including Envelope, Tat, and Vpr. In contrast, Nef has been shown to possess antiapoptotic properties. A number of studies, including those examining lymphoid tissue, have demonstrated that the rate of apoptosis is elevated in HIV infection and that apoptosis is seen in "bystander" cells such as CD8+ T cells and B cells as well as in CD4+ T cells. The intensity of apoptosis correlates with the general state of activation of the immune system and not with the stage of disease or with viral burden. The potential role of apoptosis in the pathogenesis of HIV disease is underscored by results from animal studies that show an increased frequency of apoptosis in CD4+ T cells in primates infected with pathogenic strains of SIV but not in primates infected with nonpathogenic strains of SIV. It is likely that apoptosis of immunocompetent cells contributes to the immune abnormalities in HIV disease; however, this is probably a nonspecific mechanism that merely reflects the aberrant state of immune activation.

Autoimmune Phenomena The autoimmune phenomena that are common in HIV-infected individuals reflect, at least in part, chronic immune system activation as well as molecular mimickry by viral components. Although these phenomena usually occur in the absence of autoimmune disease, a wide spectrum of clinical manifestations that may be associated with autoimmunity have been described (see below). Autoimmune phenomena include antibodies to lymphocytes and, less commonly, to platelets and neutrophils. Antiplatelet antibodies have some clinical relevance, in that they may contribute to the thrombocytopenia of HIV disease (see below). Antibodies to nuclear and cytoplasmic components of cells have been reported, as have antibodies to cardiolipin; CD4 molecules; CD43 molecules, C1q-A; variable regions of the T cell receptor α, β, and γ chains; Fas; denatured collagen; and IL-2. In addition, autoantibodies to a range of serum proteins, including albumin, immunoglobulin, and thyroglobulin, have been reported. There is antigenic cross-reactivity between HIV viral proteins (gp120 and gp41) and MHC class II determinants, and anti-MHC class II antibodies have been reported in HIV infection. These antibodies could potentially lead to the elimination of MHC class II–bearing cells via antibody-dependent cellular cytotoxicity (ADCC) (Chap. 295). In addition, regions of homology exist between HIV envelope glycoproteins and IL-2 as well as MHC class I molecules.

THE CYTOKINE NETWORK IN HIV PATHOGENESIS The immune system is homeostatically regulated by a complex network of immunoregulatory cytokines, which are pleiotropic and redundant and operate in an autocrine and paracrine manner. They are expressed continuously, even during periods of apparent quiescence of the immune system. On perturbation of the immune system by antigenic challenge, the expression of cytokines increases to varying degrees (Chap. 295). Cytokines that are important components of this immunoregulatory network have been demonstrated to play a major role in the regulation of HIV expression in vitro. Potent modulation of HIV expression has been demonstrated either by manipulating endogenous cytokines or by adding exogenous cytokines to culture. Cytokines that induce HIV expression in one or more of these systems include IL-1, IL-2, IL-3, IL-6, IL-12, TNF-α, TNF-β, macrophage colony-stimulating factor (M-CSF), and granulocyte-macrophage colony-stimulating factor (GM-CSF). Among these cytokines, the most consistent and potent inducers of HIV expression are the *proinflammatory cytokines* TNF-α, IL-1β, and IL-6. Interferon (IFN)-α and -β suppress HIV replication, whereas transforming growth factor (TGF) β, IL-4, IL-10, and IFN-γ can either induce or suppress HIV expression, depending on the system involved. The *CC-chemokines* RANTES, macrophage inflammatory protein (MIP) 1α, and MIP-1β (Chap. 295) inhibit infection by and spread of R5 (macrophage-tropic) HIV-1 strains, while *stromal cell–derived factor* (SDF) 1 inhibits infection by and spread of X4 (T cell–tropic) strains (see below). The alpha defensin family of cytokines has been shown to inhibit both R5 and X4 viruses, and other soluble factors that have not yet been fully characteized have also been shown to suppress HIV replication. Blocking of endogenous HIV-inducing cytokines or addition of inhibitors of HIV suppressor cytokines in cultures of peripheral blood and lymph node mononuclear cells from HIV-infected individuals has demonstrated that HIV replication is controlled tightly by endogenous cytokines that act synergistically and in an autocrine and paracrine manner, similar to their physiologic function in the regulation of the immune system. Indeed, the net level of virus replication in an HIV-infected individual reflects at least in part a balance between inductive and suppressive host factors, mediated mainly by cytokines.

The molecular mechanisms of HIV regulation are best understood for TNF-α, which activates NF-κB proteins that function as transcriptional activators of HIV expression. The HIV-inducing effect of IL-1β is thought to occur at the level of viral transcription in an NF-κB-independent manner. IL-6, GM-CSF, and IFN-γ regulate HIV expression mainly by posttranscriptional mechanisms. Elevated levels of TNF-α and IL-6 have been demonstrated in plasma and cerebrospinal fluid (CSF), and increased expression of TNF-α, IL-1β, IFN-γ, and IL-6 has been demonstrated in the lymph nodes of HIV-infected individuals. The mechanisms whereby the CC-chemokines RANTES, MIP-1α, and MIP-1β inhibit infection of R5 strains of HIV involve blocking of the binding of the virus to its co-receptor, the CC-chemokine receptor CCR5 (see above and below). Of note is the fact that CC-chemokines that inhibit infection by R5 strains of virus actually enhance infection by X4 strains of virus by inducing intracellular signal transduction through the CCR5 and CD4 molecules. The mechanisms whereby other less well characterized factors (see above) inhibit HIV replication are not completely understood.

LYMPHOCYTE TURNOVER IN HIV INFECTION The immune systems of patients with HIV infection are characterized by a profound increase in lymphocyte turnover that is immediately reduced with effective antiretroviral therapy. Studies utilizing in vivo or in vitro labelling of lymphocytes in the S-phase of the cell cycle have demonstrated a tight correlation between the degree of lymphocyte turnover and plasma levels of HIV RNA. This increase in turnover is seen in CD4+ and CD8+ T lymphocytes as well as B lymphocytes and can be observed in peripheral blood and lymphoid tissue. Mathematical models derived from these data suggest that one can view the lymphoid pool as consisting of dynamically distinct subpopulations of cells that are differentially affected by HIV infection. A major consequence of HIV infection appears to be a shift in cells from a more quiescent pool to a pool with a higher turnover rate. It is likely that a consequence of a higher rate of turnover is a higher rate of death. The role of the thymus in adult human T cell homeostasis and HIV pathogenesis is an area of controversy. While some data point to an important role for the thymus in maintaining T cell numbers and suggest that impairment of thymic function may be responsible for the declines in CD4+ T cells seen in the setting of HIV infection, other studies have concluded that the thymus plays a minor role in HIV pathogenesis. Among the data supporting an important role for the thymus are those that demonstrate an increase in the levels of T cell receptor excision circles (TRECs) following initiation of antiretroviral therapy. TRECs are a byproduct of T cell development and represent episomal fragments of DNA that are excised during T cell receptor gene rearrangement (Chap. 295). Levels of TRECs will be the net result of changes in thymic output and changes in T cell turnover. An increase in thymic output and/or a decrease in T cell turnover will lead to an increase in levels of TRECs. While it is clear that levels of TRECs increase following initiation of antiretroviral therapy, it is not clear whether this is a consequence of increased thymic output or decreased T cell turnover.

CELLULAR TROPISM FOR HIV: ROLE OF CO-RECEPTORS HIV-1 utilizes two major co-receptors along with CD4 to bind to, fuse with, and enter target cells; these co-receptors are CCR5 and CXCR4, which are receptors for certain endogenous chemokines and belong to the seven-transmembrane-domain G protein–coupled family of receptors (see

above). Strains of HIV that utilize CCR5 as a co-receptor are referred to as *R5 viruses*. Strains of HIV that utilize CXCR4 are referred to as *X4 viruses*. Many virus strains are *dual tropic* in that they utilize both CCR5 and CXCR4; these are referred to as *R5X4 viruses*. Other terminology that has been associated with R5 versus X4 viruses is *non-syncytium-inducing viruses* versus *syncytium-inducing viruses*, respectively, based on the observation that R5 viruses generally do not form syncytia in culture with certain T cell lines, whereas X4 viruses readily form syncytia. In reality, under certain conditions both R5 and X4 viruses are capable of forming syncytia in culture.

The natural chemokine ligands for the major HIV co-receptors can readily block entry of HIV. For example, the CC-chemokines RANTES, MIP-1α, and MIP-1β, which are the natural ligands for CCR5, block entry of R5 viruses, whereas SDF-1, the natural ligand for CXCR4, blocks entry of X4 viruses. The mechanism of inhibition of viral entry is a steric inhibition of binding that is not dependent on signal transduction (Fig. 173-20).

The transmitting virus is almost invariably an R5 virus that predominates during the early stages of HIV disease. In ~40% of HIV-infected individuals, there is a transition to a predominantly X4 virus that is associated with a relatively rapid progression of disease. However, at least 60% of infected individuals progress in their disease while maintaining predominance of an R5 virus. Other chemokine receptor family members may function as coreceptors for HIV and SIV entry, but to a much lesser extent than do CCR5 and CXCR4; these include CCR3, BOB/GPR15, Bonzo/STRL33/TYMSTR, CCR2, CCR8, CX_3CR1(V28), and GPR1.

The basis for the tropism of different envelope glycoproteins for either CCR5 or CXCR4 relates to the ability of the HIV envelope, particularly the third variable region (V3 loop) of gp120, to interact with these co-receptors. In this regard, binding of gp120 to CD4 induces a conformational change in gp120 that increases its affinity for CCR5. It appears that the interaction of gp120 with CXCR4 is less dependent on the conformational change induced in gp120 by CD4. In fact, there are X4 strains of HIV that bind to CXCR4 in the absence of surface-bound or soluble CD4. Finally, R5 viruses are more efficient in infecting monocyte/macrophages and microglial cells of the brain (see "Neuropathogenesis," below).

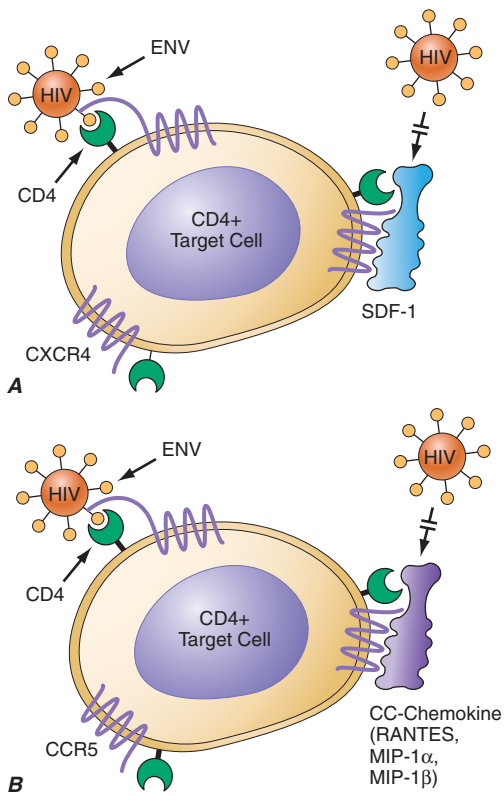

FIGURE 173-20 Model for the role of co-receptors CXCR4 and CCR5 in the efficient binding and entry of X4 (*A*) and R5 (*B*) strains of HIV-1, respectively, into CD4+ target cells. Blocking of this initial event in the virus life cycle can be accomplished by inhibition of binding to the co-receptor by the normal ligand for the receptor in question. The ligand for CXCR4 is stromal cell–derived factor (SDF-1); the ligands for CCR5 are RANTES, MIP-1α, and MIP-1β.

CELLULAR TARGETS OF HIV Although the CD4+ T lymphocytes and CD4+ cells of monocyte lineage are the principal targets of HIV, virtually any cell that expresses the CD4 molecule together with co-receptor molecules (see above and below) can potentially be infected with HIV. Circulating dendritic cells have been reported to express low levels of CD4, and depending on their stage of maturation, these cells can be infected with HIV (see below). Epidermal Langerhans cells express CD4 and have been infected by HIV in vivo. In vitro, HIV has been reported also to infect a wide range of cells and cell lines that express low levels of CD4, no detectable CD4, or only CD4 mRNA; among these are FDCs; megakaryocytes; eosinophils; astrocytes; oligodendrocytes; microglial cells; CD8+ T cells; B cells; NK cells; renal epithelial cells; cervical cells; rectal and bowel mucosal cells such as enterochromaffin, goblet, and columnar epithelial cells; trophoblastic cells; and cells from a variety of organs, such as liver, lung, heart, salivary gland, eye, prostate, testis, and adrenal gland. Since the only cells that have been shown unequivocally to be infected with HIV and to support replication of the virus are CD4+ T lymphocytes and cells of monocyte/macrophage lineage, the relevance of the in vitro infection of these other cell types is questionable.

Of potentially important clinical relevance is the demonstration that thymic precursor cells, which were assumed to be negative for CD3, CD4, and CD8 molecules, actually do express low levels of CD4 and can be infected with HIV in vitro. In addition, human thymic epithelial cells transplanted into an immunodeficient mouse can be infected with HIV by direct inoculation of virus into the thymus. Since these cells may play a role in the normal regeneration of CD4+ T cells, it is possible that their infection and depletion contribute, at least in part, to the impaired ability of the CD4+ T cell pool to completely reconstitute itself in certain infected individuals in whom antiretroviral therapy has suppressed viral replication to <50 copies of HIV RNA per milliliter (see below). In addition, CD34+ monocyte precursor cells have been shown to be infected in vivo in patients with advanced HIV disease. It is likely that these cells express low levels of CD4, and therefore it is not essential to invoke CD4-independent mechanisms to explain the infection.

ABNORMALITIES OF MONONUCLEAR CELLS ■ CD4+ T Cells The range of T cell abnormalities in advanced HIV infection is broad. The defects are both quantitative and qualitative and affect virtually every limb of the immune system (see below), indicating the critical dependence of the integrity of the immune system on the inducer/helper function of CD4+ T cells. In advanced HIV disease, virtually all of the observed immune defects can ultimately be explained by the quantitative depletion of CD4+ T cells. However, T cell dysfunction (see below) can be demonstrated in patients early in the course of infection, even when the CD4+ T cell count is in the low-normal range. The degree and spectrum of dysfunctions increase as the disease progresses. One of the first abnormalities to be detected is a defect in response to remote recall antigens, such as tetanus toxoid and influenza, at a time when mononuclear cells can still respond normally to mitogenic stimulation. Defects in responses to soluble antigens are followed in time by the loss of T cell proliferative responses to alloantigens, and subsequently to mitogens. Essentially every T cell function has been reported to be abnormal at some stage of HIV infection. These abnormalities include defective T cell cloning and colony-forming efficiencies, impaired expression of IL-2 receptors, defective IL-2 production, and decreased IFN-γ production in response to antigens. The proportion of CD4+ T cells that express CD28, which is a major co-stimulatory molecule necessary for the normal activation of T cells, is reduced during HIV infection. Cells lacking expression of CD28 do not respond normally

to activation signals and may express markers of terminal activation including HLA-DR, CD38, and CD45RO. CD4+ T cells from HIV-infected individuals express abnormally low levels of CD40 ligand, which may contribute to the dysregulation of B cell function observed in HIV disease.

It is difficult to explain completely the profound immunodeficiency noted in HIV-infected individuals solely on the basis of direct infection and quantitative depletion of CD4+ T cells. This is particularly apparent during the early stages of HIV disease, when CD4+ T cell numbers may be only marginally decreased. In this regard, it is likely that CD4+ T cell dysfunction results from a combination of depletion of cells due to direct infection of the cell and a number of virus-related but indirect effects on the cell (Table 173-6). Indeed, it has been demonstrated that patients with high levels of plasma viremia have a variety of subtle abnormalities of CD4+ T cell function, particularly involving aberrancies in signal transduction pathways. These abnormalities could be due either to aberrant activation induced by the cascade of cytokines that are expressed in viremic patients or by the direct effect of virus on the cell. In this regard, certain of these abnormalities can be reproduced by exposing CD4+ T cells of normal individuals to oligomeric HIV envelope proteins in vitro (see below).

Single-cell killing and the formation of syncytia between infected and uninfected cells have been demonstrated clearly in vitro, although the precise mechanisms of cell death in vivo have not been determined. Cytopathicity in an infected cell in vitro may result from a number of mechanisms, including copious budding of virions from the cell surface with resulting disruption of the integrity of the cell membrane; interference with cellular RNA processing or the accumulation of high levels of heterodisperse RNA molecules; disruption of cellular protein synthesis owing to high levels of viral RNA; accumulation of high levels of unintegrated viral DNA in the cell cytoplasm; induction of aberrant patterns of protein tyrosine phosphorylation; and the interaction between HIV gp120 and CD4 intracellularly. Strain differences in single-cell killing are determined largely by gp120 sequences, which supports the importance of the viral envelope in this process. *Syncytia formation* involves fusion of the cell membrane of an infected cell with the cell membranes of variable numbers of uninfected CD4+ cells. Although cell fusion has not been shown to be an important pathogenic process in vivo, a direct relationship between the presence of syncytia and the degree of cytopathic effect has been demonstrated in vitro, and a correlation has been reported between the presence of virus isolates that readily induce syncytia in vitro and a more aggressive clinical course in the patient. Humoral and cellular immune responses to HIV may contribute to protective immunity by eliminating virus and virus-infected cells (see below). However, since the main targets of HIV infection are immunocompetent cells, these responses may contribute to immune cell depletion and immunologic dysfunction by eliminating both infected cells and "innocent bystander" cells. Soluble viral proteins, particularly gp120, can bind with high affinity to the CD4 molecules on uninfected T cells and monocytes; in addition, virus and/or viral proteins can bind to dendritic cells or FDCs. HIV-specific antibody can recognize these bound molecules and potentially collaborate in the elimination of the cells by ADCC.

TABLE 173-6 *Mechanisms of CD4+ T Cell Dysfunction and Depletion*

Direct Mechanisms	Indirect Mechanisms
Loss of plasma membrane integrity due to viral budding	Aberrant intracellular signaling events
Accumulation of unintegrated viral DNA	Autoimmunity
Interference with cellular RNA processing	Innocent bystander killing of viral antigen–coated cells
Intracellular gp120-CD4 autofusion events	Apoptosis
Syncytia formation	Inhibition of lymphopoiesis
	Activation-induced cell death
	Elimination of HIV-infected cells by virus-specific immune responses

Nonpolymorphic determinants of MHC class I products share a degree of homology with gp120 and gp41 proteins of HIV. Such similarities may lead to the generation of autoantibodies to self-MHC determinants. In fact, anti-HLA-DR antibodies have been demonstrated in the sera of HIV-infected individuals (see "Autoimmune Phenomena," above). These antibodies could contribute to the elimination of HLA-DR–expressing cells by ADCC; in addition, it has been suggested that these antibodies may inhibit certain T cell functions that involve HLA-DR molecules.

HIV envelope glycoproteins gp120 and gp160 manifest high-affinity binding to CD4 as well as to various chemokine receptors (see above). Intracellular signals transduced by gp120 have been associated with a number of immunopathogenic processes including anergy, apoptosis, and abnormalities of cell trafficking. The molecular mechanisms responsible for these abnormalities include dysregulation of the T cell receptor–phosphoinositide pathway, p56lck activation, phosphorylation of focal adhesion kinase, activation of the MAP kinase and ras signaling pathways, and downregulation of the co-stimulatory molecules CD40 ligand and CD80.

Finally, the inexorable decline in CD4+ T cell counts that occurs in most HIV-infected individuals may result in part from the inability of the immune system to regenerate the rapidly turning over CD4+ T cell pool efficiently enough to compensate for both HIV-mediated and naturally occurring attrition of cells. At least two major mechanisms may contribute to the failure of the CD4+ T cell pool to reconstitute itself adequately over the course of HIV infection. The first is the destruction of lymphoid precursor cells, including thymic and bone marrow progenitor cells (see above); the other is the gradual disruption of the lymphoid tissue microenvironment, which is essential for efficient regeneration of immunocompetent cells (see above).

CD8+ T Cells A relative C8+ T lymphocytosis is generally associated with high levels of HIV plasma viremia and may in part reflect the expansion of clones of HIV-specific CD8+ CTLs. During the late stages of HIV infection, there may be a significant reduction in the numbers of CD8+ T cells despite the presence of high levels of viremia. HIV-specific CD8+ CTLs have been demonstrated in HIV-infected individuals early in the course of disease (see below). The emergence of HIV escape mutants may ultimately evade these HIV-specific CD8+ T cells. However, as the disease progresses, the functional capability of these cells may decrease and may be lost entirely. The cause of this loss of cytolytic activity is unclear. However, it has been demonstrated that, as disease progresses, CD8+ T cells assume an abnormal phenotype characterized by expression of activation markers such as HLA-DR with an absence of expression of the IL-2 receptor (CD25) and a loss of clonogenic potential. In this regard, it has been reported that nonprogressors can be distinguished from progressors by the maintenance in the former of a high proliferative capacity of their HIV-specific CD8+ T cells coupled to increases in perforin expression. It has been reported that the phenotype of CD8+ T cells in HIV-infected individuals may be of prognostic significance. Those individuals whose CD8+ T cells developed a phenotype of HLA-DR+/CD38− following seroconversion had stabilization of their CD4+ T cell counts, whereas those whose CD8+ T cells developed a phenotype of HLA-DR+/CD38+ had a more aggressive course and a poorer prognosis. In addition to the defects in HIV-specific CTLs, functional defects in other MHC-restricted CTLs, such as those directed against influenza and CMV, have been demonstrated. CD8+ T cells secrete a variety of soluble factors that inhibit HIV replication including the CC-chemokines RANTES, MIP-1α, MIP-1β, and the alpha defensins -1, -2, and -3, as well as one or more as yet poorly identified factors (see above). The presence of high levels of HIV viremia in vivo as well as exposure of CD8+ T cells in vitro to HIV envelope has been shown to be associated with a variety of cellular functional abnormalities. Finally, since the integrity of CD8+ T cell function depends in part on adequate inductive signals from CD4+ T cells, the defect in CD8+ CTLs is likely compounded by the quantitative loss and qualitative dysfunction of CD4+ T cells.

B Cells The predominant defect in B cells from HIV-infected individuals is one of aberrant cellular activation, which is reflected by spontaneous proliferation and immunoglobulin secretion and by increased spontaneous secretion of TNF-α and IL-6. In addition, B cells from HIV viremic patients manifest a decreased capacity to mount a proliferative response to ligation of the B cell antigen receptor (surface IgM) at the same time as they are capable of robust differentiation in response to a variety of stimuli. B cells from HIV-infected individuals manifest enhanced spontaneous in vitro transformation with EBV, a process that is likely due to defective T cell immune surveillance. The in vivo counterpart of this phenomenon is an increase in the incidence of EBV-related B cell lymphomas. Untransformed B cells cannot be infected with HIV. However, HIV or its products can activate B cells directly; portions of the HIV gp41 envelope protein have been reported to induce polyclonal B cell activation. In addition, it has been reported that products of the VH_3 genes on the surface of B cells can serve as a receptor for HIV. B cells from patients with high levels of viremia bind virions to their surface via the CD21 complement receptor. It is likely that in vivo activation of B cells by virus products during the viremic state accounts at least in part for the spontaneous activation of these cells noted ex vivo. B cells from HIV-infected individuals express abnormally low levels of HLA-DR and CD21 on their surface. Cognate B cell–CD4+ T cell interactions are abnormal in viremic HIV-infected individuals. B cells respond poorly to CD4+ T cell help; this is due at least in part to an intrinsic defect in responder B cells with regard to their inability to normally upregulate CD25 (IL-2 receptor) and thus to proliferate normally in response to IL-2; in addition, B cells fail to adequately upregulate CD80 and CD86 following stimulation with activated T cells. In vivo, the aberrant activated state of B cells manifests itself by hypergammaglobulinemia and by the presence of circulating immune complexes and autoantibodies (see above). HIV-infected individuals respond poorly to primary and secondary immunizations with protein and polysaccharide antigens. These B cell defects are likely responsible in part for the increase in certain bacterial infections seen in advanced HIV disease in adults, as well as for the important role of bacterial infections in the morbidity and mortality of HIV-infected children, who cannot mount an adequate humoral response to common bacterial pathogens. The absolute number of circulating B cells may be depressed in primary HIV infection; however, this phenomenon is usually transient and likely reflects in part a redistribution of cells out of the circulation and into the lymphoid tissue. In certain patients, the number of circulating B cells decreases in advanced-stage disease.

Monocyte/Macrophages Circulating monocytes are generally normal in number in HIV-infected individuals. Monocytes express the CD4 molecule and several co-receptors for HIV on their surface, including CCR5, CXCR4, and CCR3, and thus are targets of HIV infection. Of note is the fact that the degree of cytopathicity of HIV for cells of the monocyte lineage is low, and HIV can replicate extensively in cells of the monocyte lineage with little cytopathic effect. Hence, monocyte-lineage cells may play a role in the dissemination of HIV in the body and can serve as reservoirs of HIV infection, thus representing an obstacle to the eradication of HIV by antiretroviral drugs. In vivo infection of circulating monocytes is difficult to demonstrate; however, infection of tissue macrophages and macrophage-lineage cells in the brain (infiltrating macrophages or resident microglial cells) and lung (pulmonary alveolar macrophages) can be demonstrated easily. Tissue macrophages are an important source of HIV during opportunistic infections. Infection of monocyte precursors in the bone marrow may directly or indirectly be responsible for certain of the hematologic abnormalities in HIV-infected individuals. A number of abnormalities of circulating monocytes have been reported in HIV-infected individuals, including decreased secretion of IL-1 and IL-12; increased secretion of IL-10; defects in antigen presentation and induction of T cell responses due to decreased MHC class II expression; and abnormalities of Fc receptor function, C3 receptor–mediated clearance, oxidative burst responses, and certain cytotoxic functions such as ADCC, possibly related to low levels of expression of Fc and complement receptors. Exposure of monocytes to viral proteins such as gp120 and Tat, as well as to certain cytokines, can cause abnormal activation, and this may play a role in cellular dysfunction (see above).

Dendritic and Langerhans Cells Dendritic cells play an important role in the initiation of HIV infection by virtue of the ability of HIV to bind to cell surface C-type lectin receptors, particularly DC-SIGN (see above). This allows efficient presentation of virus to CD4+ T cell targets that become infected; complexes of infected CD4+ T cells and dendritic cells provide an optimal microenvironment for virus replication. There has been considerable disagreement regarding the HIV infectibility and hence the depletion as well as the dysfunction of dendritic cells themselves. Depending on their state of maturation, dendritic cells express varying levels of CD4 as well as several chemokine receptors. In this regard, it appears that the ability of a dendritic cell to become infected depends in part on its state of maturation. Mature dendritic cells have been demonstrated to be infectable by both R5 and X4 isolates of HIV-1. Immature tissue dendritic cells have been less well studied in their native state. Even in those dendritic cells in which infection occurs, the efficiency of infection and level of productivity of infection is quite low compared to CD4+ T cells.

Natural Killer Cells The role of NK cells is to provide immunosurveillance against virus-infected cells, certain tumor cells, and allogeneic cells (Chap. 295). Functional abnormalities in NK cells have been observed throughout the course of HIV disease, and the severity of these abnormalities increases as disease progresses. Most studies report that NK cells are normal in number and phenotype in HIV-infected individuals; however, a numerical decrease in the CD16+/CD56+ subpopulation of NK cells has been reported together with an increase in activation markers. The abnormality in NK cell function is thought to result from a defect in postbinding lysis. However, the lytic machinery does not appear to be impaired, since NK cells from HIV-infected individuals mediate ADCC normally. The addition of either IL-2, IL-12, IL-15, or IFN-α to cultures improves the defective in vitro NK cell function of HIV-infected individuals. HIV-mediated downregulation of HLA-A and -B, but not HLA-C and -D molecules may inhibit NK-mediated killing of HIV-infected target cells. NK cells serve as important sources of HIV-inhibitory CC-chemokines. NK cells isolated from HIV-infected individuals constitutively produce high levels of MIP-1α, MIP-1β, and RANTES. In addition, high levels of these chemokines are seen when NK cells are stimulated with IL-2 or IL-15 or when CD16 is cross-linked or during the process of lytic killing of target cells. HIV-infected patients with high levels of plasma viremia manifest a decreased ability, compared to HIV-infected individuals who are aviremic, of their NK cells to block HIV replication in vitro in assays of both cell contact and supernatant-mediated suppression of virus. In addition, viremic patients have a decrease in expression of activating receptors (responsible for killer activity) and an increase in certain inhibitory receptors (responsible for inhibition of killer activity) on NK cells, suggesting one potential mechanism whereby viremia might inhibit the ability of NK cells to kill HIV-infected target cells.

GENETIC FACTORS IN HIV PATHOGENESIS Several reports have described MHC alleles and other host factors that may influence the pathogenesis and course of HIV disease. These include associations with certain HIV-related manifestations, such as KS and diffuse lymphadenopathy, or with the type of clinical course, such as long-term survival or rapid progression (Table 173-7). A number of mechanisms have been proposed whereby MHC-encoded molecules might predispose an individual either to rapid progression or to nonprogression to AIDS. These proposed mechanisms include the ability to present certain immunodominant HIV T helper or CTL epitopes, leading to a relatively protective immune response against HIV and hence to slow progression of disease. In contrast, certain MHC class I or class II alleles might predispose an individual to an immunopathogenic response against

TABLE 173-7 *Genetic Factors Implicated in the Pathogenesis of HIV Disease*

Factor	Association
MAJOR HISTOCOMPATIBILITY LOCI-ENCODED GENES	
B35, C4, DR1, DQ1	Kaposi's sarcoma
DR1	Kaposi's sarcoma
DR2, DR5	Kaposi's sarcoma
DR5	Kaposi's sarcoma
Aw23, Bw49	Kaposi's sarcoma
B62	Fever, skin rash in primary HIV infection
Aw19	HIV seropositivity in individuals multiply exposed to HIV
A1, A24, C7, B8, DR3	Rapid progression to AIDS
DR4, DQB1*0302	Rapid progression to AIDS
DR3, DQ1	Rapid progression to AIDS
B*35	Rapid progression to AIDS
Cw*04	Rapid progression to AIDS
TAP2.1	Promotes HIV progression to AIDS
DR5	Thrombocytopenia and lymphadenopathy in HIV infection
DR5, DR6	Diffuse infiltrative CD8+ lymphocytosis with Sjögren-like syndrome in HIV infection
Bw4	Slow decline in CD4+ T cell count
B13, B27, B51, B57, DQB1*0302,0303	Protects from progression to AIDS
B*5701	Strong protection from progression to AIDS
A26, B38, TAP1.4, TAP2.3	Ability to clear HIV infection in transiently infected seronegative individuals
A28, Bw70, Aw69, B18	Protection from HIV infection
A32, B4, C2	Long-term survival in HIV infection
A11, A32, B13, C2, DQA1*0301, DQB1*0302, DRB1*0400, DRB4*0101	Long-term survival in HIV infection
Heterozygosity for class I loci (A, B, and C)	Delayed onset to AIDS
Homozygosity for class I loci (A, B, and C)	Rapid onset to AIDS and death
OTHER GENES	
p53 tumor-suppressor gene	Controls HIV replicative patterns and determinant of viral latency
CCR5 gene	Homozygous defect involving a 32-bp deletion corresponding to the second extracellular loop of the receptor results in resistance to infection; heterozygous defect appears to result in partial protection against disease progression. Also, several single nucleotide polymorphisms (SNPs) in the CCR5 promoter have been shown to be associated with variable rates of progression in AIDS.
CCR2 gene	Heterozygosity for CCR2-641 mutation is associated with delay in progression of HIV disease
CX3CR1 gene	Mutations in I249 and M280 associated with rapid progression to AIDS
RANTES gene	A mutation of the RANTES gene (RANTES-28G) results in increased transcription and expression of RANTES on mononuclear cells with resulting inhibition of infection with R5 strains of HIV and delay of disease progression. Three SNPs; 403A in the RANTES promoter, In1.1C in the first intron, and 3′222C in the 3′ untranslated region of the gene are associated with increased frequency of HIV-1 infection. The SNP In1.1C allele results in decreased RANTES production and correlates with rapid progression to AIDS.
IL-10 gene	Individuals carrying the IL10-5′-592A promoter allele were at increased risk for HIV infection and, once infected, progressed more rapidly than homozygotes for the alternative IL10-5′-592 C/C genotype
VDR gene	Homozygosity for vitamin D receptor gene polymorphism B (VDR-BB) correlates with rapid progression to AIDS
IL-4 gene	SNP IL-4-589T causes higher levels of IL-4 production in vivo, resulting in downregulation of CCR5. The presence of SNP IL-4-589T is modestly associated with protection from acquisition of HIV-1 by heterosexual contact. This SNP also correlates with slower disease progression and decreased viral load early in infection.
IL-1ra gene	Homozygosity IL-1ra gene*2 correlates with significantly lower viral loads.
TNF-α gene	SNP TNF-α-238A, but not the -308A allele correlates with a higher frequency of lipodystrophy.
IL-6 gene	Among HIV-positive men, homozygosity for SNP IL-6-174G carries an increased risk of development of Kaposi sarcoma; men with homozygosity for SNP IL-6-174C were less likely to develop Kaposi sarcoma.
GENE INTERACTIONS	
KIR gene with *HLA-B*	In the absence of HLA-B Bw4-80I, KIR3DS1 is strongly associated with rapid progression to AIDS. This effect is reversed by the presence of HLA-B Bw4-80I. Individuals carrying both genes have a delayed progression to AIDS; in the absence of KIR3DS1, HLA-B Bw4-80I has no effect on disease progression.

Sources: Adapted from BF Haynes et al: Science 271:324, 1996; O'Brien and Moore.

viral epitopes in certain tissues, such as the CNS or lungs, or against certain HIV-infected cell types, such as macrophages or dendritic cells/Langerhans cells. In addition, certain rare MHC class I and class II alleles might facilitate rapid recognition of HIV-infected cells from the infecting partner in primary HIV infection and promote rejection of these cells by alloreactive responses. Similarly, common MHC alleles could lead to less effective removal of HIV-infected allogeneic cells. It has been clearly demonstrated that maximal *HLA* heterozygosity for class I loci (A, B, and C) is associated with a delayed onset of AIDS among HIV-infected individuals, whereas homozygosity for these loci was associated with a more rapid progression to AIDS and death. This observation is likely due to the fact that individuals who are heterozygous at *HLA* loci are able to present a greater variety of antigenic peptides to cytotoxic T lymphocytes than are homozygotes, resulting in a more effective immune response against a number of pathogens including HIV. Of particular note is the fact that the HLA class I alleles B*35 and Cw*04 were consistently associated with rapid development of AIDS. Other data have indicated that transporter associated with antigen-presenting (TAP) genes play a role in determining the outcome of HIV infection. HLA profiles that reflect certain combinations of MHC-encoded TAP and class I and class II genes are strongly associated with different rates of progression to AIDS. A recent finding of genetic association with HIV disease progression has highlighted the role for NK cells in HIV disease. A single nucleotide

polymorphism (SNP) in the killer immunoglobulin-like receptor (KIR) gene was shown to be strongly associated with rapid progression to AIDS. However, when the KIR3 DS1 SNP was present with HLA-B Bw4-80I, the resultant phenotype was delayed progression to AIDS, even though this HLA-B allele alone has no effect on HIV disease progression. Furthermore, the KIR3 DS1/HLA-B Bw4-80I-carrying individuals had a significantly reduced viral load, beginning early in the course of infection. This points to the potential role of NK cells in the maintenance of the viral set point, strongly suggesting that HLA-B Bw4-80I serves as the ligand activating this KIR receptor, resulting in the death of the target cell.

The most dramatic example of a genetic factor influencing HIV infection and/or pathogenesis relates to the gene that codes for the HIV cellular co-receptor CCR5. Rare individuals have been reported who had had repetitive sexual exposure to HIV in high-risk situations but remained uninfected. The peripheral blood mononuclear cells of two such individuals were found to be highly resistant to infection in vitro with R5 strains of HIV-1, but they were readily infected with X4 strains. Genetic analysis revealed that these two individuals inherited a homozygous defect in the gene that codes for CCR5, the cellular co-receptor for R5 strains of HIV-1. The defective *CCR5* allele contained a 32-bp deletion corresponding to the second extracellular loop of the receptor. The encoded protein was severely truncated, and the receptor was nonfunctional, explaining the refractoriness to infection with R5 strains of HIV-1. Population studies revealed that ~1% of the Caucasian population of western European ancestry possessed the homozygous defect. Up to 20% of this group had the heterozygous defect. Of note, cohort studies of hundreds of DNA samples originating from western and central Africa and Japan did not reveal a single mutant allele, suggesting that the allele is either absent or extremely rare in Africa and Japan. In a cohort of 1400 HIV-1–infected Caucasian individuals, no subject homozygous for the mutation was found, strongly supporting the concept that the homozygous defect confers protection against infection. This finding is particularly compelling in light of the fact that transmitting viruses are strongly biased towards R5 strains of HIV-1 (see above). Furthermore, there was a higher frequency of individuals heterozygous for the genetic defect among HIV-infected patients who were long-term nonprogressors compared to HIV-infected individuals who progressed more rapidly (see above). Of note, several individuals have been identified who were homozygous for the *CCR5*-Δ32 defect who in fact did become infected with HIV. These individuals were found to have an X4 strain of HIV that was associated in some cases with an accelerated course of disease. Slow progression of HIV disease is also seen in individuals who are heterozygous for the *CCR2-64I* mutation or SNP; this is felt to be due to dimerization of CXCR4 with the mutated CCR2-64I resulting in a decreased expression of CXCR4 on the cell surface. Delayed progression of disease is also seen in those individuals who have any of a number of SNPs in the *CCR5* promoter. In addition, individuals who carry a certain allele (IL-10-5-592A) of the IL-10 promoter are at increased risk of infection and, once infected, progress more rapidly than homozygotes for the alternative genotype. The mechanism of this effect is felt to be a downregulation of the inhibitory cytokine IL-10 resulting in facilitation of HIV replication. The SNP, IL-4-589T, increases IL-4 production. This allele associates with a slower progression to AIDS, presumably through the downregulation of CCR5 by higher and more sustained levels of IL-4. Separate SNPs have been found in the RANTES gene that correlate with either an increased or decreased expression of this chemokine (Table 173-7). As expected, based upon the effect of RANTES as an inhibitor of R5 HIV, RANTES-28G SNP upregulates RANTES and is associated with delayed progression to AIDS. The opposite effects are seen with SNP RANTES In1.1C. This SNP decreases RANTES expression and correlates strongly with rapid progression to AIDS. Other SNPs that decrease RANTES expression are associated with a higher rate of HIV infection, reinforcing the central role for R5 viruses in the establishment of HIV infection.

Additional genes have been found that are associated with rapid progression to AIDS or susceptibility to significant AIDS complication. Homozygosity for the vitamin D receptor form B correlates with rapid progression to AIDS. The mechanism is thought to relate to the known effects of vitamin D on immune modulation. The TNF-α SNP-238A is associated with a higher frequency of lipodystrophy. The underlying causes of this complication of AIDS remain to be defined, including the role of combination antiretroviral therapy. Finally, SNP IL-6-174G has been shown to lead to higher levels of IL-6. Homozygosity at this locus correlates with an increased risk of development of KS. Not surprisingly, homozygosity for SNP IL-6-174C, which results in lower levels of IL-6, was protective, correlating with significantly lower levels of KS.

NEUROPATHOGENESIS HIV-infected individuals can experience a variety of neurologic abnormalities due either to opportunistic infections and neoplasms (see below) or to direct effects of HIV or its products. With regard to the latter, HIV has been demonstrated in the brain and CSF of infected individuals with and without neuropsychiatric abnormalities. The main cell types that are infected in the brain in vivo are the perivascular macrophages and the microglial cells; monocytes that have already been infected in the blood can migrate into the brain, where they then reside as macrophages, or macrophages can be directly infected within the brain. The precise mechanisms whereby HIV enters the brain are unclear; however, they are felt to relate, at least in part, to the ability of virus-infected and immune-activated macrophages to induce adhesion molecules such as E-selectin and vascular cell adhesion molecule-1 (VCAM-1) on brain endothelium. Other studies have demonstrated that HIV gp120 enhances the expression of intercellular adhesion molecule-1 (ICAM-1) in glial cells; this effect may facilitate entry of HIV-infected cells into the CNS and may promote syncytia formation. Virus isolates from the brain are preferentially R5 strains as opposed to X4 strains (see above); in this regard, HIV-infected individuals who are heterozygous for *CCR5-δ32* appear to be relatively protected against the development of HIV encephalopathy compared to wild-type individuals. Distinct HIV envelope sequences are associated with the clinical expression of the AIDS dementia complex (see below). Although there have been reports of infrequent HIV infection of neuronal cells and astrocytes, there is no convincing evidence that brain cells other than those of monocyte/macrophage lineage can be productively infected in vivo.

HIV-infected individuals may manifest white matter lesions as well as neuronal loss. Given the relative absence of evidence of HIV infection of neurons either in vivo or in vitro, it is unlikely that direct infection of these cells accounts for their loss. Rather, the HIV-mediated effects on neurons and oligodendrocytes are felt to involve indirect pathways whereby viral proteins, particularly gp120 and Tat, trigger the release of endogenous neurotoxins from macrophages and to a lesser extent from astrocytes. In addition, it has been demonstrated that both HIV-1 Nef and Tat can induce chemotaxis of leukocytes, including monocytes, into the CNS. Neurotoxins can be released from monocytes as a consequence of infection and/or immune activation. Monocyte-derived neurotoxic factors have been reported to kill neurons via the *N*-methyl-D-aspartate (NMDA) receptor. In addition, HIV gp120 shed by virus-infected monocytes could cause neurotoxicity by antagonizing the function of vasoactive intestinal peptide (VIP), by elevating intracellular calcium levels, and by decreasing nerve growth factor levels in the cerebral cortex. A variety of monocyte-derived cytokines can contribute directly or indirectly to the neurotoxic effects in HIV infection; these include TNF-α, IL-1, IL-6, TGF-β, IFN-γ, platelet-activating factor, and endothelin. Furthermore, among the CC-chemokines, elevated levels of monocyte chemotactic protein (MCP)1 in the brain and CSF have been shown to correlate best with the presence and degree of HIV encephalopathy. In addition, infection and/or activation of monocyte-lineage cells can result in increased production of eicosanoids, nitric oxide, and quinolinic acid, which may contribute to neurotoxicity. Astrocytes may play diverse roles in HIV

neuropathogenesis. Reactive gliosis or astrocytosis has been demonstrated in the brains of HIV-infected individuals, and TNF-α and IL-6 have been shown to induce astrocyte proliferation. In addition, astrocyte-derived IL-6 can induce HIV expression in infected cells in vitro. Furthermore, it has been suggested that astrocytes may downregulate macrophage-produced neurotoxins. It has been reported that HIV-infected individuals with the E4 allele for apolipoprotein E (apo E) are at increased risk for AIDS encephalopathy and peripheral neuropathy. The likelihood that HIV or its products are involved in neuropathogenesis is supported by the observation that neuropsychiatric abnormalities may undergo remarkable and rapid improvement upon the initiation of antiretroviral therapy; this is true of HIV-infected children as well as adults. In fact, there has been a remarkable decrease in the incidence of HIV encephalopathy in the era of successful combination antiretroviral therapy.

PATHOGENESIS OF KAPOSI'S SARCOMA There are at least four distinct epidemiologic forms of KS: (1) the classic form that occurs in older men of predominantly Mediterranean or eastern European Jewish backgrounds with no recognized contributing factors; (2) the equatorial African form that occurs in all ages, also without any recognized precipitating factors; (3) the form associated with organ transplantation and its attendent iatrogenic immunosuppressed state; and (4) the form associated with HIV-1 infection. In the latter two forms, KS is an opportunistic disease; in HIV-infected individuals, unlike typical opportunistic infections, its occurrence is not strictly related to the level of depression of CD4+ T cell counts (see below). The pathogenesis of KS is complex; fundamentally, it is an angioproliferative disease that is not a true neoplastic sarcoma, at least not in its early stages. It is a manifestation of excessive proliferation of spindle cells that are believed to be of vascular origin and have features in common with endothelial and smooth-muscle cells. In HIV disease the development of KS is dependent on the interplay of a variety of factors including HIV-1 itself, human herpes virus 8 (HHV-8), immune activation, and cytokine secretion. A number of epidemiologic and virologic studies have clearly linked HHV-8, which is also referred to as *Kaposi's sarcoma–associated herpesvirus* (KSHV), to KS not only in HIV-infected individuals but also in individuals with the other forms of KS. HHV-8 is a γ-herpesvirus related to EBV and herpesvirus saimiri. It encodes a homologue to human IL-6 and in addition to KS has been implicated in the pathogenesis of body cavity lymphoma, multiple myeloma, and monoclonal gammopathy of undetermined significance. Sequences of HHV-8 are found universally in the lesions of KS, and patients with KS are virtually all seropositive for HHV-8. HHV-8 DNA sequences can be found in the B cells of 30 to 50% of patients with KS and 7% of patients with AIDS without clinically apparent KS.

Between 1 and 2% of eligible blood donors are positive for antibodies to HHV-8, while the prevalence of HHV-8 seropositivity in HIV-infected men is 30 to 35%. The prevalence in HIV-infected women is ~4%. This finding is reflective of the lower incidence of KS in women. It has been debated whether HHV-8 is actually the transforming agent in KS; the bulk of the cells in the tumor lesions of KS are not neoplastic cells. However, it has been demonstrated that endothelial cells can be transformed in vitro by HHV-8. In this regard, HHV-8 possesses a number of genes including homologues of the IL-8 receptor, Bcl-2, and cyclin D, which can potentially transform the host cell. Despite the complexity of the pathogenic events associated with the development of KS in HIV-infected individuals, it is generally agreed that HHV-8 is indeed the etiologic agent of this disease. The initiation and/or propagation of KS requires an activated state and is mediated, at least in part, by cytokines. A number of factors, including TNF-α, IL-1β, IL-6, GM-CSF, basic fibroblast growth factor, and oncostatin M, function in an autocrine and paracrine manner to sustain the growth and chemotaxis of the KS spindle cells. In this regard, KSHV-derived IL-6 has been demonstrated to induce proliferation of lymphoma cells and to inhibit the cytostatic effects of INF-α on KSHV-infected lymphoma cells. It has been suggested that the HIV Tat protein plays a major role in the pathogenesis of KS. In this regard, it has been demonstrated that IFN-γ can induce endothelial cells to proliferate and to invade the extracellular matrix in response to HIV Tat. This occurs as a result of the upregulation by IFN-γ of the expression and activity of the receptors for Tat, which are the integrins $\alpha_5\beta_1$ and $\alpha_v\beta_3$. In addition, the HIV-1 Tat protein has been shown to act synergistically with basic fibroblast growth factor in the induction of lesions resembling KS lesions in mice by increasing matrix-metalloproteinase-2 secretion and activation in endothelial cells. Glucocorticoids have been shown to have a stimulatory effect, and human chorionic gonadotropin an inhibitory effect, on KS spindle cells, suggesting that modulation of the balance of autocrine factors may have therapeutic potential in KS. It has been demonstrated that HIV protease inhibitors have potent anti-angiogenic properties and, as such, promote regression of KS.

IMMUNE RESPONSE TO HIV

As detailed above and below, following the initial burst of viremia during primary infection, HIV-infected individuals mount a robust immune response that usually substantially curtails the levels of plasma viremia and likely contributes to delaying the ultimate development of clinically apparent disease for a median of 10 years. This immune response contains elements of both humoral and cell-mediated immunity (Table 173-8; Fig. 173-21). It is directed against multiple antigenic determinants of the HIV virion as well as against viral proteins expressed on the surface of infected cells. Ironically, those CD4+ T cells with T cell receptors specific for HIV are theoretically those CD4+ T cells most likely to bind to infected cells and themselves be infected and destroyed. Thus, an early consequence of HIV infection may be interference with the generation of an effective immune response through the elimination or compromise of HIV-specific CD4+ T lymphocytes.

Although a great deal of investigation has been directed toward delineating and better understanding the components of this immune response, it remains unclear which of these phenomena are most important in delaying progression of infection and which, if any, play a role in the pathogenesis of HIV disease. This lack of knowledge has also hampered the ability to develop an effective vaccine for HIV disease.

HUMORAL IMMUNE RESPONSE Antibodies to HIV usually appear within 6 weeks and almost invariably within 12 weeks of primary infection (Fig. 173-22); rare exceptions are individuals who have defects in the ability to produce HIV-specific antibodies. Detection of these antibodies forms the basis of most diagnostic screening tests for HIV infection. The appearance of HIV-binding antibodies detected by ELISA and western blot assays occurs prior to the appearance of neutralizing antibodies; the latter generally appear following the initial decreases in plasma viremia, which is more closely related to the appearance of HIV-specific CD8+ T lymphocytes. The first antibodies detected are

those directed against the structural or gag proteins of HIV, p24 and p17, and the gag precursor p55. The development of antibodies to p24 is associated with a decrease in the serum levels of free p24 antigen. Antibodies to the gag proteins are followed by the appearance of antibodies to the envelope proteins (gp160, gp120, p88, and gp41) and to the products of the *pol* gene (p31, p51, and p66). In addition, one may see antibodies to the low-molecular-weight regulatory proteins encoded by the HIV genes *vpr*, *vpu*, *vif*, *rev*, *tat*, and *nef*.

While antibodies to multiple antigens of HIV are produced, the precise functional significance of these different antibodies is unclear. The best studied have been the antibodies directed toward the envelope proteins of the virus. As noted above, the envelope of HIV consists of an outer envelope glycoprotein with a molecular mass of 120 kDa and a transmembrane glycoprotein with a molecular mass of 41 kDa. These are initially synthesized as a 160-kDa precursor that is cleaved by cellular proteases. Most of the antienvelope antibodies are directed either toward an epitope in the gp41 region comprising amino acids 579 to 613 or toward a hypervariable region in the gp120 molecule, known as the *V3 loop region*, comprising amino acids 303 through 338. This V3 region is a major site for the development of mutations that lead to variants of HIV that are not well recognized by the immune system.

Antibodies directed toward the envelope proteins of HIV have been characterized both as being protective and as possibly contributing to the pathogenesis of HIV disease. Among the protective antibodies are those that function to neutralize HIV directly and prevent the spread of infection to additional cells, as well as those that participate in ADCC. *Neutralizing antibodies* may be a component of primary HIV infection, and some long-term nonprogressors have been reported to have increased titers of neutralizing antibodies. Neutralizing antibodies appear to be of two forms, type-specific and group-specific. *Type-specific neutralizing antibodies* are generally directed to the V3 loop region. These antibodies neutralize only viruses of a given strain and are present in low titer in most infected individuals. *Group-specific neutralizing antibodies* are capable of neutralizing a wide variety of HIV isolates. At least two forms of group-specific antibodies have been identified: those binding to amino acids 423 to 437 of gp120 and those binding to amino acids 728 to 745 of gp41. The other major class of protective antibodies are those that participate in ADCC, which is actually a form of cell-mediated immunity (Chap. 295) in which NK cells that bear Fc receptors are armed with specific anti-HIV antibodies that bind to the NK cells via their Fc portion. These armed NK cells then bind to and destroy cells expressing HIV antigens. Antibodies to both gp120 and gp41 have been shown to participate in ADCC-mediated killing of HIV-infected cells. The levels of antienvelope antibodies capable of mediating ADCC are highest in the earlier stages of HIV infection. In vitro, IL-2 can augment ADCC-mediated killing.

In addition to playing a role in host defense, HIV-specific antibodies have also been implicated in disease pathogenesis. Antibodies directed to gp41, when present in low titer, have been shown in vitro to be capable of facilitating infection of cells through an Fc receptor–mediated mechanism known as *antibody enhancement*. Thus, the same regions of the envelope protein of HIV that give rise to antibodies capable of mediating ADCC also elicit the production of antibodies that can facilitate infection of cells in vitro. In addition, it has been postulated that anti-gp120 antibodies that participate in the ADCC killing of HIV-infected cells might also kill uninfected CD4+ T cells if the uninfected cells had bound free gp120, a phenomenon referred to as *bystander killing*.

CELLULAR IMMUNE RESPONSE Given the fact that T cell–mediated immunity is known to play a major role in host defense against most viral infections (Chap. 295), it is generally thought to be an important component of the host immune response to HIV. T cell immunity can be divided into two major categories, mediated respectively by the *helper/inducer CD4+ T cells* and the *cytotoxic/immunoregulatory CD8+ T cells*.

HIV-specific CD4+ T cells can be detected in the majority of HIV-infected patients through the use of flow cytometry to measure single-

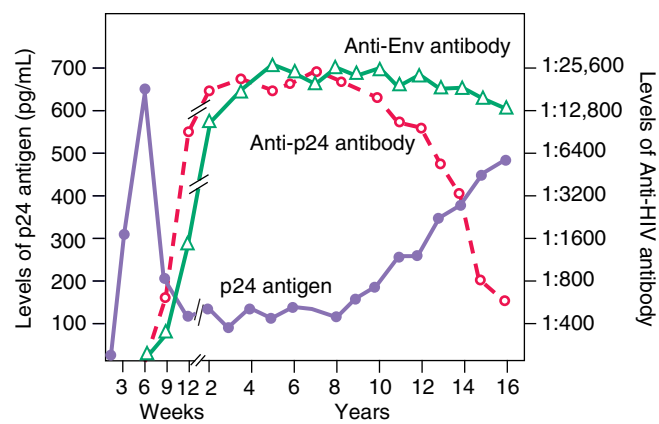

FIGURE 173-22 Relationship between antigenemia and the development of antibodies to HIV. Antibodies to HIV proteins are generally seen 6 to 12 weeks following infection and 3 to 6 weeks after the development of plasma viremia. Late in the course of illness, antibody levels to p24 decline, generally in association with a rising titer of p24 antigen.

cell IFN-γ production in response to HIV antigens, binding to MHC class II tetramers, or HIV p24 lymphocyte proliferation assays. Although these cells, with their high affinity for binding to HIV-infected cells, may be among the first to be infected and destroyed during HIV infection, they also are likely to undergo clonal expansions in response to HIV antigens and thus survive as a population of cells. No clear correlations exist between levels of HIV-specific CD4+ T lymphocytes and plasma HIV RNA levels; however, in the setting of high viral loads, CD4+ T cell responses to HIV antigens appear to shift from one of proliferaton to one of IFN-γ production. Thus, while a reverse correlation exists between the level of p24-specific proliferation and levels of plasma HIV viremia, the nature of the causal relationship between these parameters is unclear. Through the use of computer modeling, several regions of the HIV-1 envelope molecule have been identified that are structurally analogous to other known T cell epitopes by virtue of having structures known as *amphipathic helices*. Peptides from these envelope regions have been used to identify the presence of CD4+ T cells specific for these regions in the peripheral blood of HIV-infected individuals. Other studies have demonstrated that peripheral blood T cells of some healthy, HIV-negative individuals also react to the envelope proteins of HIV. It is unclear whether or not this represents the presence of a degree of protective immunity in these individuals.

MHC class I–restricted, HIV-specific CD8+ T cells have been identified in the peripheral blood of patients with HIV-1 infection. These cells include CTLs and T cells that can be induced by HIV antigens to express cytokines such as IFN-γ. CTLs have been identified in the peripheral blood of patients within weeks of HIV infection. These CD8+ T lymphocytes, through their HIV-specific antigen receptors, bind to and cause the lytic destruction of target cells bearing autologous MHC class I molecules associated with HIV antigens. Two types of CTL activity can be demonstrated in the peripheral blood or lymph node mononuclear cells of HIV-infected individuals. The first type directly lyses appropriate target cells in culture without prior in vitro stimulation (*spontaneous CTL activity*). The other type of CTL activity reflects the *precursor frequency of CTLs* (CTLp); this type of CTL activity can be demonstrated by stimulation of CD8+ T cells in vitro with a mitogen such as phytohemagglutinin or anti-CD3 antibody. Following primary HIV infection, the qualitative nature of the HIV-specific CTL response is an important predictor of eventual clinical outcome. Patients who mount a broad CD8+ CTL response generally have a more favorable clinical course than do patients who mount a more restricted CTL response. These data are consistent with studies in the SIV model where deletion of CD8+ T cells leads to a more accelerated clinical course.

In addition to CTLs, CD8+ T cells capable of being induced by HIV antigens to express cytokines such as IFN-γ also appear in the setting of HIV-1 infection. It is not clear whether these are the same or different effector pools compared to those cells mediating cytotoxicity; in addition, the relative roles of each in host defense against HIV are not fully understood. It does appear that these CD8+ T cells are driven to in vivo expansion by HIV antigen. There is a direct correlation between levels of CD8+ T cells capable of producing IFN-γ in response to HIV antigens and plasma levels of HIV-1 RNA. Thus, while these cells are clearly induced by HIV-1 infection, their overall ability to control infection remains unclear. Multiple HIV antigens, including Gag, Env, Pol, Tat, Rev, and Nef, can elicit CD8+ T cell responses. Among patients who control viral replication in the absence of antiretrovirual drugs are a subset of patients whose peripheral blood contains a population of CD8+ T cells that undergo substantial proliferation and perforin expression in response to HIV antigens. It is possible that these cells play an important role in HIV-specific host defense.

At least three other forms of cell-mediated immunity to HIV have been described: CD8+ T cell–mediated suppression of HIV replication, ADCC, and NK cell activity. *CD8+ T cell–mediated suppression of HIV replication* refers to the ability of CD8+ T cells from an HIV-infected patient to inhibit the replication of HIV in tissue culture in a noncytolytic manner. There is no requirement for HLA compatibility between the CD8+ T cells and the HIV-infected cells. This effector mechanism is thus nonspecific and appears to be mediated by soluble factor(s) including the CC-chemokines RANTES, MIP-1α, and MIP-1β (see above) and the alpha defensin family of cytokines. The CC-chemokines are potent suppressors of HIV replication and operate at least in part via blockade of the co-receptor (CCR5) on peripheral blood mononuclear cells for R5 or macrophage-tropic strains of HIV (see above). The alpha defensins appear able to inhibit replication of either R5 or X4 viruses. The mechanism of this inhibition remains unclear. *ADCC*, as described above in relation to humoral immunity, involves the killing of HIV-expressing cells by NK cells armed with specific antibodies directed against HIV antigens. Finally, *NK cells* alone have been shown to be capable of killing HIV-infected target cells in tissue culture. This primitive cytotoxic mechanism of host defense is directed toward nonspecific surveillance for neoplastic transformation and viral infection through recognition of altered class I MHC molecules.

DIAGNOSIS AND LABORATORY MONITORING OF HIV INFECTION

The establishment of HIV as the causative agent of AIDS and related syndromes early in 1984 was followed by the rapid development of sensitive screening tests for HIV infection. By March, 1985, blood donors in the United States were routinely screened for antibodies to HIV. In June 1996, blood banks in the United States added the p24 antigen capture assay to the screening process to help identify the rare infected individuals who were donating blood in the time (up to 3 months) between infection and the development of antibodies. In 2002 the ability to detect early infection with HIV was further enhanced by the licensure of nucleic acid amplification testing as a routine part of blood donor screening. These refinements decreased the interval between infection and detection (window period) from 22 days for antibody testing to 16 days with p24 antigen testing and subsequently to 12 days with nucleic acid testing. The development of sensitive assays for monitoring levels of plasma viremia ushered in a new era of being able to monitor the progression of HIV disease more closely. Utilization of these tests, coupled with the measurement of levels of CD4+ T lymphocytes in peripheral blood, is essential in the management of patients with HIV infection.

DIAGNOSIS OF HIV INFECTION The diagnosis of HIV infection depends upon the demonstration of antibodies to HIV and/or the direct detection of HIV or one of its components. As noted above, antibodies to HIV generally appear in the circulation 2 to 12 weeks following infection.

The standard screening test for HIV infection is the ELISA, also referred to as an enzyme immunoassay (EIA). This solid-phase assay is an extremely good screening test with a sensitivity of >99.5%. Most diagnostic laboratories use a commercial EIA kit that contains antigens from both HIV-1 and HIV-2 and thus are able to detect either. These kits use both natural and recombinant antigens and are continuously updated to increase their sensitivity to newly discovered species, such as group O viruses (Fig. 173-6). EIA tests are generally scored as positive (highly reactive), negative (nonreactive), or indeterminate (partially reactive). While the EIA is an extremely sensitive test, it is not optimal with regard to specificity. This is particularly true in studies of low-risk individuals, such as volunteer blood donors. In this latter population, only 10% of EIA-positive individuals are subsequently confirmed to have HIV infection. Among the factors associated with false-positive EIA tests are antibodies to class II antigens, autoantibodies, hepatic disease, recent influenza vaccination, and acute viral infections. For these reasons, anyone suspected of having HIV infection based upon a positive or inconclusive EIA result must have the result confirmed with a more specific assay. One can estimate whether or not an indivdual has a recent infection with HIV-1 by comparing the results on a standard assay that will score positive for

all infected individuals to the results on an assay modified to be less sensitive ("detuned assay") that will only score positive for individuals with established HIV infection.

The most commonly used confirmatory test is the western blot (Fig. 173-23). This assay takes advantage of the fact that multiple HIV antigens of different, well-characterized molecular weights elicit the production of specific antibodies. These antigens can be separated on the basis of molecular weight, and antibodies to each component can be detected as discrete bands on the western blot. A negative western blot is one in which no bands are present at molecular weights corresponding to HIV gene products. In a patient with a positive or indeterminate EIA and a negative western blot, one can conclude with certainty that the EIA reactivity was a false positive. On the other hand, a western blot demonstrating antibodies to products of all three of the major genes of HIV (*gag*, *pol*, and *env*) is conclusive evidence of infection with HIV. Criteria established by the U.S. Food & Drug Administration (FDA) in 1993 for a positive western blot state that a result is considered positive if antibodies exist to two of the three HIV proteins: p24, gp41, and gp120/160. Using these criteria, ~10% of all blood donors deemed positive for HIV-1 infection lacked an antibody band to the *pol* gene product p31. Some 50% of these blood donors were subsequently found to be false positives. Thus, the absence of the p31 band should increase the suspicion that one may be dealing with a false-positive test result. In this setting it is prudent to obtain additional confirmation with an RNA-based test and/or a follow-up western blot. By definition, western blot patterns of reactivity that do not fall into the positive or negative categories are considered "indeterminate." There are two possible explanations for an indeterminate western blot result. The most likely explanation in a low-risk individual is that the patient being tested has antibodies that cross-react with one of the proteins of HIV. The most common patterns of cross-reactivity are antibodies that react with p24 and/or p55. The least likely explanation in this setting is that the individual is infected with HIV and is in the process of mounting a classic antibody response. In either instance, the western blot should be repeated in 1 month to determine whether or not the indeterminate pattern is a pattern in evolution. In addition, one may attempt to confirm a diagnosis of HIV infection with the p24 antigen capture assay or one of the tests for HIV RNA (discussed below). While the western blot is an excellent confirmatory test for HIV infection in patients with a positive or indeterminate EIA, it is a poor screening test. Among individuals with a negative EIA and PCR for HIV, 20 to 30% may show one or more bands on western blot. While these bands are usually faint and represent cross-reactivity, their presence creates a situation in which other diagnostic modalities [such as DNA PCR, RNA PCR, the (b)DNA assay, or p24 antigen capture] must be employed to ensure that the bands do not indicate early HIV infection.

A guideline for the use of these serologic tests in attempting to make a diagnosis of HIV infection is depicted in Fig. 173-24. In patients in whom HIV infection is suspected, the appropriate initial test is the EIA. If the result is negative, unless there is strong reason to suspect early HIV infection (as in a patient exposed within the previous 3 months), the diagnosis is ruled out and retesting should be performed only as clinically indicated. If the EIA is indeterminate or positive, the test should be repeated. If the repeat is negative on two occasions, one can assume that the initial positive reading was due to a technical error in the performance of the assay and that the patient is negative. If the repeat is indeterminate or positive, one should proceed to the HIV-1 western blot. If the western blot is positive, the diagnosis is HIV-1 infection. If the western blot is negative, the EIA can be assumed to have been a false positive for HIV-1 and the diagnosis of HIV-1 infection is ruled out. It would be prudent at this point to perform specific serologic testing for HIV-2 following the same type of algorithm. If the western blot for HIV-1 is indeterminate, it should be repeated in 4 to 6 weeks; in addition, one may proceed to a p24 antigen capture assay, HIV-1 RNA assay, or HIV-1 DNA PCR and specific serologic testing for HIV-2. If the p24 and HIV RNA assays are negative and there is no progression in the western blot, a diagnosis of HIV-1 is ruled out. If either the p24 or HIV-1 RNA assay is positive and/or the HIV-1 western blot shows progression, a tentative diagnosis of HIV-1 infection can be made and later confirmed with a follow-up western blot demonstrating a positive pattern.

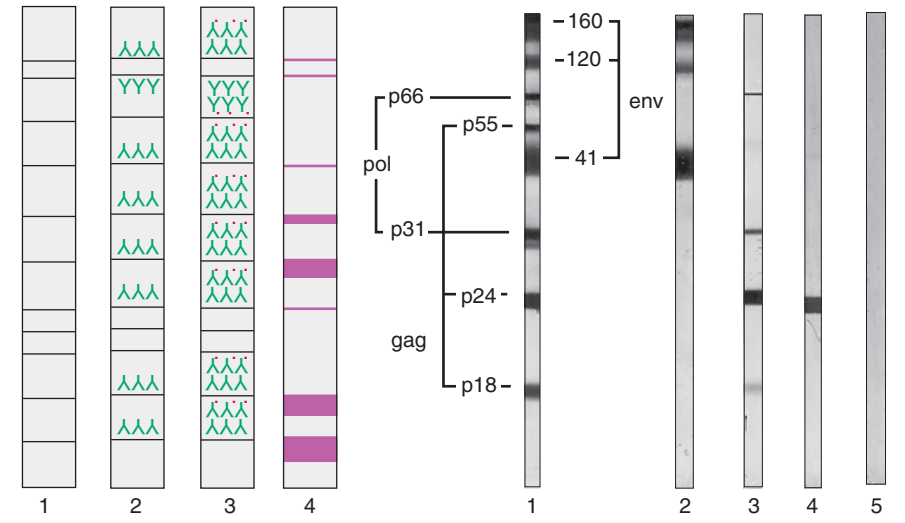

FIGURE 173-23 *A*. Schematic representation of how a western blot is performed. *B*. Examples of patterns of western blot reactivity. In each instance the western blot strip contains antigens to HIV-1. The sera from the patient immunized to the HIV-1 envelope only contains antibodies to the HIV-1 envelope proteins. The sera from the patient with HIV-2 infection cross-reacts with both *reverse transcriptase* and *gag* gene products of HIV-1.

As mentioned above, a variety of laboratory tests are available for the direct detection of HIV or its components (Table 173-9; Fig. 173-25). These tests may be of considerable help in making a diagnosis of HIV infection when the western blot results are indeterminate. In addition, the tests detecting levels of HIV RNA can be used to determine prognosis and to assess the response to antiretroviral therapies. The

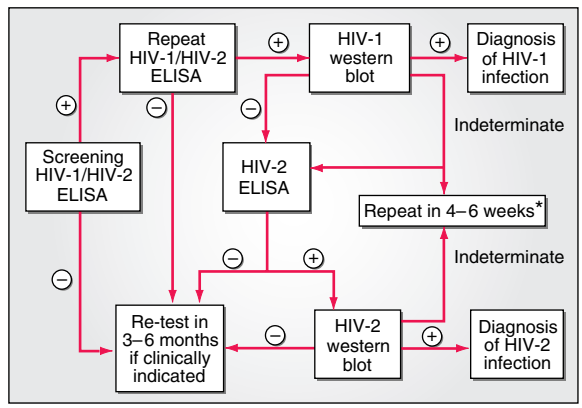

FIGURE 173-24 Algorithm for the use of serologic tests in the diagnosis of HIV-1 or HIV-2 infection. * Stable indeterminate western blot 4 to 6 weeks later makes HIV infection unlikely. However, it should be repeated twice at 3-month intervals to rule out HIV infection. Alternatively, one may test for HIV-1 p24 antigen or HIV RNA.

TABLE 173-9 *Characteristics of Tests for Direct Detection of HIV*

Test	Technique	Sensitivity[a]	Cost/Test
Immune complex–dissociated p24 antigen capture assay	Measurement of levels of HIV-1 core protein in an ELISA-based format following dissociation of antigen-antibody complexes by weak acid treatment	Positive in 50% of patients; detects down to 15 pg/mL of p24 protein	$1–2
HIV RNA by PCR	PCR amplification of cDNA generated from viral RNA (target amplification)	Reliable to 40 copies/mL of HIV RNA	$75–150
HIV RNA by bDNA	Measurement of levels of particle-associated HIV RNA in a nucleic acid capture assay employing signal amplification	Reliable to 75 copies/mL of HIV RNA	$75–150
HIV RNA by NASBA	Isothermic nucleic acid amplification with internal controls	Reliable to 176 copies/mL of HIV RNA	$75–150

[a] Sensitivity figures refer to those approved by the US FDA. Prices may be lower in large volume settings.
Note: ELISA, enzyme-linked immunosorbent assay; PCR, polymerase chain reaction; NASBA, nucleic acid sequence based assay.

simplest of the direct detection tests is the *p24 antigen capture assay*. This is an EIA-type assay in which the solid phase consists of antibodies to the p24 antigen of HIV. It detects the viral protein p24 in the blood of HIV-infected individuals where it exists either as free antigen or complexed to anti-p24 antibodies. Overall, ~30% of individuals with untreated HIV infection have detectable levels of free p24 antigen. This increases to about 50% when samples are treated with a weak acid to dissociate antigen-antibody complexes. Throughout the course of HIV infection, an equilibrium exists between p24 antigen and anti-p24 antibodies. During the first few weeks of infection, before an immune response develops, there is a brisk rise in p24 antigen levels (Fig. 173-22). After the development of anti-p24 antibodies, these levels decline. Late in the course of infection, when circulating levels of virus are high, p24 antigen levels also increase, particularly when detected by techniques involving dissociation of antigen-antibody complexes. This assay has its greatest use as a screening test for HIV infection in patients suspected of having the acute HIV syndrome, as high levels of p24 antigen are present prior to the development of antibodies. In addition, it is currently used routinely along with the HIV EIA and nucleic acid test to screen blood donors in the United States for evidence of HIV infection. The ability to measure and monitor levels of HIV RNA in the plasma of patients with HIV infection has been of extraordinary value in furthering our understanding of the pathogenesis of HIV infection and in providing a diagnostic tool in settings where measurements of anti-HIV antibodies may be misleading, such as in acute infection and neonatal infection. Three assays are predominantly used for this purpose. They are the reverse transcriptase PCR (*RT-PCR*; Amplicor); the branched DNA (*bDNA*; VERSANT); and the nucleic acid sequenced based assay (*NASBA*; NucliSens). While routinely used in the past, along with testing for HIV antibodies, to screen blood donors for HIV infection, this use of the p24 assay has been replaced by the use of nucleic acid testing. These tests are of value in making a diagnosis of HIV infection, in establishing intial prognosis and determining the need for therapy, and for monitoring the effects of therapy. In addition to these three commercially available tests, the *DNA PCR* is also employed by research laboratories for making a diagnosis of HIV infection by amplifying HIV proviral DNA from peripheral blood mononuclear cells. The commercially available RNA detection tests have a sensitivity of 50 to 75 copies of HIV RNA per milliliter of plasma, while the DNA PCR tests can detect proviral DNA at a frequency of one copy per 10,000 to 100,000 cells. Thus, these tests are extremely sensitive. One frequent consequence of a high degree of sensitivity is some loss of specificity, and false-positive results have been reported with each of these techniques. For this reason, a positive EIA with a confirmatory western blot remains the "gold standard" for a diagnosis of HIV infection, and the interpretation of other test results must be done with this in mind.

In the RT-PCR technique, following DNase treatment, a cDNA copy is made of all RNA species present in plasma. Insofar as HIV is an RNA virus, this will result in the production of DNA copies of the HIV genome in amounts proportional to the amount of HIV RNA present in plasma. This cDNA is then amplified and characterized using standard PCR techniques, employing primer pairs that can distinguish genomic cDNA from messenger cDNA. The bDNA assay involves the use of a solid-phase nucleic acid capture system and signal amplification through successive nucleic acid hybridizations to detect small quantities of HIV RNA. Both tests can achieve a tenfold increase in sensitivity to 40 to 50 copies of HIV RNA per milliliter with a preconcentration step in which plasma undergoes ultracentrifugation to pellet the viral particles. The NASBA technique involves the isothermal amplification of a sequence within the gag region of HIV in the presence of internal standards and employs the production of multiple RNA copies through the action of T7-RNA polymerase. The lower limit of detection for the NASBA is 176 copies/mL.

In addition to being a diagnostic and prognostic tool, RT-PCR is also useful for amplifying defined areas of the HIV genome for sequence analysis and has become an important technique for studies of sequence diversity and microbial resistance to antiretroviral agents. In patients with a positive or indeterminate EIA test and an indeterminate western blot, and in patients in whom serologic testing may be unreliable (such as patients with hypogammaglobulinemia or advanced HIV disease), these tests for quantitating HIV RNA in plasma provide valuable tools for making a diagnosis of HIV infection; however, they should be used for diagnosis only when standard serologic testing has failed to provide a definitive result.

LABORATORY MONITORING OF PATIENTS WITH HIV INFECTION The epidemic of HIV infection and AIDS has provided the clinician with new challenges for integrating clinical and laboratory data to effect optimal patient management.

The close relationship between clinical manifestations of HIV infection and CD4+ T cell count has made measurement of the latter a routine part of the evaluation of HIV-infected individuals. Determinations of CD4+ T cell counts and measurements of the levels of HIV RNA in serum or plasma provide a powerful set of tools for determining prognosis and monitoring response to therapy. While the CD4+ T cell count provides information on the current immunologic status of the patient, the HIV RNA level predicts what will happen to the CD4+ T cell count in the near future, and hence provides an important piece of prognostic information.

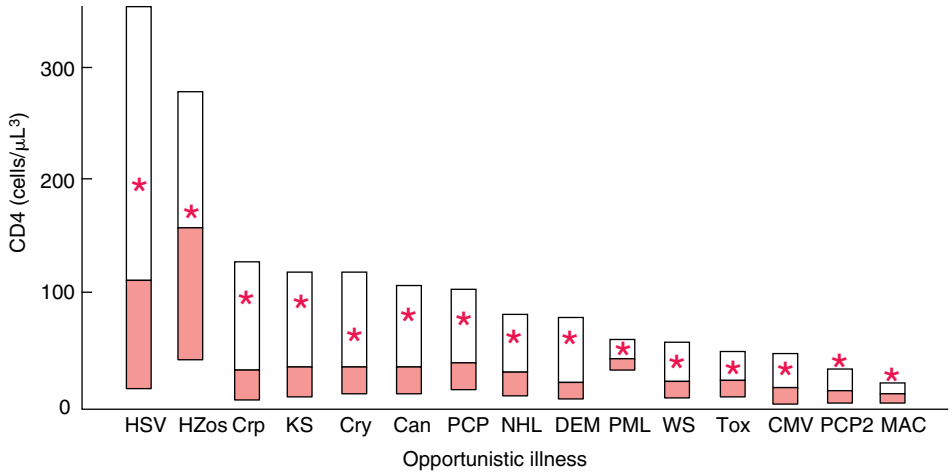

FIGURE 173-26 Relationship between CD4+ T cell counts and the development of opportunistic diseases. Boxplot of the median (line inside the box), first quartile (bottom of the box), third quartile (top of the box), and mean (asterisk) CD4+ lymphocyte count at the time of the development of opportunistic disease. Can, candidal esophagitis; CMV, cytomegalovirus infection; Crp, cryptosporidiosis; Cry, cryptococcal meningitis; DEM, AIDS dementia complex; HSV, herpes simplex virus infection; HZos, herpes zoster; KS, Kaposi's sarcoma; MAC, *Mycobacterium avium* complex bacteremia; NHL, non-Hodgkin's lymphoma; PCP, primary *Pneumocystis carinii* pneumonia; PCP2, secondary *Pneumocystis carinii* pneumonia; PML, progressive multifocal leukoencephalopathy; Tox, *Toxoplasma gondii* encephalitis; WS, wasting syndrome. (*From RD Moore, RE Chaisson: Ann Intern Med 124:633, 1996.*)

CD4+ T Cell Counts The CD4+ T cell count is the laboratory test generally accepted as the best indicator of the immediate state of immunologic competence of the patient with HIV infection. This measurement, which is the product of the percent of CD4+ T cells (determined by flow cytometry) and the total lymphocyte count [determined by the white blood cell count (WBC) and the differential percent] has been shown to correlate very well with the level of immunologic competence. Patients with CD4+ T cell counts $<200/\mu L$ are at high risk of infection with *P. carinii*, while patients with CD4+ T cell counts $<50/\mu L$ are at high risk of infection with CMV and mycobacteria of the *M. avium complex* (MAC) (Fig. 173-26). Patients with HIV infection should have CD4+ T cell measurements performed at the time of diagnosis and every 3 to 6 months thereafter. More frequent measurements should be made if a declining trend is noted. According to most guidelines, a CD4 T cell count $<350/\mu L$ is an indication for consideration of initiating antiretroviral therapy, and a decline in CD4+ T cell count of >25% is an indication for considering a change in therapy. Once the CD4+ T cell count is $<200/\mu L$, patients should be placed on a regimen for *P. carinii* prophylaxis, and once the count is $<50/\mu L$, primary prophylaxis for MAC infection is indicated. As with any laboratory measurement, one may wish to obtain two determinations prior to any significant changes in patient management based upon CD4+ T cell count alone.

HIV RNA Determinations Facilitated by highly sensitive techniques for the precise quantitation of small amounts of nucleic acids, the measurement of serum or plasma levels of HIV RNA has become an essential component in the monitoring of patients with HIV infection. As discussed under diagnosis of HIV infection, the two most commonly used techniques are the RT-PCR assay and the bDNA assay. Both assays generate data in the form of number of copies of HIV RNA per milliliter of serum or plasma and, by employing a 1:10 concentration step with ultracentrifugation, can detect as few as 50 to 75 copies of HIV RNA per milliliter of plasma. Although earlier versions of the bDNA assay generated values that were ~50% of those of the RT-PCR assay, the more recent versions (version 3 or higher) provide numbers essentially identical to those of the RT-PCR test (Fig. 173-25). While it is common practice to describe levels of HIV RNA below these cut-offs as "undetectable," this is a term that should be avoided as it is imprecise and leaves the false impression that the level of virus is 0. By utilizing more sensitive, nested PCR techniques and by studying tissue levels of virus as well as plasma levels, HIV RNA can be detected in virtually every patient with HIV infection. Measurements of changes in HIV RNA levels over time have been of great value in delineating the relationship between levels of virus and rates of disease progression (Fig. 173-17), the rates of viral turnover, the relationship between immune system activation and viral replication, and the time to development of drug resistance. HIV RNA measurements are greatly influenced by the state of activation of the immune system and may fluctuate greatly in the setting of secondary infections or immunization. For these reasons, decisions based upon HIV RNA levels should never be made on a single determination. Measurements of plasma HIV RNA levels should be made at the time of HIV diagnosis and every 3 to 4 months thereafter in the untreated patient. In general, most guidelines suggest that therapy be considered in patients with >50,000 copies of HIV RNA per milliliter (see below). Following the initiation of therapy or any change in therapy, plasma HIV RNA levels should be monitored approximately every 4 weeks until the effectiveness of the therapeutic regimen is determined by the development of a new steady-state level of HIV RNA. In most instances of effective therapy this will be <50 copies per milliliter. This level of virus is generally achieved within 6 months of the initiation of effective treatment. During therapy, levels of HIV RNA should be monitored every 3 to 4 months to evaluate the continuing effectiveness of therapy.

HIV Resistance Testing The availability of multiple antiretroviral drugs as treatment options has generated a great deal of interest in the potential for measuring the sensitivity of an individual's HIV virus(es) to different antiretroviral agents. HIV resistance testing can be done through either genotypic or phenotypic measurements. In the genotypic assays, sequence analyses of the HIV genomes obtained from patients are compared to sequences of viruses with known antiretroviral resistance profiles. In the phenotypic assays, the in vivo growth of viral isolates obtained from the patient are compared to the growth of reference strains of the virus in the presence or absence of different antiretroviral drugs. A modification of this phenotypic approach utilizes a comparison of the enzymatic activities of the reverse transcriptase or protease genes obtained by molecular cloning of patients' isolates to the enzymatic activities of genes obtained from reference strains of HIV in the presence or absence of different drugs targeted to these genes. These tests are quite good in identifying those antiretroviral agents that have been utilized in the past in a given patient. In the hands of experts, resistance testing enhances the short-term ability to decrease viral load by ~0.5 log compared to changing drugs merely on the basis of drug history. While some have advocated the use of resistance testing in the selection of an intial treatment regimen, the value of resistance testing in this setting is unknown.

Other Tests A variety of other laboratory tests have been studied as potential markers of HIV disease activity. Among these are quantitative culture of replication-competent HIV from plasma, peripheral

blood mononuclear cells, or resting CD4+ T cells; circulating levels of β_2-microglobulin, soluble IL-2 receptor, IgA, acid-labile endogenous interferon, or TNF-α; and the presence or absence of activation markers such as CD38 or HLA-DR on CD8+ T cells. While these measurements have value as markers of disease activity and help to increase our understanding of the pathogenesis of HIV disease, they do not currently play a major role in the monitoring of patients with HIV infection.

CLINICAL MANIFESTATIONS

The clinical consequences of HIV infection encompass a spectrum ranging from an acute syndrome associated with primary infection to a prolonged asymptomatic state to advanced disease. It is best to regard HIV disease as beginning at the time of primary infection and progressing through various stages. As mentioned above, active virus replication and progressive immunologic impairment occur throughout the course of HIV infection in most patients. With the exception of the rare true long-term nonprogressors (see above), HIV disease in untreated patients inexorably progresses even during the clinically latent stage. However, antiretroviral therapy has had a major impact on blocking or slowing the progression of disease over extended periods of time in a substantial proportion of adequately treated patients (see below).

THE ACUTE HIV SYNDROME It is estimated that 50 to 70% of individuals with HIV infection experience an acute clinical syndrome approximately 3 to 6 weeks after primary infection (Fig. 173-27). Varying degrees of clinical severity have been reported, and although it has been suggested that symptomatic seroconversion leading to the seeking of medical attention indicates an increased risk for an accelerated course of disease, this has not been shown definitively. In fact, there does not appear to be a correlation between the level of the initial burst of viremia in acute HIV infection and the subsequent course of disease. The typical clinical findings in the acute HIV syndrome are listed in Table 173-10; they occur along with a burst of plasma viremia. It has been reported that several symptoms of the acute HIV syndrome (fever, skin rash, pharyngitis, and myalgia) occur less frequently in those infected by injection drug use versus those infected by sexual contact. The syndrome is typical of an acute viral syndrome and has been likened to acute infectious mononucleosis. Symptoms usually persist for 1 to several weeks and gradually subside as an immune response to HIV develops and the levels of plasma viremia decrease. Opportunistic infections have been reported during this stage of infection, reflecting the immunodeficiency that results from reduced numbers of CD4+ T cells and likely also from the dysfunction of CD4+ T cells owing to viral protein and endogenous cytokine-induced perturbations

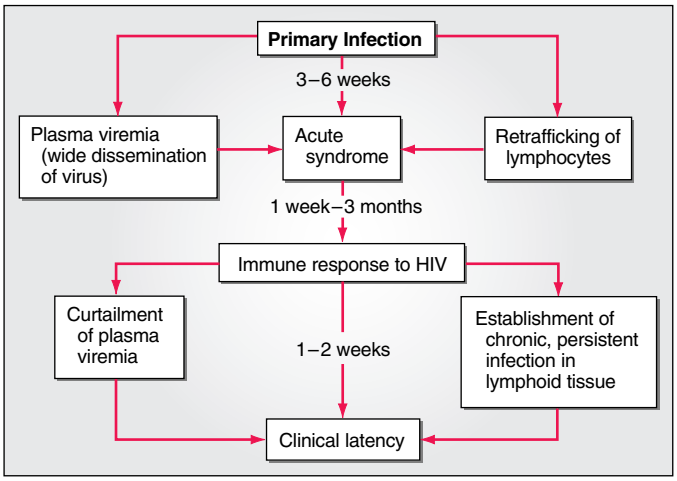

FIGURE 173-27 The acute HIV syndrome. See text for detailed description. (*Adapted from G Pantaleo et al: N Engl J Med 328:327, 1993.*)

TABLE 173-10 Clinical Findings in the Acute HIV Syndrome

General	Neurologic
Fever	Meningitis
Pharyngitis	Encephalitis
Lymphadenopathy	Peripheral neuropathy
Headache/retroorbital pain	Myelopathy
Arthralgias/myalgias	Dermatologic
Lethargy/malaise	Erythematous maculopapular rash
Anorexia/weight loss	Mucocutaneous ulceration
Nausea/vomiting/diarrhea

of cells (see "Mechanisms of CD4+ T Lymphocyte Depletion and Dysfunction," above) associated with the extremely high levels of plasma viremia. A number of immunologic abnormalities accompany the acute HIV syndrome, including multiphasic perturbations of the numbers of circulating lymphocyte subsets. The number of total lymphocytes and T cell subsets (CD4+ and CD8+) are initially reduced. An inversion of the CD4+/CD8+ T cell ratio occurs later because of a rise in the number of CD8+ T cells. In fact, there may be a selective and transient expansion of CD8+ T cell subsets, as determined by T cell receptor analysis (see above). The total circulating CD8+ T cell count may remain elevated or return to normal; however, CD4+ T cell levels usually remain somewhat depressed, although there may be a slight rebound towards normal. Lymphadenopathy occurs in ~70% of individuals with primary HIV infection. Most patients recover spontaneously from this syndrome and many are left with only a mildly depressed CD4+ T cell count that remains stable for a variable period before beginning its progressive decline (see below); in some individuals, the CD4+ T cell count returns to the normal range. Approximately 10% of patients manifest a fulminant course of immunologic and clinical deterioration after primary infection, even after the disappearance of initial symptoms. In most patients, primary infection with or without the acute syndrome is followed by a prolonged period of clinical latency.

THE ASYMPTOMATIC STAGE—CLINICAL LATENCY Although the length of time from initial infection to the development of clinical disease varies greatly, the median time for untreated patients is ~10 years. As emphasized above, HIV disease with active virus replication is ongoing and progressive during this asymptomatic period. The rate of disease progression is directly correlated with HIV RNA levels. Patients with high levels of HIV RNA in plasma progress to symptomatic disease faster than do patients with low levels of HIV RNA (Fig. 173-17). Some patients referred to as long-term nonprogressors show little if any decline in CD4+ T cell counts over extended periods of time. These patients generally have extremely low levels of HIV RNA. Certain other patients remain entirely asymptomatic despite the fact that their CD4+ T cell counts show a steady progressive decline to extremely low levels. In these patients, the appearance of an opportunistic disease may be the first manifestation of HIV infection. During the asymptomatic period of HIV infection, the average rate of CD4+ T cell decline is ~50/μL per year. When the CD4+ T cell count falls to <200/μL, the resulting state of immunodeficiency is severe enough to place the patient at high risk for opportunistic infection and neoplasms, and hence for clinically apparent disease.

SYMPTOMATIC DISEASE Symptoms of HIV disease can appear at any time during the course of HIV infection. Generally speaking, the spectrum of illness that one observes changes as the CD4+ T cell count declines. The more severe and life-threatening complications of HIV infection occur in patients with CD4+ T cells counts <200/μL. A diagnosis of AIDS is made in anyone with HIV infection and a CD4+ T cell count <200/μL and in anyone with HIV infection who develops one of the HIV-associated diseases considered to be indicative of a severe defect in cell-mediated immunity (category C, Table 173-2). While the causative agents of the secondary infections are characteristically opportunistic organisms such as *P. carinii*, atypical mycobacteria, CMV, and other organisms that do not ordinarily cause disease

in the absence of a compromised immune system, they also include common bacterial and mycobacterial pathogens. Approximately 60% of deaths among AIDS patients are as a direct result of an infection other than HIV, with *P. carinii*, viral hepatitis, and non-AIDS-defining bacterial infections heading the list. Following the widespread use of combination antiretroviral therapy and implementation of guidelines for the prevention of opportunistic infections (Table 173-11), the incidence of secondary infections has decreased dramatically (Fig. 173-28). Overall, the clinical spectrum of HIV disease is constantly changing as patients live longer and new and better approaches to treatment and prophylaxis are developed. In general, it should be stressed that a key element of treatment of symptomatic complications of HIV disease, whether they are primary or secondary, is achieving good control of HIV replication through the use of combination antiretroviral therapy and instituting primary and secondary prophylaxis as indicated.

Disease of the Respiratory System Acute bronchitis and sinusitis are prevalent during all stages of HIV infection. The most severe cases tend to occur in patients with lower CD4+ T cell counts. Sinusitis presents as fever, nasal congestion, and headache. The diagnosis is made by computed tomography (CT) or magnetic resonance imaging (MRI). The maxillary sinuses are most commonly involved; however, disease is also frequently seen in the ethmoid, sphenoid, and frontal sinuses. While some patients may improve without antibiotic therapy, radiographic improvement is quicker and more pronounced in patients who have received antimicrobial therapy. It is postulated that this high incidence of sinusitis results from an increased frequency of infection with encapsulated organisms such as *H. influenzae* and *Streptococcus pneumoniae*. In patients with low CD4+ T cell counts one may see mucormycosis infections of the sinuses. In contrast to the course of this infection in other patient populations, mucormycosis of the sinuses in patients with HIV infection may progress more slowly. In this setting aggressive, frequent local debridement in addition to local and systemic amphotericin B may be needed for effective treatment.

Pulmonary disease is one of the most frequent complications of HIV infection. The most common manifestation of pulmonary disease is pneumonia. The two most common causes of pneumonia are bacterial infections and *P. carinii* infection. Other major causes of pulmonary infiltrates include mycobacterial infections, fungal infections, nonspecific interstitial pneumonitis, KS, and lymphoma.

Pneumonia is seen with an increased frequency in patients with HIV infection; they appear to be particularly prone to infections with encapsulated organisms. *S. pneumoniae* (Chap. 119) and *H. influenzae* (Chap. 130) are responsible for most cases of bacterial pneumonia in patients with AIDS. This may be a consequence of altered B cell function and/or defects in neutrophil function that may be secondary to HIV disease (see above). Pneumococcal infection may be the earliest serious infection to occur in patients with HIV disease. This can present as pneumonia, sinusitis, and/or bacteremia. Patients with HIV infection have a sixfold increase in the incidence of pneumococcal pneumonia and a 100-fold increase in the incidence of pneumococcal bacteremia. Pneumococcal disease may be seen in patients with relatively intact immune systems. In one study, the baseline CD4+ T cell count at the time of a first episode of pneumococcal pneumonia was ~300/μL. Of interest is the fact that the inflammatory response to pneumococcal infection appears proportional to the CD4+ T cell count. Due to this high risk of pneumococcal disease, immunization with pneumococcal polysaccharide is one of the generally recommended prophylactic measures for patients with HIV infection and CD4+ T cell counts >200/μL. It is less clear if this intervention is of benefit in patients with more advanced disease and high viral loads.

P. carinii pneumonia (PCP), once the hallmark of AIDS, has dramatically declined in incidence following the development of effective prophylactic regimens and the widespread use of combination antiretroviral therapy. It is, however, the single most common cause of pneumonia in patients with HIV infection in the United States and can be identified as a likely etiologic agent in 25% of cases of pneumonia in patients with HIV infection. Approximately 25% of cases of HIV-associated PCP occur in patients who are unaware of their HIV status. The risk of PCP is greatest among those who have experienced a previous bout of PCP and those who have CD4+ T cell counts of <200/μL. Overall, 79% of patients with PCP have CD4+ T cell counts <100/μL and 95% of patients have CD4+ T cell counts <200/μL. Recurrent fever, night sweats, thrush, and unexplained weight loss are also associated with an increased incidence of PCP. For these reasons, it is strongly recommended that all patients with CD4+ T cell counts <200/μL (or a CD4 percentage <15) receive some form of PCP prophylaxis. At present the incidence of PCP is approaching zero in patients with known HIV infection receiving appropriate antiretroviral therapy and prophylaxis. In the United States, primary PCP is now occurring at a median CD4+ T cell count of 36/μL, while secondary PCP is occurring at a median CD4+ T cell count of 10/μL. Patients with PCP generally present with fever and a cough that is usually nonproductive or productive of only scant amounts of white sputum. They may complain of a characteristic retrosternal chest pain that is worse on inspiration and is described as sharp or burning. HIV-associated PCP may have an indolent course characterized by weeks of vague symptoms and should be included in the differential diagnosis of fever, pulmonary complaints, or unexplained weight loss in any patient with HIV infection and <200 CD4+ T cells/μL. The most common finding on chest x-ray is either a normal film, if the disease is suspected early, or a faint bilateral interstitial infiltrate. The classic finding of a dense perihilar infiltrate is unusual in patients with AIDS. In patients with PCP who have been receiving aerosolized pentamidine for prophylaxis, one may see an x-ray picture of upper lobe cavitary disease, reminiscent of TB. Other less common findings on chest x-ray include lobar infiltrates and pleural effusions. Routine laboratory evaluation is usually of little help in the differential diagnosis of PCP. A mild leukocytosis is common, although this may not be obvious in patients with prior neutropenia. Arterial blood gases may indicate hypoxemia with a decline in Pa_{O_2} and an increase in the arterial-alveolar (a − A) gradient. Arterial blood gas measurements not only aid in making the diagnosis of PCP but also provide important information for staging the severity of the disease and directing treatment (see below). A definitive diagnosis of PCP requires demonstration of the trophozoite or cyst form of the organism in samples obtained from induced sputum, bronchoalveolar lavage, transbronchial biopsy, or open lung biopsy. PCR has been used to detect specific DNA sequences for *P. carinii* in clinical specimens where histologic examinations have failed to make a diagnosis.

In addition to pneumonia, a number of other clinical problems have been reported in HIV-infected patients as a result of infection with *P. carinii*. Otic involvement may be seen as a primary infection, presenting as a polypoid mass involving the external auditory canal. In patients receiving aerosolized pentamidine for prophylaxis against PCP one may see a variety of extrapulmonary manifestations of *P. carinii*. These include ophthalmic lesions of the choroid, a necrotizing vasculitis that resembles Burger's disease, bone marrow hypoplasia, and intestinal obstruction. Other organs that have been involved include lymph nodes, spleen, liver, kidney, pancreas, pericardium, heart, thyroid, and adrenals. Organ infection may be associated with cystic lesions that may appear calcified on CT or ultrasound.

The standard treatment for PCP or disseminated pneumocystosis is trimethoprim/sulfamethoxazole (TMP/SMX). A high incidence of side effects, particularly skin rash and bone marrow suppression, is seen with TMP/SMX in patients with HIV infection. Alternative treatments for mild to moderate PCP include dapsone/trimethoprim and clindamycin/primaquine. Intravenous pentamidine is the treatment of choice for severe disease in the patient unable to tolerate TMP/SMX. For patients with a Pa_{O_2} < 70 mmHg or with an a − A gradient >35 mmHg, adjunct glucocorticoid therapy should be used in addition to specific antimicrobials. Overall, treatment should be for 21 days and followed by secondary prophylaxis. Prophylaxis for PCP is indicated for any HIV-infected individual who has experienced a prior bout of

TABLE 173-11 *2001 USPHS/IDSA Guidelines for the Prevention of Opportunistic Infections in Persons Infected with HIV*

Pathogen	Indications	First Choice(s)	Alternatives
STRONGLY RECOMMENDED AS STANDARD OF CARE FOR PRIMARY AND SECONDARY PROPHYLAXIS			
Pneumocystis carinii	CD4 count <200/μL or Oropharyngeal candidiasis or Unexplained fever >2 weeks or Prior bout of PCP	Trimethoprim/sulfamethoxazole (TMP/SMZ), 1 DS tablet qd	Dapsone 50 mg bid PO or 100 mg/d PO Dapsone 50 mg/d PO+ Pyrimethamine 50 mg/wk PO+ Leucovorin 25 mg/wk PO
	May stop prophylaxis if CD4+ T cell count > 200/μL for 6 mo	TMP/SMZ, 1 SS tablet qd	Dapsone 200 mg PO+ Pyrimethamine 75 mg + Leucovorin 25 mg PO weekly Aerosolized pentamidine, 300 mg qm via Respirgard II nebulizer Atovoquone 1500 mg/d PO TMP/SMZ 1 DS tablet PO 3×/wk
Mycobacterium tuberculosis			
Isoniazid sensitive	Skin test >5 mm or Prior positive test without treatment or Contact with case of active TB	Isoniazid 300 mg PO+ Pyridoxine 50 mg/d PO ×9 mo	Rifampin 600 mg/d PO or Rifabutin 300 mg/d PO+ Pyrazinamide 20 (mg/kg)/d PO ×2 mo
		Isoniazid 900 mg PO+ Pyridoxine 100 mg PO 2 ×/wk ×9 mo	Rifampin 600 mg/d PO or Rifabutin 300 mg/d PO ×4 mo
Isoniazid resistant	Same with high probability of exposure to isoniazid-resistant TB	Rifabutin 300 mg or Rifampin 600 mg; PO qd ×4 mo	Pyrazinamide 20 (mg/kg)/d PO ×2 mo + either Rifampin 600 mg/d or Rifabutin 300 mg/d PO ×4 mo
Multidrug resistant	Same with high probability of exposure to multidrug resistant TB	Consult local public health authorities	
Mycobacterium-avium complex	CD4 count <50/μL Prior documented disseminated disease	Azithromycin 1200 mg weekly PO Clarithromycin 500 mg bid PO	Rifabutin 300 mg/d PO Azithromycin 1200 mg weekly PO + Rifabutin 300 mg/d PO
	May stop prophylaxis if CD4+ T cell count > 100/μL for 6 mo	Clarithromycin 500 mg bid PO + Ethambutol 15 (mg/kg)/d PO +/− Rifabutin 300 mg/d PO	Azithromycin 500 mg/d PO + Ethambutol 15 (mg/kg)/d PO +/− Rifabutin 300 mg/d PO
Toxoplasma gondii	IgG antibody and CD4 count <100/μL	TMP/SMZ 1 DS tablet qd	TMP/SMZ 1 SS tablet qd Dapsone 50 mg/d PO + Pyrimethamine 50 mg weekly PO + Leucovorin 25 mg weekly PO Dapsone 200 mg PO + Pyrimethamine 75 mg PO + Leucovorin 25 mg PO weekly Atovaquone 1500 mg PO + Pyrimethamine 25 mg PO + Leucovorin 10 mg PO daily
	Prior toxoplasmic encephalitis	Sulfadiazine 500–1000 mg qid PO+ Pyrimethamine 25–50 mg/d PO+ Leucovorin 10–25 mg/d PO Atovaquone 750 mg PO q6–12 h +/− Pyrimethamine 25 mg/d + Leucovorin 10 mg/d PO	Clindamycin 300–450 mg q6–8h PO+ Pyrimethamine 25–75 mg/d PO+ Leucovorin 10–25 mg/d PO
Varicella zoster virus	Significant exposure to chickenpox or shingles in a patient with no history of immunization or prior exposure to either	Varicella zoster immune globulin 6.25 mL, IM, within 96 h	
Cryptococcus neoformans	Prior documented disease	Fluconazole 200 mg/d PO	Amphotericin B 0.6–1.0 mg/kg 3 ×/wk IV Itraconazole 200 mg/d PO
Histoplasma capsulatum	Prior documented disease	Itraconazole 200 mg bid PO	Amphotericin B 1.0 (mg/kg)/wk IV
Coccidioides immitis	Prior documented disease	Fluconazole 400 mg/d PO	Amphotericin B 1.0 (mg/kg)/wk IV Itraconazole 200 mg/d PO
Salmonella species	Prior bacteremia	Ciprofloxacin 500 mg bid PO for several months	
Cytomegalovirus	Prior end-organ disease May stop prophylaxis if CD4+ T cell count > 100/μL for 6 mo	Ganciclovir, 5–6 mg/kg 5–7 d/wk IV Ganciclovir 1000 mg tid PO	Cidofovir 5 mg/kg every other week IV + Probenecid Formivirsen 330 μg intravitreal q2–4 wk
	Prior retinitis	Foscarnet 90–120 (mg/kg)/d IV Ganciclovir implant q6–9 mo + Ganciclovir 1–1.5 g PO tid Ganciclovir sustained-release implant q6–9mo + Ganciclovir 1– 1.5 g tid PO	Valganciclovir 900 mg PO daily Fomivirsen, 1 vial injected into the vitreous q2–4wk

(continued)

TABLE 173-11—(Continued)

Pathogen	Indications	First Choice(s)	Alternatives
IMMUNIZATIONS GENERALLY RECOMMENDED			
Hepatitis B virus	All susceptible (anti-HBc and anti-HBs negative) patients	Hepatitis B vaccine: 3 doses	
Hepatitis A virus	All susceptible (anti-HAV negative) patients with chronic hepatitis C or at increased risk for hepatitis A	Hepatitis A vaccine: 2 doses	
Influenza virus	All patients annually	Inactivated trivalent influenza virus vaccine 1 dose yearly Oseltamivir 75 mg PO qd Rimantadine or amantadine 100 mg PO qd	
Streptococcus pneumoniae	All patients	Pneumoccal vaccine 0.5 mL IM ×1 if CD4 count >200/μL Reimmunize patients initially immunized at a CD4 count <200/μL whose CD4 count then increases to >200/μL	
RECOMMENDED FOR PREVENTION OF SEVERE OR FREQUENT RECURRENCES			
Herpes simplex	Frequent/severe recurrences	Acyclovir 200 mg tid PO Acyclovir 400 mg bid PO Famciclovir 250 mg bid PO	Valacyclovir 500 mg PO bid
Candida	Frequent/severe recurrences	Fluconazole 100–200 mg/d PO	Itraconazole solution 200 mg/d PO

Note: DS, double strength; SS, single strength; PCP, *Pneumocystis carinii* pneumonia; TB, tuberculosis

PCP, any patient with a CD4+ T cell count of <200/μL or a CD4 percentage <15, any patient with unexplained fever for >2 weeks, and any patient with a history of oropharyngeal candidiasis. The preferred regimen for prophylaxis is TMP/SMX, one double-strength tablet daily. This regimen also provides protection against toxoplasmosis and some bacterial respiratory pathogens. For patients who cannot tolerate TMP/SMX, alternatives include dapsone plus pyrimethamine plus leucovorin, aerosolized pentamidine administered by the Respirgard II nebulizer, and atovaquone. Primary or secondary prophylaxis for PCP can be discontinued in those patients treated with combination antiretroviral therapy who maintain good suppression of HIV (<500 copies per milliliter) and CD4+ T cell counts >200/μL for at least 3 to 6 months.

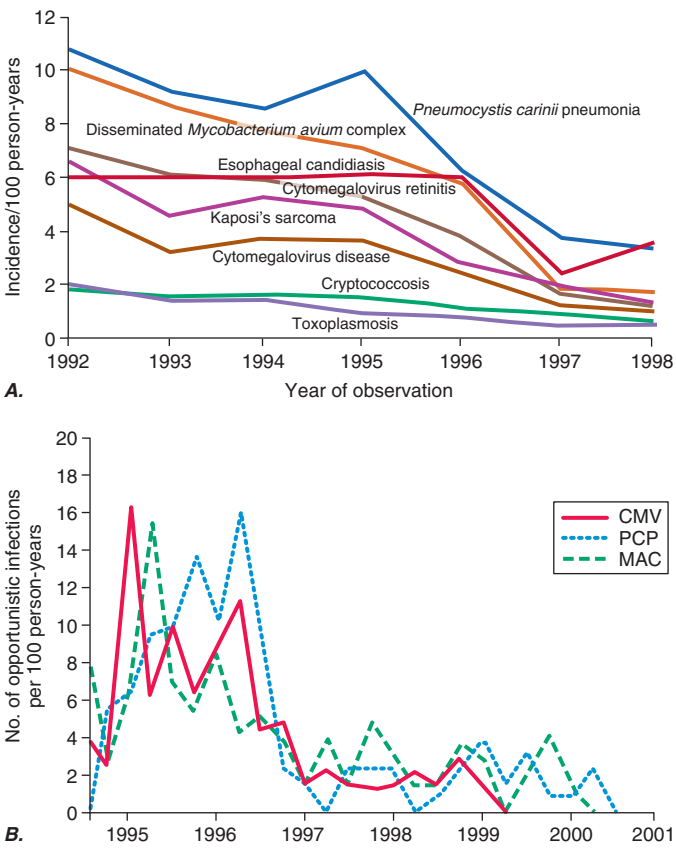

FIGURE 173-28 *A*. Decrease in the incidence of opportunistic infections and Kaposi's sarcoma in HIV-infected individuals with CD4+ T cell counts <100/μL from 1992 through 1998. [*Adapted and updated from Palella et al, and JE Kaplan et al: Clin Infect Dis 30(51):55, 2000, with permission.*] *B*. Quarterly incidence rates of cytomegalovirus (CMV), *Pneumocystis carinii* pneumonia (PCP), and *Mycobacterium avium* complex (MAC) from 1995–2001. (*From FJ Palella et al: AIDS 16:1617, 2002.*)

M. tuberculosis, once thought to be on its way to extinction in the United States, experienced a resurgence associated with the HIV epidemic (Chap. 150). Worldwide, approximately one-third of all AIDS-related deaths are associated with TB. In the United States ~5% of AIDS patients have active TB. HIV infection increases the risk of developing active TB by a factor of 100. For the patient with untreated HIV infection and a positive PPD skin test, the rate of reactivation TB is 7 to 10% per year. Untreated TB can accelerate the course of HIV infection. Levels of plasma HIV RNA increase in the setting of active TB and decline in the setting of successful TB treatment. Active TB is most common in patients 25 to 44 years of age, in African Americans and Hispanics, in patients in New York City and Miami, and in patients in developing countries. In these demographic groups, 20 to 70% of the new cases of active TB are in patients with HIV infection. The epidemic of TB embedded in the epidemic of HIV infection probably represents the greatest health risk to the general public and the health care profession associated with the HIV epidemic. In contrast to infection with atypical mycobacteria such as MAC, active TB often develops relatively early in the course of HIV infection and may be an early clinical sign of HIV disease. In one study, the median CD4+ T cell count at presentation of TB was 326/μL. The clinical manifestations of TB in HIV-infected patients are quite varied and generally show different patterns as a function of the CD4+ T cell count. In patients with relatively high CD4+ T cell counts, the typical pattern of pulmonary reactivation occurs in which patients present with fever, cough, dyspnea on exertion, weight loss, night sweats, and a chest x-ray revealing cavitary apical disease of the upper lobes. In patients with lower CD4+ T cell counts, disseminated disease is more common. In these patients the chest x-ray may reveal diffuse or lower lobe bilateral reticulonodular infiltrates consistent with miliary spread, pleural effusions, and hilar and/or mediastinal adenopathy. Infection may be present in bone, brain, meninges, gastrointestinal tract, lymph nodes (particularly cervical lymph nodes), and viscera. Approximately 60 to 80% of patients have pulmonary disease, and 30 to 40% have extrapulmonary disease. Respiratory isolation and a negative-pressure room should be used for patients in whom a diagnosis of pulmonary

TB is being considered. This approach is critical to limit nosocomial and community spread of infection. Culture of the organism from an involved site provides a definitive diagnosis. Blood cultures are positive in 15% of patients. In the setting of fulminant disease one cannot rely upon the accuracy of a negative PPD skin test to rule out a diagnosis of TB. TB is one of the conditions associated with HIV infection for which cure is possible. Therapy for TB is generally the same in the HIV-infected patient as in the HIV-negative patient (Chap. 150). Due to pharmacokinetic interactions, rifabutin should be substituted for rifampin in patients receiving the HIV protease inhibitors or nonnucleoside reverse transcriptase inhibitors; both drugs should be avoided in patients receiving ritonavir. Treatment is most effective in programs that involve directly observed therapy. Effective prevention of active TB can be a reality if the health care professional is aggressive in looking for evidence of latent TB by making sure that all patients with HIV infection receive a PPD skin test. Anergy testing is not of value in this setting. HIV-infected individuals with a skin test reaction of >5 mm or those who are close household contacts of persons with active TB should receive treatment with 9 months of isoniazid.

Atypical mycobacterial infections are also seen with an increased frequency in patients with HIV infection. Infections with at least 12 different mycobacteria have been reported, including *M. bovis* and representatives of all four Runyon groups. The most common atypical mycobacterial infection is with *M. avium* or *M. intracellulare* species—MAC. Infections with MAC are seen mainly in patients in the United States and are rare in Africa. It has been suggested that prior infection with *M. tuberculosis* decreases the risk of MAC infection. MAC infections probably arise from organisms that are ubiquitous in the environment, including both soil and water. The presumed portals of entry are the respiratory and gastrointestinal tract. MAC infection is a late complication of HIV infection, predominantly occurring in patients with CD4+ T cell counts of $<50/\mu$L. The average CD4+ T cell count at the time of diagnosis is $10/\mu$L. The most common presentation is disseminated disease with fever, weight loss, and night sweats. At least 85% of patients with MAC infection are mycobacteremic, and large numbers of organisms can often be demonstrated on bone marrow biopsy. The chest x-ray is abnormal in ~25% of patients, with the most common pattern being that of a bilateral, lower lobe infiltrate suggestive of miliary spread. Alveolar or nodular infiltrates and hilar and/or mediastinal adenopathy can also occur. Other clinical findings include endobronchial lesions, abdominal pain, diarrhea, and lymphadenopathy. The diagnosis is made by the culture of blood or involved tissue. The finding of two consecutive sputum samples positive for MAC is highly suggestive of pulmonary infection. Cultures may take 2 weeks to turn positive. Therapy consists of a macrolide, usually clarithromycin, with ethambutol. Some physicians elect to add a third drug from among rifabutin, ciprofloxacin, or amikacin in patients with extensive disease. Therapy is generally for life; however, with the advent of highly active antiretroviral therapy (HAART), it may be possible to discontinue therapy in patients with sustained suppression of HIV replication and CD4+ T cell counts $>100/\mu$L for >6 months. Primary prophylaxis for MAC is indicated in patients with HIV infection and CD4+ T cell counts $<50/\mu$L. This may be discontinued in patients in whom HAART induces a sustained suppression of viral replication and increases in CD4+ T cell counts to $>100/\mu$L for 3 to 6 months.

Rhodococcus equi is a gram-positive pleomorphic acid-fast nonspore-forming bacillus that can cause pulmonary and/or disseminated infection in patients with HIV infection. Fever and cough are the most common presenting signs. Radiographically one may see cavitary lesions and consolidation. Blood cultures are often positive. Treatment is based upon antimicrobial sensitivity testing.

Fungal infections of the lung, in addition to PCP, can be seen in patients with AIDS. Patients with pulmonary cryptococcal disease present with fever, cough, dyspnea, and in some cases, hemoptysis. A focal or diffuse interstitial infiltrate is seen on chest x-ray in >90% of patients. In addition, one may see lobar disease, cavitary disease, pleural effusions, and hilar or mediastinal adenopathy. Over half of patients are fungemic, and 90% of patients have concomitant CNS infection. *Coccidioides immitis* is a mold that is endemic in the southwest United States. It can cause a reactivation pulmonary syndrome in patients with HIV infection. Most patients with this condition will have CD4+ T cell counts $<250/\mu$L. Patients present with fever, weight loss, cough, and extensive, diffuse reticulonodular infiltrates on chest x-ray. One may also see nodules, cavities, pleural effusions, and hilar adenopathy. While serologic testing is of value in the immunocompetent host, serologies are negative in 25% of HIV-infected patients with coccidioidal infection. Invasive aspergillosis is not an AIDS-defining illness and is generally not seen in patients with AIDS in the absence of neutropenia or administration of glucocorticoids. *Aspergillus* infection may have an unusual presentation in the respiratory tract of patients with AIDS where it gives the appearance of a pseudomembranous tracheobronchitis. Primary pulmonary infection of the lung may be seen with *histoplasmosis*. The most common pulmonary manifestation of histoplasmosis, however, is in the setting of disseminated disease, presumably due to reactivation. In this setting respiratory symptoms are usually minimal, with cough and dyspnea occurring in 10 to 30% of patients. The chest x-ray is abnormal in ~50% of patients, showing either a diffuse interstitial infiltrate or diffuse small nodules.

Two forms of *idiopathic interstitial pneumonia* have been identified in patients with HIV infection: lymphoid interstitial pneumonitis (LIP) and nonspecific interstitial pneumonitis (NIP). LIP, a common finding in children, is seen in about 1% of adult patients with HIV infection. This disorder is characterized by a benign infiltrate of the lung and is felt to be part of the polyclonal activation of lymphocytes seen in the context of HIV and EBV infections. Transbronchial biopsy is diagnostic in 50% of the cases, with an open-lung biopsy required for diagnosis in the remainder of cases. This condition is generally self-limited and no specific treatment is necessary. Severe cases have been managed with brief courses of glucocorticoids. Although rarely a clinical problem since the use of HAART, evidence of NIP may be seen in up to half of all patients with untreated HIV infection. Histologically, interstitial infiltrates of lymphocytes and plasma cells in a perivascular and peribronchial distribution are present. When symptomatic, patients present with fever and nonproductive cough occasionally accompanied by mild chest discomfort. Chest x-ray is usually normal or may reveal a faint interstitial pattern. Similar to LIP, this is a self-limited process for which no therapy is indicated other than appropriate management of the underlying HIV infection.

Neoplastic diseases of the lung including KS and lymphoma are discussed below in the section on malignancies.

Diseases of the Cardiovascular System Heart disease is a relatively common postmortem finding in HIV-infected patients (25 to 75% in autopsy series). Cardiovascular disease may be seen as a direct consequence of HIV infection or as a consequence of antiretroviral therapy as part of the lipodystrophy syndrome. As a primary consequence of HIV infection, the most common clinically significant finding is a dilated cardiomyopathy associated with congestive heart failure referred to as *HIV-associated cardiomyopathy*. This generally occurs as a late complication of HIV infection and, histologically, displays elements of myocarditis. For this reason some have advocated treatment with intravenous Ig. HIV can be directly demonstrated in cardiac tissue in this setting, and there is debate over whether or not it plays a direct role in this condition. Patients present with typical findings of congestive heart failure, namely edema and shortness of breath. Patients with HIV infection may also develop cardiomyopathy as a side effect of IFN-α nucleoside analogue therapy, which is reversible once therapy is stopped. KS, cryptococcosis, Chagas disease, and toxoplasmosis can involve the myocardium, leading to cardiomyopathy. In one series, most patients with HIV infection and a treatable myocarditis were found to have myocarditis associated with toxoplasmosis. Most of these patients also had evidence of CNS toxoplasmosis. Thus, MRI or double-dose contrast CT scan of the brain

should be included in the workup of any patient with advanced HIV infection and cardiomyopathy.

A variety of other cardiovascular problems are found in patients with HIV infection. Pericardial effusions may be seen in the setting of advanced HIV infection. Predisposing factors include TB, congestive heart failure, mycobacterial infection, cryptococcal infection, pulmonary infection, lymphoma, and KS. While pericarditis is quite rare, in one series 5% of patients with HIV disease had pericardial effusions that were considered to be moderate or severe. Tamponade and death have occurred in association with pericardial KS, presumably owing to acute hemorrhage. Nonbacterial thrombotic endocarditis has been reported and should be considered in patients with unexplained embolic phenomena. Intravenous pentamidine, when given rapidly, can result in hypotension as a consequence of cardiovascular collapse. A high percentage of patients have hypertriglyceridemia and elevations in serum cholesterol, and coronary artery disease has been a relatively frequent finding at autopsy. This problem appears to becoming even more prevalent as a side effect of HAART. While the clinical significance of these findings has not been precisely defined, recent data suggest a linear relationship between time on HAART and development of ischemic heart disease. In one large series the overall rate of myocardial infarction was 3.5/1000 years, 28% of these events were fatal, and myocardial infarction was responsible for 7% of all deaths in the cohort. The risk of myocardial infarction increased by 26% per year of HAART. This small increase in the risk of death from myocardial infarction in the setting of HAART has to be balanced against the marked increase in overall survival brought about by HAART.

FIGURE 173-29 Barium swallow of a patient with *Candida* esophagitis. The flow of barium along the mucosal surface is grossly irregular.

Diseases of the Oropharynx and Gastrointestinal System Oropharyngeal and gastrointestinal diseases are common features of HIV infection. They are most frequently due to secondary infections. In addition, oral and gastrointestinal lesions may occur with KS and lymphoma.

Oral lesions, including *thrush*, *hairy leukoplakia*, and *aphthous ulcers*, are particularly common in patients with untreated HIV infection. Thrush, due to *Candida* infection, and oral hairy leukoplakia, presumed due to EBV, are usually indicative of fairly advanced immunologic decline; they generally occur in patients with CD4+ T cell counts of $<300/\mu L$. In one study, 59% of patients with oral candidiasis went on to develop AIDS in the next year. Thrush appears as a white, cheesy exudate, often on an erythematous mucosa in the posterior oropharynx (see Fig. 187-1). While most commonly seen on the soft palate, early lesions are often found along the gingival border. The diagnosis is made by direct examination of a scraping for pseudohyphal elements. Culturing is of no diagnostic value, as most patients with HIV infection will have a positive throat culture for *Candida* even in the absence of thrush. Oral hairy leukoplakia presents as white, frondlike lesions, generally along the lateral borders of the tongue and sometimes on the adjacent buccal mucosa (see Fig. 165-1). Despite its name, oral hairy leukoplakia is not considered a premalignant condition. Lesions are associated with florid replication of EBV. While usually more disconcerting as a sign of HIV-associated immunodeficiency than a clinical problem in need of treatment, severe cases have been reported to respond to topical podophyllin or systemic therapy with anti-herpesvirus agents. Aphthous ulcers of the posterior oropharynx are also seen with regularity in patients with HIV infection. These lesions are of unknown etiology and can be quite painful and interfere with swallowing. Topical anesthetics provide immediate symptomatic relief of short duration. The fact that thalidomide is an effective treatment for this condition suggests that the pathogenesis may involve the action of tissue-destructive cytokines. Palatal, glossal, or gingival ulcers may also result from cryptococcal disease or histoplasmosis.

Esophagitis (Fig. 173-29) may present with odynophagia and retrosternal pain. Upper endoscopy is generally required to make an accurate diagnosis. Esophagitis may be due to *Candida*, CMV, or HSV. While CMV tends to be associated with a single large ulcer, HSV infection is more often associated with multiple small ulcers. The esophagus may also be the site of KS and lymphoma. Like the oral mucosa, the esophageal mucosa may have large, painful ulcers of unclear etiology that may respond to thalidomide. While achlorhydria is a common problem in patients with HIV infection, other gastric problems are generally rare. Among the conditions involving the stomach are KS and lymphoma. Infections of the small and large intestine leading to diarrhea, abdominal pain, and occasionally fever are among the most significant gastrointestinal problems in the HIV-infected patients. They include infections with bacteria, protozoa, and viruses.

Bacteria may be responsible for secondary infections of the gastrointestinal tract. Infections with enteric pathogens such as *Salmonella*, *Shigella*, and *Campylobacter* are more common in homosexual men and are often more severe and more apt to relapse in patients with HIV infection. Patients with untreated HIV have approximately a 20-fold increased risk of infection with *S. typhimurium*. They may present with a variety of nonspecific symptoms including fever, anorexia, fatigue, and malaise of several weeks' duration. Diarrhea is common but may be absent. Diagnosis is made by culture of blood and stool. Long-term therapy with ciprofloxacin is the recommended treatment. HIV-infected patients also have an increased incidence of *S. typhi* infection in areas of the world where typhoid is a problem. *Shigella* spp., particularly *S. flexneri*, can cause severe intestinal disease in HIV-infected individuals. Up to 50% of patients will develop bacteremia. *Campylobacter* infections occur with an increased frequency in patients with HIV infection. While *C. jejuni* is the strain most frequently isolated, infections with many other strains have been reported. Patients usually present with crampy abdominal pain, fever, and bloody diarrhea. Infection may present as proctitis. Stool examination reveals the presence of fecal leukocytes. Systemic infection can occur, with up to 10% of infected patients exhibiting bacteremia. Most strains are sensitive to erythromycin. Abdominal pain and diarrhea may be seen with MAC infection.

Fungal infections may also be a cause of diarrhea in patients with HIV infection. Histoplasmosis, coccidioidomycosis, and penicilliosis have all been identified as a cause of fever and diarrhea in patients with HIV infection. Peritonitis has been seen with *C. immitis*.

Cryptosporidia, microsporidia, and *Isospora belli* (Chap. 199) are the most common opportunistic protozoa that infect the gastrointestinal tract and cause diarrhea in HIV-infected patients. Cryptosporidial infection may present in a variety of ways, ranging from a self-limited

or intermittent diarrheal illness in patients in the early stages of HIV infection to a severe, life-threatening diarrhea in severely immunodeficient individuals. In patients with untreated HIV infection and CD4+ T cell counts of $<300/\mu L$, the incidence of cryptosporidiosis is ~1% per year. In 75% of cases the diarrhea is accompanied by crampy abdominal pain, and 25% of patients have nausea and/or vomiting. Cryptosporidia may also cause biliary tract disease in the HIV-infected patient, leading to cholecystitis with or without accompanying cholangitis. The diagnosis of cryptosporidial diarrhea is made by stool examination. The diarrhea is noninflammatory, and the characteristic finding is the presence of oocysts that stain with acid-fast dyes. Therapy is predominantly supportive, and marked improvements have been reported in the setting of effective antiretroviral therapy. Treatment with up to 2000 mg/d of nitazoxanide (NTZ) is associated with improvement in symptoms or a decrease in shedding of organisms in about half of patients. Its overall role in the management of this condition remains unclear. Patients can minimize their risk of developing cryptosporidiosis by avoiding contact with human and animal feces and by not drinking untreated water from lakes or rivers.

Microsporidia are small, unicellular, obligate intracellular parasites that reside in the cytoplasm of enteric cells (Chap. 199). The main species causing disease in humans is *Enterocytozoon bieneusi*. The clinical manifestations are similar to those described for cryptosporidia and include abdominal pain and diarrhea. The small size of the organism may make it difficult to detect; however, with the use of chromotrope-based stains, organisms can be identified in stool samples by light microscopy. Definitive diagnosis generally depends on electron microscopic examination of a stool specimen, intestinal aspirate, or intestinal biopsy specimen. In contrast to cryptosporidia, microsporidia have been noted in a variety of extraintestinal locations, including the eye, muscle, and liver, and have been associated with conjunctivitis and hepatitis. Albendazole, 400 mg bid, has been reported to be of benefit in some patients.

I. belli is a coccidian parasite (Chap. 199) most commonly found as a cause of diarrhea in patients from the Caribbean and Africa. Its cysts appear in the stool as large, acid-fast structures that can be differentiated from those of cryptosporidia on the basis of size, shape, and number of sporocysts. The clinical syndromes of *Isospora* infection are identical to those caused by cryptosporidia. The important distinction is that infection with *Isospora* is generally relatively easy to treat with TMP/SMX. While relapses are common, a thrice-weekly regimen, similar to that used to provide prophylaxis against PCP, appears adequate to prevent recurrence.

CMV colitis was once seen in 5 to 10% of patients with AIDS. It is much less common with the advent of HAART. CMV colitis presents as diarrhea, abdominal pain, weight loss, and anorexia. The diarrhea is usually nonbloody, and the diagnosis is achieved through endoscopy and biopsy. Multiple mucosal ulcerations are seen at endoscopy, and biopsies reveal characteristic intranuclear inclusion bodies. Secondary bacteremias may result as a consequence of thinning of the bowel wall. Treatment is with either ganciclovir or foscarnet for 3 to 6 weeks. Relapses are common, and maintenance therapy is typically necessary in patients whose HIV infection is poorly controlled. Patients with CMV disease of the gastrointestinal tract should be carefully monitored for evidence of retinitis.

In addition to disease caused by specific secondary infections, patients with HIV infection may also experience a chronic diarrheal syndrome for which no etiologic agent other than HIV can be identified. This entity is referred to as *AIDS enteropathy* or *HIV enteropathy*. It is most likely a direct result of HIV infection in the gastrointestinal tract. Histologic examination of the small bowel in these patients reveals low-grade mucosal atrophy with a decrease in mitotic figures, suggesting a hyporegenerative state. Patients often have decreased or absent small-bowel lactase and malabsorption with accompanying weight loss.

The initial evaluation of a patient with HIV infection and diarrhea should include a set of stool examinations, including culture, examination for ova and parasites, and examination for *Clostridium difficile* toxin. Approximately 50% of the time this workup will demonstrate infection with pathogenic bacteria, mycobacteria, or protozoa. If the initial stool examinations are negative, additional evaluation, including upper and/or lower endoscopy with biopsy, will yield a diagnosis of microsporidial or mycobacterial infection of the small intestine ~30% of the time. In patients for whom this diagnostic evaluation is nonrevealing, a presumptive diagnosis of HIV enteropathy can be made if the diarrhea has persisted for >1 month. An algorithm for the evaluation of diarrhea in patients with HIV infection is given in Fig. 173-30.

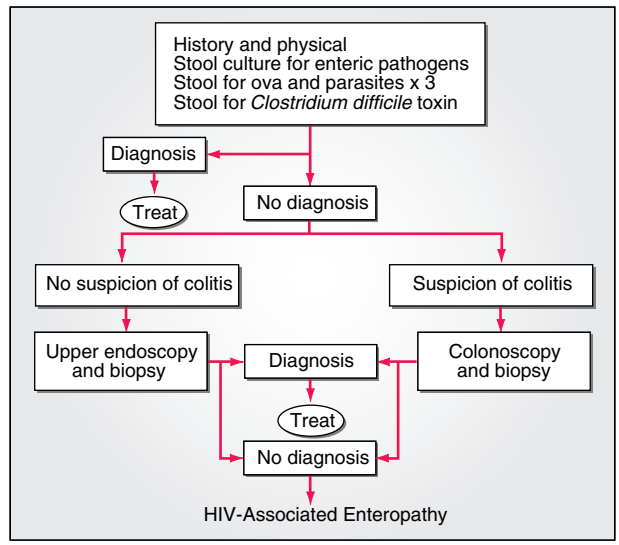

FIGURE 173-30 Algorithm for the evaluation of diarrhea in a patient with HIV infection. HIV-associated enteropathy is a diagnosis of exclusion and can be made only after other, generally treatable, forms of diarrheal illness have been ruled out.

Rectal lesions are common in HIV-infected patients, particularly the perirectal ulcers and erosions due to the reactivation of HSV (Fig. 173-31). These may appear quite atypical, as denuded skin without vesicles, and they respond well to treatment with acyclovir, famciclovir, or foscarnet. Other rectal lesions encountered in patients with HIV infection include condylomata acuminata, KS, and intraepithelial neoplasia (see below).

FIGURE 173-31 Severe, erosive perirectal herpes simplex in a patient with AIDS.

Hepatobiliary Disease Diseases of the hepatobiliary system are a major problem in patients with HIV infection. It has been estimated that approximately one-third of the deaths of patients with HIV infection are in some way related to liver disease. While this is predominantly a reflection of the problems encountered in the setting of co-infection with hepatitis B or C, it is also a reflection of the hepatic injury, ranging from hepatic steatosis to hypersensitivity reactions to immune reconstitution, that can be seen in the context of antiretroviral therapy.

Approximately 95% of HIV-infected individuals have evidence of infection with HBV; 5 to 40% of patients are co-infected with HCV; and co-infection with hepatitis D, E, and/or G viruses is common. HIV infection has a significant impact on the course of hepatitis virus infection. It is associated with approximately a threefold increase in the development of persistent hepatitis B surface antigenemia. Patients infected with both HBV and HIV have decreased evidence of inflammatory liver disease. The presumption that this is due to the immunosuppressive effects of HIV infection is supported by the observations that this situation can be reversed, and one may see the development of more severe hepatitis following the initiation of effective antiretroviral therapy. In a study of the impact of HIV on hepatitis B infection a tenfold increase in liver-related mortality was noted in patients with HIV and active HBV infection compared to rates in patients with either infection alone. IFN-α is less successful as a treatment of HBV in patients with HIV co-infection, and lamivudine or adefovir/tenofovir is the treatment of choice. It is important to remember that these drugs are also potent antiretroviral agents in the setting of combination antiretroviral therapy. They should not be used as single agents in patients with HIV infection, even if it is only being used to treat HBV, in order to avoid the rapid development of resistant quasispecies of HIV. In contrast to the situation with HBV, HCV infection is more severe in the patient with HIV infection; however, it does not appear to affect overall mortality when other variables such as age, baseline CD4+ T cell count, and use of HAART are taken into account. In the setting of HIV and HCV co-infection, levels of HCV are approximately tenfold higher than in the HIV-negative patient with HCV infection and there is an increased rate of progression to cirrhosis. Treatment for HCV infection consists of pegylated IFN-α and ribavirin. If a 2-log drop in levels of HCV RNA is not seen within 12 weeks, it is unlikely that therapy will be of value. Hepatitis A virus infection is not seen with an increased frequency in patients with HIV infection. It is recommended that all patients with HIV infection who have not experienced natural infection be immunized with hepatitis A and/or hepatitis B vaccines. Infection with hepatits G virus, also known as GB virus C, is seen in ~50% of patients with HIV infection. For reasons that are currently unclear there are data to suggestion that patients with HIV infection co-infected with this virus have a decreased rate of progression to AIDS.

A variety of other infections may also involve the liver. Granulomatous hepatitis may be seen as a consequence of mycobacterial or fungal infections, particularly MAC infection. Hepatic masses may be seen in the context of TB, peliosis hepatis, or fungal infection. Among the fungal opportunistic infections *C. immitis* and *Histoplasma capsulatum* are those most likely to involve the liver. Biliary tract disease in the form of papillary stenosis or sclerosing cholangitis has been reported in the context of cryptosporidiosis, CMV infection, and KS.

Many of the drugs used to treat HIV infection are metabolized by the liver and can cause liver injury. Fatal hepatic reactions have been reported with a wide array of antiretrovirals including nucleoside analogues, nonnucleoside analogues, and protease inhibitors. Nucleoside analogues work by inhibiting DNA synthesis. This can result in toxicity to mitochondria, which can lead to disturbances in oxidative metabolism. This may be manifest as hepatic steatosis and, in severe cases, lactic acidosis and fulminant liver failure. It is important to be aware of this condition and to watch for it in patients with HIV infection receiving nucleoside analogues. It is reversible if diagnosed early and the offending agent(s) discontinued. Nevirapine has been associated with at times fatal fulminant and cholestatic hepatitis, hepatic necrosis, and hepatic failure. Indinavir may cause mild to moderate elevations in serum bilirubin in 10 to 15% of patients in a syndrome similar to Gilbert's syndrome. A similar pattern of hepatic injury may be seen with atazanavir. In the patient receiving HAART with an unexplained increase in hepatic transaminases, strong consideration should be given to drug toxicity. *Pancreatic injury* is most commonly a consequence of drug toxicity, notably that secondary to pentamidine or dideoxynucleosides. While up to half of patients in some series have biochemical evidence of pancreatic injury, <5% of patients show any clinical evidence of pancreatitis that is not linked to a drug toxicity.

Diseases of the Kidney and Genitourinary Tract Diseases of the kidney or genitourinary tract may be a direct consequence of HIV infection, due to an opportunistic infection or neoplasm, or related to drug toxicity. *HIV-associated nephropathy* was first described in IDUs and was initially thought to be IDU nephropathy in patients with HIV infection; it is now recognized as a true direct complication of HIV infection. HIV-associated nephropathy can be an early manifestation of HIV infection and is also seen in children. Over 90% of reported cases have been in African-American or Hispanic individuals; the disease is not only more prevalent in these populations but also more severe. Proteinuria is the hallmark of this disorder. Overall, microalbuminuria is seen in ~20% of untreated HIV-infected patients; significant proteinuria is seen in closer to 2%. Edema and hypertension are rare. Ultrasound examination reveals enlarged, hyperechogenic kidneys. A definitive diagnosis is obtained through renal biopsy. Histologically, focal segmental glomerulosclerosis is present in 80%, and mesangial proliferation in 10 to 15% of cases. Prior to effective antiretroviral therapy, this disease was characterized by relatively rapid progression to end-stage renal disease. Treatment with prednisone, 60 mg/d, has been reported to be of benefit in some cases. The incidence of this disease in patients receiving adequate antiretroviral therapy has not been well defined; however, the impression is that it has decreased in frequency. It is the leading cause of end-stage renal disease in patients with HIV infection.

Among the drugs commonly associated with renal damage in patients with HIV disease are pentamidine, amphotericin, adefovir, cidofovir, and foscarnet. TMP/SMX may compete for tubular secretion with creatinine and cause an increase in the serum creatinine level. Sulfadiazine may crystallize in the kidney and result in an easily reversible form of renal shutdown. One of the most common drug-induced renal complications is indinavir-associated renal calculi. This condition is seen in ~10% of patients receiving this HIV protease inhibitor. It may present with a variety of manifestations, ranging from asymptomatic hematuria to renal colic. Adequate hydration is the mainstay of treatment and prevention for this condition.

Genitourinary tract infections are seen with a high frequency in patients with HIV infection; they present with dysuria, hematuria, and/or pyuria and are managed in the same fashion as in patients without HIV infection. Infections with *T. pallidum*, the etiologic agent of *syphilis*, play an important role in the HIV epidemic (Chap. 172). In HIV-negative individuals, genital syphilitic ulcers as well as the ulcers of chancroid are major predisposing factors for heterosexual transmission of HIV infection. While most HIV-infected individuals with syphilis have a typical presentation, a variety of formerly rare clinical problems may be encountered in the setting of dual infection. Among them are *lues maligna*, an ulcerating lesion of the skin due to a necrotizing vasculitis; unexplained fever; nephrotic syndrome; and neurosyphilis. The most common presentation of syphilis in the HIV-infected patient is that of *condylomata lata*, a form of secondary syphilis. Neurosyphilis may be asymptomatic or may present as acute meningitis, neuroretinitis, deafness, or stroke. The rate of neurosyphilis may be as high as 1% in patients with HIV infection. As a consequence of the immunologic abnormalities seen in the setting of HIV infection, diagnosis of syphilis through standard serologic testing may be challenging. On the one hand, a significant number of patients have false-positive Venereal Disease Research Laboratory (VDRL) tests

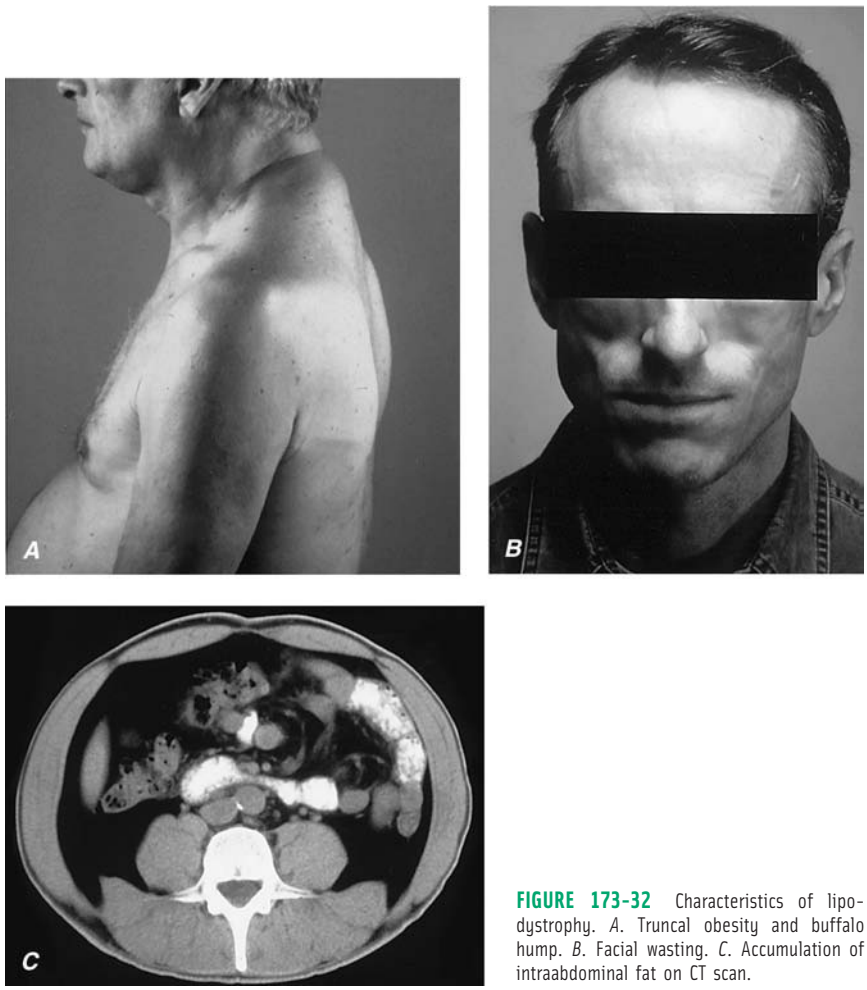

FIGURE 173-32 Characteristics of lipodystrophy. *A*. Truncal obesity and buffalo hump. *B*. Facial wasting. *C*. Accumulation of intraabdominal fat on CT scan.

due to polyclonal B cell activation. On the other hand, the development of a new positive VDRL may be delayed in patients with new infections, and the anti-fluorescent treponema antibody (anti-FTA) test may be negative due to immunodeficiency. Thus, dark-field examination of appropriate specimens should be performed in any patient in whom syphilis is suspected, even if the patient has a negative VDRL. Similarly, any patient with a positive serum VDRL test, neurologic findings, and an abnormal spinal fluid examination should be considered to have neurosyphilis, regardless of the CSF VDRL result. In any setting, patients treated for syphilis need to be carefully monitored to ensure adequate therapy.

Vulvovaginal candidiasis is a common problem in women with HIV infection. Symptoms include pruritus, discomfort, dyspareunia, and dysuria. Vulvar infection may present as a morbilliform rash that may extend to the thighs. Vaginal infection is usually associated with a white discharge, and plaques may be seen along an erythematous vaginal wall. Diagnosis is made by microscopic examination of the discharge for pseudohyphal elements in a 10% potassium hydroxide solution. Mild disease can be treated with topical therapy. More serious disease can be treated with fluconazole. Other causes of vaginitis include *Trichomonas* and mixed bacteria.

Diseases of the Endocrine System and Metabolic Disorders A variety of endocrine and metabolic disorders are seen in the context of HIV infection. Between 33 and 75% of patients with HIV infection receiving HAART develop a syndrome often referred to as *lipodystrophy*, consisting of elevations in plasma triglycerides, total cholesterol, and apolipoprotein B, as well as hyperinsulinemia and hyperglycemia. Many of these patients have been noted to have a characteristic set of body habitus changes associated with fat redistribution, consisting of truncal obesity coupled with peripheral wasting (Fig. 173-32). Truncal obesity is apparent as an increase in abdominal girth related to increases in mesenteric fat, a dorsocervical fat pad ("buffalo hump") reminiscent of patients with Cushing's syndrome, and enlargement of the breasts. The peripheral wasting or lipoatrophy is particularly noticeable in the face and buttocks and by the prominence of the veins in the legs. These changes may develop at any time ranging from ~6 weeks to several years following the initiation of HAART. The syndrome has been reported in association with regimens containing a variety of different drugs, and while initially reported in the setting of protease inhibitor therapy, it appears similar changes can also be induced by potent protease-sparing regimens. It has been suggested that the lipoatrophy changes are particularly severe in patients receiving thymidine analogues. National Cholesterol Education Program (NCEP) guidelines should be followed in the management of these lipid abnormalities (Chap. 225). Due to concerns regarding drug interactions, the most commonly utilized agents in this setting are gemfibrozil and atorvostatin. In addition to these abnormalities, patients with HIV infection treated with HAART have been found to have an increased incidence of osteonecrosis or avascular necrosis of the hip and shoulders. In a study of asymptomatic patients, 4.4% were found to have evidence of osteonecrosis on MRI. This complication was associated with the use of lipid-lowering agents, systemic glucocorticoids or testosterone; bodybuilding exercise; and the presence of anticardiolipin antibodies. Lactic acidosis is also associated with antiretroviral therapy. This is most commonly seen with nucleoside reverse transcriptase inhibitors and can be fatal (see below).

Patients with advanced HIV disease may develop hyponatremia due to the syndrome of inappropriate antidiuretic hormone (vasopressin) secretion (SIADH) as a consequence of increased free water intake and decreased free water excretion. SIADH is usually seen in conjunction with pulmonary or CNS disease. Low serum sodium may also be due to adrenal insufficiency; concomitant high serum potassium should alert one to this possibility. Adrenal gland disease may be due to mycobacterial infections, CMV disease, cryptococcal disease, histoplasmosis, or ketoconazole toxicity.

Thyroid function is generally normal in patients with HIV infection although ~2 to 3% of patients may have elevations in thyroid-stimulating hormone (TSH). In the setting of HAART up to 10% of patients have been noted to have elevated TSH levels, suggesting that this may be a manifestation of immune reconstitution. In advanced HIV disease, infection of the thyroid gland may occur with opportunistic pathogens, including *P. carinii*, CMV, mycobacteria, *Toxoplasma gondii*, and *Cryptococcus neoformans*. These infections are generally associated with a nontender, diffuse enlargement of the thyroid gland. Thyroid function is usually normal. Diagnosis is made by fine-needle aspirate or open biopsy.

Advanced HIV disease is associated with *hypogonadism* in ~50% of men. While this is generally a complication of underlying illness, testicular dysfunction may also be a side effect of ganciclovir therapy. In some surveys, up to two-thirds of patients report decreased libido and one-third complain of impotence. Androgen replacement therapy should be considered in patients with symptomatic hypogonadism. HIV infection does not seem to have a significant effect on the menstrual cycle outside the setting of advanced disease.

Rheumatologic Diseases Immunologic and rheumatologic disorders are common in patients with HIV infection and range from excessive immediate-type hypersensitivity reactions (Chap. 298) to an increase in the incidence of reactive arthritis (Chap. 305) to conditions character-

ized by a diffuse infiltrative lymphocytosis. The occurrence of these phenomena is an apparent paradox in the setting of the profound immunodeficiency and immunosuppression that characterizes HIV infection. In addition, following the initiation of antiretroviral therapy, one may see a variety of exaggerated immune responses to existing opportunistic infections referred to as *immune reactivation syndromes*.

Drug allergies are the most significant allergic reactions occurring in HIV-infected patients and appear to become more common as the disease progresses. They occur in 65% of patients who receive therapy with TMP/SMX for PCP. In general, these drug reactions are characterized by erythematous, morbilliform eruptions that are pruritic, tend to coalesce, and are often associated with fever. Nonetheless, ~33% of patients can be maintained on the offending therapy, and thus these reactions are not an immediate indication to stop the drug. Anaphylaxis is extremely rare in patients with HIV infection, and patients who have a cutaneous reaction during a single course of therapy can still be considered candidates for future treatment or prophylaxis with the same agent. The one exception to this is the nucleoside analogue abacavir, where fatal hypersensitivity reactions have been reported with rechallenge. A hypersensitivity reaction to abacavir is an absolute contraindication to future therapy. For other agents, including TMP/SMX, desensitization regimens are moderatively successful. While the mechanisms underlying these allergic-type reactions remain unknown, patients with HIV infection have been noted to have elevated IgE levels that increase as the CD4+ T cell count declines. The numerous examples of patients with multiple drug reactions suggest that a common pathway is involved.

HIV infection shares many similarities with a variety of autoimmune diseases, including a substantial polyclonal B cell activation that is associated with a high incidence of antiphospholipid antibodies, such as anticardiolipin antibodies, VDRL antibodies, and lupus-like anticoagulants. In addition, HIV-infected individuals have an increased incidence of antinuclear antibodies. Despite these serologic findings, there is no evidence that HIV-infected individuals have an increase in two of the more common autoimmune diseases, i.e., systemic lupus erythematosus and rheumatoid arthritis. In fact, it has been observed that these diseases may be somewhat ameliorated by the concomitant presence of HIV infection, suggesting that an intact CD4+ T cell limb of the immune response plays an integral role in the pathogenesis of these conditions. Similarly, there are anecdotal reports of patients with common variable immunodeficiency (Chap. 297), characterized by hypogammaglobulinemia, who have had a normalization of Ig levels following the development of HIV infection, suggesting a possible role for overactive CD4+ T cell immunity in certain forms of that syndrome. The one autoimmune disease that may occur with an increased frequency in patients with HIV infection is a variant of primary Sjögren's syndrome (Chap. 304). Patients with HIV infection may develop a syndrome consisting of parotid gland enlargement, dry eyes, and dry mouth that is associated with lymphocytic infiltrates of the salivary gland and lung. In contrast to Sjögren's syndrome, in which these infiltrates are composed predominantly of CD4+ T cells, in patients with HIV infection the infiltrates are composed predominantly of CD8+ T cells. In addition, while patients with Sjögren's syndrome are mainly women who have autoantibodies to Ro and La and who frequently have HLA-DR3 or -B8 MHC haplotypes, HIV-infected individuals with this syndrome are usually African-American men who do not have anti-Ro or anti-La and who most often are HLA-DR5. This syndrome appears to be less common with the increased use of effective antiretroviral therapy. The term *diffuse infiltrative lymphocytosis syndrome* (DILS) has been proposed to describe this entity and to distinguish it from Sjögren's syndrome.

Approximately one-third of HIV-infected individuals experience arthralgias; furthermore, 5 to 10% are diagnosed as having some form of reactive arthritis, such as Reiter's syndrome or psoriatic arthritis (Chap. 305). These syndromes occur with increasing frequency as the competency of the immune system declines. This association may be related to an increase in the number of infections with organisms that may trigger a reactive arthritis with progressive immunodeficiency or to a loss of important regulatory T cells. Reactive arthritides in HIV-infected individuals generally respond well to standard treatment; however, therapy with methotrexate has been associated with an increase in the incidence of opportunistic infections and should be used with caution and only in severe cases.

HIV-infected individuals also experience a variety of joint problems without obvious cause that are referred to generically as *HIV- or AIDS-associated arthropathy*. This syndrome is characterized by subacute oligoarticular arthritis developing over a period of 1 to 6 weeks and lasting 6 weeks to 6 months. It generally involves the large joints, predominantly the knees and ankles, and is nonerosive with only a mild inflammatory response. X-rays of the joint are nonrevealing. Nonsteroidal anti-inflammatory drugs are only marginally helpful; however, relief has been noted with the use of intraarticular glucocorticoids. A second form of arthritis also thought to be secondary to HIV infection is called *painful articular syndrome*. This condition, found in as many as 10% of AIDS patients, presents as an acute, severe, sharp pain in the affected joint. It affects primarily the knees, elbows, and shoulders; lasts 2 to 24 h; and may be severe enough to require narcotic analgesics. The cause of this arthropathy is unclear; however, it is thought to result from a direct effect of HIV on the joint. This condition is reminiscent of the fact that other lentiviruses, in particular the caprine arthritis-encephalitis virus, are capable of directly causing arthritis.

A variety of other immunologic or rheumatologic diseases have been reported in HIV-infected individuals, either de novo or in association with opportunistic infections or drugs. Using the criteria of widespread musculoskeletal pain of at least 3 months' duration and the presence of at least 11 of 18 possible tender points by digital palpation, 11% of an HIV-infected cohort containing 55% IDUs were diagnosed as having *fibromyalgia* (Chap. 315). While the incidence of frank arthritis was less in this population than in other studied populations that consisted predominantly of homosexual men, these data support the concept that there are musculoskeletal problems that occur as a direct result of HIV infection. In addition there have been reports of leukocytoclastic vasculitis in the setting of zidovudine therapy. CNS angiitis and polymyositis have also been reported in HIV-infected individuals. Septic arthritis is surprisingly rare, especially given the increased incidence of staphylococcal bacteremias seen in this population. When septic arthritis has been reported, it has usually been due to systemic fungal infections with *C. neoformans*, *Sporothrix schenckii*, or *H. capsulatum*, or to systemic mycobacterial infection with *M. haemophilum*.

Following the initiation of effective antiretroviral therapy, a paradoxical worsening of preexisting, untreated, or partially treated opportunistic infections may be noted. These *immune reactivation syndromes* are particularly common in patients with underlying untreated mycobacterial infections. They appear to be related to a phenomenon similar to type IV hypersensitivity reactions and reflect the immediate improvements in immune function that occur as levels of HIV RNA drop and the immunosuppressive effects of HIV infection are controlled. In severe cases the use of immunosuppressive drugs such as glucocorticoids may be required to blunt the inflammatory component of these reactions while specific antimicrobial therapy takes effect.

Diseases of the Hematopoietic System Disorders of the hematopoietic system including lymphadenopathy, anemia, leukopenia, and/or thrombocytopenia are common throughout the course of HIV infection and may be the direct result of HIV, manifestations of secondary infections and neoplasms, or side effects of therapy (Table 173-12). Direct histologic examination and culture of lymph node or bone marrow tissue are often diagnostic. A significant percentage of bone marrow aspirates from patients with HIV infection have been reported to contain lymphoid aggregates, the precise significance of which is un-

TABLE 173-12 Causes of Bone Marrow Suppression in Patients with HIV Infection

HIV infection	Medications
Mycobacterial infections	Zidovudine
Fungal infections	Dapsone
B19 parvovirus infection	Trimethoprim/sulfamethoxazole
Lymphoma	Pyrimethamine
	5-Flucytosine
	Ganciclovir
	Interferon-α
	Trimetrexate
	Foscarnet

known. Initiation of HAART will lead to reversal of most hematologic complications that are the direct result of HIV infection.

Some patients, otherwise asymptomatic, may develop *persistent generalized lymphadenopathy* as an early clinical manifestation of HIV infection. This condition is defined as the presence of enlarged lymph nodes (>1 cm) in two or more extrainguinal sites for >3 months without an obvious cause. The lymphadenopathy is due to marked follicular hyperplasia in the node in response to HIV infection. The nodes are generally discrete and freely movable. This feature of HIV disease may be seen at any point in the spectrum of immune dysfunction and is not associated with an increased likelihood of developing AIDS. Paradoxically, a loss in lymphadenopathy or a decrease in lymph node size outside the setting of antiretroviral therapy may be a prognostic marker of disease progression. In patients with CD4+ T cell counts >200/μL, the differential diagnosis of lymphadenopathy includes KS, TB, and lymphoma. In patients with more advanced disease, lymphadenopathy may also be due to atypical mycobacterial infection, toxoplasmosis, systemic fungal infection, or bacillary angiomatosis. While indicated in patients with CD4+ T cell counts <200/μL, lymph node biopsy is not indicated in patients with early-stage disease unless there are signs and symptoms of systemic illness, such as fever and weight loss, or unless the nodes begin to enlarge, become fixed, or coalesce.

Anemia is the most common hematologic abnormality in HIV-infected patients. While generally mild, anemia can be quite severe and require chronic blood transfusions. Among the specific reversible causes of anemia in the setting of HIV infection are drug toxicity, systemic fungal and mycobacterial infections, nutritional deficiencies, and parvovirus B19 infections. Zidovudine may block erythroid maturation, prior to its effects on other marrow elements. A characteristic feature of zidovudine therapy is an elevated mean corpuscular volume (MCV). Another drug used in patients with HIV infection that has a selective effect on the erythroid series is dapsone. This drug can cause a serious hemolytic anemia in patients who are deficient in glucose-6-phosphate dehydrogenase and can create a functional anemia in others through induction of methemoglobinemia. Folate levels are usually normal in HIV-infected individuals; however, vitamin B_{12} levels may be depressed as a consequence of achlorhydria or malabsorption. True autoimmune hemolytic anemia is rare, although ~20% of patients with HIV infection may have a positive direct antiglobulin test as a consequence of polyclonal B cell activation. Infection with parvovirus B19 may also cause anemia. It is important to recognize this possibility given the fact that it responds well to treatment with intravenous immunoglobulin. Erythropoietin levels in patients with HIV infection and anemia are generally less than expected given the degree of anemia. Treatment with erythropoietin at doses of 100 μg/kg three times a week may result in an increase in hemoglobulin levels. An exception to this is a subset of patients with zidovudine-associated anemia in whom erythropoietin levels may be quite high.

During the course of HIV infection, neutropenia may be seen in approximately half of patients. In most instances it is mild; however, it can be severe and can put patients at risk of spontaneous bacterial infections. This is most frequently seen in patients with severely advanced HIV disease and in patients receiving any of a number of potentially myelosuppressive therapies. In the setting of neutropenia, diseases that are not commonly seen in HIV-infected patients, such as aspergillosis or mucormycosis, may occur. The potential role of colony-stimulating factors in the management of patients with HIV infection has undergone extensive evaluation. Both granulocyte colony-stimulating factor (G-CSF) and GM-CSF increase neutrophil counts in patients with HIV infection regardless of the cause of the neutropenia. Earlier concerns about the potential of these agents to also increase levels of HIV were not confirmed in controlled clinical trials.

Thrombocytopenia may be an early consequence of HIV infection. Approximately 3% of patients with untreated HIV infection and CD4+ T cell counts ≥400/μL have platelet counts <150,000/μL. For untreated patients with CD4+ T cell counts <400/μL, this incidence increases to 10%. Thrombocytopenia is rarely a serious clinical problem in patients with HIV infection and generally responds well to antiretroviral therapy. Clinically, it resembles the thrombocytopenia seen in patients with idiopathic thrombocytopenic purpura (Chap. 101). Immune complexes containing anti-gp120 antibodies and anti-anti-gp120 antibodies have been noted in the circulation and on the surface of platelets in patients with HIV infection. Patients with HIV infection have also been noted to have a platelet-specific antibody directed towards a 25-kDa component of the surface of the platelet. Other data suggest that the thrombocytopenia in patients with HIV infection may be due to a direct effect of HIV on megakaryocytes. Whatever the cause, it is very clear that the most effective medical approach to this problem has been the use of HAART. For patients with platelet counts <20,000/μL a more aggressive approach combining intravenous Ig or anti-Rh Ig for an immediate response with antiretroviral therapy for a more lasting response is appropriate. Splenectomy is a rarely needed option and is reserved for patients refractory to medical management. Because of the risk of serious infection with encapsulated organisms, all patients with HIV infection about to undergo splenectomy should be immunized with pneumococcal polysaccharide. It should be noted that, in addition to causing an increase in the platelet count, removal of the spleen will result in an increase in the peripheral blood lymphocyte count, making CD4+ T cell counts unreliable. In this setting, the clinician should rely on the CD4+ T cell percent for making diagnostic decisions with respect to the likelihood of opportunistic infections. A CD4+ T cell percent of 15 is approximately equivalent to a CD4+ T cell count of 200/μL. In patients with early HIV infection, thrombocytopenia has also been reported as a consequence of classic thrombotic thrombocytopenic purpura (Chap. 101). This clinical syndrome, consisting of fever, thrombocytopenia, hemolytic anemia, and neurologic and renal dysfunction, is a rare complication of early HIV infection. As in other settings, the appropriate management is the use of salicylates and plasma exchange. Other causes of thrombocytopenia include lymphoma, mycobacterial infections, and fungal infections.

Dermatologic Diseases Dermatologic problems occur in >90% of patients with HIV infection. From the macular, roseola-like rash seen with the acute seroconversion syndrome to extensive end-stage KS, cutaneous manifestations of HIV disease can be seen throughout the course of HIV infection. Among the more common nonneoplastic problems are seborrheic dermatitis, eosinophilic pustular folliculitus, and opportunistic infections. Extrapulmonary pneumocystosis may cause a necrotizing vasculitis. Neoplastic conditions are covered below in the section on malignant diseases.

Seborrheic dermatitis occurs in 3% of the general population and in up to 50% of patients with HIV infection. Seborrheic dermatitis increases in prevalence and severity as the CD4+ T cell count declines. In HIV-infected patients, seborrheic dermatitis may be aggravated by concomitant infection with *Pityrosporum*, a yeastlike fungus; use of topical antifungal agents has been recommended in cases refractory to standard topical treatment.

Eosinophilic pustular folliculitis is a rare dermatologic condition that is seen with increased frequency in patients with HIV infection.

It presents as multiple, urticarial perifollicular papules that may coalesce into plaquelike lesions. Skin biopsy reveals an eosinophilic infiltrate of the hair follicle, which in certain cases has been associated with the presence of a mite. Patients typically have an elevated serum IgE level and may respond to treatment with topical anthelminthics. Patients with HIV infection have also been reported to develop a severe form of *Norwegian scabies* with hyperkeratotic psoriasiform lesions.

Both *psoriasis* and *ichthyosis*, although they are not reported to be increased in frequency, may be particularly severe when they occur in patients with HIV infection. Preexisting psoriasis may become guttate in appearance and more refractory to treatment in the setting of HIV infection.

Reactivation herpes zoster (*shingles*) is seen in 10 to 20% of patients with HIV infection. This reactivation syndrome of varicella-zoster virus indicates a modest decline in immune function and may be the first indication of clinical immunodeficiency. In one series, patients who developed shingles did so an average of 5 years after HIV infection. In a cohort of patients with HIV infection and localized zoster, the subsequent rate of the development of AIDS was 1% per month. In that study, AIDS was more likely to develop if the outbreak of zoster was associated with severe pain, extensive skin involvement, or involvement of cranial or cervical dermatomes. The clinical manifestations of reactivation zoster in HIV-infected patients, although indicative of immunologic compromise, are not as severe as those seen in other immunodeficient conditions. Thus, while lesions may extend over several dermatomes (see Fig. 164-3) and frank cutaneous dissemination may be seen, visceral involvement has not been reported. In contrast to patients without a known underlying immunodeficiency state, patients with HIV infection tend to have recurrences of zoster with a relapse rate of ~20%. Acyclovir or famciclovir is the treatment of choice. Foscarnet is of value in patients with acyclovir-resistant virus.

Infection with *herpes simplex virus* in HIV-infected individuals is associated with recurrent orolabial, genital, and perianal lesions as part of recurrent reactivation syndromes (Chap. 163). As HIV disease progresses and the CD4+ T cell count declines, these infections become more frequent and severe. Lesions often appear as beefy red, are exquisitely painful, and have a tendency to occur high in the gluteal cleft (Fig. 173-31). Perirectal HSV may be associated with proctitis and anal fissures. HSV should be high in the differential diagnosis of any HIV-infected patient with a poorly healing, painful perirectal lesion. In addition to recurrent mucosal ulcers, recurrent HSV infection in the form of *herpetic whitlow* can be a problem in patients with HIV infection, presenting with painful vesicles or extensive cutaneous erosion. Acyclovir or famciclovir is the treatment of choice in these settings. Of note is the fact that even subclinical reactivation of herpes simplex may be associated with increases in plasma HIV RNA levels. Consideration should be given to chronic suppressive therapy in patients with recurrent outbreaks of herpesvirus.

Diffuse skin eruptions due to *Molluscum contagiosum* may be seen in patients with advanced HIV infection. These flesh-colored, umbilicated lesions may be treated with local therapy. They tend to regress with effective antiretroviral therapy. Similarly, *condyloma acuminatum* lesions may be more severe and more widely distributed in patients with low CD4+ T cell counts. Atypical mycobacterial infections may present as erythematous cutaneous nodules as may fungal infections, *Bartonella*, *Acanthamoeba*, and KS.

The skin of patients with HIV infection is often a target organ for drug reactions (Chap. 50). Although most skin reactions are mild and not necessarily an indication to discontinue therapy, patients may have particularly severe cutaneous reactions, including erythroderma and *Stevens-Johnson syndrome*, as a reaction to drugs, particularly sulfa drugs, the nonnucleoside reverse transcriptase inhibitors, abacavir, and amprenavir. Similarly, patients with HIV infection are often quite photosensitive and burn easily following exposure to sunlight or as a side effect of radiation therapy (Chap. 51).

HIV infection and its treatment may be accompanied by cosmetic changes of the skin that are not of great clinical importance but may be troubling to patients. Yellowing of the nails and straightening of the hair, particularly in African-American patients, have been reported as a consequence of HIV infection. Zidovudine therapy has been associated with elongation of the eyelashes and the development of a bluish discoloration to the nails, again more common in African-American patients. Therapy with clofazimine may cause a yellow-orange discoloration of the skin.

Neurologic Diseases Clinical disease of the nervous system accounts for a significant degree of morbidity in a high percentage of patients with HIV infection (Table 173-13). The neurologic problems that occur in HIV-infected individuals may be either primary to the pathogenic processes of HIV infection or secondary to opportunistic infections or neoplasms (see above). Among the more frequent opportunistic diseases that involve the CNS are toxoplasmosis, cryptococcosis, progressive multifocal leukoencephalopathy, and primary CNS lymphoma. Other less common problems include mycobacterial infections; syphilis; and infection with CMV, HTLV-I, *T. cruzi*, or *Acanthamoeba*. Overall, secondary diseases of the CNS occur in approximately one-third of patients with AIDS. These data antedate the widespread use of combination antiretroviral therapy, and this frequency is considerably less in patients receiving effective antiretroviral drugs. Primary processes related to HIV infection of the nervous system are reminiscent of those seen with other lentiviruses, such as the Visna-Maedi virus of sheep. Neurologic problems occur throughout the course of disease and may be inflammatory, demyelinating, or degenerative in nature. While only one of these, the *AIDS dementia complex*, or *HIV encephalopathy*, is considered an AIDS-defining illness, most HIV-infected patients have some neurologic problem during the course of their disease. As noted in the section on pathogenesis, damage to the CNS may be a direct result of viral infection of the CNS macrophages or glial cells or may be secondary to the release of neurotoxins and potentially toxic cytokines such as IL-1β, TNF-α, IL-6, and TGF-β. It has been reported that HIV-infected individuals with the E4 allele for apolipoprotein E (apo E) are at increased risk for AIDS encephalopathy and peripheral neuropathy. Virtually all patients with HIV infection have some degree of nervous system involvement with the virus. This is evidenced by the fact that CSF findings are abnormal in ~90% of patients, even during the asymptomatic phase of HIV infection. CSF abnormalities include pleocytosis (50 to 65% of patients), detection of viral RNA (~75%), elevated CSF protein (35%), and evidence of intrathecal synthesis of anti-HIV antibodies (90%). It is important to point out that evidence of infection of the CNS with HIV does not imply impairment of cognitive function. The neurologic function of an HIV-infected individual should be considered normal unless clinical signs and symptoms suggest otherwise.

Aseptic meningitis may be seen in any but the very late stages of HIV infection. In the setting of acute primary infection patients may

TABLE 173-13 Neurologic Diseases in Patients with HIV Infection

- Opportunistic infections
  - Toxoplasmosis
  - Cryptococcosis

  - Chronic inflammatory demyelinating polyneuropathy (CIDP)
  - Mononeuritis multiplex
  - Distal symmetric polyneuropathy
- Myopathy

experience a syndrome of headache, photophobia, and meningismus. Rarely, an acute encephalopathy due to encephalitis may occur. Cranial nerve involvement may be seen, predominantly cranial nerve VII but occasionally V and/or VIII. CSF findings include a lymphocytic pleocytosis, elevated protein level, and normal glucose level. This syndrome, which cannot be clinically differentiated from other viral meningitides (Chap. 361), usually resolves spontaneously within 2 to 4 weeks; however, in some patients, signs and symptoms may become chronic. Aseptic meningitis may occur any time in the course of HIV infection; however, it is rare following the development of AIDS. This fact suggests that clinical aseptic meningitis in the context of HIV infection is an immune-mediated disease.

C. neoformans is the leading infectious cause of meningitis in patients with AIDS (Chap. 186). It is the initial AIDS-defining illness in ~2% of patients and generally occurs in patients with CD4+ T cell counts <100/μL. Cryptococcal meningitis is particularly common in patients with AIDS in Africa, occurring in ~20% of patients. Most patients present with a picture of subacute meningoencephalitis with fever, nausea, vomiting, altered mental status, headache, and meningeal signs. The incidence of seizures and focal neurologic deficits is low. The CSF profile may be normal or may show only modest elevations in WBC or protein levels. In addition to meningitis, patients may develop cryptococcomas. Approximately one-third of patients also have pulmonary disease. Uncommon manifestations of cryptococcal infection include skin lesions that resemble *molluscum contagiosum*, lymphadenopathy, palatal and glossal ulcers, arthritis, gastroenteritis, myocarditis, and prostatitis. The prostate gland may serve as a reservoir for smoldering cryptococcal infection. The diagnosis of cryptococcal meningitis is made by identification of organisms in spinal fluid with India ink examination or by the detection of cryptococcal antigen. A biopsy may be needed to make a diagnosis of CNS cryptococcoma. Treatment is with intravenous amphotericin B, at a dose of 0.7 mg/kg daily, with flucytosine, 25 mg/kg qid for 2 weeks, followed by fluconazole, 400 mg/d orally for 10 weeks, and then fluconazole, 200 mg/d until the CD4+ T cell count has increased to >200 cells/μl for 6 months in response to HAART. Symptoms may recur with initiation of HAART as an immune reconstitution syndrome (see above). Other fungi that may cause meningitis in patients with HIV infection are *C. immitis* and *H. capsulatum*. Meningoencephalitis has also been reported due to *Acanthamoeba* or *Naegleria*.

HIV encephalopathy, also called HIV-associated dementia or AIDS dementia complex, consists of a constellation of signs and symptoms of CNS disease. While this is generally a late complication of HIV infection that progresses slowly over months it can be seen in patients with CD4 counts >350 cells/μl. A major feature of this entity is the development of dementia, defined as a decline in cognitive ability from a previous level. It may present as impaired ability to concentrate, increased forgetfulness, difficulty reading, or increased difficulty performing complex tasks. Initially these symptoms may be indistinguishable from findings of situational depression or fatigue. In contrast to "cortical" dementia (such as Alzheimer's disease), aphasia, apraxia, and agnosia are uncommon, leading some investigators to classify HIV encephalopathy as a "subcortical dementia" (see below). In addition to dementia, patients with HIV encephalopathy may also have motor and behavioral abnormalities. Among the motor problems are unsteady gait, poor balance, tremor, and difficulty with rapid alternating movements. Increased tone and deep tendon reflexes may be found in patients with spinal cord involvement. Late stages may be complicated by bowel and/or bladder incontinence. Behavioral problems include apathy and lack of initiative, with progression to a vegetative state in some instances. Some patients develop a state of agitation or mild mania. These changes usually occur without significant changes in level of alertness. This is in contrast to the finding of somnolence in patients with dementia due to toxic/metabolic encephalopathies.

HIV encephalopathy is the initial AIDS-defining illness in ~3% of patients with HIV infection and thus only rarely precedes clinical evidence of immunodeficiency. Clinically significant encephalopathy eventually develops in approximately one-fourth of patients with AIDS. As immunologic function declines, the risk and severity of HIV encephalopathy increases. Autopsy series suggest that 80 to 90% of patients with HIV infection have histologic evidence of CNS involvement. Several classification schemes have been developed for grading HIV encephalopathy; a commonly used clinical staging system is outlined in Table 173-14.

The precise cause of HIV encephalopathy remains unclear, although the condition is thought to be a result of direct effects of HIV on the CNS. HIV has been found in the brains of patients with HIV encephalopathy by Southern blot, in situ hybridization, PCR, and electron microscopy. Multinucleated giant cells, macrophages, and microglial cells appear to be the main cell types harboring virus in the CNS. Histologically, the major changes are seen in the subcortical areas of the brain and include pallor and gliosis, multinucleated giant cell encephalitis, and vacuolar myelopathy. Less commonly, diffuse or focal spongiform changes occur in the white matter.

There are no specific criteria for a diagnosis of HIV encephalopathy, and this syndrome must be differentiated from a number of other diseases that affect the CNS of HIV-infected patients (Table 173-13). The diagnosis of dementia depends upon demonstrating a decline in cognitive function. This can be accomplished objectively with the use of a Mini-Mental Status Examination (MMSE) in patients for whom prior scores are available. For this reason, it is advisable for all patients with a diagnosis of HIV infection to have a baseline MMSE. However, changes in MMSE scores may be absent in patients with mild HIV encephalopathy. Imaging studies of the CNS, by either MRI or CT, often demonstrate evidence of cerebral atrophy (Fig. 173-33). MRI may also reveal small areas of increased density on T2-weighted images. Lumbar puncture is an important element of the evaluation of patients with HIV infection and neurologic abnormalities. It is generally most helpful in ruling out or making a diagnosis of opportunistic infections. In HIV encephalopathy, patients may have the nonspecific findings of an increase in CSF cells and protein level. While HIV RNA can often be detected in the spinal fluid and HIV can be cultured from the CSF, this finding is not specific for HIV encephalopathy. There

TABLE 173-14 *Clinical Staging of HIV Encephalopathy (AIDS Dementia Complex)*

Stage	Definition
Stage 0 (normal)	Normal mental and motor function
Stage 0.5 (equivocal/ subclinical)	Absent, minimal, or equivocal symptoms without impairment of work or capacity to perform activities of daily living. Mild signs (snout response, slowed ocular or extremity movements) may be present. Gait and strength are normal.
Stage 1 (mild)	Able to perform all but the more demanding aspects of work or activities of daily living but with unequivocal evidence (signs or symptoms that may include performance on neuropsychological testing) of functional, intellectual, or motor impairment. Can walk without assistance.
Stage 2 (moderate)	Able to perform basic activities of self-care but cannot work or maintain the more demanding aspects of daily life. Ambulatory, but may require a single prop.
Stage 3 (severe)	Major intellectual incapacity (cannot follow news or personal events, cannot sustain complex conversation, considerable slowing of all output) or motor disability (cannot walk unassisted, usually with slowing and clumsiness of arms as well).
Stage 4 (end-stage)	Nearly vegetative. Intellectual and social comprehension and output are at a rudimentary level. Nearly or absolutely mute. Paraparetic or paraplegic with urinary and fecal incontinence.

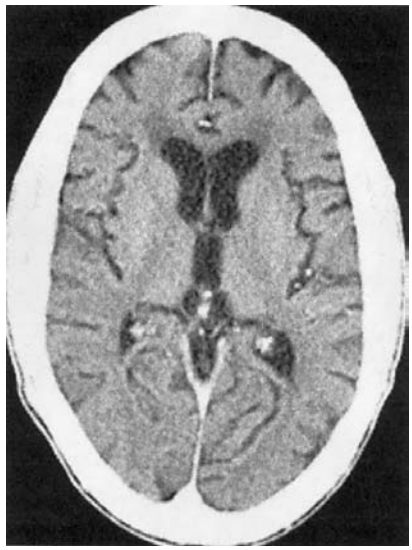

FIGURE 173-33 AIDS dementia complex. Postcontrast CT scan through the lateral ventricles of a 47-year-old man with AIDS, altered mental status, and dementia. The lateral and third ventricles and the cerebral sulci are abnormally prominent. Mild white matter hypodensity is also seen adjacent to the frontal horns of the lateral ventricles.

appears to be no correlation between the presence of HIV in the CSF and the presence of HIV encephalopathy. Elevated levels of β_2-microglobulin, neopterin, and quinolinic acid (a metabolite of tryptophan reported to cause CNS injury) have been noted in the CSF of patients with HIV encephalopathy. These findings suggest that these factors as well as inflammatory cytokines may be involved in the pathogenesis of this syndrome.

Combination antiretroviral therapy is of benefit in patients with HIV encephalopathy. Improvement in neuropsychiatric test scores has been noted for both adult and pediatric patients treated with antiretrovirals. The rapid improvement in cognitive function noted with the initiation of antiretroviral therapy suggests that at least some component of this problem is quickly reversible, again supporting at least a partial role of soluble mediators in the pathogenesis. It should also be noted that these patients have an increased sensitivity to the side effects of neuroleptic drugs. The use of these drugs for symptomatic treatment is associated with an increased risk of extrapyramidal side effects; therefore, patients with HIV encephalopathy who receive these agents must be monitored carefully.

Seizures may be a consequence of opportunistic infections, neoplasms, or HIV encephalopathy (Table 173-15). The seizure threshold is often lower than normal in these patients owing to the frequent presence of electrolyte abnormalities. Seizures are seen in 15 to 40% of patients with cerebral toxoplasmosis, 15 to 35% of patients with primary CNS lymphoma, 8% of patients with cryptococcal meningitis, and 7 to 50% of patients with HIV encephalopathy. Seizures may also be seen in patients with CNS tuberculosis, aseptic meningitis, and progressive multifocal leukoencephalopathy. Seizures may be the presenting clinical symptom of HIV disease. In one study of 100 patients with HIV infection presenting with a first seizure, cerebral mass lesions were the most common cause, responsible for 32 of the 100 new-onset seizures. Of these 32 cases, 28 were due to toxoplasmosis and 4 to lymphoma. HIV encephalopathy accounted for an additional 24 new-onset seizures. Cryptococcal meningitis was the third most common diagnosis, responsible for 13 of the 100 seizures. In 23 cases, no cause could be found, and it is possible that these cases represent a subcategory of HIV encephalopathy. Of these 23 cases, 16 (70%) had two or more seizures, suggesting that anticonvulsant therapy is indicated in all patients with HIV infection and seizures unless a rapidly correctable cause is found. While phenytoin remains the initial treatment of choice, hypersensitivity reactions to this drug have been reported in >10% of patients with AIDS, and therefore the use of phenobarbital or valproic acid must be considered as alternatives.

Patients with HIV infection may present with *focal neurologic deficits* from a variety of causes. The most common causes are toxoplasmosis, progressive multifocal leukoencephalopathy, and CNS lymphoma. Other causes include cryptococcal infections (discussed above; also Chap. 186), stroke, and reactivation Chagas' disease.

Toxoplasmosis has been one of the most common causes of secondary CNS infections in patients with AIDS, but its incidence is decreasing in the era of HAART. It is most common in patients from the Caribbean and from France. Toxoplasmosis is generally a late complication of HIV infection and usually occurs in patients with CD4+ T cell counts <200/μL. Cerebral toxoplasmosis is thought to represent a reactivation syndrome. It is 10 times more common in patients with antibodies to the organism than in patients who are seronegative. Patients diagnosed with HIV infection should be screened for IgG antibodies to *T. gondii* during the time of their initial workup. Those who are seronegative should be counseled about ways to minimize the risk of primary infection including avoiding the consumption of undercooked meat and careful hand washing after contact with soil or changing the cat litter box. The most common clinical presentation of cerebral toxoplasmosis in patients with HIV infection is fever, headache, and focal neurologic deficits. Patients may present with seizure, hemiparesis, or aphasia as a manifestation of these focal deficits or with a picture more influenced by the accompanying cerebral edema and characterized by confusion, dementia, and lethargy, which can progress to coma. The diagnosis is usually suspected on the basis of MRI findings of multiple lesions in multiple locations, although in some cases only a single lesion is seen. Pathologically, these lesions generally exhibit inflammation and central necrosis and, as a result, demonstrate ring enhancement on contrast MRI (Fig. 173-34) or, if MRI is unavailable or contraindicated, on double-dose contrast CT. There is usually evidence of surrounding edema. In addition to toxoplasmosis, the differential diagnosis of single or multiple enhancing mass lesions in the HIV-infected patient includes primary CNS lymphoma (see below) and, less commonly, TB or fungal or bacterial abscesses.

TABLE 173-15 *Causes of Seizures in Patients with HIV Infection*

Disease	Overall Contribution to First Seizure, %	Fraction of Patients Who Have Seizures, %
HIV encephalopathy	24–47	7–50
Cerebral toxoplasmosis	28	15–40
Cryptococcal meningitis	13	8
Primary central nervous system lymphoma	4	15–30
Progressive multifocal leukoencephalopathy	1

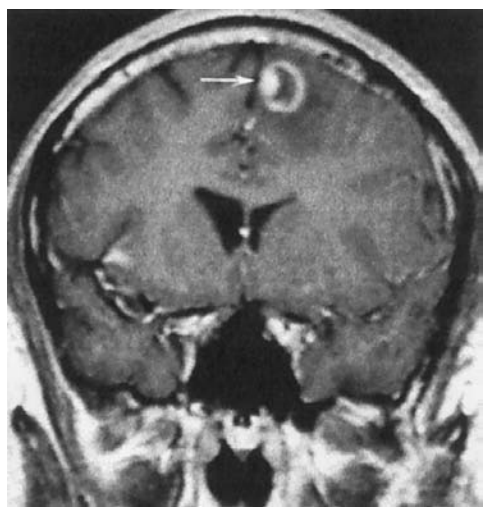

FIGURE 173-34 Central nervous system toxoplasmosis. A coronal postcontrast T1-weighted MR scan demonstrates a peripheral enhancing lesion in the left frontal lobe, associated with an eccentric nodular area of enhancement (*arrow*); this so-called "eccentric target sign" is typical of toxoplasmosis.

The definitive diagnostic procedure is brain biopsy. However, given the morbidity than can accompany this procedure, it is usually reserved for the patient who has failed 2 to 4 weeks of empirical therapy. If the patient is seronegative for *T. gondii*, the likelihood that a mass lesion is due to toxoplasmosis is <10%. In that setting, one may choose to be more aggressive and perform a brain biopsy sooner. Standard treatment is sulfadiazine and pyrimethamine with leucovorin as needed for a minimum of 4 to 6 weeks. Alternative therapeutic regimens include clindamycin in combination with pyrimethamine; atovaquone plus pyrimethamine; and azithromycin plus pyrimethamine plus rifabutin. Relapses are common, and it is recommended that patients with a history of prior toxoplasmic encephalitis receive maintenance therapy with sulfadiazine, pyrimethamine, and leucovorin. Patients with CD4+ T cell counts <100/μL and IgG antibody to *Toxoplasma* should receive primary prophylaxis for toxoplasmosis. Fortunately, the same daily regimen of a single double-strength tablet of TMP/SMX used for *P. carinii* prophylaxis provides adequate primary protection against toxoplasmosis. Secondary prophylaxis for toxoplasmosis may be discontinued in the setting of effective antiretroviral therapy and increases in CD4+ T cell counts to >200/μL for 6 months.

JC virus, a human polyomavirus that is the etiologic agent of *progressive multifocal leukoencephalopathy* (PML), is an important opportunistic pathogen in patients with AIDS (Chap. 361). While ~70% of the general adult population have antibodies to JC virus, indicative of prior infection, <10% of healthy adults show any evidence of ongoing viral replication. PML is the only known clinical manifestation of JC virus infection. It is a late manifestation of AIDS and is seen in ~4% of patients with AIDS. The lesions of PML begin as small foci of demyelination in subcortical white matter that eventually coalesce. The cerebral hemispheres, cerebellum, and brainstem may all be involved. Patients typically have a protracted course with multifocal neurologic deficits, with or without changes in mental status. Ataxia, hemiparesis, visual field defects, aphasia, and sensory defects may occur. MRI typically reveals multiple, nonenhancing white matter lesions that may coalesce and have a predeliction for the occipital and parietal lobes. The lesions show signal hyperintensity on T2-weighted images and diminished signal on T1-weighted images. Prior to the availability of potent antiretroviral combination therapy, the majority of patients with PML died within 3 to 6 months of the onset of symptoms. Paradoxical worsening of PML has been seen with initiation of HAART as an immune reactivation syndrome. There is no specific treatment for PML; however, regressions of >2.5 years in duration have been reported in patients with PML treated with HAART for their HIV disease. Studies with antiviral agents such as cidofovir have failed to show clear benefit. Factors influencing a favorable prognosis for PML in the setting of HIV infection include a CD4+ T cell count >100/μL at baseline and the ability to maintain an HIV viral load of <500 copies per milliliter. Baseline viral load does not have independent predictive value of survival. PML is one of the few opportunistic infections that continues to occur with some frequency despite the widespread use of HAART.

Reactivation American trypanosomiasis may present as acute meningoencephalitis with focal neurologic signs, fever, headache, vomiting, and seizures. In South America, reactivation of *Chagas' disease* is considered to be an AIDS-defining condition and may be the initial AIDS-defining condition. Lesions appear radiographically as single or multiple hypodense areas, typically with ring enhancement and edema. They are found predominantly in the subcortical areas, a feature that differentiates them from the deeper lesions of toxoplasmosis. *Trypanosoma cruzi* amastigotes, or trypanosomes, can be identified from biopsy specimens or CSF. Other CSF findings include elevated protein and a mild (<100 cells/μL) lymphocytic pleocytosis. Organisms can also be identified by direct examination of the blood. Treatment consists of benzimidazole (2.5 mg/kg bid) or nifurtimox (2 mg/kg qid) for at least 60 days, followed by maintenance therapy for life with either drug at a dose of 5 mg/kg three times a week. As is the case with cerebral toxoplasmosis, successful therapy with antiretrovirals may allow discontinuation of therapy for Chagas' disease.

Stroke may occur in patients with HIV infection. In contrast to the other causes of focal neurologic deficits in patients with HIV infection, the symptoms of a stroke are sudden in onset. Among the secondary infectious diseases in patients with HIV infection that may be associated with stroke are vasculitis due to cerebral varicella zoster or neurosyphilis and septic embolism in association with fungal infection. Other elements of the differential diagnosis of stroke in the patient with HIV infection include atherosclerotic cerebral vascular disease, thrombotic thrombocytopenic purpura, and cocaine or amphetamine use.

Primary CNS lymphoma is discussed below in the section on neoplastic diseases.

Spinal cord disease, or myelopathy, is present in ~20% of patients with AIDS, often as part of HIV encephalopathy. In fact, 90% of the patients with HIV-associated myelopathy have some evidence of dementia, suggesting that similar pathologic processes may be responsible for both conditions. Three main types of spinal cord disease are seen in patients with AIDS. The first of these is a vacuolar myelopathy, as discussed above under HIV encephalopathy. This condition is pathologically similar to subacute combined degeneration of the cord such as occurs with pernicious anemia. Although vitamin B_{12} deficiency can be seen in patients with AIDS, it does not appear to be responsible for the myelopathy seen in the majority of patients. Vacuolar myelopathy is characterized by a subacute onset and often presents with gait disturbances, predominantly ataxia and spasticity; it may progress to include bladder and bowel dysfunction. Physical findings include evidence of increased deep tendon reflexes and extensor plantar responses. The second form of spinal cord disease involves the dorsal columns and presents as a pure sensory ataxia. The third form is also sensory in nature and presents with paresthesias and dysesthesias of the lower extremities. In contrast to the cognitive problems seen in patients with HIV encephalopathy, these spinal cord syndromes do not respond well to antiretroviral drugs, and therapy is mainly supportive.

One important disease of the spinal cord that also involves the peripheral nerves is a *myelopathy* and *polyradiculopathy* seen in association with CMV infection. This entity is generally seen late in the course of HIV infection and is fulminant in onset, with lower extremity and sacral paresthesias, difficulty in walking, areflexia, ascending sensory loss, and urinary retention. The clinical course is rapidly progressive over a period of weeks. CSF examination reveals a predominantly neutrophilic pleocytosis, and CMV DNA can be detected by CSF PCR. Therapy with ganciclovir or foscarnet can lead to rapid improvement, and prompt initiation of foscarnet or ganciclovir therapy is important in minimizing the degree of permanent neurologic damage. Combination therapy with both drugs should be considered in patients who have been previously treated for CMV disease. Other diseases involving the spinal cord in patients with HIV infection include HTLV-I-associated myelopathy (HAM) (Chap. 172), neurosyphilis (Chap. 153), infection with herpes simplex (Chap. 163) or varicella-zoster (Chap. 164), TB (Chap. 150), and lymphoma (Chap. 97).

Peripheral neuropathies are common in patients with HIV infection. They occur at all stages of illness and take a variety of forms. Early in the course of HIV infection, an acute inflammatory demyelinating polyneuropathy resembling Guillain-Barré syndrome may occur (Chap. 366). In other patients, a progressive or relapsing-remitting inflammatory neuropathy resembling chronic inflammatory demyelinating polyneuropathy (CIDP) has been noted. Patients commonly present with progressive weakness, areflexia, and minimal sensory changes. CSF examination often reveals a mononuclear pleocytosis, and peripheral nerve biopsy demonstrates a perivascular infiltrate suggesting an autoimmune etiology. Plasma exchange or intravenous immunoglobulin has been tried with variable success. Because of the immunosuppressive effects of glucocorticoids, they should be reserved for severe cases of CIDP refractory to other measures. Another autoimmune peripheral neuropathy seen in patients with AIDS is mononeuritis multiplex (Chaps. 366 and 306) due to a necrotizing arteritis

of peripheral nerves. The most common peripheral neuropathy in patients with HIV infection is a *distal sensory polyneuropathy* that may be a direct consequence of HIV infection or a side effect of dideoxynucleoside therapy. Two-thirds of patients with AIDS may be shown by electrophysiologic studies to have some evidence of peripheral nerve disease. Presenting symptoms are usually painful burning sensations in the feet and lower extremities. Findings on examination include a stocking-type sensory loss to pinprick, temperature, and touch sensation and a loss of ankle reflexes. Motor changes are mild and are usually limited to weakness of the intrinsic foot muscles. Response of this condition to antiretrovirals has been variable, perhaps because antiretrovirals are responsible for the problem in some instances. When due to dideoxynucleoside therapy, patients with lower extremity peripheral neuropathy may complain of a sensation that they are walking on ice. Other entities in the differential diagnosis of peripheral neuropathy include diabetes mellitus, vitamin B_{12} deficiency, and side effects from metronidazole or dapsone. For distal symmetric polyneuropathy that fails to resolve following the discontinuation of dideoxynucleosides, therapy is symptomatic; gabapentin, carbamazepine, tricyclics, or analgesics may be effective for dysesthesias. Treatment-naive patients may respond to combination antiretroviral therapy, and preliminary data suggest that nerve growth factor may benefit some cases.

Myopathy may complicate the course of HIV infection; causes include HIV infection itself, zidovudine, and the generalized wasting syndrome. HIV-associated myopathy may range in severity from an asymptomatic elevation in creatine kinase levels to a subacute syndrome characterized by proximal muscle weakness and myalgias. Quite pronounced elevations in creatine kinase may occur in asymptomatic patients, particularly after exercise. The clinical significance of this as an isolated laboratory finding is unclear. A variety of both inflammatory and noninflammatory pathologic processes have been noted in patients with more severe myopathy, including myofiber necrosis with inflammatory cells, nemaline rod bodies, cytoplasmic bodies, and mitochondrial abnormalities. Profound muscle wasting, often with muscle pain, may be seen after prolonged zidovudine therapy. This toxic side effect of the drug is dose-dependent and is related to its ability to interfere with the function of mitochondrial polymerases. It is reversible following discontinuation of the drug. Red ragged fibers are a histologic hallmark of zidovudine-induced myopathy.

Ophthalmologic Disease Ophthalmologic problems occur in approximately half of patients with advanced HIV infection. The most common abnormal findings on funduscopic examination are cotton-wool spots. These are hard white spots that appear on the surface of the retina and often have an irregular edge. They represent areas of retinal ischemia secondary to microvascular disease. At times they are associated with small areas of hemorrhage and thus can be difficult to distinguish from CMV retinitis. In contrast to CMV retinitis, however, these lesions are not associated with visual loss and tend to remain stable or improve over time.

One of the most devastating consequences of HIV infection is CMV retinitis. Patients at high risk of CMV retinitis (CD4+ T cell count $<100/\mu$L) should undergo an ophthalmologic examination every 3 to 6 months. The majority of cases of CMV retinitis occur in patients with a CD4+ T cell count $<50/\mu$L. Prior to the availability of HAART, this CMV reactivation syndrome was seen in 25 to 30% of patients with AIDS. CMV retinitis usualy presents as a painless, progressive loss of vision. Patients may also complain of blurred vision, "floaters," and scintillations. The disease is usually bilateral, affecting one eye more than the other. The diagnosis is made on clinical grounds by an experienced ophthalmologist. The characteristic retinal appearance is that of perivascular hemorrhage and exudate (see Fig. 25-5). In situations where the diagnosis is in doubt due to an atypical presentation or an unexpected lack of response to therapy, vitreous or aqueous humor sampling with molecular diagnostic techniques may be of value. CMV infection of the retina results in a necrotic inflammatory process, and the visual loss that develops is irreversible. CMV retinitis may be complicated by rhegmatogenous retinal detachment as a consequence of retinal atrophy in areas of prior inflammation. Therapy for CMV retinitis consists of oral valganciclovir, intravenous ganciclovir, or intravenous foscarnet, with cidofovir as an alternative. Combination therapy with ganciclovir and foscarnet has been shown to be slightly more effective than either ganciclovir or foscarnet alone in the patient with relapsed CMV retinitis. A 3-week induction course is followed by maintenance therapy with oral valganciclovir. If CMV disease is limited to the eye, a ganciclovir-releasing intraocular implant, periodic injections of the antisense nucleic acid preparation formivirsen, or intravitreal injections of ganciclovir or foscarnet may be considered; some choose to combine intraocular implants with oral valganciclovir. Intravitreal injections of cidofovir are generally avoided due to the increased risk of uveitis and hypotony. Maintenance therapy is continued until the CD4+ T cell count remains >100 to $150/\mu$L for >6 months. The majority of patients with HIV infection and CMV disease develop some degree of uveitis with the initiation of antiretroviral therapy. The etiology of this is unknown; however, it has been suggested that this may be due to the generation of an enhanced immune response to CMV as an immune reactivation syndrome. In some instances this has required the use of topical glucocorticoids.

Both HSV and varicella zoster virus can cause a rapidly progressing, bilateral necrotizing retinitis referred to as the *acute retinal necrosis syndrome* or progressive outer retinal necrosis (PORN). This syndrome, in contrast to CMV retinitis, is associated with pain, keratitis, and iritis. It is often associated with orolabial HSV or trigeminal zoster. Ophthalmologic examination reveals widespread pale gray peripheral lesions. This condition is often complicated by retinal detachment. It is important to recognize and treat this condition with intravenous acyclovir as quickly as possible to minimize the loss of vision.

Several other secondary infections may cause ocular problems in HIV-infected patients. *P. carinii* can cause a lesion of the choroid that may be detected as an incidental finding on ophthalmologic examination. These lesions are typically bilateral, are from half to twice the disc diameter in size, and appear as slightly elevated yellow-white plaques. They are usually asymptomatic and may be confused with cotton-wool spots. Chorioretinitis due to toxoplasmosis can be seen alone or, more commonly, in association with CNS toxoplasmosis. Kaposi's sarcoma may involve the eyelid or conjunctiva while lymphoma may involve the retina.

Additional Disseminated Infections and Wasting Syndrome Infections with species of the small, gram-negative rickettsia-like organism *Bartonella* (Chap. 144) are seen with increased frequency in patients with HIV infection. While not considered an AIDS-defining illness by the CDC, many experts view infection with *Bartonella* as indicative of a severe defect in cell-mediated immunity. It is usually seen in patients with CD4+ T cell counts $<100/\mu$L. Among the clinical manifestations of *Bartonella* infection are bacillary angiomatosis, cat-scratch disease, and trench fever. *Bacillary angiomatosis* is usually due to infection with *B. henselae*. It is characterized by a vascular proliferation that leads to a variety of skin lesions that have been confused with the skin lesions of KS. In contrast to the lesions of KS, the lesions of bacillary angiomatosis generally blanch, are painful, and typically occur in the setting of systemic symptoms. Infection can extend to the lymph nodes, liver (peliosis hepatis), spleen, bone, heart, CNS, respiratory tract, and gastrointestinal tract. *Cat-scratch disease* generally begins with a papule at the site of inoculation. This is followed several weeks later by the development of regional adenopathy and malaise. Infection with *B. quintana* is transmitted by lice and has been associated with case reports of trench fever, endocarditis, adenopathy, and bacillary angiomatosis. The organism is quite difficult to culture, and diagnosis often relies upon identifying the organism in biopsy specimens using the Warthin-Starry or similar stains. Treatment is with either erythromycin or doxycyline for at least 3 months.

Histoplasmosis is an opportunistic infection that is seen most frequently in patients in the Mississippi and Ohio River valleys, Puerto Rico, the Dominican Republic, and South America. These are all areas in which infection with *H. capsulatum* is endemic (Chap. 183). Because of this limited geographic distribution, the percentage of AIDS cases in the United States with histoplasmosis is only ~0.5. Histoplasmosis is generally a late manifestation of HIV infection; however, it may be the initial AIDS-defining condition. In one study, the median CD4+ T cell count for patients with histoplasmosis and AIDS was 33/μL. While disease due to *H. capsulatum* may present as a primary infection of the lung, disseminated disease, presumably due to reactivation, is the most common presentation in HIV-infected patients. Patients usually present with a 4- to 8-week history of fever and weight loss. Hepatosplenomegaly and lymphadenopathy are each seen in about 25% of patients. CNS disease, either meningitis or a mass lesion, is seen in 15% of patients. Bone marrow involvement is common, with thrombocytopenia, neutropenia, and anemia occurring in 33% of patients. Approximately 7% of patients have mucocutaneous lesions consisting of a maculopapular rash and skin or oral ulcers. Respiratory symptoms are usually mild, with chest x-ray showing a diffuse infiltrate or diffuse small nodules in approximately half of cases. Diagnosis is made by culturing the organisms from blood, bone marrow, or tissue. Treatment is typically with amphotericin B, 0.7 to 1.0 mg/kg daily to a total dose of 1 g followed by maintenance therapy with itraconazole. In the setting of mild infection, it may be appropriate to treat with itraconazole alone.

Following the spread of HIV infection to southeast Asia, disseminated infection with the fungus *Penicillium marneffei* was recognized as a complication of HIV infection and is considered an AIDS-defining condition in those parts of the world where it occurs. *P. marneffei* is the third most common AIDS-defining illness in Thailand, following TB and cryptococcosis. It is more frequently diagnosed in the rainy than the dry season. Clinical features include fever, generalized lymphadenopathy, hepatosplenomegaly, anemia, thrombocytopenia, and papular skin lesions with central umbilication. Treatment is with amphotericin B followed by itraconazole.

Visceral leishmaniasis (Chap. 196) is recognized with increasing frequency in patients with HIV infection who live in or travel to areas endemic for this protozoal infection transmitted by sandflies. The clinical presentation is one of hepatosplenomegaly, fever, and hematologic abnormalities. Lymphadenopathy and other constitutional symptoms may be present. Organisms can be isolated from cultures of bone marrow aspirates. Histologic stains may be negative, and antibody titers are of little help. Patients with HIV infection usually respond well initially to standard therapy with pentavalent antimony compounds. Eradication of the organism is difficult, however, and relapses are common.

Generalized wasting is an AIDS-defining condition; it is defined as involuntary weight loss of >10% associated with intermittent or constant fever and chronic diarrhea or fatigue lasting >30 days in the absence of a defined cause other than HIV infection. It is the initial AIDS-defining condition in ~10% of patients with AIDS in the United States and is an indication for intiation of HAART. A constant feature of this syndrome is severe muscle wasting with scattered myofiber degeneration and occasional evidence of myositis. Glucocorticoids may be of some benefit; however, this approach must be carefully weighed against the risk of compounding the immunodeficiency of HIV infection. Androgenic steroids, growth hormone, and total parenteral nutrition have been used as therapeutic interventions with variable success.

Neoplastic Diseases The neoplastic diseases clearly seen with an increased frequency in patients with HIV infection are KS and non-Hodgkin's lymphoma. In addition, there also appears to be an increased incidence of Hodgkin's disease; multiple myeloma; leukemia; melanoma; and cervical, brain, testicular, oral, lung, and anal cancers. Recent years have witnessed a marked reduction in the incidence of KS (Fig. 173-28), felt to be primarily due to the use of potent antiretroviral therapy. Rates of non-Hodgkin's lymphoma have declined as well; however, this decline has not been as dramatic as the decline in rates of KS.

Kaposi's sarcoma is a multicentric neoplasm consisting of multiple vascular nodules appearing in the skin, mucous membranes, and viscera. The course ranges from indolent, with only minor skin or lymph node involvement, to fulminant, with extensive cutaneous and visceral involvement. In the initial period of the AIDS epidemic, KS was a prominent clinical feature of the first cases of AIDS, occurring in 79% of the patients diagnosed in 1981. By 1989 it was seen in only 25% of cases, by 1992 the number had decreased to 9%, and by 1997 the number was <1%. HHV-8 or KSHV has been strongly implicated as a viral cofactor in the pathogenesis of KS (see above).

Clinically, KS has varied presentations and may be seen at any stage of HIV infection, even in the presence of a normal CD4+ T cell count. The initial lesion may be a small, raised reddish-purple nodule on the skin, a discoloration on the oral mucosa, or a swollen lymph node (Fig. 173-35). Lesions often appear in sun-exposed areas, particularly the tip of the nose, and have a propensity to occur in areas of trauma (Koebner phenomenon). Because of the vascular nature of the tumors and the presence of extravasated red blood cells in the lesions, their color ranges from reddish to purple to brown and often take the appearance of a bruise, with yellowish discoloration and tattooing. Lesions range in size from a few millimeters to several centimeters in diameter and may be either discrete or confluent. KS lesions most commonly appear as raised macules; however, they also can be papular, particularly in patients with higher CD4+ T cell counts. Confluent lesions may give rise to surrounding lymphedema and may be disfiguring when they involve the face and disabling when they involve the lower extremities or the surfaces of joints. Apart from skin, lymph nodes, gastrointestinal tract, and lung are the organ systems most commonly affected by KS. Lesions have been reported in virtually every organ, including the heart and the CNS. In contrast to most malignancies, in which lymph node involvement implies metastatic spread and a poor prognosis, lymph node involvement may be seen very early in KS and is of no special clinical significance. In fact, some patients may present with disease limited to the lymph nodes. These are generally patients with relatively intact immune function and thus the patients with the best prognosis. Pulmonary involvement with KS generally presents with shortness of breath. Some 80% of patients with pulmonary KS also have cutaneous lesions. The chest x-ray characteristically shows bilateral lower lobe infiltrates that obscure the margins of the mediastinum and diaphragm (Fig. 173-36). Pleural effusions are seen in 70% of cases of pulmonary KS, a fact that is often helpful in the differential diagnosis. Gastrointestinal involvement is seen in 50% of patients and usually takes one of two forms. The first is mucosal involvement, which may lead to bleeding that can be

FIGURE 173-35 Kaposi's sarcoma in a patient with AIDS demonstrating patch, plaque, and tumor stages.

FIGURE 173-36 Chest x-ray of a patient with AIDS and pulmonary Kaposi's sarcoma. The characteristic findings include dense bilateral lower lobe infiltrates obscuring the heart borders and a pleural effusion.

severe. These patients sometimes also develop symptoms of gastrointestinal obstruction if lesions become large. The second gastrointestinal manifestation is due to biliary tract involvement. KS lesions may infiltrate the gallbladder and biliary tree, leading to a clinical picture of obstructive jaundice similar to that seen with sclerosing cholangitis. Several staging systems have been proposed for KS. One in common use was developed by the National Institute of Allergy and Infectious Diseases AIDS Clinical Trials Group; it distinguishes patients on the basis of tumor extent, immunologic function, and presence or absence of systemic disease (Table 173-16).

A diagnosis of KS is based upon biopsy of a suspicious lesion. Histologically one sees a proliferation of spindle cells and endothelial cells, extravasation of red blood cells, hemosiderin-laden macrophages, and, in early cases, an inflammatory cell infiltrate. Included in the differential diagnosis are lymphoma (particularly for oral lesions), bacillary angiomatosis, and cutaneous mycobacterial infections.

Management of KS (Table 173-17) should be carried out in consultation with an expert since definitive treatment guidelines do not exist. In the majority of cases effective antiretroviral therapy will go a long way in achieving control. Indeed, spontaneous regressions have been reported in the setting of HAART. For patients in whom tumor persists or in whom control of HIV replication is not possible, a variety of options exist. In some cases, lesions remain quite indolent, and many of these patients can be managed with no specific treatment. Fewer than 10% of AIDS patients with KS die as a consequence of their malignancy, and death from secondary infections is considerably more common. Thus, whenever possible one should avoid treatment regimens that may further suppress the immune system and increase susceptibility to opportunistic infections. Treatment is indicated under two main circumstances. The first is when a single lesion or a limited number of lesions are causing significant discomfort or cosmetic problems, such as with prominent facial lesions, lesions overlying a joint, or lesions in the oropharynx that interfere with swallowing or breathing. Under these circumstances, treatment with localized radiation, intralesional vinblastine, or cryotherapy may be indicated. It should be noted that patients with HIV infection are particularly sensitive to the side effects of radiation therapy. This is especially true with respect to the development of radiation-induced mucositis; doses of radiation directed at mucosal surfaces, particularly in the head and neck region, should be adjusted accordingly. The use of systemic therapy, either IFN-α or chemotherapy, should be considered in patients with a large number of lesions or in patients with visceral involvement. The single most important determinant of response appears to be the CD4+ T cell count. This relationship between response rate and baseline CD4+ T cell count is particularly true for IFN-α. The response rate for patients with CD4+ T cell counts $>600/\mu$L is ~80%, while the response rate for patients with counts $<150/\mu$L is <10%. In contrast to the other systemic therapies, IFN-α provides an added advantage of having antiretroviral activity; thus, it may be the appropriate first choice for single-agent systemic therapy for early patients with disseminated disease. A variety of chemotherapeutic agents have also been shown to have activity against KS. Three of them, liposomal daunorubicin, liposomal doxorubicin, and paclitaxel have been approved by the FDA for this indication. Liposomal daunorubicin is approved as first-line therapy for patients with advanced KS. It has fewer side effects than conventional chemotherapy. In contrast, liposomal doxorubicin and paclitaxel are approved only for KS patients who have failed standard chemotherapy. Response rates vary from 23 to 88%, appear to be comparable to what had been achieved earlier with combination chemotherapy regimens, and are greatly influenced by CD4+ T cell count.

Lymphomas occur with an increased frequency in patients with congenital or acquired T cell immunodeficiencies (Chap. 297). AIDS is no exception; at least 6% of all patients with AIDS develop lymphoma at some time during the course of their illness. This is a 120-fold increase in incidence compared to the general population. In contrast to the situation with KS, primary CNS lymphoma, and most opportunistic infections, the incidence of AIDS-associated systemic lymphomas has not experienced as dramatic a decrease as a consequence of the widespread use of effective antiretroviral therapy. Lymphoma occurs in all risk groups, with the highest incidence in patients with hemophilia and the lowest incidence in patients from the Caribbean or Africa with heterosexually acquired infection. Lymphoma is a late manifestation of HIV infection, generally occurring in patients with CD4+ T cell counts $<200/\mu$L. As HIV disease progresses, the risk of lymphoma increases. In contrast to KS, which occurs at a relatively constant rate throughout the course of HIV disease, the attack rate for lymphoma increases exponentially with increasing duration of HIV infection and decreasing level of immunologic function. At 3 years following a diagnosis of HIV infection, the risk of lymphoma is 0.8% per year; by 8 years after infection, it is 2.6% per year. As people with HIV infection live longer as a consequence of improved antiretroviral therapy and better treatment and prophylaxis of opportunistic infections, it is anticipated that the incidence of lymphomas may increase.

Three main categories of lymphoma are seen in patients with HIV infection: grade III or IV immunoblastic lymphoma, Burkitt's lym-

TABLE 173-16 *National Institute of Allergy and Infectious Diseases AIDS Clinical Trials Group TIS Staging System for Kaposi's Sarcoma*

Parameter	Good Risk (stage 0): All of the Following	Poor Risk (stage 1): Any of the Following
Tumor (T)	Confined to skin and/or lymph nodes and/or minimal oral disease	Tumor-associated edema or ulceration Extensive oral lesions Gastrointestinal lesions Nonnodal visceral lesions
Immune system (I)	CD4+ T cell count $\geq 200/\mu$L	CD4+ T cell count $<200/\mu$L
Systemic illness (S)	No B symptoms[a] Karnofsky performance status >70 No history of opportunistic infection, neurologic disease, lymphoma, or thrush	B symptoms[a] present Karnofsky performance status <70 History of opportunistic infection, neurologic disease, lymphoma, or thrush

[a] Defined as unexplained fever, night sweats, >10% involuntary weight loss, or diarrhea persisting for more than 2 weeks.

TABLE 173-17 *Management of AIDS-Associated Kaposi's Sarcoma*

Observation and optimization of antiretroviral therapy
Single or limited number of lesions
Radiation
Intralesional vinblastine
Cryotherapy
Extensive disease
Initial therapy
Interferon-α (if CD4+ T cells >150/μL)
Liposomal daunorubicin
Subsequent therapy
Liposomal doxorubicin
Paclitaxel
Combination chemotherapy with low-dose doxorubicin, bleomycin, and vinblastine (ABV)
Radiation treatment

phoma, and primary CNS lymphoma. Approximately 90% of these lymphomas are B cell in phenotype, and half contain EBV DNA. These tumors may be either monoclonal or oligoclonal in nature and are probably in some way related to the pronounced polyclonal B cell activation seen in patients with AIDS.

Immunoblastic lymphomas account for ~60% of the cases of lymphoma in patients with AIDS. These are generally high grade and would have been classified as diffuse histiocytic lymphomas in earlier classification schemes. This tumor is more common in older patients, increasing in incidence from 0% in HIV-infected individuals <1 year old to >3% in those >50. One variant of immunoblastic lymphoma is body cavity lymphoma. This malignancy presents with lymphomatous pleural, pericardial, and/or peritoneal effusions in the absence of discrete nodal or extranodal masses. The tumor cells do not express surface markers for B cells or T cells. HHV-8 DNA sequences have been found in the genome of the malignant cells (see above).

Small non-cleaved cell lymphoma (*Burkitt's lymphoma*) accounts for ~20% of the cases of lymphoma in patients with AIDS. It is most frequent in patients 10 to 19 years old and usually demonstrates characteristic c-*myc* translocations from chromosome 8 to chromosomes 14 or 22. Burkitt's lymphoma is not commonly seen in the setting of immunodeficiency other than HIV-associated immunodeficiency, and the incidence of this particular tumor is over 1000-fold higher in the setting of HIV infection than in the general population. In contrast to African Burkitt's lymphoma, where 97% of the cases contain EBV genome, only 50% of HIV-associated Burkitt's lymphomas are EBV-positive.

Primary CNS lymphoma accounts for ~20% of the cases of lymphoma in patients with HIV infection. In contrast to HIV-associated Burkitt's lymphoma, primary CNS lymphomas are usually positive for EBV. In one study, the incidence of Epstein-Barr positivity was 100%. This malignancy does not have a predilection for any particular age group. The median CD4+ T cell count at the time of diagnosis is ~50/μL. Thus, CNS lymphoma generally presents at a later stage of HIV infection than systemic lymphoma. This fact may at least in part explain the poorer prognosis for this subset of patients.

The clinical presentation of lymphoma in patients with HIV infection is quite varied, ranging from focal seizures to rapidly growing mass lesions in the oral mucosa (Fig. 173-37) to persistent unexplained fever. At least 80% of patients present with extranodal disease, and a similar percentage have B-type symptoms of fever, night sweats, or weight loss. Virtually any site in the body may be involved. The most common extranodal site is the CNS, which is involved in approximately one-third of all patients with lymphoma. Approximately 60% of these cases are primary CNS lymphoma. Primary CNS lymphoma generally presents with focal neurologic deficits, including cranial nerve findings, headaches, and/or seizures. MRI or CT generally reveals a limited number (one to three) of 3- to 5-cm lesions (Fig. 173-38). The lesions often show ring enhancement on contrast administration and may occur in any location. Locations that are most commonly involved with CNS lymphoma are deep in the white matter. Contrast enhancement is usually less pronounced than that seen with toxoplasmosis. The main diseases in the differential diagnosis are cerebral toxoplasmosis and cerebral Chagas' disease. In addition to the 20% of lymphomas in HIV-infected individuals that are primary CNS lymphomas, CNS disease is also seen in HIV-infected patients with systemic lymphoma. Approximately 20% of patients with systemic lymphoma have CNS disease in the form of leptomeningeal involvement. This fact underscores the importance of lumbar puncture in the staging evaluation of patients with systemic lymphoma.

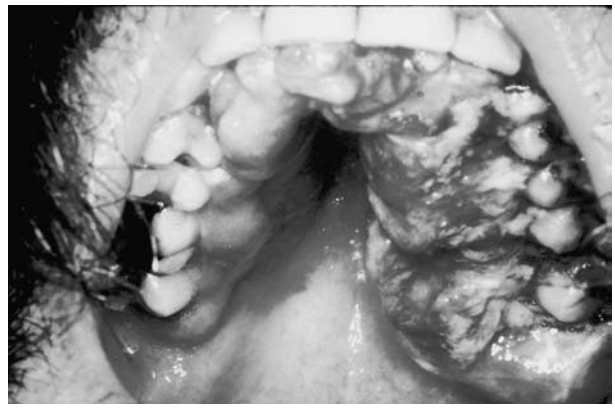

FIGURE 173-37 Diffuse histiocytic lymphoma involving the hard palate of a patient with AIDS.

Systemic lymphoma is seen at earlier stages of HIV infection than primary CNS lymphoma. In one series the mean CD4+ T cell count was 189/μL. In addition to lymph node involvement, systemic lymphoma may commonly involve the gastrointestinal tract, bone marrow, liver, and lung. Gastrointestinal tract involvement is seen in ~25% of patients. Any site in the gastrointestinal tract may be involved, and patients may complain of difficulty swallowing or abdominal pain. The diagnosis is usually suspected on the basis of CT or MRI of the abdomen. Bone marrow involvement is seen in ~20% of patients and may lead to pancytopenia. Liver and lung involvement are each seen in ~10% of patients. Pulmonary disease may present as either a mass lesion, multiple nodules, or an interstitial infiltrate.

Both conventional and unconventional approaches have been employed in an attempt to treat HIV-related lymphomas. Systemic lymphoma is generally treated by the oncologist with combination

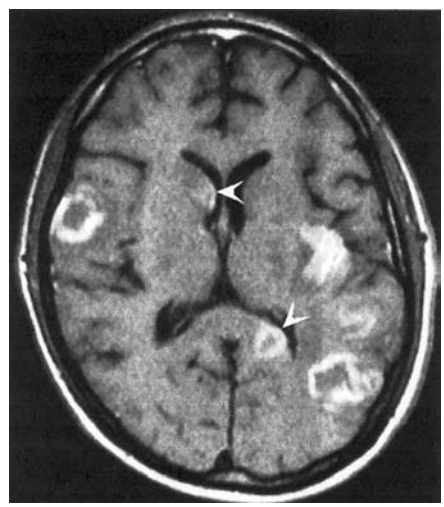

FIGURE 173-38 Central nervous system lymphoma. Postcontrast T1-weighted MR scan in a patient with AIDS, an altered mental status, and hemiparesis. Multiple enhancing lesions, some ring-enhancing, are present. The left Sylvian lesion shows gyral and subcortical enhancement, and the lesions in the caudate and splenium (*arrowheads*) show enhancement of adjacent ependymal surfaces.

chemotherapy. Earlier disappointing figures are being replaced with more optimistic results for the treatment of systemic lymphoma following the availability of more effective combination antiretroviral therapy. As in most situations in patients with HIV disease, those with the higher CD4+ T cell counts tend to do better. Response rates as high as 72% and disease-free intervals >15 months have been reported. Treatment of primary CNS lymphoma remains a significant challenge. Treatment is complicated by the fact that this illness usually occurs in patients with advanced HIV disease. Palliative measures such as radiation therapy provide some relief. The prognosis remains poor in this group, with median survival <1 year.

Evidence of infection with *human papilloma virus* (HPV), associated with *intraepithelial dysplasia of the cervix or anus*, is approximately twice as common in HIV-infected individuals as in the general population and can lead to intraepithelial neoplasia and eventually invasive cancer. In two separate studies, HIV-infected men without anorectal symptoms were studied for evidence of dysplasia, and Papanicolauo (Pap) smears were found to be abnormal in 40%. These changes were persistent at 1 year follow-up, raising the possibility of a subsequent transition to a more malignant condition. While the incidence of an abnormal Pap smear of the cervix is ~5% in otherwise healthy women, the incidence of abnormal cervical smears in women with HIV infection is 60%. Based on this finding, *invasive cervical cancer* was added to the list of AIDS-defining conditions. Thus far, however, only small increases in the incidence of cervical or anal cancer have been seen as a consequence of HIV infection. However, given this high rate of dysplasia, a comprehensive gynecologic and rectal examination, including Pap smear, is indicated at the initial evaluation and 6 months later for all patients with HIV infection. If these examinations are negative at both time points, the patient should be followed with yearly evaluations. If an initial or repeat Pap smear shows evidence of severe inflammation with reactive squamous changes, the next Pap smear should be performed at 3 months. If, at any time, a Pap smear shows evidence of squamous intraepithelial lesions, colposcopic examination with biopsies as indicated should be performed. HAART has been found to reduce the rate of progression and in some instances to induce regression of HPV-induced dysplasia.

IDIOPATHIC CD4+ T LYMPHOCYTOPENIA

A syndrome was recognized in 1992 that was characterized by an absolute CD4+ T cell count of <300/μL or <20% of total T cells on more than one occasion; no evidence of HIV-1, HIV-2, HTLV-I, or HTLV-II on testing; and the absence of any defined immunodeficiency or therapy associated with decreased levels of CD4+ T cells. By mid-1993, ~100 patients had been described. After extensive multicenter investigations, a series of reports were published in early 1993, which together allowed a number of conclusions. Idiopathic CD4+ lymphocytopenia (ICL) is a very rare syndrome, as determined by studies of blood donors and cohorts of HIV-seronegative homosexual men. Cases were clearly identified as early as 1983, and cases remarkably similar to ICL had been identified decades ago. The definition of ICL based on CD4+ T cell counts coincided with the ready availability of testing for CD4+ T cells in patients suspected of being immunosuppressed. Although, as a result of immune deficiency, certain patients with ICL develop some of the opportunistic diseases (particularly cryptococcosis) seen in HIV-infected patients, the syndrome is demographically, clinically, and immunologically unlike HIV infection and AIDS. Fewer than half of the reported ICL patients had risk factors for HIV infection, and there were wide geographic and age distributions. The fact that a significant proportion of patients did have risk factors probably reflects a selection bias, in that physicians who take care of HIV-infected patients are more likely to monitor CD4+ T cells. Approximately one-third of the patients are women, compared to 16% of women among HIV-infected individuals in the United States. Many patients with ICL remained clinically stable, and their condition did not deteriorate progressively as is common with seriously immunodeficient HIV-infected patients. Certain patients with ICL even experienced spontaneous reversal of the CD4+ T lymphocytopenia. Immunologic abnormalities in ICL are somewhat different from those of HIV infection. ICL patients often also have decreases in CD8+ T cells and in B cells. Furthermore, immunoglobulin levels were either normal or, more commonly, decreased in patients with ICL, compared to the usual hypergammaglobulinemia of HIV-infected individuals. Finally, virologic studies revealed no evidence of HIV-1, HIV-2, HTLV-I, or HTLV-II or of any other mononuclear cell–tropic virus. Furthermore, there was no epidemiologic evidence to suggest that a transmissible microbe was involved. The cases of ICL were widely dispersed, with no clustering. Close contacts and sexual partners who were studied were clinically well and were serologically, immunologically, and virologically negative for HIV. ICL is a heterogeneous syndrome, and it is highly likely that there is no common cause; however, there may be common causes among subgroups of patients that are currently unrecognized.

Patients who present with laboratory data consistent with ICL should be worked up for underlying diseases that could be responsible for the immune deficiency. If no underlying cause is detected, no specific therapy should be initiated. However, if opportunistic diseases occur, they should be treated appropriately (see above). Depending on the level of the CD4+ T cell count, patients should receive prophylaxis for the commonly encountered opportunistic infections.

TREATMENT

General Principles of Patient Management The treatment of patients with HIV infection requires not only a comprehensive knowledge of the possible disease processes that may occur but also the ability to deal with the problems of a chronic, potentially life-threatening illness. Great advances have been made in the treatment of patients with HIV infection. The appropriate use of potent combination antiretroviral therapy and other treatment and prophylactic interventions is of critical importance in providing each patient with the best opportunity to live a long and healthy life despite the presence of HIV infection. In contrast to the earlier days of this epidemic, a diagnosis of HIV infection need no longer be equated with an inevitably fatal disease. In addition to medical interventions, the health care provider has a responsibility to provide each patient with appropriate counseling and education concerning their disease as part of a comprehensive care plan. Patients must be educated about the potential transmissibility of their infection and about the fact that while health care providers may refer to levels of the virus as "undetectable," this is more a reflection of the sensitivity of the assay being used to measure the virus than a comment on the presence or absence of the virus. It is important for patients to be aware that the virus is still present and capable of being transmitted at all stages of HIV disease. Thus, there need to be frank discussions concerning sexual practices and the sharing of needles. The treating physician must not only be aware of the latest medications available for patients with HIV infection but must also educate patients concerning the natural history of their illness and listen and be sensitive to their fears and concerns. As with other diseases, therapeutic decisions should be made in consultation with the patient, when possible, and with the patient's proxy if the patient is incapable of making decisions. In this regard, it is recommended that all patients with HIV infection, and in particular those with CD4+ T cell counts <200/μL, designate a trusted individual with durable power of attorney to make medical decisions on their behalf, if necessary.

No matter how well prepared a patient is for adversity, the discovery of a diagnosis of HIV infection is a devastating event. For this reason, it is recommended that anyone about to undergo testing have "pretest counseling" to prepare him or her at least partially should the results demonstrate the presence of HIV infection. Following a diagnosis of HIV infection, the health care provider should be prepared to activate support systems immediately for the newly diagnosed patient. These should include an experienced social worker or nurse who can spend time talking to the person and ensuring that he or she is emo-

tionally stable. Most communities have HIV crisis centers that can be of great help in these difficult situations.

Following a diagnosis of HIV infection, there are several examinations and laboratory studies that should be performed to help determine the extent of disease and provide baseline standards for future reference (Table 173-18). In addition to routine chemistry and hematology screening panels and chest x-ray, one should also obtain a CD4+ T cell count, two separate plasma HIV RNA levels, a VDRL test, and an anti-*Toxoplasma* antibody titer. A PPD test should be done, and a MMSE performed and recorded. Patients should be immunized with pneumococcal polysaccharide and, if seronegative for these viruses, with hepatitis A and hepatitis B vaccines. The status of hepatitis C infection should be determined. In addition, patients should be counseled with regard to sexual practices and needle sharing, and counseling should be offered to those whom the patient knows or suspects may also be infected. Once these baseline activities are performed, short- and long-term medical management strategies should be developed based upon the most recent information available and modified as new information becomes available. The field of HIV medicine is changing rapidly, and it is difficult to remain fully up to date. Fortunately there are a series of excellent sites on the internet that are frequently updated, and they provide the most recent information on a variety of topics, including consensus panel reports on treatment (Table 173-19).

Antiretroviral Therapy Combination antiretroviral therapy, or HAART, is the cornerstone of management of patients with HIV infection. Following the initiation of widespread use of HAART in the United States in 1995 to 1996, marked declines have been noted in the incidence of most AIDS-defining conditions (Fig. 173-28). Suppression of HIV replication is an important component in prolonging life as well as improving the quality of life in patients with HIV infection. Unfortunately, many of the most important questions related to the treatment of HIV disease currently lack definitive answers. Among them are the questions of when should therapy be started, what is the best initial regimen, when should a given regimen be changed, and what should it be changed to when a change is made. Notwithstanding these uncertainties, the physician and patient must come to a mutually agreeable plan based upon the best available data. In an effort to facilitate this process, the United States Department of Health and Human Services has published a series of frequently updated guidelines including the "*Principles of Therapy of HIV Infection*," "*Guidelines for the Use of Antiretroviral Agents in HIV-Infected Adults and Adolescents*," and "*Guidelines for the Prevention of Opportunistic Infections in Persons Infected with Human Immunodeficiency Virus*." At present, an extensive clinical trials network, involving both clinical investigators and patient advocates, is in place attempting to develop improved approaches to therapy. Consortia comprising representatives of academia, industry, and the federal government are involved in the process of drug development, including a wide-ranging series of clinical trials. As a result, new therapies and new therapeutic strategies are continually emerging. New drugs are often available through expanded access programs prior to official licensure. Given the complexity of this field, decisions regarding antiretroviral therapy are best made in consultation with experts. Currently licensed drugs for the treatment of HIV infection fall into three categories: those that inhibit the viral reverse transcriptase enzyme (Table 173-20, Fig. 173-39), those that inhibit the viral protease enzyme, and those that interfere with viral entry. There are numerous drug-drug interactions that one must take into consideration when using these agents (Table 173-21).

The FDA-approved reverse transcriptase inhibitors include the *nucleoside analogues* zidovudine, didanosine, zalcitabine, stavudine, lamivudine, abacavir, and emtricitabine; the *nucleotide analogue* tenofovir; and the *nonnucleoside reverse transcriptase inhibitors* nevirapine, delavirdine, and efavirenz (Fig. 173-39; Table 173-20). These were the first class of drugs that were licensed for the treatment of HIV infection. They are indicated for this use as part of combination regimens. It should be stressed that none of these drugs should be used as monotherapy for HIV infection. Thus, when lamivudine or tenofovir are used to treat hepatitis B infection in the setting of HIV infection, one should ensure that the patient is also on additional antiretroviral medication. The reverse transcriptase inhibitors block the HIV replication cycle at the point of RNA-dependent DNA synthesis, the reverse transcription step. While the nonnucleoside reverse transcriptase inhibitors are quite selective for the HIV-1 reverse transcriptase, the nucleoside and nucleotide analogues inhibit a variety of DNA polymerization reactions in addition to those of the HIV-1 reverse transcriptase. For this reason, serious side effects are more common with the nucleoside analogues and include mitochondrial damage that can lead to hepatic steatosis and lactic acidosis as well as peripheral neuropathy and pancreatitis. One of the more recently recognized problems that has been encountered with the widespread use of HAART therapy has been a syndrome of hyperlipidemia, glucose intolerance, and fat distribution often referred to as *lipodystrophy syndrome* (discussed above under metabolic abnormalities).

Zidovudine (AZT; 3′-azido-2′,3′-dideoxythymidine) was the first drug approved for the treatment of HIV infection and is the prototype nucleoside analogue. These compounds, in which the hydroxyl group in the 3′ position of the ribose moiety is substituted with a hydrogen or other chemical group, act as DNA chain terminators owing to their inability to form a 3′-5′ phosphodiester linkage with another nucleoside. They bind much more avidly to the active site of the RNA-dependent DNA polymerase of HIV (reverse transcriptase) than to the active site of mammalian cell DNA polymerases; this explains their selective effect on HIV replication. Zidovudine also has a relatively high avidity for the DNA polymerase-γ of human mitochondria. This may contribute to the development of the fatty liver and the myopathy sometimes observed in patients taking zidovudine. As with all the nucleoside analogues, the active form of zidovudine is the triphosphate, and the rate of phosphorylation, a thymidine kinase–dependent pathway, may be different in different cells. This may explain why zidovudine is more effective at inhibiting HIV replication in some cells than others. The clinical efficacy of zidovudine was clearly established in 1986 in a phase II, randomized, placebo-controlled trial in patients

TABLE 173-18 Initial Evaluation of the Patient with HIV Infection

History and physical examination
Routine chemistry and hematology
CD4+ T lymphocyte count
Two plasma HIV RNA levels
RPR test
Anti-*Toxoplasma* antibody titer
PPD skin test
Mini-mental status examination
Serologies for hepatitis A, hepatitis B, and hepatitis C
Immunization with pneumococcal polysaccharide; influenza as indicated
Immunization with hepatitis A and hepatitis B if seronegative
Counseling regarding natural history and transmission
Help contacting others who might be infected

Note: VDRL, Venereal Disease Research Laboratory; PPD, purified protein derivative.

TABLE 173-20 *Antiretroviral Drugs Used in the Treatment of HIV Infection*

Drug	Status	Indication	Dose as Monotherapy	Dose in Combination	Supporting Data	Toxicity
REVERSE TRANSCRIPTASE INHIBITORS						
Zidovudine (AZT, azidothymidine, Retrovir, 3′azido-3′-deoxythymidine)	Licensed	Treatment of HIV infection in combination with other antiretroviral agents	Not indicated	200 mg q8h or 300 mg bid	19 vs 1 death in original placebo-controlled trial in 281 patients with AIDS or ARC. Decreased progression to AIDS in patients with CD4+ T cell counts <500/μL, $n = 2051$	Anemia, granulocytopenia, myopathy, lactic acidosis, hepatomegaly with steatosis, headache, nausea
		Prevention of maternal-fetal HIV transmission	*Mother:* 200 mg tid or 300 mg bid until the start of labor, then 2 mg/kg over 1 h IV, followed by 1 mg/kg per h IV until clamping of umbilical cord; *Infant:* 2 mg/kg q6h PO beginning within 12 h birth, or 1.5 mg/kg q6h IV over 30 min for 6 weeks		In pregnant women with CD4+ T cell count ≥200/μL, AZT PO beginning at weeks 14–34 of gestation plus IV drug during labor and delivery plus PO AZT to infant for 6 wk decreased transmission of HIV by 67.5% (from 25.5% to 8.3%), $n = 363$	
Didanosine (Videx, Videx EC, ddI, dideoxyinosine, 2′,3′-dideoxyinosine)	Licensed	For treatment of HIV infection in combination with other antiretroviral agents	Not indicated	Buffered: Requires 2 tablets to achieve adequate buffering of stomach acid; should be administered on an empty stomach ≥60 kg: 200 mg bid <60 kg: 125 mg bid Enteric coated: ≥60 kg: 400 mg qd < 60 kg: 250 mg qd	Clinically superior to AZT as monotherapy in 913 patients with prior AZT therapy. Clinically superior to AZT and comparable to AZT + ddI and AZT + ddC in 1067 AZT-naive patients with CD4+ T cell counts of 200–500/μL	Pancreatitis, peripheral neuropathy, abnormalities on liver function tests, lactic acidosis, hepatomegaly with steatosis
Zalcitabine (ddC, HIVID, 2′3′-dideoxycytidine)	Licensed	In combination with other antiretroviral agents for the treatment of HIV infection	Not indicated	0.75 mg tid	Clinically inferior to AZT monotherapy as initial treatment. Clinically as good as ddI in advanced patients intolerant to AZT. In combination with AZT, was clinically superior to AZT alone in patients with AIDS or CD4+ T cell count <350/μL	Peripheral neuropathy, pancreatitis, lactic acidosis, hepatomegaly with steatosis, oral ulcers
Stavudine (d4T, Zerit, 2′3′-didehydro-3′-dideoxythymidine)	Licensed	Treatment of HIV-infected patients in combination with other antiretroviral agents	Not indicated	≥60 kg: 40 mg bid <60 kg: 30 mg bid	Superior to AZT with respect to changes in CD4+ T cell counts in 359 patients who had received ≥24 wk of AZT. Following 12 wk of randomization, the CD4+ T cell count had decreased in AZT-treated controls by a mean of 22/μL, while in stavudine-treated patients, it had increased by a mean of 22/μL	Peripheral neuropathy, pancreatitis, lactic acidosis, hepatomegaly with steatosis, ascending neuromuscular weakness, lipodystrophy
Lamivudine (Epivir, 2′3′-dideoxy-3′-thiacytidine, 3TC)	Licensed	In combination with other antiretroviral agents for the treatment of HIV infection	Not indicated	150 mg bid 300 mg qd	Superior to AZT alone with respect to changes in CD4 counts in 495 patients who were zidovudine-naive and 477 patients who were zidovudine-experienced. Overall CD4+ T cell counts for the zidovudine group were at baseline by 24 wk, while in the group treated with zidovudine plus lamivudine, they were 10–50 cells/μL above baseline. 54% decrease in progression to AIDS/death compared to AZT alone	

(continued)

TABLE 173-20 *Antiretroviral Drugs Used in the Treatment of HIV Infection—(Continued)*

Drug	Status	Indication	Dose as Monotherapy	Dose in Combination	Supporting Data	Toxicity
Emtricitabine (FTC, Emtriva)	Licensed	In combination with other antiretroviral agents for the treatment of HIV infection	Not indicated	200 mg qd	Comparable to d4T in combination with ddI and efavirenz in 571 treatment-naive patients. Similar to 3TC in combination with 2DV or d4T + NNRT1 or PI in 440 patients doing well for at least 12 weeks on a 3TC regimen.	
Abacavir (Ziagen)	Licensed	For treatment of HIV infection in combination with other antiretroviral agents	Not indicated	300 mg bid	Abacavir + AZT + 3TC equivalent to indinavir + AZT + 3TC with regard to viral load suppression (~60% in each group with <400 HIV RNA copies/mL plasma) and CD4 cell increase (~100/μL in each group) at 24 weeks	Hypersensitivity reaction (can be fatal); fever, rash, nausea, vomiting, malaise or fatigue, and loss of appetite
Tenofovir (Viread)	Licensed	For use in combination with other antiretroviral agents when treatment is indicated	Not indicated	300 mg qd	Reduction of ~0.6 log in HIV-1 RNA levels when added to background regimen in treatment-experienced patients	Potential for renal toxicity
Delavirdine (Rescriptor)	Licensed	For use in combination with appropriate antiretrovirals when treatment is warranted	Not indicated	400 mg tid	Delavirdine + AZT superior to AZT alone with regard to viral load suppression at 52 weeks	Skin rash, abnormalities in liver function tests
Nevirapine (Viramune)	Licensed	In combination with other antiretroviral agents for treatment of progressive HIV infection	Not indicated	200 mg/d × 14 days then 200 mg bid	Increases in CD4+ T cell count, decrease in HIV RNA when used in combination with nucleosides	Skin rash, hepatotoxicity
Efavirenz (Sustiva)	Licensed	For treatment of HIV infection in combination with other antiretroviral agents	Not indicated	600 mg qhs	Efavirenz + AZT + 3TC comparable to indinavir + AZT + 3TC with regard to viral load suppression (a higher percentage of the efavirenz group achieved viral load <50 copies/mL; however, the discontinuation rate in the indinavir group was unexpectedly high, accounting for most treatment "failures") and CD4 cell increase (~140/μL in each group) at 24 weeks	Rash, dysphoria, elevated liver function tests, drowsiness, abnormal dreams, depression
PROTEASE INHIBITORS						
Saquinavir mesylate (Invirase—hard gel capsule)	Licensed	In combination with other antiretroviral agents when therapy is warranted	Not indicated	600 mg q8h	Increases in CD4+ T cell counts, reduction in HIV RNA most pronounced in combination therapy with ddC. 50% reduction in first AIDS-defining event or death in combination with ddC compared to either agent alone	Diarrhea, nausea, headaches, hyperglycemia, fat redistribution, lipid abnormalities
(Fortovase—soft gel capsule)	Licensed	For use in combination with other antiretroviral agents when treatment is warranted	Not indicated	1200 mg tid	Reduction in the mortality rate and AIDS-defining events for patients who received hard-gel formulation in combination with ddC	Diarrhea, nausea, abdominal pain, headaches, hyperglycemia, fat redistribution, lipid abnormalities
Ritonavir (Norvir)	Licensed	In combination with other antiretroviral agents for treatment of HIV infection when treatment is warranted	Not indicated	600 mg bid	Reduction in the cumulative incidence of clinical progression or death from 34 to 17% in patients with CD4+ T cell count <100/μL treated for a median of 6 months	Nausea, abdominal pain, hyperglycemia, fat redistribution, lipid abnormalities, may alter levels of many other drugs, including saquinavir

(continued)

TABLE 173-20—*(Continued)*

Drug	Status	Indication	Dose as Monotherapy	Dose in Combination	Supporting Data	Toxicity
Indinavir sulfate (Crixivan)	Licensed	For treatment of HIV infection in combination with other antiretroviral agents when antiretroviral treatment is warranted	Not indicated	800 mg q8h	Increase in CD4+ T cell count by 100/μL and 2-log decrease in HIV RNA levels when given in combination with zidovudine and lamivudine. Decrease of 50% in risk of progression to AIDS or death when given with zidovudine and lamivudine compared with zidovudine and lamivudine alone	Nephrolithiasis, indirect hyperbilirubinemia, hyperglycemia, fat redistribution, lipid abnormalities
Nelfinavir mesylate (Viracept)	Licensed	For treatment of HIV infection in combination with other antiretroviral agents when antiretroviral therapy is warranted	Not indicated	750 mg tid or 1250 mg bid	2.0-log decline in HIV RNA when given in combination with stavudine	Diarrhea, loose stools, hyperglycemia, fat redistribution, lipid abnormalities
Amprenavir (Agenerase)	Licensed	In combination with other antiretroviral agents for treatment of HIV infection	Not indicated	1200 mg bid or 600 mg bid + Ritonavir 100 mg bid or 1200 mg qd + Ritonavir 200 mg qd	In treatment-naïve patients, amprenavir + AZT + 3TC superior to AZT + 3TC with regard to viral load suppression (53% vs 11% with <400 HIV RNA copies/mL plasma at 24 weeks). CD4+ T cell responses similar between treatment groups. In treatment-experienced patients, amprenavir + NRTIs similar to indinavir + NRTIs with regard to viral load suppression (43% vs 53% with <400 HIV RNA copies/mL plasma at 24 weeks). CD4+ T cell responses superior in the indinavir + NRTIs group	Nausea, vomiting, diarrhea, rash, oral paresthesias, elevated liver function tests, hyperglycemia, fat redistribution, lipid abnormalities
Fosamprenavir (Lexiva)	Licensed			1400 mg bid or 700 mg bid + Ritonavir 100 mg bid		
Lopinavir/ritonavir (Kaletra)	Licensed	For treatment of HIV infection in combination with other antiretroviral agents	Not indicated	400 mg/100 mg bid	In treatment of naïve patients, lopinavir/ritonavir + d4T + 3TC superior to nelfinavir + d4T + 3TC with regard to viral load suppression (79% vs 64% with <400 HIV RNA copies/mL at 40 weeks). CD4+ T cell increases similar in both groups.	Diarrhea, hyperglycemia, fat redistribution, lipid abnormalities
Atazanavir (Reyataz)	Licensed	For treatment of HIV infection in combination with other antiretroviral agents	Not indicated	400 mg qd or 300 mg qd + Ritonavir 100 mg qd when given with efavirenz	Comparable to efavirenz when given in combination with AZT + 3TC in a study of 810 treatment-naive patients. Comparable to nelfinavir when given in combination with d4T + 3TC in a study of 467 treatment-naive patients.	Hyperbilirubinemia, PR prolongation, nausea, vomiting, hyperglycemia, fat maldistribution
FUSION INHIBITOR						
Enfuvirtide (Fuzeon)	Licensed	In combination with other agents in treatment-experienced patients with evidence of HIV-1 replication despite ongoing antiretroviral therapy	Not indicated	90 mg SC bid	In treatment of experienced patients, superior to placebo when added to new optimized background (37% vs 16% with <400 HIV RNA copies/mL at 24 weeks; + 71 vs + 35 CD4+ T cells at 24 weeks)	Local injection reactions, hypersensitivity reactions, increased rate of bacterial pneumonia

Note: ARC, AIDS-related complex; NRTIs, nonnucleoside reverse transcriptase inhibitors.

with advanced HIV disease. However, while treatment of patients with early stages of HIV infection was associated with increases in CD4+ T cell count, it was not associated with a better overall outcome than waiting until later to treat. Subsequent trials established the ability of this drug to dramatically decrease the incidence of perinatal transmission of HIV from infected mother to infant. Eventually a series of studies demonstrated the superiority of combination antiretroviral regimens over zidovudine alone, and combination therapy (discussed below) remains the standard of treatment today. Among the side effects of zidovudine at the initiation of therapy are fatigue, malaise, nausea, and headache. These side effects often subside over time. Patients on zidovudine may develop a macrocytic anemia, myopathy, cardiomyopathy, and lactic acidosis associated with fatty infiltration of the liver. As with every antiretroviral drug, HIV has the ability to develop re-

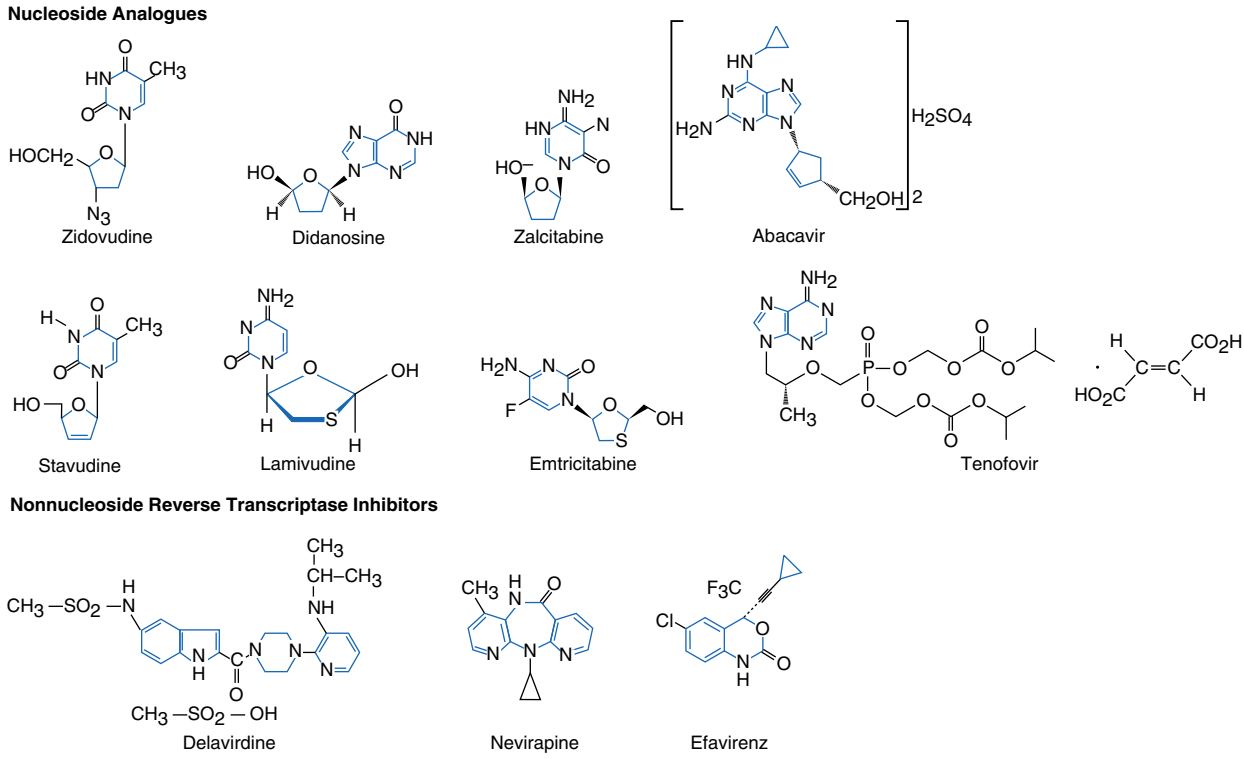

FIGURE 173-39 Molecular structures of antiretroviral agents.

sistance to zidovudine. Zidovudine resistance has been reported to occur ~6 months following the initiation of zidovudine monotherapy. More recently, zidovudine-resistant viruses have been noted in patients with acute infection prior to the initiation of therapy, implying that zidovudine-resistant viruses can be transmitted from person to person. Resistance emerges more rapidly in late-stage patients, presumably as a consequence of a greater degree of viral replication and thus a greater opportunity for mutation. A variety of amino acid changes including substitutions, insertions, and deletions have been reported to confer zidovudine resistance (Fig. 173-40). One combination preparation, Combivir, consists of zidovudine and lamivudine, while another, Trizivir, consists of zidovudine, lamivudine, and abacavir.

Didanosine (ddI; 2′,3′-dideoxyinosine) was the second drug licensed for the treatment of HIV infection, followed shortly thereafter by zalcitabine. Didanosine is metabolized to dideoxyadenosine in vivo. It is best absorbed on an empty stomach at a high pH. For this reason, the formulations of didanosine either contain a buffer, and each dose must be administered in no fewer than two tablets to ensure adequate buffering of stomach acid, or are provided as an extended-release enteric-coated capsule. The toxicity profile of didanosine is quite different from that of zidovudine. The most common toxicity is a painful sensory peripheral neuropathy that occurs in ~30% of patients receiving >400 mg/d. It generally resolves with discontinuation of the drug and may not recur if the drug is resumed at a reduced dose. At higher doses than are currently used one may see pancreatitis in ~10% of patients. Pancreatitis associated with didanosine therapy can be fatal. Didanosine should be discontinued if a patient experiences abdominal pain consistent with pancreatitis or if an elevated serum amylase or lipase level is found in association with an edematous pancreas on ultrasound. Didanosine is contraindicated in patients with a prior history of pancreatitis, regardless of etiology.

Zalcitabine (ddC; 2′,3′-dideoxycytidine) is rarely used today in the management of patients with HIV infection. Among the nucleoside analogues licensed for the treatment of HIV infection, it is probably the weakest. The main toxicity of ddC is pancreatitis.

Stavudine (d4T; 2′,3′-didehydro-3′-deoxythymidine) was the fourth drug licensed for the treatment of HIV infection. Like zidovudine, stavudine is a thymidine analogue. These two drugs are antagonistic in vitro and in vivo and should not be given together. Peripheral neuropathy and hepatic steatosis are the main toxicities of stavudine. It is commonly used with lamivudine as part of an initial treatment regimen.

Lamivudine (3TC; 2′,3′-dideoxy-3′-thiacytidine) is the fifth of the nucleoside analogues to be licensed in the United States. It is licensed for use in combination with zidovudine in situations where zidovudine is indicated. In actual practice, lamivudine is a frequent element of many different combination regimens currently in use. It is available either alone or in combination with zidovudine (Combivir). One reason behind the excellent synergy seen between lamivudine and the other nucleoside analogues may be that strains of HIV resistant to lamivudine (M184V substitution) appear to have enhanced sensitivity to other nucleosides, and thus development of dual resistance is quite difficult. In addition, there is a suggestion that 3TC-resistant strains of HIV may be less virulent and are less able to generate new mutants than are strains of HIV that are 3TC-sensitive. Lamivudine is among the best tolerated and least toxic nucleoside analogues.

Emtricitabine (FTC; 5-fluoro-1-(2R,5S)-[2-(hydroxymethyl)-1,3-oxathiolan-5-y]cytosine) is the negative enantiomer of a thio analogue of cytidine with a fluorine in the 5 position. It is licensed for use in combination with other antiretroviral agents for treatment of HIV-1 infection in adults. Similar in activity to lamivudine, resistance to emtricitabine is associated with the M184V mutation in reverse transcriptase. Viruses showing the K65R mutation in reverse transcriptase may have reduced susceptibility to emtricitabine.

Abacavir {(1S,cis)-4-[2-amino-6-(cyclopropylamino)-9H-purin-9-yl]-2-cyclopentene-1-methanol sulfate (salt)(2:1)} is a synthetic carbocyclic analogue of the nucleoside guanosine. It is licensed to be used in combination with other antiretroviral agents for the treatment of HIV-1 infection. Hypersensitivity reactions have been reported in ~4% of patients treated with this drug, and patients developing signs or symptoms of hypersensitivity such as fever, skin rash, fatigue, and gastrointestinal symptoms should discontinue the drug and not restart it. Fatal hyper-

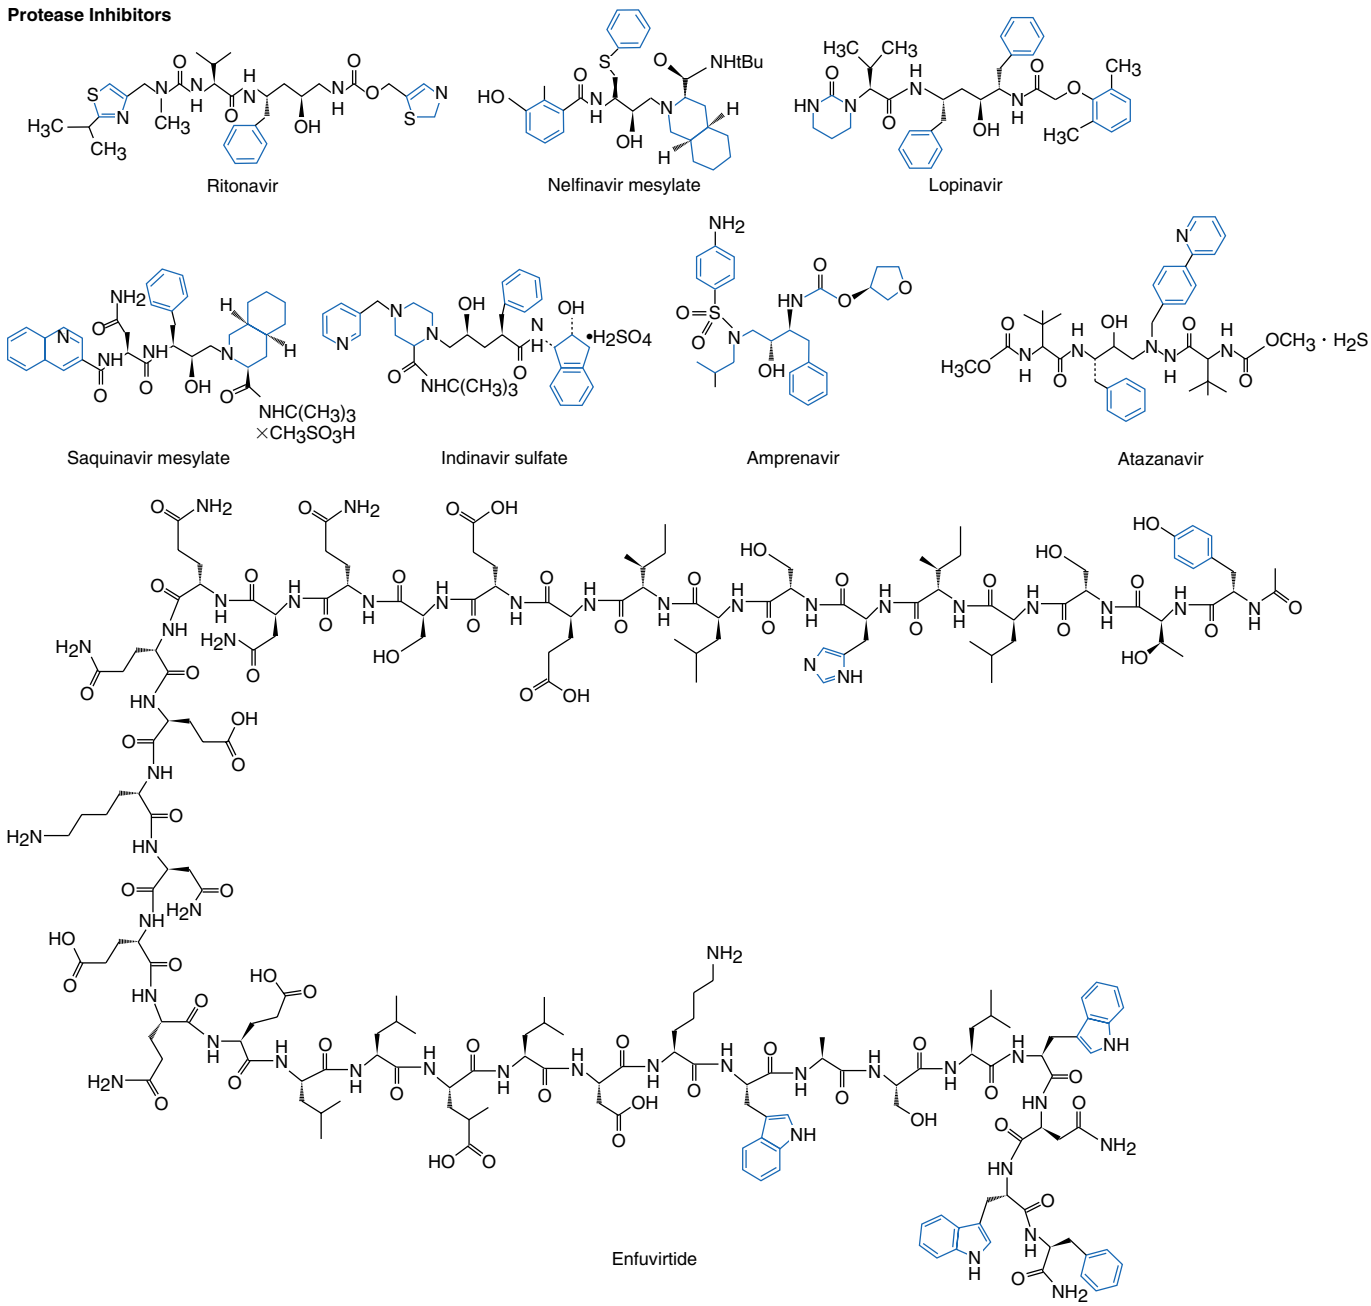

FIGURE 173-39—*(Continued)*

sensitivity reactions have been reported with rechallenge. Abacavir hypersensitiviy appears to occur with a higher frequency in patients who are HLA-B57. Abacavir-resistant strains of HIV are typically also resistant to lamivudine, didanosine, and zalcitabine.

Tenofovir disoproxil fumarate (9-[(R)-2-[[bis[[(isopropoxycarbonyl)oxy]methoxy]phosphinyl]methoxy]propyl]adenine fumarate (1:1)) is an acyclic nucleoside phosphonate diester analogue of adenosine monophosphate. It undergoes diester hydrolysis to form tenofovir and is the first nucleotide analogue to be licensed for treatment of HIV infection. It is indicated in combination with other antiretroviral agents for the treatment of HIV-1 infection. HIV isolates with increased resistance typically express a K65R mutation in reverse transcriptase and a three- to four-fold reduction in sensitivity to tenofovir. Tenofovir is primarily eliminated by the kidneys, and renal impairment with hypophosphatemia may occur. Tenofovir is contraindicated in patients with renal impairment. Coadministration with didanosine leads to a 60% increase in didanosine levels, and thus doses of didanosine need to be adjusted and patients monitored carefully if these two drugs are used in combination.

Nevirapine, *delavirdine*, and *efavirenz* are nonnucleoside inhibitors of the HIV-1 reverse transcriptase. They are licensed for use in combination with nucleoside analogues for the treatment of HIV-infected adults. These agents inhibit reverse transcriptase by binding to regions of the enzyme outside the active site and causing conformational changes in the enzyme that render it inactive. Although these agents are active in the nanomolar range, they are also very selective for the reverse transcriptase of HIV-1, have no activity against HIV-2, and, when used as monotherapy, are associated with the rapid emergence of drug-resistant mutants (Table 173-20; Fig. 173-40). Efavirenz is administered once a day, nevirapine twice a day, and delavirdine three times a day. All three drugs are associated with the development of a maculopapular rash, generally seen within the first few weeks of therapy. While it is possible to treat through this rash, it is important to be sure that one is not dealing with a more severe eruption such as

TABLE 173-21 *Drug-Drug Interactions Involving Antiretroviral Agents*

Index Drug	Interacting Drug(s)	Mechanism/Effect	Recommendation
Amprenavir	Efavirenz	Induction of metabolism, decreased amprenavir AUC	Consider dosage increase to 1200 mg tid or add ritonavir 200 mg bid
	Indinavir	Inhibition of metabolism—drug levels increased 33%	No change
	Ritonavir	Inhibition of metabolism—amprenavir AUC increased 2.5-fold	Decrease to 600 mg bid
Amprenavir, indinavir, saquinavir, ritonavir, nelfinavir	Rifampin	Induction of metabolism—marked decrease in protease inhibitor drug levels	Avoid concomitant use
Antiarrhythmics (flecainaide, quinidine, propafenone, amiodarone)	Ritonavir	Inhibition of metabolism—potential for increased levels and toxicity	Use with caution or avoid concomitant use
Atorvastatin	Protease inhibitors	Inhibition of metabolism—increased drug levels	Use with caution
Atovaquone	Rifampin	Induction of metabolism—decreased drug levels	Concentrations may not be therapeutic—avoid or increase dose
Benzodiazepines (flurazepam, diazepam, midazolam, triazolam)	Protease inhibitors, delavirdine, efavirenz	Inhibition of metabolism—increased drug levels	Monitor for toxicity such as increased sedation, decrease dose, or use temazepam, lorazepam Not recommended for use with triazolam
Bepridil	Ritomavir, amprenavir	Inhibition of metabolism—increased drug levels	Avoid concomitant use
Carbamazepine	Indinavir, ritonavir	Inhibition of metabolism—increased toxicity	Avoid concomitant use or monitor levels
Cidofovir	Nephrotoxic drugs (aminoglycosides, amphotericin, foscarnet)	Potential for increased side effects	Monitor renal function
Cisapride	Protease inhibitors, azole antifungals, macrolides, delavirdine, efavirenz	Inhibition of metabolism	Cardiotoxic life-threatening effects possible—avoid concomitant use
Clarithromycin	Efavirenz	Induction of metabolism—40% decrease in clarithromycin AUC	Clinical significance unknown, but clarithromycin effectiveness may be altered
	Nevirapine	Induction of metabolism—decrease in clarithromycin AUC by 30%, increase in 14-OH clarithromycin by 58%	No dosage adjustments necessary
	Delavirdine	Inhibition of metabolism—100% increase in clarithromycin	Adjust dose in renal failure
	Ritonavir Atazanavir	Inhibition of metabolism—drug levels increased 77%	No adjustment needed in normal renal function
	Agents that increase gastric pH—antacids, H_2 blockers, proton pump inhibitors, didanosine	Delavirdine absorption decreased with increased pH	Avoid concomitant use with H_2 blockers and proton pump inhibitors; separate from antacids by at least 2 h
	Rifabutin	Induction of metabolism—50–60% decrease in delavirdine levels	Clinical significance unknown; may require increased delavirdine dose
	Rifampin	Induction of metabolism—marked decrease in drug levels	Avoid concomitant use
Didanosine (ddl)	Allopurinol	Increased ddl AUC by 2-fold	Clinical significance unknown
	Methadone	Decrease in ddl AUC by 52%	No clinical data, but potential for decreased ddl efficacy
	Tenofovir	Increase in ddl AUC by 44%	Consider ddI dose reduction
	Ganciclovir	Increased ddI AUC by 111%	Monitor for ddI toxicity
Efavirenz	Fluconazole	Inhibition of metabolism—efavirenz AUC increased 15%	No dosage adjustment necessary
	Indinavir	Induction of hepatic metabolism—indinavir AUC decreased 35%	Consider increasing indinavir dose to 1000 mg q8h
	Nelfinavir	Nelfinavir AUC increased 21%	No dosage adjustment necessary
	Rifampin	Induction of metabolism—significant reduction in efavirenz AUC	Clinical significance unknown; increase in efavirenz dose may be required
	Rifampin	Induction of metabolism—efavirenz AUC decreased 26%	Clinical significance unknown
	Ritonavir	Inhibition of metabolism—efavirenz AUC increased 21%	No dosage adjustment necessary
Ergot alkaloids (ergotamine, dihydroergotamine, ergoloid mesylates)	Protease inhibitors, azole antifungals, macrolides, delavirdine, efavirenz	Inhibition of metabolism—potential for acute toxicity	Use with caution or avoid concomitant use; monitor for toxicity such as peripheral vasoconstriction, nausea and vomiting, and impaired mental status

(continued)

TABLE 173-21—(Continued)

Index Drug	Interacting Drug(s)	Mechanism/Effect	Recommendation
Ethinyl estradiol	Efavirenz	Inhibition of metabolism—37% increase in estradiol AUC	No dosage adjustment necessary
	Protease inhibitors, nevirapine	Induction of metabolism—decreased levels of oral contraceptive	Use alternative or additional method of contraception
Fluvastatin, lovastatin, simvastatin	Protease inhibitors, azole antifungals, macrolides, delavirdine	Inhibition of metabolism—potential for increased levels and toxicity	Potential for hypolipidemic toxicity (dizziness, headache, GI side effects); monitor patient closely and consider dose reduction or use pravastatin or atorvastatin
Foscarnet	Nephrotoxic drugs (aminoglycosides, amphotericin, cidofovir)	Potential for increased toxicity	Monitor renal function
Ganciclovir	Drugs causing bone marrow suppression (i.e., TMP/SMZ, zidovudine)	Potential for increased hematologic toxicity	Monitor for anemia and neutropenia—adjust/change doses and drugs if required; consider supportive therapy with G-CSF
	Tenofovir	Competition for tubular secretion	Monitor for renal toxicity
Indinavir, saquinavir, ritonavir, nelfinavir, amprenavir	Anticonvulsants (carbamazepine, phenytoin, phenobarbital)	Induction of metabolism—potential decrease in drug levels	Clinical effects unknown; monitor blood levels, consider dosage increase, or avoid concomitant use
Indinavir	Delavirdine	Increased indinavir levels	Consider reducing indinavir dose to 600 mg q8h
	St. John's wort	Decreased indinavir levels	Avoid use of St. John's wort
	Didanosine, antacids	ddl buffer decreases absorption of indinavir	Separate doses by at least 1 h
	Methadone	Indinavir C_{max} decreased 16–36%; indinavir C_{min} increased by 50–100%	No dosage adjustments necessary
	Nelfinavir	Inhibition of metabolism—indinavir drug levels increased by 51%, nelfinavir drug levels by 83%	Avoid concommitant use
	Nevirapine	Induction of metabolism—decreased drug levels of indinavir by 30%	Consider increasing indinavir dose to 1000 mg q8h
	Ritonavir	Inhibition of metabolism—indinavir AUC increased 3–7-fold	Consider 800 mg indinavir/200 mg ritonavir bid
	Efavirenz	Induction of metabolism—31% decrease in indinavir levels	Dose indinavir at 1000 mg q8h or add ritomavir
Lopinavir/ritonavir	Nevirapine, efavirenz	Induction of metabolism—40–55% decrease in lopinavir levels	Dose lopinavir/ritonavir at 533/133 mg bid
Meperidine	Ritonavir	Likely induction of metabolism—decrease in meperidine AUC 67%, increase in normeperidine 47%	Potential for decreased meperidine effectiveness—may require increased dose; caution with chronic dosing
Methadone	Abacavir	Methadone clearance decreased 22%	Low potential for opiate withdrawal; monitor closely and increase methadone dose as required to control symptoms
	Fluconazole	Inhibition of metabolism—drug levels increased 30%	Monitor for methadone toxicity such as respiratory depression, drop in blood pressure, and mental status changes; consider dosage adjustment
	Nevirapine, efavirenz, ritonavir	Induction of metabolism—substantial decrease in methadone levels	Potential for opiate withdrawal; monitor closely and increase methadone dose as required to control symptoms
Nelfinavir	Ritonavir	Inhibition of metabolism—increased drug levels of nelfinavir by 152%	Consider nelfinavir 500–750 mg bid + ritonavir 200–400 mg bid
Pentamidine	Drugs that cause pancreatitis (didanosine, zalcitabine)	Increased risk of pancreatitis	Monitor amylase, lipase
Quinolone antibiotics (ciprofloxacin, levofloxacin, ofloxaxin, etc)	Didanosine buffered tablet, antacids, iron products, calcium products, sucralfate	Chelation resulting in marked decrease in quinolone drug levels	Administer cation preparations at least 2 h after quinolone
Rifabutin	Amprenavir, atazanavir, ritonavir, indinavir, nelfinavir, lopinavir/ritonavir	Inhibition of metabolism—marked increase in rifabutin drug levels	Use 150 mg qd with indinavir, nelfinavir, amprenavir; increase nelfinavir to 1000 mg tid Use 150 mg every other day with ritonavir, lopinavir/ritonavir, atazanavir
	Delavirdine	Induction of delavirdine metabolism; inhibition of rifabutin metabolism	Avoid concomitant use
	Efavirenz	Induction of rifabutin metabolism—levels decrease 35%	Increase rifabutin to 450–600 mg qd
	Fluconazole	Inhibition of metabolism—marked increase in rifabutin drug levels	Monitor for rifabutin toxicity such as uveitis, nausea, neutropenia

(continued)

TABLE 173-21 *Drug-Drug Interactions Involving Antiretroviral Agents—(Continued)*

Index Drug	Interacting Drug(s)	Mechanism/Effect	Recommendation
Rifampin	Protease inhibitors, delavirdine, nevirapine	Induction of metabolism—decreased drug levels	Avoid concomitant use
	Efavirenz	Induction of metabolism	Increase efavirenz to 800 mg qd
Ritonavir	Delavirdine	Inhibition of metabolism—70% increase in ritonavir levels	No data to base recommendations
Saquinavir	Nevirapine	Induction of metabolism—drug levels decreased 27%	Clinical significance unknown—consider dosage increase of saquinavir or add ritonavir
	Ritonavir	Inhibition of metabolism—3-fold or higher increase in saquinavir drug levels	Various combinations used to optimize saquinavir therapy including 400 mg saquinavir/400 mg ritonavir
	Delavirdine	Inhibition of metabolism—5-fold increase in saquinavir drug levels	Dose saquinavir at 800 mg tid
	Nelfinavir	Inhibition of metabolism—3–5-fold increase in saquinavir drug levels	Dose saquinavir at 800 mg tid or 1200 mg bid
	Efavirenz	Induction of metabolism—saquinavir AUC decreased 62%	Avoid concomitant use unless saquinavir is administered with ritonavir
Sildenafil	Protease inhibitors, delavirdine	Inhibition of metabolism—sildenafil AUC increased 2–11-fold	Use 25-mg sildenafil dose and do not repeat for 48 h
St. John's Wort	Protease inhibitors, NRT1s	Induction of metabolism—decreased drug levels	Avoid concomitant use
Terfenadine, astemizole	Protease inhibitors, azole antifungals, macrolides, delavirdine, efavirenz	Inhibition of metabolism	Cardiotoxic life-threatening effects possible—avoid concomitant use
Theophylline	Ritonavir	Induction of metabolism—decreased blood levels	Monitor theophylline levels
Tipranavir	Ritonavir	Inhibition of metabolism—tipranavir AUC increased 7–45-fold	Combination under investigation to optimize tipranavir levels
TMP/SMZ	Rifampin	TMP AUC decreased 63%, SMX AUC decreased 23%	Clinical significance unknown
Zalcitabine, stavudine, didanosine	Drugs that cause peripheral neuropathy—INH, d4T, ddI, ddC	Potential for increased risk of peripheral neuropathy	Monitor for signs and symptoms such as numbness and tingling in extremities
Zidovudine	Drugs causing bone marrow suppression (i.e., TMP/SMX, ganciclovir, sulfadiazine)	Increased bone marrow suppression	Monitor for anemia, neutropenia—may require supportive therapy (EPO, G-CSF)

Note: AUC, area under the curve; *C*, concentration; EPO, erythropoietin; G-CSF, granulocyte colony stimulating factor; TMP/SMX, trimethoprim/sulfamethoxazole.

Stevens-Johnson syndrome by looking carefully for signs of mucosal involvement, significant fever, or painful lesions with desquamation. Severe, life-threatening, and in some cases fatal hepatotoxicity, including fulminant and cholestatic hepatitis, hepatic necrosis and hepatic failure, have been reported in patients treated with nevirapine. Many patients treated with efavirenz note a feeling of light-headedness, dizziness, or out of sorts following the initiation of therapy. Some complain of vivid dreams. These symptoms tend to disappear after several weeks of therapy. Aside from difficulties with dreams, taking efavirenz at bedtime may minimize the side effects. Nevirapine and efavirenz are both commonly used as part of initial treatment regimens in combination with two nucleoside analogues. Another common use of these drugs is as part of salvage regimens in patients whose current regimen is inadequate.

The introduction of the HIV-1 protease inhibitors (saquinavir, indinavir, ritonavir, nelfinavir, amprenavir, lopinavir/ritonavir, and atazanavir) to the therapeutic armamentarium of antiretrovirals has had a profound impact on the efficacy of antiretroviral therapy. When used as part of initial regimens in combination with reverse transcriptase inhibitors, these agents have been shown to be capable of suppressing levels of HIV replication to under 50 copies per milliliter in the majority of patients for a minimum of 5 years. HIV protease inhibitors appear to be good substrates for the drug transporters MDR-1 and MRP-2. Whether or not genetic variations in these genes will lead to variability in protease inhibitor activity remains to be determined. As in the case of reverse transcriptase inhibitors, resistance to protease inhibitors can develop rapidly in the setting of monotherapy, and thus these agents should only be used as part of combination therapeutic regimens. A summary of known resistance mutations for protease inhibitors is shown in Fig. 173-40.

Saquinavir was the first of the HIV-1 protease inhibitors to be licensed. Initially provided as a hard gel (Invirase) with poor bioavailability, the soft-gel formulation (Fortavase) provides good plasma levels of drug, particularly when administered in conjunction with ritonavir. Saquinavir is metabolized by the cytochrome P450 system, and ritonavir therapy results in inhibition of cytochrome P450 action. Thus, when both drugs are administered together there is the potential for increases in saquinavir levels. The use of low doses of ritonavir to provide pharmacodynamic boosting of other agents has become a fairly common strategy in HIV therapy. Saquinavir is among the best-tolerated protease inhibitors.

Ritonavir was the first protease inhibitor for which clinical efficacy was demonstrated. In a study of 1090 patients with CD4+ T cell counts $<100/\mu L$ who were randomized to receive either placebo or ritonavir in addition to any other licensed medications, patients receiving ritonavir had a reduction in the cumulative incidence of clinical progression or death from 34% to 17%. Mortality decreased from 10.1% to 5.8%. At full doses, ritonavir is poorly tolerated. Among the main side effects are nausea, diarrhea, abdominal pain, and circumoral paresthesia. Ritonavir has a high affinity for several isoforms of cytochrome P450, and its use can result in large increases in the plasma concentrations of drugs metabolized by this pathway. Among the agents affected in this manner are saquinavir, indinavir, macrolide antibiotics, R-warfarin, ondansetron, rifampin, most calcium channel blockers, glucocorticoids, and some of the chemotherapeutic agents used to treat KS. In addition, ritonavir may increase the activity of glucuronyltransferases, thus decreasing the levels of drugs metabolized by this pathway. Overall, great care must be taken when prescribing additional drugs to patients taking ritonavir. As mentioned above, the pharmacodynamic boosting property of ritonavir, seen with

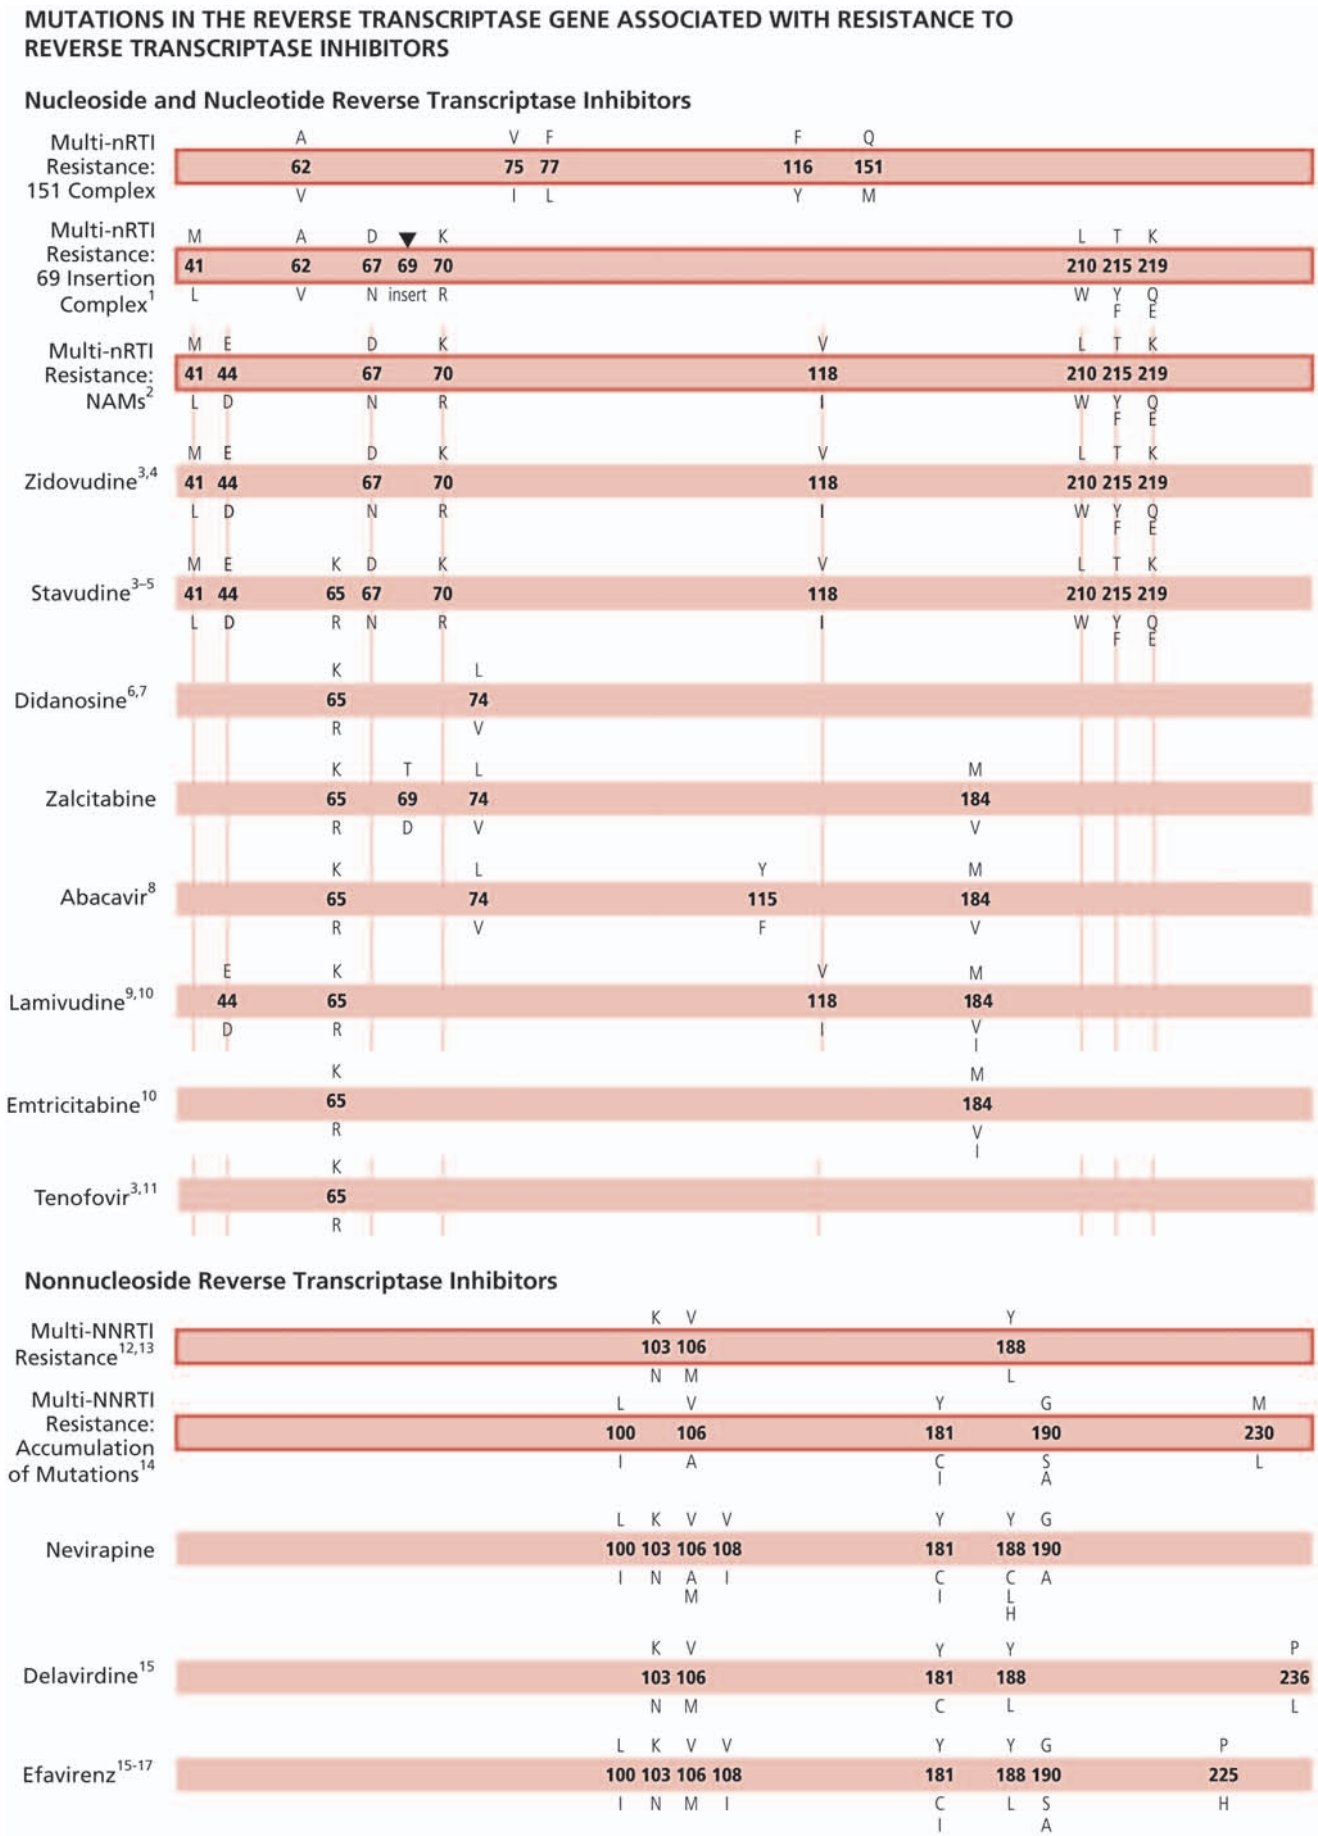

FIGURE 173-40— *(Continued)*

doses as low as 100 to 200 mg twice a day, is often used in the setting of HIV infection to derive more convenient regimens. For example, when given with low-dose ritonavir, saquinavir and indinavir can both be given on twice-a-day schedules and taken with food.

Indinavir is among the best studied of the HIV-1 protease inhibitors. It was the first protease inhibitor used in combination with dual nucleoside therapy. The combination of zidovudine, lamivudine, and indinavir was the first "triple combination" shown to have a profound effect on HIV replication. The main side effects of indinavir are nephrolithiasis (seen in 4% of patients) and asymptomatic indirect hyperbilirubinemia (seen in 10%). Indinavir is predominantly metabolized by the liver. The dose should be lowered in patients with cirrhosis. Indinavir shares metabolic pathways with terfenadine, astemizole, cisapride, triazolam, and midazolam. To avoid the potential for cardiac arrhythmias or prolonged sedation, these drugs should not be administered to patients taking indinavir. Levels of indinavir are decreased during concurrent therapy with rifabutin or nevirapine and increased during concurrent therapy with ketoconazole, delavirdine, efavirenz, or ritonavir. Dosages should be modified appropriately in these circumstances (Table 173-21).

Nelfinavir was approved in 1997 and *amprenavir* was approved in 1999 for the treatment of adult or pediatric HIV infection when antiretroviral therapy is warranted. As with most of the newer antiretroviral agents, these approvals were based on randomized, controlled trials that demonstrated decreases in plasma HIV RNA levels and increases in CD4+ T cell counts. Both agents have unique resistance profiles. Nelfinavir resistance is associated with a D30N substitution in the protease gene. Viruses harboring this single mutation retain sensitivity to other protease inhibitors, and it has been suggested that for this reason nelfinavir is a good initial protease inhibitor. It is not clear, however, whether this theoretical consideration will be borne out in the results of clinical trials. Protease inhibitor resistance typically involves multiple amino acid substitutions and reduced susceptibility across the class. Amprenavir resistance is associated with a unique substitution at amino acid 50 (I50V), and it has been suggested that amprenavir may be of particular value in salvage regimens. This assumption also awaits verification in controlled clinical trials. Nelfinavir and amprenavir are both associated with gastrointestinal side effects. About 1% of patients receiving amprenavir have experienced severe and life-threatening skin reactions. An additional disadvantage of amprenavir is that the original formulation requires the patient to take 8 large capsules twice a day.

Fosamprenavir (Lexiva) is a recently licensed prodrug of amprenavir that is rapidly converted to amprenavir by cellular phosphatases. It is supplied as a 700-mg tablet. The recommended dosage is 1400 mg bid or 700 mg bid with ritonavir 100 mg bid or 1400 mg once a day with ritonavir 200 mg once a day.

Lopinavir/ritonavir (Kaletra) is a fixed dose combination of the protease inhibitors lopinavir (133.3 mg) and ritonavir (33.3 mg). It is indicated for treatment of HIV-1 infection in combination with other agents. A main advantage of this pill is that it combines the pharmacologic enhancement of low-dose ritonavir with a second protease inhibitor in a single capsule. In a randomized, controlled trial, this combination capsule was found to be superior to nelfinavir.

Atazanavir (Reytaz) is an azapeptide inhibitor of the HIV-1 protease. Initial studies suggest that total cholesterol and triglyceride levels may not increase as much with atazanavir as is seen with other protease inhibitors. Atazanavir is associated with increases in serum bilirubin and prolongations of the PR interval. Atazanavir-resistant isolates emerging in previously treatment-naïve individuals frequently harbor an I50L substitution. This mutation in some instances is associated with increased sensitivity to other protease inhibitors. Atazanavir is an inhibitor of cytochrome P3A and its use may be associated with increased levels of calcium channel blockers, HMB-CoA reductase inhibitors, and sildenafil.

The newest class of antiretroviral compounds are the entry inhibitors. These agents act by interfering with the binding of HIV to its receptor or co-receptor or by interfering with the process of fusion (see above). A variety of small molecules that bind to HIV-1 co-receptors are currently in clinical trials. The first drug in this class to be licensed is the fusion inhibitor enfuvirtide (Fuzeon), or T-20.

Enfuvirtide is a linear 36-amino acid synthetic peptide with the N-terminus acetylated and the C-terminus a carboxamide. It is composed of naturally occurring L-amino acid residues and interferes with the fusion of the viral and cellular membranes by binding to the HR1 region in the gp41 subunit of the HIV-1 envelope. This binding interferes with the coil-coil interaction required to approximate the two membranes. Resistant isolates of HIV exhibit amino acid changes in positions 36 to 45 of gp41. In two independent studies, patients who had persistent viremia despite prior treatment with agents from all three available classes of drugs were randomized to receive an individualized regimen (based upon prior treatment history and resistance profile) with or without enfuvirtide. The change in plasma HIV-1 RNA from baseline was approximately 1 log greater (−1.53 vs. −0.68) in patients randomized to receive enfuvirtide. Among the drawbacks of this agent are the requirement for twice-a-day injection, the occurrence of injection site reactions in 98% of patients, and an increase in bacterial pneumonia in the enfuvirtide-treated patients compared to the patients in the control arm (4.68 vs. 0.61 events per 100 patient years) in the phase III studies.

The principles of therapy for HIV infection have been articulated by a panel sponsored by the U.S. Department of Health and Human Services and the Henry J. Kaiser Family Foundation. These principles are summarized in Table 173-22. As noted in these guidelines, eradication of HIV infection has not yet been possible. Treatment decisions must take into account the fact that one is dealing with a chronic infection. While early therapy is generally the rule in infectious diseases, immediate treatment of every HIV-infected individual upon diagnosis may not be prudent, and therapeutic decisions must take into account the balance between risks and benefits. At present, a reasonable course of action is to initiate antiretroviral therapy in anyone with the acute HIV syndrome; patients with symptomatic disease; patients with asymptomatic disease with CD4+ T cell counts $<250/\mu L$ or with $>50{,}000$ copies of HIV RNA per milliliter (Table 173-23). In addition, one may wish to administer a 6-week course of therapy to uninfected

TABLE 173-22 Principles of Therapy of HIV Infection

1. Ongoing HIV replication leads to immune system damage and progression to AIDS.
2. Plasma HIV RNA levels indicate the magnitude of HIV replication and the rate of CD4+ T cell destruction. CD4+ T cell counts indicate the current level of competence of the immune system.
3. Rates of disease progression differ among individuals, and treatment decisions should be individualized based upon plasma HIV RNA levels and CD4+ T cell counts.
4. Maximal suppression of viral replication is a goal of therapy; the greater the suppression the less likely the appearance of drug-resistant quasispecies.
5. The most effective therapeutic strategies involve the simultaneous initiation of combinations of effective anti-HIV drugs with which the patient has not been previously treated and that are not cross-resistant with antiretroviral agents that the patient has already received.
6. The antiretroviral drugs used in combination regimens should be used according to optimum schedules and dosages.
7. The number of available drugs is limited. Any decisions on antiretroviral therapy have a long-term impact on future options for the patient.
8. Women should receive optimal antiretroviral therapy regardless of pregnancy status.
9. The same principles apply to children and adults. The treatment of HIV-infected children involves unique pharmacologic, virologic, and immunologic considerations.
10. Compliance is an important part of ensuring maximal effect from a given regimen. The simpler the regimen, the easier it is for the patient to be compliant.

TABLE 173-23 Indications for the Initiation of Antiretroviral Therapy in Patients with HIV Infection

I. Acute infection syndrome
II. Chronic infection
  A. Symptomatic disease
  B. Asymptomatic diseases[a]
    1. CD4+ T cell count <350/μL or decreasing
    2. HIV RNA >50,000 copies mL or increasing
III. Postexposure prophylaxis

[a] This is the area of greatest controversy. Some experts would wait until the CD4 cell count declines to 200/μL, whereas others would treat everyone regardless of CD4+ T cell count.

Source: *Guidelines for the Use of Antiretroviral Agents in HIV-Infected Adults and Adolescents*. USPHS.

individuals immediately following a high-risk exposure to HIV (see below).

Once the decision has been made to initiate therapy, the health care provider must decide which drugs to use as the first regimen. The decision regarding choice of drugs not only will affect the immediate response to therapy but also will have implications regarding options for future therapeutic regimens. The initial regimen is usually the most effective insofar as the virus has yet to develop significant resistance. The two options for initial therapy most commonly in use today are two different three-drug regimens. The first regimen utilizes two nucleoside analogues (one of which is usually lamivudine) and a nonnucleoside reverse transcriptase inhibitor. The second regimen utilizes two nucleoside analogues and a protease inhibitor. Unfortunately there are no clear data at present on which to base distinctions between these two approaches. Following the initiation of therapy one should expect a 1 log (tenfold) reduction in plasma HIV RNA levels within 1 to 2 months and eventually a decline in plasma HIV RNA levels to <50 copies per milliliter. During this same time there should be a rise in the CD4+ T cell count of 100 to 150/μL that is particularly brisk during the first month of therapy. Many clinicians feel that failure to achieve this endpoint is an indication for a change in therapy. Other reasons for a change in therapy include a persistently declining CD4+ T cell count, clinical deterioration, or drug toxicity (Table 173-24). As in the case of initiating therapy, changing therapy may have a lasting impact on future therapeutic options. When changing therapy because of treatment failure (clinical progression or worsening laboratory parameters), it is important to attempt to provide a regimen with at least two new drugs. In the patient in whom a change is made for reasons of drug toxicity, a simple replacement of one drug is reasonable. It should be stressed that in attempting to sort out a drug toxicity it may be advisable to hold all therapy for a period of time to distinguish between drug toxicity and disease progression. Drug toxicity will usually begin to show signs of reversal within 1 to 2 weeks. Prior to changing a treatment regimen because of drug failure, it is important to ensure that the patient has been adherent to the prescribed regimen.

TABLE 173-24 Indications for Changing Antiretroviral Therapy in Patients with HIV Infection[a]

Less than a 1-log drop in plasma HIV RNA by 4 weeks following the initiation of therapy
A reproducible significant increase (defined as 3-fold or greater) from the nadir of plasma HIV RNA level not attributable to intercurrent infection, vaccination, or test methodology
Persistently declining CD4+ T cell numbers
Clinical deterioration
Side effects

[a] Generally speaking, a change should involve the initiation of at least 2 drugs felt to be effective in the given patient. The exception to this is when change is being made to manage toxicity, in which case a single substitution is reasonable.

Source: *Guidelines for the Use of Antiretroviral Agents in HIV-Infected Adults and Adolescents*. USPHS.

As in the case of initial therapy, the simpler the therapeutic regimen, the easier it is for the patient to be compliant. Plasma HIV RNA levels and CD4+ T lymphocyte counts should be monitored every 3 to 4 months during therapy and more frequently if one is contemplating a change in regimen or immediately following a change in regimen.

In an attempt to determine an optimal therapeutic regimen, one may attempt to measure antiretroviral drug susceptibility through genotyping or phenotyping of HIV quasispecies and determine adequacy of dosing through measurement of drug levels. Genotyping may be done through dideoxynucleotide sequencing, DNA chip hybridization, or line probe assays. Phenotypic assays measure the performance of reverse transcriptase or protease in the presence or absence of different concentrations of different drugs. These assays will generally detect quasispecies present at a frequency of at least 10%. The precise role of resistance testing in the management of patients with HIV infection is not yet clear. While randomized studies have suggested that information regarding HIV resistance profiles may improve virologic outcomes in patients failing their current antiretroviral regimen, the degree of improvement thus far has been small and the duration of the benefit limited. Resistance testing may be of particular value in distinguishing drug-resistant virus from poor patient compliance; it may also be of value to help guide initial therapy in a setting where transmission of a drug-resistant isolate is felt to be likely. Measurement of plasma drug levels can also be used to tailor an individual treatment. The inhibitory quotient, defined as the trough blood level/IC50 of the patient's virus is used by some to determine the adequacy of dosing of a given treatment regimen.

In addition to the licensed medications discussed above, a large number of experimental agents are being evaluated as possible therapies for HIV infection. Therapeutic strategies are being developed that interfere with virtually every step of the replication cycle of the virus (Fig. 173-3). In addition, as more is discovered about the role of the immune system in controlling viral replication, additional strategies, generically referred to as "immune-based therapies," are being developed as a complement to antiviral therapy. Among the antiviral agents in early clinical trials are additional nucleoside and nucleotide analogues, additional protease inhibitors including nonpeptidomimetic compounds, additional fusion inhibitors, receptor and co-receptor antagonists, integrase inhibitors, and antisense nucleic acids. Among the immune-based therapies being evaluated are IFN-α, bone marrow transplantation, adoptive transfer of lymphocytes genetically modified to resist infection or enhance HIV-specific immunity, active immunotherapy with inactivated HIV or its components, and IL-2.

HIV AND THE HEALTH CARE WORKER

Health care workers, especially those who deal with large numbers of HIV-infected patients, have a small but definite risk of becoming infected with HIV as a result of professional activities. As of January 1, 2002, 57 health care workers in the United States had been documented as having seroconverted to HIV following occupational exposure; 26 have developed AIDS. The individuals who seroconverted include 19 laboratory workers (16 of whom were clinical laboratory workers), 24 nurses, 6 physicians, 2 surgical technicians, 1 dialysis technician, 1 respiratory therapist, 1 health aide, 1 embalmer/morgue technician, and 2 housekeeper/maintenance workers. The exposures included 48 percutaneous (puncture/cut injury), 5 mucocutaneous (mucous membrane and/or skin), 2 both percutaneous and mucocutaneous, and 2 unknown route of exposure. Forty-nine exposures were to HIV-infected blood, three to concentrated virus in a laboratory, one to visibly bloody fluid, and four to an unspecified fluid. As of January 1, 2002, there had been 138 other cases of HIV infection or AIDS among health care workers who have not reported other risk factors for HIV infection and who report a history of exposure to blood, body fluids, or HIV-infected laboratory material, but for whom seroconversion after exposure was not documented. The number of these workers who actually acquired their infection through occupational exposures is not known. Taken together, the data from several large studies suggest that the risk of HIV infection following a percutaneous exposure to HIV-contami-

nated blood is ~0.3%, and after a mucous membrane exposure, approximately 0.09%. Although episodes of HIV transmission after non-intact skin exposure have been documented, the average risk for transmission by this route has not been precisely quantified but is estimated to be less than the risk for mucous membrane exposures. The risk for transmission after exposure to fluids or tissues other than HIV-infected blood also has not been quantified but is probably considerably lower than for blood exposures. A seroprevalence survey of 3420 orthopedic surgeons, 75% of whom practiced in an area with a relatively high prevalence of HIV infection and 39% of whom reported percutaneous exposure to patient blood, usually through an accident involving a suture needle, failed to reveal any cases of possible occupational infection, suggesting that the risk of infection with a suture needle may be considerably less than that with a blood-drawing needle.

Most cases of health care worker seroconversion occur as a result of needle-stick injuries. When one considers the circumstances that result in needle-stick injuries, it is immediately obvious that adhering to the standard guidelines for dealing with sharp objects would result in a significant decrease in this type of accident. In one study, 27% of needle-stick injuries resulted from improper disposal of the needle (over half of these were due to recapping the needle), 23% occurred during attempts to start an intravenous line, 22% occurred during blood drawing, 16% were associated with an intramuscular or subcutaneous injection, and 12% were associated with giving an intravenous infusion.

Recommendations regarding postexposure prophylaxis must take into account that several circumstances determine the risk of transmission of HIV following occupational exposure. In this regard, several factors have been associated with an increased risk for occupational transmission of HIV infection including: deep injury, the presence of visible blood on the instrument causing the exposure, injury with a device that had been placed in the vein or artery of the source patient, terminal illness in the source patient, and lack of postexposure antiretroviral therapy in the exposed health care worker. Other important considerations include pregnancy in the health care worker and the possibility of exposure to drug-resistant virus. Regardless of the decision to use postexposure prophylaxis, the wound should be cleansed immediately and antiseptic applied. If a decision is made to offer postexposure prophylaxis, U.S. Public Health Service guidelines recommend (1) a combination of two nucleoside analogue reverse transcriptase inhibitors given for 4 weeks for routine exposures, or (2) a combination of two nucleoside analogue reverse transcriptase inhibitors plus a third drug given for 4 weeks for high-risk or otherwise complicated exposures, although most clinicians administer the latter regimen in all cases in which a decision is made to treat. Further details are available from the *Updated U.S. Public Health Service Guidelines for the Management of Occupational Exposures to HBV, HCV and HIV and Recommendations for Postexposure Prophylaxis* (CDC, 2001).

Health care workers can minimize their risk of occupational HIV infection by following the CDC guidelines of July 1991, which include adherence to universal precautions, refraining from direct patient care if one has exudative lesions or weeping dermatitis, and disinfecting and sterilizing reusable devices employed in invasive procedures. The premise of universal precautions is that every specimen should be handled as if it came from someone infected with a bloodborne pathogen. All samples should be double-bagged, gloves should be worn when drawing blood, and spills should be immediately disinfected with bleach.

In attempting to put this small but definite risk to the health care worker in perspective, it is important to point out that ~200 health care workers die each year as a result of occupationally acquired hepatitis B infection. The tragedy in this instance is that these infections and deaths due to HBV could be greatly decreased by more extended use of the HBV vaccine. The risk of HBV infection following a needle-stick injury from a hepatitis antigen–positive patient is much higher than the risk of HIV infection (see "Transmission," above). There are multiple examples of needle-stick injuries where the patient was positive for both HBV and HIV and the health care worker became infected only with HBV. For these reasons, it is advisable, given the high prevalence of HBV infection in HIV-infected individuals, that all health care workers dealing with HIV-infected patients be immunized with the HBV vaccine.

TB is another infection common to HIV-infected patients that can be transmitted to the health care worker. For this reason, all health care workers should know their PPD status, have it checked yearly, and receive 1 year of isoniazid treatment if their skin test converts to positive. In addition, all patients in whom a diagnosis of TB is being entertained should be placed immediately in respiratory isolation, pending results of the diagnostic evaluation. The emergence of drug-resistant organisms has made TB an increasing problem for health care workers. This is particularly true for the health care worker with preexisting HIV infection.

One of the most charged issues ever to come between health care workers and patients is that of transmission of infection from HIV-infected health care workers to their patients. This is discussed under "Occupational Transmission of HIV: Health Care Workers and Laboratory Workers." Theoretically, the same universal precautions that are used to protect the health care worker from the HIV-infected patient will also protect the patient from the HIV-infected health care worker.

VACCINES

Historically, vaccines have provided a safe, cost-effective, and efficient means of preventing illness, disability, and death from infectious diseases. Given the fact that human behavior, especially human sexual behavior, is extremely difficult to change, the best hope for preventing the spread of HIV infection rests with the development of a safe and effective vaccine. This task is problematic for a number of reasons, including the high mutability of the virus, the fact that the infection can be transmitted by cell-free or cell-associated virus, the likely need for the development of effective mucosal immunity, and the fact that it has been difficult to establish the precise correlates of protective immunity to HIV infection. Some HIV-infected individuals are long-term nonprogressors (see above), and a number of individuals have been exposed to HIV multiple times but remain uninfected; these facts suggest that there are protective elements of an HIV-specific immune response. In addition, studies using animal models, specifically SIV in the monkey and HIV-1 in the chimpanzee, have been encouraging and suggest that an HIV vaccine is possible. It should be pointed out that while the ideal goal of an HIV vaccine is to prevent infection, a vaccine given to an uninfected individual that significantly alters the course of disease or the infectivity of the individual, should that person become infected, could have an impact not only on the individual in question but also on the spread of infection in the community.

A number of clinical trials ranging from several small phase I trials to determine safety to fewer intermediate-sized phase II trials to determine safety and immunogenicity have taken place and are under way. The single completed phase III trial of a recombinant gp120 protein failed to show protection despite evidence of HIV-specific antibodies and CD4+T cells in phase II. These results suggest the potential importance of CD8+ T cell immunity in host defense against HIV-1. The furthest advanced among the current phase II trials involves a combination approach using a live canarypox vector expressing one or multiple HIV epitopes given together with gp120 or using the gp120 as a boost. This approach has resulted in neutralizing antibodies in virtually all recipients and HIV-specific cytolytic T cells in ~30% of individuals at any given time during the course of the trial. Other work is exploring the effects of recombinant adenovirus or naked DNA in combination with protein immunization.

Other approaches currently being tested in phase I and/or phase II trials in humans include vaccines employing vectors such as modified vaccinia Ankara (MVA), salmonella, and Venezuela equine encepha-

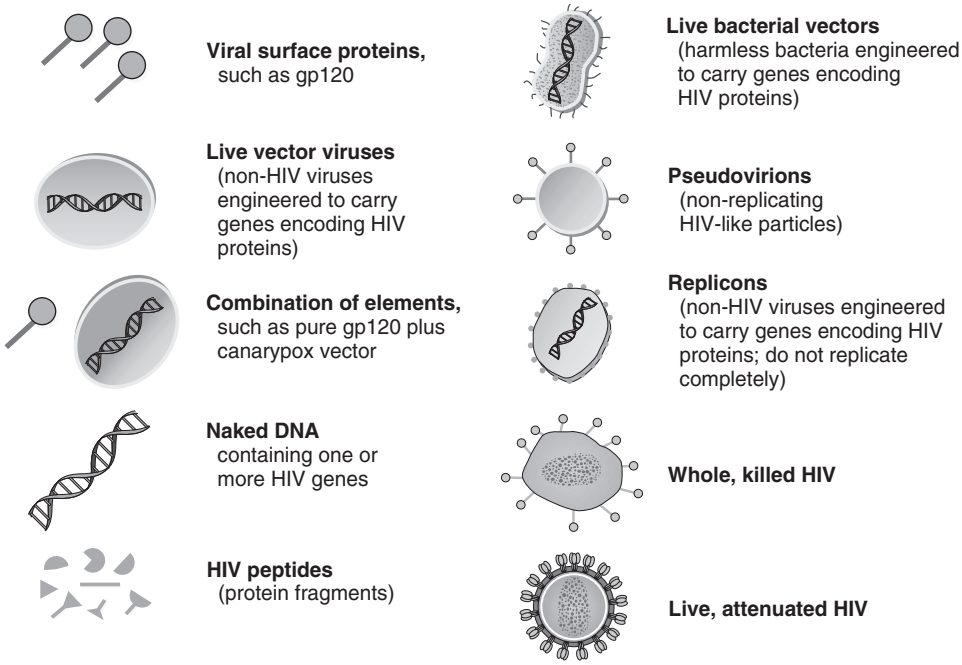

FIGURE 173-41 Candidate HIV vaccines. See text for detailed discussion. (*Adapted from D Baltimore, C Heilman: Sci Am 279:98, 1998. Copyright Slim Films.*)

litis (VEE) virus, among others; peptide and subunit vaccines; and pseudovirions (Fig. 173-41). Live attenuated HIV vaccines have not proceeded into human trials at this time because of safety concerns. It is clear that it will take several years of clinical trials to establish the efficacy or lack thereof of a candidate vaccine for HIV.

PREVENTION

Education, counseling, and behavior modification are the cornerstones of an HIV prevention strategy. Widespread voluntary testing of individuals who have practiced or are practicing high-risk behavior, together with counseling of infected individuals, is recommended. Information gathered from such an approach should serve as the basis for behavior-modification programs, both for infected individuals who may be unaware of their HIV status and who could infect others and for uninfected individuals practicing high-risk behavior. The practice of "safer sex" is the most effective way for sexually active uninfected individuals to avoid contracting HIV infection and for infected individuals to avoid spreading infection. Abstinence from sexual relations is the only absolute way to prevent sexual transmission of HIV infection. However, for many people this may not be feasible, and there are a number of relatively safe practices that can markedly decrease the chances of transmission of HIV infection. Partners engaged in monogamous sexual relationships who wish to be assured of safety should both be tested for HIV antibody. If both are negative, it must be understood that any divergence from monogamy puts both partners at risk; open discussion of the importance of honesty in such relationships should be encouraged. When the HIV status of either partner is not known, or when one partner is positive, there are a number of options. Use of condoms can markedly decrease the chance of HIV transmission. It should be remembered that condoms are not 100% effective in preventing transmission of HIV infection, and there is an ~10% failure rate of condoms used for contraceptive purposes. Most condom failures result from breakage or improper usage, such as not wearing the condom for the entire period of intercourse. Latex condoms are preferable, since virus has been shown to leak through natural skin condoms. Petroleum-based gels should never be used for lubrication of the condom, since they increase the likelihood of condom rupture. There has been a tendency among homosexual men to practice fellatio as a "minimal risk" activity compared to receptive anal intercourse. It should be emphasized that receptive fellatio is definitely not safe sex, and although the incidence of transmission via fellatio is considerably less than that of rectal or vaginal intercourse, there has been documentation of transmission of HIV where receptive fellatio was the only sexual act performed (see "Transmission," above). Topical microbicides for vaginal and anal use are being pursued actively as a means by which individuals could avoid infection when the insertive partner cannot be relied on to use a condom. Kissing is considered safe, although there is a theoretical possibility of transmission via virus in saliva. The low concentration of virus in saliva of infected individuals, as well as the presence in saliva of HIV-inhibitory proteins (see above), lessens any risk of transmission by kissing.

The most effective way to prevent transmission of HIV infection among IDUs is to stop the use of injectable drugs. Unfortunately, that is extremely difficult to accomplish unless the individual enters a treatment program. For those who will not or cannot participate in a drug treatment program and who will continue to inject drugs, the avoidance of sharing of needles and other paraphernalia ("works") is the next best way to avoid transmission of infection. The cultural and social factors that contribute to the sharing of paraphernalia are complex and difficult to overcome. In addition, needles and syringes may be in short supply. Under these circumstances, paraphernalia should be cleaned after each usage with a virucidal solution, such as undiluted sodium hypochlorite (household bleach). Data from a number of studies have indicated that programs that provide sterile needles to addicts in exchange for used needles have resulted in a decrease in HIV transmission without increasing the use of injection drugs. It is important for IDUs to be tested for HIV infection and counseled, to avoid transmission to their sexual partners. Secondary and tertiary spread of HIV infection by the heterosexual route within settings of a high level of injection drug use has increased greatly in the United States (see above).

Transmission of HIV via transfused blood or blood products has been decreased dramatically by a combination of screening of all blood donors for HIV infection by assays for both HIV antibody and p24 antigen and self-deferral of individuals at risk for HIV infection. In addition, clotting factor concentrates are heat-treated, essentially eliminating the risk to hemophiliacs who require these products. Autologous transfusions are preferable to transfusions from another individual. However, logistic constraints as well as the unpredictability of the need for most transfusions limit the feasibility of this approach. At present the risk of becoming HIV-infected from a contaminated blood transfusion is approximately 1 in 725,000 to 1 in 835,000 donations.

Treatment of an HIV-infected mother with antiretroviral therapy during pregnancy and the infant during the first weeks following birth has proven very effective in dramatically decreasing mother to child transmission of HIV. In situations such as that seen in certain developing countries where pregnant women frequently present to a health care system during labor, administration of a short course (as little as a single dose of one drug) of antiretroviral therapy to the mother during labor and to the infant within 48 h of birth has also been successful in decreasing the incidence of mother to child transmission of HIV.

HIV can be transmitted via breast milk and colostrum. The avoidance of breast-feeding may not be practical in developing countries, where nutritional concerns override the risk of HIV transmission. However, it is becoming appreciated that 5 to 15% of infants who were born of HIV-infected mothers and who were fortunate enough

not to have been infected intrapartum or peripartum become infected via breast-feeding. Therefore, in developing countries, breast-feeding from an infected mother should be avoided if at all possible. Unfortunately, this is rarely the case, and given the disadvantages of withholding breast-feeding in developing countries (see above), health authorities in most developing countries continue to recommend breast-feeding despite the potential for HIV transmission. Treatment of the infected mother with antiretroviral therapy, in addition to decreasing perinatal mother-to-child transmission can also decrease transmission by breast-feeding. In developed countries such as the United States, where bottled formula and milk are readily accessible, breast-feeding is absolutely contraindicated when a mother is HIV positive.

174 VIRAL GASTROENTERITIS

Umesh D. Parashar, Roger I. Glass

Acute infectious gastroenteritis is a common illness that affects persons of all ages worldwide. It is a leading cause of mortality among children in developing countries, accounting for an estimated 2.4 to 2.9 million deaths each year, and is responsible for up to 10 to 12% of all hospitalizations among children in industrialized countries, such as the United States. Elderly persons, especially those with debilitating health conditions, are also at risk of severe complications and death from acute gastroenteritis. Acute gastroenteritis rarely causes mortality among healthy young adults, but it incurs substantial medical and social costs, including those of time lost from work.

Several enteric viruses have been recognized as important etiologic agents of acute infectious gastroenteritis (Table 174-1). Illness caused by these viruses is characterized by the acute onset of vomiting and/or diarrhea, which may be accompanied by fever, nausea, abdominal cramps, anorexia, and malaise. As shown in Table 174-2, several features can help distinguish gastroenteritis caused by viruses from that caused by bacterial agents. However, the distinction based on clinical and epidemiologic parameters alone is often difficult, and laboratory tests may be required to confirm the diagnosis.

The Norwalk and related human caliciviruses affect both adults and children and are a leading cause of epidemics of gastroenteritis. Rotaviruses are the leading cause of severe childhood gastroenteritis worldwide. Enteric adenoviruses and astroviruses are recognized as less common causes of gastroenteritis, and the role of some viruses, such as toroviruses and picobirnaviruses, remains to be elucidated. A brief discussion of these agents of acute infectious gastroenteritis among humans follows.

NORWALK AND RELATED HUMAN CALICIVIRUSES

Etiologic Agent The Norwalk virus is the prototype strain of a group of nonenveloped, small (27 to 40 nm), round, icosahedral viruses with relatively amorphous surface features on visualization by electron microscopy. These viruses are usually named after the geographic location of the gastroenteritis outbreak from which they were first identified (e.g., Norwalk virus, Hawaii virus, Toronto virus) and have been difficult to classify because they have not been adapted to cell culture, no animal models are available, and often they are shed in low titers for only a few days. Molecular cloning and characterization have demonstrated that these viruses have a single, positive-strand RNA genome that is ~7.5 kb in length and that they possess a single virion-associated protein with a molecular mass of 60 kDa, similar to that of typical caliciviruses. On the basis of these molecular characteristics, these viruses are presently classified in two genera belonging to the family Caliciviridae: the *noroviruses* and the *sapoviruses* (previously called Norwalk-like viruses and Sapporo-like viruses, respectively).

Epidemiology Infections with the Norwalk and related human caliciviruses are common, and most adults have antibodies to these viruses. Antibody is acquired at an earlier age in developing countries—a pattern consistent with the presumed fecal-oral mode of transmission of these viruses. Infections occur year-round, although, in temperate climates, a distinct increase has been noted in cold-weather months.

Noroviruses may be the most common infectious agents of mild gastroenteritis in the community and affect all age groups, whereas sapoviruses primarily cause gastroenteritis in children. Noroviruses are also a cause of traveler's diarrhea, and outbreaks have occurred among military personnel deployed to various parts of the world. The etiologic role of noroviruses in moderate to severe gastroenteritis requiring a visit to a physician or hospitalization is still being studied, but data from industrialized countries indicate that norovirus may be the second most common viral agent (after rotavirus) among young children and the most common agent among older children and adults.

Noroviruses are also recognized as the major cause of epidemics of gastroenteritis worldwide. In the United States, more than 90% of outbreaks of nonbacterial gastroenteritis are caused by noroviruses. Epidemics occur throughout the year, in all age groups, and in a variety of settings, such as schools, camps and recreational facilities, nursing homes, cruise ships, swimming facilities, and restaurants. Food items contaminated either by infectious food handlers or at the source are often implicated in outbreaks of infection. Because of their capacity to concentrate virus through filtration, shellfish harvested from fecally contaminated waters pose a special risk.

Transmission occurs predominantly by the fecal-oral route, but virus is also present in vomitus. Because an inoculum with very few viruses can be infectious, transmission can occur by aerosolization, by contact with contaminated formites, and by person-to-person contact. Viral shedding and infectivity are greatest during the acute illness, but challenge studies of volunteers with Norwalk virus indicate that viral antigen may be shed by asymptomatically infected persons and also by symptomatic persons prior to the onset of symptoms and for up to 2 weeks after the resolution of illness.

Pathogenesis The exact sites and cellular receptors for attachment of viral particles have not been determined. Data suggest that carbohydrates that are similar to human histo-blood group antigens and are present on the gastroduodenal epithelium of individuals with the secretor phenotype may serve as ligands for the attachment of Norwalk virus. Additional studies must more fully elucidate norovirus-carbohydrate interactions, including potential strain-specific variations. After the infection of volunteers, reversible lesions are noted in the upper jejunum, with broadening and blunting of the villi, shortening of the microvilli, vacuolization of the lining epithelium, crypt hyperplasia, and infiltration of the lamina propria by polymorphonuclear cells and lymphocytes. The lesions persist for at least 4 days after the resolution of symptoms and are associated with malabsorption of carbohydrates and fats and a decreased level of brush-border enzymes. Adenylate cyclase activity is not altered. No histopathologic changes are seen in the stom-

TABLE 174-1 Viral Causes of Gastroenteritis among Humans

Virus	Family	Genome	Primary Age Group at Risk	Clinical Severity	Detection Assays[a]
Group A rotavirus	Reoviridae	Double-strand segmented RNA	Children <5 years	+++	EM, EIA (commercial), PAGE, RT-PCR
Norovirus	Caliciviridae	Positive-sense single-strand RNA	All ages	++	EM, EIA, RT-PCR
Sapovirus	Caliciviridae	Positive-sense single-strand RNA	Children <5 years	+	EM, EIA, RT-PCR
Astrovirus	Astroviridae	Positive-sense single-strand RNA	Children <5 years	+	EM, EIA, RT-PCR
Adenovirus (types 40 and 41)	Adenoviridae	Double-strand DNA	Children <5 years	+/++	EM, EIA (commercial), RT-PCR

[a] EIA, enzyme immunoassay; EM, electron microscopy; PAGE, polyacrylamide gel electrophoresis; RT-PCR, reverse-transcriptase polymerase chain reaction.

ach or colon, but gastric motor function is delayed, and this alteration is believed to contribute to the nausea and vomiting that are typical of this illness.

Clinical Manifestations Gastroenteritis caused by Norwalk and related human caliciviruses has a sudden onset, following an average incubation period of 24 h (range, 12 to 72 h). The illness generally lasts 12 to 60 h and is characterized by one or more of the following symptoms: nausea, vomiting, abdominal cramps, and diarrhea. Vomiting is more prevalent among children, whereas a greater proportion of adults develop diarrhea. Constitutional symptoms are common, including headache, fever, chills, and myalgias. Noroviruses appear to cause more severe illness than sapoviruses, although both illnesses are less severe than that due to rotavirus. The stools are characteristically loose and watery, without blood, mucus, or leukocytes. White cell counts are generally normal; rarely, leukocytosis with relative lymphopenia may be observed. Death is a rare outcome and usually results from severe dehydration in vulnerable persons (e.g., elderly patients with debilitating health conditions).

Immunity Approximately 50% of persons challenged with Norwalk virus become ill and acquire short-term immunity against the infecting strain. Immunity to Norwalk virus appears to correlate inversely with level of antibody; i.e., persons with higher levels of preexisting antibody to Norwalk virus are more susceptible to illness. This observation suggests that some individuals have a genetic predisposition to illness. Recent data indicate that specific ABO, Lewis, and secretor blood group phenotypes may influence susceptibility to Norwalk virus infection.

TABLE 174-2 *Characteristics of Gastroenteritis Caused by Viral and Bacterial Agents*

Feature	Viral Gastroenteritis	Bacterial Gastroenteritis
Setting	Incidence similar in developing and developed countries	More common in settings with poor hygiene and sanitation
Infectious dose	Low (10–100 viral particles) for most agents	High ($>10^5$ bacteria) for *Escherichia coli*, *Salmonella*, *Vibrio*; medium (10^2–10^5 bacteria) for *Campylobacter jejuni*; low (10–100 bacteria) for *Shigella*
Seasonality	In temperate climates, winter seasonality for most agents; year-round occurrence in tropical areas	More common in summer or rainy months, particularly in developing countries with a high disease burden
Incubation period	1–3 days for most agents; can be shorter for norovirus	1–7 days for common agents (e.g., *Campylobacter*, *E. coli*, *Shigella*, *Salmonella*); few hours for bacteria producing preformed toxins (e.g., *Staphylococcus aureus*, *Bacillus cereus*)
Reservoir	Primarily humans	Depending on species, both human (e.g., *Shigella*, *Salmonella*) and animal (e.g., *Campylobacter*, *Salmonella*, *E. coli*) reservoirs exist.
Fever	Common with rotavirus and norovirus; uncommon with other agents	Common with agents causing inflammatory diarrhea (e.g., *Salmonella*, *Shigella*)
Vomiting	Prominent and can be the only presenting feature, especially in children	Common with bacteria producing preformed toxins; less prominent in diarrhea due to other agents
Diarrhea	Common; nonbloody in almost all cases	Prominent and frequently bloody with agents causing inflammatory diarrhea
Duration	1–3 days for norovirus and sapovirus; 2–8 days for other viruses	1–2 days for bacteria producing preformed toxins; 2–8 days for most other bacteria
Diagnosis	This is often a diagnosis of exclusion in clinical practice. Commercial enzyme immunoassays are available for detection of rotavirus and adenovirus, but identification of other agents is limited to research and public health laboratories.	Fecal examination for leukocytes and blood is helpful in differential diagnosis. Culture of stool specimens, sometimes on special media, can identify several pathogens. Molecular techniques are useful epidemiologic tools but are not routinely used in most laboratories.
Treatment	Supportive therapy to maintain adequate hydration and nutrition should be given. Antibiotics and antimotility agents are contraindicated.	Supportive hydration therapy is adequate for most patients. Antibiotics are recommended for patients with dysentery caused by *Shigella* or *Vibrio cholerae* and for some patients with *Clostridium difficile* colitis.

Diagnosis Cloning and sequencing of the genome of Norwalk and several other human caliciviruses have allowed the development of assays based on polymerase chain reaction (PCR) for detection of virus in stool and vomitus. Virus-like particles produced by expression of capsid proteins in a recombinant baculovirus vector have been used to develop enzyme immunoassays (EIAs) for detection of virus in stool or a serologic response to a specific viral antigen. These newer diagnostic techniques are considerably more sensitive than previous detection methods such as electron microscopy, immune electron microscopy, and EIAs based on reagents derived from humans. However, no currently available single assay can detect all human caliciviruses because of their great genetic and antigenic diversity. In addition, the assays are still cumbersome and are available primarily in research laboratories, although they are increasingly being adopted by public health laboratories for routine screening of fecal specimens from patients affected by outbreaks of gastroenteritis.

TREATMENT

Treatment generally is not required because the disease is self-limited. If severe dehydration develops, oral or intravenous fluid therapy is indicated. No specific antiviral therapy is available.

Prevention Epidemic prevention relies on situation-specific measures, such as control of contamination of food and water, exclusion of ill food handlers, and reduction of person-to-person spread through good personal hygiene and disinfection of contaminated fomites. The role of immunoprophylaxis is not clear, given the lack of long-term immunity from natural disease and the paradoxic inverse association between the level of immune response and protection from disease.

ROTAVIRUS ■ Etiologic Agent Rotaviruses are members of the family Reoviridae. The viral genome consists of 11 segments of double-strand RNA that are enclosed in a triple-layered, nonenveloped, icosahedral capsid 75 nm in diameter. Viral protein 6 (VP6), the major structural protein, is the target of commercial immunoassays and determines the group specificity of rotaviruses. There are seven major groups of rotavirus (A through G); human illness is caused primarily by group A and, to a much lesser extent, by groups B and C. Two outer-capsid proteins, VP7 (G-protein) and VP4 (P-protein), determine serotype specificity, induce neutralizing antibodies, and form the basis of the binary classification of rotaviruses (G and P types). The segmented genome of rotavirus allows genetic reassortment (i.e., exchange of genome segments between viruses) during co-infection—a property that may play a role in viral evolution and has been utilized in the development of reassortant animal-human rotavirus–based vaccines.

Epidemiology Nearly all children are infected with rotavirus by 3 to 5 years of age. Neonatal infections are common but are often asymptomatic or mild, presumably because of protection from maternal antibody or breast-feeding. Nevertheless, rotavirus is known to cause disease in neonates, particularly in those admitted to intensive care units, and some data suggest that the clinical manifestations in full-

term infants may differ from those in preterm infants. First infections after 3 months of age are likely to be symptomatic, and the incidence of disease peaks among children 4 to 23 months of age. Reinfections are common, but the severity of disease decreases with each repeat infection. Therefore, severe rotavirus infections are relatively uncommon in older children and adults. However, rotavirus can cause illness in parents and caretakers of children with rotavirus diarrhea, immunocompromised persons, travelers, and elderly individuals and should be considered in the differential diagnosis of gastroenteritis among adults.

In temperate climates, rotavirus disease occurs predominantly during the cooler fall and winter months. In the United States, the annual rotavirus epidemic begins in the Southwest in autumn (October through December) and migrates across the continent, peaking in the Northeast during spring (March through May). In tropical settings, rotavirus disease occurs year-round, with less pronounced seasonal peaks.

Rotavirus gastroenteritis is more frequently associated with dehydration than is gastroenteritis caused by other pathogens. Therefore, the proportion of gastroenteritis cases that are attributable to rotavirus increases with increasing severity of illness, ranging from a median of 8% of cases in the community to 18% of cases in outpatients and 30% of cases in hospitalized patients. Each year, rotavirus is estimated to cause ~500,000 childhood deaths worldwide.

During episodes of rotavirus-associated diarrhea, virus is shed in large quantities (10^7 to 10^{12}/g) in stool. Viral shedding detectable by EIA usually subsides within a week but may persist for >30 days in immunocompromised individuals. Viral shedding may be detected for longer periods by sensitive molecular assays, such as PCR. The virus is transmitted predominantly through the fecal-oral route. Spread through respiratory secretions, person-to-person contact, or contaminated environmental surfaces has also been postulated to explain the rapid acquisition of antibody in the first 3 years of life, regardless of sanitary conditions.

At least 10 different G serotypes of group A rotavirus have been identified in humans, but only 5 types (G1 through G4 and G9) are common. While human rotavirus strains that possess a high degree of genetic homology with animal strains have been identified, animal-to-human transmission appears to be uncommon. Group B rotaviruses have been associated with several large epidemics of severe gastroenteritis among adults in China since 1982 and have recently been identified in India but not in other parts of the world. Group C rotaviruses have been associated with a small proportion of pediatric gastroenteritis cases in several countries worldwide.

Pathogenesis Rotaviruses infect and ultimately destroy the mature enterocytes in the villous epithelium of the proximal small intestine. The loss of absorptive villous epithelium coupled with the proliferation of secretory crypt cells results in secretory diarrhea. Brush-border enzymes characteristic of differentiated cells are reduced, and this change leads to the accumulation of unmetabolized disaccharides and consequent osmotic diarrhea. Studies in mice indicate that a nonstructural rotavirus protein, NSP4, functions as an enterotoxin and contributes to secretory diarrhea by altering epithelial cell function and permeability. In addition, rotavirus may evoke fluid secretion through activation of the enteric nervous system in the intestinal wall. Recent data indicate that rotavirus antigen and RNA are present in serum of children with acute rotavirus infection; further investigations are needed to establish the significance of these findings in the pathogenesis of rotavirus disease.

Clinical Manifestations The clinical spectrum of rotavirus infection ranges from subclinical illness to severe gastroenteritis leading to the development of life-threatening dehydration. After an incubation period of 1 to 3 days, the illness has an abrupt onset, with vomiting frequently preceding the onset of diarrhea. Up to one-third of patients may have a temperature of >39°C. The stools are characteristically loose and watery and only infrequently contain red or white cells. The gastrointestinal symptoms generally resolve in 3 to 7 days.

Respiratory and neurologic features in children with rotavirus infection have been reported, but causal associations have not been proven. Rotavirus infection has been associated with a variety of other clinical syndromes (e.g., sudden infant death syndrome, necrotizing enterocolitis, intussusception, and diabetes mellitus type 1), but no causal relationship has been confirmed with any of these syndromes.

Rotavirus does not appear to be a major opportunistic pathogen in children with HIV infection. In severely immunodeficient children, rotavirus can cause protracted diarrhea with prolonged viral excretion and, in rare instances, can disseminate systemically. Persons who are immunosuppressed for bone marrow transplantation are also at risk for severe, or even fatal, rotavirus disease.

Immunity Protection against rotavirus disease is correlated with the presence of virus-specific secretory IgA antibodies in the intestine and, to some extent, the serum. Because virus-specific IgA production at the intestinal surface is short-lived, complete protection against disease is only temporary. However, each infection and subsequent reinfection confers progressively greater immunity, so severe disease is most common among young children with first or second infections. Immunologic memory is believed to be important in the attenuation of the severity of disease upon reinfection.

Diagnosis Illness caused by rotavirus is difficult to distinguish clinically from that caused by other enteric viruses. Because large quantities of virus are shed in feces, the diagnosis can usually be confirmed by a wide variety of commercially available EIAs or by techniques for detecting viral RNA, such as gel electrophoresis, probe hybridization, or PCR.

Rx TREATMENT

Rotavirus gastroenteritis can lead to severe dehydration. Thus appropriate treatment should be instituted early. Standard oral rehydration therapy is successful in most children who can take oral fluids, but intravenous fluid replacement may be required for patients who are severely dehydrated or are unable to tolerate oral therapy because of frequent vomiting. The therapeutic role of probiotics, bismuth salicylate, and enkephalinase inhibitors has been evaluated in clinical studies but is not clearly defined. Antibiotics and antimotility agents should be avoided. In immunocompromised children with chronic symptomatic rotavirus disease, orally administered immunoglobulins or colostrum may resolve symptoms, but the choice of agents and their doses have not been well studied and are often empirical.

Prevention Efforts to develop rotavirus vaccines were pursued because it was apparent—given the similar rates in less developed and industrialized nations—that improvements in hygiene and sanitation were unlikely to reduce disease incidence. In 1998, a rotavirus vaccine was licensed in the United States and was recommended for routine immunization of infants. However, this vaccine was withdrawn in 1999 because it was causally linked with intussusception, with an estimated 1 case per 11,000 vaccinated infants. Other rotavirus vaccines are being developed, including two leading multinational candidate vaccines whose safety and efficacy are currently being studied in large-scale clinical trials.

OTHER VIRAL AGENTS OF GASTROENTERITIS Enteric adenoviruses of serotypes 40 and 41 belonging to subgroup F are 70- to 80-nm viruses with double-strand DNA that cause ~2 to 12% of all diarrhea episodes in young children. Unlike adenoviruses that cause respiratory illness, enteric adenoviruses are difficult to cultivate in cell lines, but they can be detected with commercially available EIAs.

Astroviruses, 28- to 30-nm viruses with a characteristic icosahedral structure, contain a positive-sense, single-strand RNA. At least seven serotypes have been identified, of which serotype 1 is most common. Astroviruses are primarily pediatric pathogens, causing ~2 to 10% of cases of mild to moderate gastroenteritis in children. The availability

of simple immunoassays to detect virus in fecal specimens and of molecular methods to confirm and characterize strains will permit more comprehensive assessment of the etiologic role of these agents.

Toroviruses are 100- to 140-nm, enveloped, positive-strand RNA viruses that are recognized as causes of gastroenteritis in horses (Berne virus) and cattle (Breda virus). Their role as a cause of diarrhea in humans is still unclear, but a study from Canada demonstrated an association between torovirus excretion and nosocomial gastroenteritis in pediatric patients. In this study, more than half of the patients with torovirus in stool also had a demonstrable immune response. Patients with torovirus infection were older and experienced less vomiting and more bloody diarrhea than did those with rotavirus or astrovirus infection. Further studies are required to confirm these findings.

Picobirnaviruses are small, bi-segmented, double-strand RNA viruses that cause gastroenteritis in a variety of animals. Their role as primary causes of gastroenteritis in humans remains unclear, but several studies have found an association between picobirnaviruses and gastroenteritis in HIV-infected adults.

The recently recognized severe acute respiratory syndrome–associated coronavirus (SARS-CoV) has been associated with gastroenteritis in 20 to 66% of affected patients. In one study of 138 SARS patients in Hong Kong, 20.3% presented with watery diarrhea, and up to 38.4% had diarrhea during their illness. Diarrhea was most common during the first week of illness, lasted for an average of 3.7 days, and was self-limiting in most instances. Studies of intestinal biopsy specimens showed minimal architectural disruption but also revealed active viral replication within both the small and the large intestine. SARS-CoV RNA could be detected in the stool of patients for >10 weeks after the onset of symptoms.

Several other viruses (e.g., enteroviruses, reoviruses, pestiviruses, and parvoviruses B) have been identified in the feces of patients with diarrhea, but their etiologic role in gastroenteritis has not been proved.

175 ENTEROVIRUSES AND REOVIRUSES

Jeffrey I. Cohen

ENTEROVIRUSES

CLASSIFICATION AND CHARACTERIZATION Enteroviruses are so named because of their ability to multiply in the gastrointestinal tract. Despite their name, these viruses are not a prominent cause of gastroenteritis. Enteroviruses encompass 64 human serotypes: 3 serotypes of poliovirus, 23 serotypes of coxsackievirus A, 6 serotypes of coxsackievirus B, 28 serotypes of echovirus, and enteroviruses 68 through 71. Enterovirus surveillance conducted in the United States by the Centers for Disease Control and Prevention (CDC) in 2000 and 2001 revealed that echoviruses accounted for >60% of all enterovirus isolates (Table 175-1).

Human enteroviruses contain a single-stranded RNA genome surrounded by an icosahedral capsid comprising four viral proteins. These viruses have no lipid envelope and are stable in acidic environments, including the stomach. They are resistant to inactivation by standard disinfectants (e.g., alcohol, detergents) and can persist for days at room temperature.

PATHOGENESIS AND IMMUNITY Much of what is known about the pathogenesis of enteroviruses has been derived from studies of poliovirus infection. After ingestion, poliovirus is thought to infect epithelial cells in the mucosa of the gastrointestinal tract and then to spread to and replicate in the submucosal lymphoid tissue of the tonsils and Peyer's patches. The virus next spreads to the regional lymph nodes, a viremic phase ensues, and the virus replicates in organs of the reticuloendothelial system. In some cases, a second viremia occurs and the virus replicates further in various tissues, sometimes causing symptomatic disease.

It is uncertain whether poliovirus reaches the central nervous system (CNS) during viremia or whether it also spreads via peripheral nerves. Since viremia precedes the onset of neurologic disease in humans and in experimentally infected chimpanzees, it has been assumed that the virus enters the CNS via the bloodstream. The poliovirus receptor is a member of the immunoglobulin superfamily. Poliovirus infection is limited to primates, largely because of the ability of their cells to express the viral receptor. Studies demonstrating the poliovirus receptor in the end-plate region of muscle at the neuromuscular junction suggest that, if the virus enters the muscle during viremia, it could travel across the neuromuscular junction up the axon to the anterior horn cells. Studies of monkeys or transgenic mice expressing the poliovirus receptor show that, after intramuscular injection, poliovirus does not reach the spinal cord if the sciatic nerve is cut. Taken together, these findings suggest that poliovirus can spread directly from muscle to the CNS by neural pathways. Intercellular adhesion molecule 1 (ICAM-1) is a receptor for coxsackieviruses A13, A18, and A21; CAR for coxsackievirus B; VLA-2 integrin for echovirus types 1 and 8; and CD55 for enterovirus 70 and some serotypes of coxsackievirus B and echovirus.

Poliovirus can usually be cultured from the blood 3 to 5 days after infection, before the development of neutralizing antibodies. While viral replication at secondary sites begins to slow 1 week after infection, it continues in the gastrointestinal tract. Poliovirus is shed from the oropharynx for up to 3 weeks after infection and from the gastrointestinal tract for as long as 12 weeks; immunodeficient patients can shed poliovirus for more than 1 year. During replication in the gastrointestinal tract, attenuated oral poliovirus can mutate, reverting to a more neurovirulent phenotype within a few days. The clinical significance of this increased neurovirulence is unknown.

TABLE 175-1 *Frequency of the Most Common Non-Poliovirus Isolates of Enterovirus in the United States, 2000–2001*

Serotype	Percentage
Echovirus 18	22.0
Echovirus 13	20.8
Coxsackievirus B5	11.9
Coxsackievirus B2	6.3
Echovirus 6	6.1
Echovirus 11	4.5
Coxsackievirus A9	4.0
Echovirus 9	3.3
Coxsackievirus B4	3.2
Echovirus 4	3.1
All others	15.0

Humoral and secretory immunity in the gastrointestinal tract is important for the control of enterovirus infections. Enteroviruses induce specific IgM, which usually persists for <6 months, and specific IgG, which persists for life. Capsid protein VP1 is the predominant target of neutralizing antibody, which generally confers lifelong protection against subsequent disease caused by the same serotype but does not prevent infection or virus shedding. Enteroviruses also induce cellular immunity, but the significance of this mechanism in limiting infection is uncertain. Patients with impaired cellular immunity are not known to develop unusually severe disease when infected with enteroviruses. In contrast, the severe infections in patients with agammaglobulinemia emphasize the importance of humoral immunity in controlling enterovirus infections. IgA antibodies are instrumental in reducing poliovirus replication in and shedding from the gastrointestinal tract. Breast milk contains IgA specific for enteroviruses and can protect humans from infection.

EPIDEMIOLOGY Enteroviruses have a worldwide distribution. More than 50% of nonpoliovirus enterovirus infections and more than 90% of poliovirus infections are subclinical. When symptoms do develop, they are usually nonspecific and occur in conjunction with fever; only a minority of infections are associated with specific clinical syndromes. The incubation period for most enterovirus infections ranges from 2 to 14 days but usually is <1 week.

Enterovirus infection is more common in socioeconomically disadvantaged areas, especially in those where conditions are crowded and in tropical areas where hygiene is poor. Infection is most common among infants and young children; serious illness develops most often during the first few days of life and in older children and adults. In developing countries, where children are infected at an early age, poliovirus infection has less often been associated with paralysis; in countries with better hygiene, older children and adults are more likely to be seronegative, become infected, and develop paralysis. Passively acquired maternal antibody reduces the risk of symptomatic infection in neonates. Young children are the most frequent shedders of enteroviruses and are usually the index cases in family outbreaks. In temperate climates, enterovirus infections occur most often in the summer and fall; no seasonal pattern is apparent in the tropics.

Most enteroviruses are transmitted primarily by the fecal-oral route from fecally contaminated fingers or inanimate objects. Patients are most infectious shortly before and after the onset of symptomatic disease, when virus is present in the stool and throat. The ingestion of virus-contaminated food or water can also cause disease. Certain enteroviruses (such as enterovirus 70, which causes acute hemorrhagic conjunctivitis) can be transmitted by direct inoculation from the fingers to the eye. Airborne transmission is important for some viruses that cause respiratory tract disease, such as coxsackievirus A21. Enteroviruses can be transmitted across the placenta from mother to fetus, causing severe disease in the newborn. The transmission of enteroviruses through blood transfusions or insect bites has not been documented. Nosocomial spread of coxsackievirus and echovirus has taken place in hospital nurseries.

CLINICAL FEATURES OF INFECTION WITH POLIOVIRUS Most infections with poliovirus are asymptomatic. After an incubation period of 3 to 6 days, ~5% of patients present with a minor illness (abortive poliomyelitis) manifested by fever, malaise, sore throat, anorexia, myalgias, and headache. This condition usually resolves in 3 days. About 1% of patients present with aseptic meningitis (nonparalytic poliomyelitis). Examination of cerebrospinal fluid (CSF) reveals lymphocytic pleocytosis, a normal glucose level, and a normal or slightly elevated protein level; CSF polymorphonuclear leukocytes may be present early. In some patients, especially children, malaise and fever precede the onset of aseptic meningitis.

The least common presentation is that of paralytic disease. After one or several days, signs of aseptic meningitis are followed by severe back, neck, and muscle pain and by the rapid or gradual development of motor weakness. In some cases the disease appears to be biphasic, with aseptic meningitis followed first by apparent recovery but then (1 or 2 days later) by the return of fever and the development of paralysis; this form is more common among children than among adults. Weakness is generally asymmetric, is proximal more than distal, and may involve the legs (most commonly); the arms; or the abdominal, thoracic, or bulbar muscles. Paralysis develops during the febrile phase of the illness and usually does not progress after defervescence. Urinary retention may also occur. Examination reveals weakness, fasciculations, decreased muscle tone, and reduced or absent reflexes in affected areas. Transient hyperreflexia sometimes precedes the loss of reflexes. Patients frequently report sensory symptoms, but objective sensory testing usually yields normal results. Bulbar paralysis may lead to dysphagia, difficulty in handling secretions, or dysphonia. Respiratory insufficiency due to aspiration, involvement of the respiratory center in the medulla, or paralysis of the phrenic or intercostal nerves may develop, and severe medullary involvement may lead to circulatory collapse. Most patients with paralysis recover some function weeks to months after infection. About two-thirds of patients have residual neurologic sequelae.

Paralytic disease is more common among older individuals, pregnant women, and persons exercising strenuously or undergoing trauma at the time of CNS symptoms. Tonsillectomy predisposes to bulbar poliomyelitis, and intramuscular injections increase the risk of paralysis in the involved limb(s).

Until recently, poliomyelitis due to live poliovirus vaccine occurred in the United States. The risk of developing poliomyelitis after oral vaccination is estimated at 1 case per 2.5 million doses. The risk is ~2000 times higher among immunodeficient persons, especially in persons with hypo- or agammaglobulinemia. Before 1997, an average of eight cases of vaccine-associated poliomyelitis occurred—in both vaccinees and their contacts—in the United States each year. With the change in recommendations first to a sequential regimen of inactivated poliovirus vaccine (IPV) and oral poliovirus vaccine (OPV) in 1997 and then to an all-IPV regimen in 2000, the number of cases of vaccine-associated poliovirus declined. From 1997 to 1999, six such cases were reported in the United States; no cases have been reported since 1999.

The *postpolio syndrome* presents as a new onset of weakness, fatigue, fasciculations, and pain with additional atrophy of the muscle group involved during the initial paralytic disease 20 to 40 years earlier. The syndrome is more common among women and with increasing time after acute disease. The onset is usually insidious, and weakness occasionally extends to muscles that were not involved during the initial illness. The prognosis is generally good; progression to further weakness is usually slow, with plateau periods that range from 1 to 10 years. The postpolio syndrome is thought to be due to progressive dysfunction and loss of motor neurons that compensated for the neurons lost during the original infection and not to persistent or reactivated poliovirus infection.

CLINICAL FEATURES OF INFECTION WITH COXSACKIEVIRUS, ECHOVIRUS, AND OTHER ENTEROVIRUSES An estimated 5 to 10 million cases of symptomatic disease due to enterovirus other than poliovirus occur in the United States each year. Enteroviruses are the most common cause of aseptic meningitis and nonspecific febrile illnesses of neonates. Certain clinical syndromes are more likely to be caused by certain serotypes (Table 175-2), but there is much overlap. In 2000–2001, 85% of enterovirus infections were caused by only 10 of the 64 human serotypes. Echoviruses 13 and 18 accounted for 43% of recognized enterovirus infections (Table 175-1).

Nonspecific Febrile Illness (Summer Grippe) The most common clinical manifestation of enterovirus infection is a nonspecific febrile illness. After an incubation period of 3 to 6 days, patients present with an acute onset of fever, malaise, and headache. Occasional cases are associated with upper respiratory symptoms, and some cases include nausea and vomiting. Symptoms often last for 3 to 4 days, and most cases resolve in a week. While infections with other respiratory viruses

occur more often from late fall to early spring, enterovirus febrile illness frequently occurs in the summer and early fall.

TABLE 175-2 *Manifestations Commonly Associated with Enterovirus Serotypes*

Manifestation	Serotype(s) of Indicated Virus	
	Coxsackievirus	Echovirus (E) and Enterovirus (Ent)
Acute hemorrhagic conjunctivitis	A24	E70
Aseptic meningitis	A2, 4, 7, 9, 10; B1-5	E4, 6, 7, 9, 11, 13, 16, 18, 19, 30, 33; Ent70, 71
Encephalitis	A9; B1-5	E3, 4, 6, 9, 11, 25, 30; Ent71
Exanthem	A4, 5, 9, 10, 16; B1, 3-5	E4-7, 9, 11, 16-19, 25, 30; Ent71
Generalized disease of the newborn	B2-5	E4-6, 9, 11, 14, 16, 19
Hand-foot-and-mouth disease	A5, 7, 9, 10, 16; B2, 5	Ent71
Herpangina	A1-10, 16, 22; B1-5	E6, 9, 11, 16, 17, 25; Ent71
Myocarditis, pericarditis	A4, 9, 16; B1-5	E6, 9, 11, 22
Paralysis	A4, 7, 9; B1-5	E2, 4, 6, 9, 11, 30; Ent70, 71
Pleurodynia	A1, 2, 4, 6, 9, 10, 16; B1-6	E1-3, 6, 7, 9, 11, 12, 14, 16, 19, 24, 25, 30
Pneumonia	A9, 16; B1-5	E6, 7, 9, 11, 12, 19, 20, 30; Ent68, 71

Generalized Disease of the Newborn Most serious enterovirus infections in infants develop during the first week of life, although severe disease can occur up to 3 months of age. Neonates often present with an illness resembling bacterial sepsis, with fever, irritability, and lethargy. Laboratory abnormalities include leukocytosis with a left shift, thrombocytopenia, elevated values in liver function tests, and CSF pleocytosis. The illness can be complicated by myocarditis and hypotension, fulminant hepatitis and disseminated intravascular coagulation, meningitis or meningoencephalitis, or pneumonia. It may be difficult to distinguish enterovirus infection from bacterial sepsis, although a history of a recent virus-like illness in the mother provides a clue.

Aseptic Meningitis and Encephalitis Enteroviruses are the cause of up to 90% of cases of aseptic meningitis in children and young adults in which an etiologic agent can be identified. Patients with aseptic meningitis typically present with an acute onset of fever, chills, headache, photophobia, and pain on eye movement. Nausea and vomiting are also common. Examination reveals meningismus without localizing neurologic signs; drowsiness or irritability may also be apparent. In some cases, a febrile illness may be reported that remits but returns several days later in conjunction with signs of meningitis. Other systemic manifestations may provide clues to an enteroviral cause, including diarrhea, myalgias, rash, pleurodynia, myocarditis, and herpangina. Examination of the CSF invariably reveals pleocytosis; early in the course, polymorphonuclear leukocytes may be present or even predominant, raising the possibility of bacterial or other nonviral causes of meningitis. Partially treated bacterial meningitis may be particularly difficult to exclude in some instances. A useful rule is that the CSF cell count in enteroviral meningitis shows a shift to lymphocytic predominance within 24 h of presentation, and the total count generally does not exceed 1000 cells/μL. Additional CSF findings consist of a normal glucose content and a normal or only slightly elevated (by $\leq$100 mg/mL) level of protein. Enteroviruses and mumps virus may produce a similar picture of meningitis; a low CSF glucose level suggests mumps, whereas a normal CSF glucose level and transient CSF polymorphonuclear pleocytosis suggest enterovirus infection. Enteroviral meningitis is more frequent in summer and fall in temperate climates, while viral meningitis of other etiologies (e.g., mumps) is more common in winter and spring. Symptoms ordinarily resolve within a week, although CSF abnormalities can persist for several weeks. Enteroviral meningitis is often more severe in adults than in children. Neurologic sequelae are rare, and most patients have an excellent prognosis.

Enteroviral encephalitis is much less common than enteroviral aseptic meningitis. Occasional highly inflammatory cases of enteroviral meningitis may be complicated by a mild form of encephalitis that is recognized on the basis of progressive lethargy, disorientation, and sometimes seizures. Less commonly, severe primary encephalitis may develop. It is estimated that 10 to 20% of cases of viral encephalitis are due to enteroviruses. Immunocompetent patients generally have a good prognosis.

Patients with hypo- or agammaglobulinemia or severe combined immunodeficiency may develop chronic meningitis or encephalitis; about half of these patients have a dermatomyositis-like syndrome, with peripheral edema, rash, and myositis. They may also have chronic hepatitis. Patients may develop neurologic disease while receiving gamma globulin replacement therapy. Echoviruses (especially echovirus 11) are the most common pathogens in this situation.

Paralytic disease due to enteroviruses other than poliovirus occurs sporadically and is usually less severe than poliomyelitis. Most cases are due to enterovirus 70 or 71 or to coxsackievirus A7 or A9. Guillain-Barré syndrome is also associated with enterovirus infection. While some studies have suggested a link between enteroviruses and the chronic fatigue syndrome, most recent studies have not demonstrated such an association.

Pleurodynia (Bornholm Disease) Patients with pleurodynia present with an acute onset of fever and spasms of pleuritic chest or upper abdominal pain. Chest pain is more common in adults, and abdominal pain is more common in children. Paroxysms of severe, knifelike pain usually last 15 to 30 min and are associated with diaphoresis and tachypnea. Fever peaks within an hour after the onset of paroxysms and subsides when pain resolves. The involved muscles are tender to palpation, and a pleural rub may be detected. The white blood cell count and chest x-ray are usually normal. Most cases are due to coxsackievirus B and occur during epidemics. Symptoms resolve in a few days, and recurrences are rare. Treatment includes the administration of nonsteroidal anti-inflammatory agents or the application of heat to the affected muscles.

Myocarditis and Pericarditis Enteroviruses are estimated to cause up to one-third of cases of acute myocarditis. Coxsackievirus B and its RNA have been detected in pericardial fluid and myocardial tissue in some cases of acute myocarditis and pericarditis. Most cases of enteroviral myocarditis or pericarditis occur in newborns, adolescents, or young adults. More than two-thirds of patients are male. Patients often present with an upper respiratory tract infection that is followed by fever, chest pain, dyspnea, arrhythmias, and occasionally heart failure. A pericardial friction rub is documented in half of cases, and the electrocardiogram shows ST segment elevations or ST- and T-wave abnormalities. Serum levels of myocardial enzymes are often elevated. Neonates commonly have severe disease, while most older children and adults recover completely. Up to 10% of cases progress to chronic dilated cardiomyopathy. Chronic constrictive pericarditis may also be a sequela.

Exanthems Enterovirus infection is the leading cause of exanthems in children in the summer and fall. While exanthems are associated with many enteroviruses, certain types have been linked to specific syndromes. Echoviruses 9 and 16 have frequently been associated with exanthem and fever. Rashes may be discrete (rubelliform) or confluent (morbilliform), beginning on the face and spreading to the trunk and extremities. Echovirus 9 is the most common cause of rubelliform rash. Unlike the rash of rubella, the enteroviral rash occurs in the summer and is not associated with lymphadenopathy. Roseola-like rashes develop after defervescence, with macules and papules on the face and trunk. The Boston exanthem, caused by echovirus 16, is a roseola-like rash that often affects multiple members of a family. A variety of other rashes have been associated with enteroviruses, in-

cluding erythema multiforme and vesicular, urticarial, petechial, or purpuric lesions. Enanthems also occur, including lesions that resemble the Koplik's spots seen with measles.

Hand-Foot-and-Mouth Disease After an incubation period of 4 to 6 days, patients with hand-foot-and-mouth disease present with fever, anorexia, and malaise; these manifestations are followed by the development of sore throat and vesicles (Fig. 175-1) on the buccal mucosa and often on the tongue and then by the appearance of tender vesicular lesions on the dorsum of the hands, sometimes with involvement of the palms. The vesicles may form bullae and quickly ulcerate. About one-third of patients also have lesions on the palate, uvula, or tonsillar pillars, and one-third have a rash on the feet (including the soles) or on the buttocks. The disease is highly infectious, with attack rates of close to 100% among young children. The lesions usually resolve in 1 week. Most cases are due to coxsackievirus A16 or enterovirus 71.

An epidemic of enterovirus 71 infection in Taiwan in 1998 resulted in thousands of cases of hand-foot-and-mouth disease or herpangina. Severe complications included CNS disease, myocarditis, and pulmonary hemorrhage. About 90% of those who died were children ≤5 years old, and these deaths were associated with pulmonary edema or pulmonary hemorrhage. CNS disease included aseptic meningitis, flaccid paralysis (similar to poliomyelitis), or rhombencephalitis with myoclonus and tremor or ataxia. The mean age of patients with CNS complications was 2.5 years, and magnetic resonance imaging in cases with encephalitis usually showed brain-stem lesions.

Herpangina Herpangina is usually caused by coxsackievirus A and presents as acute-onset fever, sore throat, dysphagia, and grayish-white papulovesicular lesions on an erythematous base that ulcerate. The lesions can persist for weeks; are present on the soft palate, anterior pillars of the tonsils, and uvula; and are concentrated in the posterior portion of the mouth. In contrast to herpes stomatitis, enteroviral herpangina is not associated with gingivitis. Acute lymphonodular pharyngitis associated with coxsackievirus A10 presents as white or yellow nodules surrounded by erythema in the posterior oropharynx. The lesions do not ulcerate.

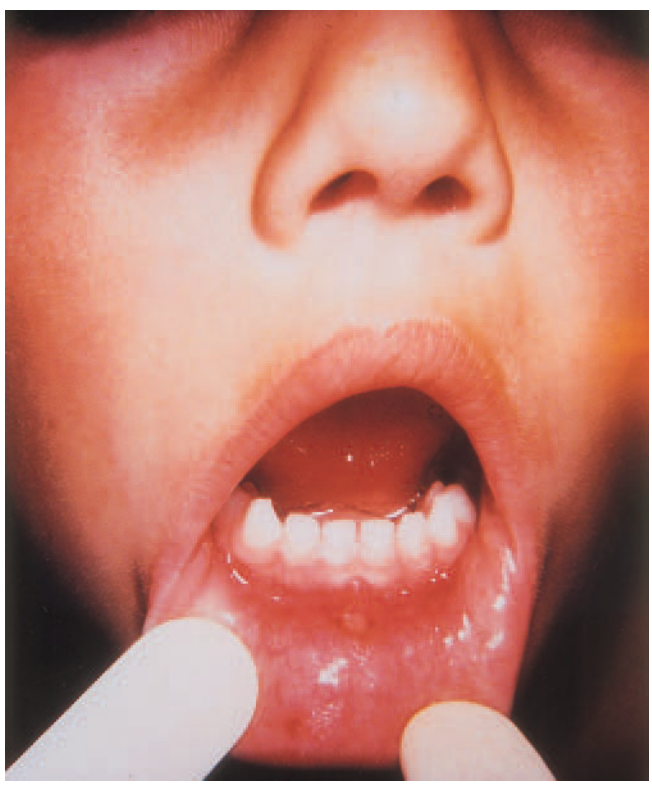

FIGURE 175-1 Tender vesicles and erosions in the mouth of a patient with hand-foot-and-mouth disease.

Acute Hemorrhagic Conjunctivitis Patients with acute hemorrhagic conjunctivitis present with an acute onset of severe eye pain, blurred vision, photophobia, and watery discharge from the eye. Examination reveals edema, chemosis, and subconjunctival hemorrhage and often shows punctate keratitis and conjunctival follicles as well. Preauricular adenopathy is often found. Epidemics and nosocomial spread have been associated with enterovirus 70 and coxsackievirus A24. Systemic symptoms, including headache and fever, develop in 20% of cases, and recovery is usually complete in 10 days. The sudden onset and short duration of the illness help to distinguish acute hemorrhagic conjunctivitis from other ocular infections such as those due to adenovirus and *Chlamydia*. Paralysis has been associated with some cases of acute hemorrhagic conjunctivitis due to enterovirus 70 during epidemics.

Other Manifestations Enteroviruses are an infrequent cause of childhood pneumonia and the common cold. Coxsackievirus B has been isolated at autopsy from the pancreas of a few children presenting with insulin-dependent diabetes mellitus; however, most attempts to isolate the virus have been unsuccessful. Other diseases that have been associated with enterovirus infection include parotitis, bronchitis, bronchiolitis, croup, infectious lymphocytosis, polymyositis, acute arthritis, and acute nephritis.

DIAGNOSIS Isolation of enterovirus in cell culture is the most common procedure for the diagnosis of infection. While cultures of stool, nasopharyngeal, or throat samples from patients with enterovirus diseases are often positive, isolation of the virus from these sites does not prove that it is directly associated with disease because these sites are frequently colonized for weeks in patients with subclinical infections. Isolation of virus from the throat is more likely to be associated with disease than isolation from the stool since virus is shed for shorter periods from the throat. Cultures of CSF, serum, fluid from body cavities, or tissues are positive less frequently, but a positive result is indicative of disease caused by enterovirus. In some cases the virus can be isolated only from the blood or only from the CSF; therefore, it is important to culture multiple sites. Cultures are more likely to be positive earlier than later in the course of infection. Most human enteroviruses can be detected within a week after inoculation of cell cultures. Cultures may be negative because of the presence of neutralizing antibody, lack of susceptibility of the cells used, or inappropriate handling of the specimen. Coxsackievirus A may require inoculation into special cell-culture lines or into suckling mice.

Identification of the serotype of an enterovirus is useful primarily for epidemiologic studies and, with a few exceptions, has little clinical utility. It is important to identify serious infections with enterovirus during epidemics and to distinguish the vaccine strain of poliovirus from the other enteroviruses in the throat or in the feces. Stool and throat samples for culture as well as acute- and convalescent-phase serum specimens should be obtained from all patients with suspected poliomyelitis. In the absence of a positive CSF culture, a positive culture of stool obtained within the first 2 weeks after the onset of symptoms is most often used to confirm the diagnosis of poliomyelitis. If poliovirus is isolated, it should be sent to the CDC in Atlanta for identification as either a wild-type or a vaccine virus.

The polymerase chain reaction (PCR) has been used to amplify viral nucleic acid from CSF, serum, urine, throat swabs, and tissues. A single pair of PCR primers can detect more than 92% of the serotypes that infect humans. With the proper controls, PCR of the CSF is highly sensitive (≥95%) and specific (>80%) and is more rapid than culture. PCR of serum is also highly sensitive and specific in the diagnosis of disseminated disease. PCR may be particularly helpful for the diagnosis and follow-up of enterovirus disease in immunodeficient patients receiving immunoglobulin therapy, whose viral cultures may be negative. Antigen detection and hybridization of enterovirus sequences in human tissues with a specific probe are additional options, but these techniques are generally less sensitive than PCR.

Serologic diagnosis of enterovirus infection is limited by the large

number of serotypes and the lack of a common antigen. Demonstration of seroconversion may be useful in rare cases for confirmation of culture results, but serologic testing is usually limited to epidemiologic studies. Serum should be collected and frozen soon after the onset of disease and again about 4 weeks later. Measurement of neutralizing titers is the most accurate method for antibody determination; measurement of complement-fixation titers is usually less sensitive. Titers of virus-specific IgM are elevated in both acute and chronic infection.

TREATMENT

Most enterovirus infections are mild and resolve spontaneously; however, intensive supportive care may be needed for cardiac, hepatic, or CNS disease. Intravenous, intrathecal, or intraventricular immunoglobulin has been used with apparent success for the treatment of chronic enterovirus meningoencephalitis and dermatomyositis in patients with hypo- or agammaglobulinemia. The disease may stabilize or resolve during therapy; however, some patients decline inexorably despite therapy. Intravenous administration of immunoglobulin with high titers of antibody to the infecting virus has been used in the treatment of some cases of life-threatening infection in neonates, who may not have maternally acquired antibody. In one trial involving neonates with enterovirus infections, immunoglobulin containing very high titers of antibody to the infecting virus reduced rates of viremia; however, the study was too small to show a substantial clinical benefit. The level of enteroviral antibodies varies with the immunoglobulin preparation. Oral pleconaril, which binds to the enterovirus capsid, reduced symptoms in a placebo-controlled trial of enteroviral aseptic meningitis. In a review of compassionate-release pleconaril therapy in patients with potentially life-threatening enteroviral infections, ~75% of persons were judged to have a clinical response associated with therapy. These individuals included patients with chronic enteroviral meningoencephalitis, neonatal sepsis, myocarditis, and vaccine-associated paralytic poliomyelitis. Further study is needed to confirm these findings. Glucocorticoids are contraindicated.

Good hand-washing practices and the use of gowns and gloves are important in limiting nosocomial transmission of enteroviruses during epidemics. Enteric precautions are indicated for 7 days after the onset of enterovirus infections.

PREVENTION AND ERADICATION OF POLIOVIRUS (See also Chap. 107) After a peak of 57,879 cases of poliomyelitis in the United States in 1952, the introduction of inactivated vaccine in 1955 and of oral vaccine in 1961 ultimately eradicated disease due to wild-type poliovirus in the Western Hemisphere. Such disease has not been documented in the United States since 1979, when cases occurred among religious groups who had declined immunization. In the Western Hemisphere, paralysis due to wild-type poliovirus was last documented in 1991.

In 1988, the World Health Organization adopted a resolution to eradicate poliomyelitis by the year 2000. From 1988 to 2001, the number of cases worldwide decreased by >99%, with fewer than 1000 confirmed cases reported in 2001. In 2002, however, there were ~1900 cases of polio, with ~1500 reported in India. Wild-type poliovirus type 2 has not been detected in the world since 1999. The Americas were certified free of indigenous wild-type poliovirus transmission in 1994, the Western Pacific Region in 2000, and the European Region in 2002. In 2002, there were 8 countries in which indigenous wild-type poliovirus was still being transmitted (Table 175-3). Polio is a source of concern for unimmunized or partially immunized travelers to these regions. Outbreaks of polio in Europe and North America have been traced to cases imported from the Indian subcontinent. Clearly, global eradication of polio is necessary to eliminate the risk of importation of wild-type virus. Outbreaks are thought to have been facilitated by suboptimal rates of vaccination, isolated pockets of unvaccinated children, poor sanitation and crowding, improper vaccine-storage conditions, and a reduced level of response to one of the serotypes in the vaccine.

TABLE 175-3 *Laboratory-Confirmed Cases of Poliomyelitis in Countries Where Wild-Type Poliovirus Was Endemic in 2002*

Country	Virus-Confirmed Cases in 2001
India	1600
Pakistan	202
Nigeria	90
Afghanistan	10
Somalia	7
Niger	3
Egypt	3
Angola, Ethiopia, Sudan, Mauritania	1 case each
Total	1916

Outbreaks of poliomyelitis due to circulating vaccine-derived poliovirus have recently occurred. In the Dominican Republic and Haiti, 21 cases of vaccine-derived polio occurred in 2000 and 2001; 32 cases occurred in Egypt from 1988 to 1993, and 3 cases occurred in the Philippines in 2001. These OPV-derived viruses reverted to a more neurovirulent phenotype after undetected circulation (probably for >2 years). The epidemic in Hispaniola was rapidly terminated after intensive vaccination with OPV. These outbreaks emphasize the need for maintaining high levels of vaccine coverage and continued surveillance for circulating virus.

IPV is used in most industrialized countries and OPV in most developing countries, including those in which polio still is or recently was endemic. After several doses of OPV alone, the seropositivity rate for individual poliovirus serotypes may still be suboptimal for children in developing countries; one or more supplemental doses of IPV can increase the rate of seropositivity for these serotypes. While intramuscular injections of other vaccines (live or attenuated) can be given concurrently with OPV, unnecessary intramuscular injections should be avoided during the first month after vaccination because they increase the risk of vaccine-associated paralysis. Since 1988, an enhanced-potency inactivated poliovirus vaccine has been available in the United States.

OPV and IPV induce antibodies that persist for at least 5 years. Both vaccines induce IgG and IgA antibodies. Compared with recipients of IPV, recipients of OPV shed less virus and less frequently develop reinfection with wild-type virus after exposure to poliovirus. Although IPV is safe and efficacious, OPV offers the advantages of ease of administration, lower cost, and induction of intestinal immunity resulting in a reduction in the risk of community transmission of wild-type virus. Because of progress toward global eradication of polio (with a reduced risk of imported cases) and the continued occurrence of cases of vaccine-associated polio, an all-IPV regimen was recommended in 2000 for childhood poliovirus vaccination in the United States, with vaccine administration at 2, 4, and 6 to 18 months and 4 to 6 years of age. OPV will be used only in special circumstances: (1) for mass immunization campaigns to control outbreaks of polio; (2) for vaccination of unimmunized children who will be traveling to a polio-endemic area within 4 weeks; and (3) for children whose parents do not accept an all-IPV regimen. The latter children should receive at least two doses of IPV before receiving OPV. The risk of vaccine-associated polio should be discussed before administering OPV. Recommendations for vaccination of adults are listed in Table 175-4.

While it is hoped that endemic spread of poliovirus may be eliminated during the first decade of the 21st century, there are concerns about stopping vaccination. These include the observations that poliovirus is shed from some immunocompromised persons for several years, that vaccine-derived poliovirus can circulate and cause disease, and that wild-type poliovirus is present in a large number of laboratories. A national survey began in October 2002 to encourage laboratories to dispose of all unneeded wild-type poliovirus materials and to identify laboratories that have wild-type poliovirus or specimens (e.g., feces) that may contain the virus.

TABLE 175-4 Recommendations for Poliovirus Vaccination of Adults

1. Routine primary poliovirus vaccination is not indicated for unvaccinated adults residing in the United States, except for:
   a. travelers to areas where poliovirus is or may be epidemic or endemic;
   b. members of communities or population groups with disease caused by wild-type polioviruses;
   c. laboratory workers handling specimens that may contain wild-type polioviruses;
   d. health care workers in close contact with patients who may be excreting wild-type polioviruses.
2. Three doses of IPV are recommended for adults who need to be immunized. The second dose should be given 1 to 2 months after the first dose; the third dose should be given 6 to 12 months after the second dose.
3. Adults who are at increased risk of exposure to wild-type poliovirus and who have previously completed primary immunization should receive a single dose of IPV.

Abbreviation: IPV, inactivated poliovirus vaccine.

REOVIRUSES

Reoviruses are double-stranded RNA viruses encompassing three serotypes. Serologic studies indicate that most humans are infected with reoviruses during childhood; however, it has been difficult to establish a definite link of reovirus infection with a particular disease. It is likely that most infections either are asymptomatic or cause very mild disease. One outbreak of reovirus infection in children resulted in minor upper respiratory tract symptoms. Reovirus is considered a rare cause of mild gastroenteritis in infants and children. Speculation regarding an association of reovirus type 3 with idiopathic neonatal hepatitis and extrahepatic biliary atresia is based on an elevated prevalence of antibody to reovirus among some of these patients, detection of viral RNA by PCR in hepatobiliary tissues in some studies, and detection of virus in the porta hepatis in one case.

176 MEASLES (RUBEOLA)

Anne Gershon

DEFINITION Measles (rubeola) is a highly contagious, acute, exanthematous respiratory disease with a characteristic clinical picture and a pathognomonic enanthem: Koplik's spots, an eruption on the buccal mucous membranes (Fig. 176-1). A successful live attenuated measles vaccine became available in 1963 in the United States and elsewhere, and measles is now an unusual disease in most developed countries where this vaccine is widely used. However, measles continues to occur sporadically in miniepidemics in the United States, and major epidemics in developing nations make this disease a persistent cause of childhood morbidity and mortality.

ETIOLOGIC AGENT Measles virus is the only member of the genus *Morbillivirus* that infects humans. Part of the family Paramyxoviridae, it is closely related to the viruses causing canine and porcine distemper, rinderpest of cattle, morbilli of certain aquatic mammals, and *peste des petits ruminants* of goats and sheep. There is only one antigenic type. Measles virions are pleomorphic spherical structures having a diameter of 100 to 250 nm and consisting of six proteins. The inner capsid is composed of a coiled helix of RNA and three proteins, and the outer envelope consists of a matrix protein bearing two types of short surface-glycoprotein projections or peplomers. One peplomer is a conical hemagglutinin (H) and the other a dumbbell-shaped fusion (F) protein. Sequencing of the single-stranded genome has made it possible to distinguish vaccine-type measles virus from the wild type. The genetic variability of wild-type measles virus permits the identification of strains that are endemic within a given locale where measles cases have occurred. In all, 20 genotypes have been identified. The cellular receptors for measles virus are the CD46 and CD150 molecules expressed on human lymphocytes and many other human cell types.

EPIDEMIOLOGY Measles has a worldwide distribution; humans are the only natural hosts, although other primates can be experimentally infected. During the prevaccination era in the United States, measles epidemics occurred every 2 to 5 years in the winter and spring. In an epidemic year, roughly half a million measles cases were reported; 99% of adults had serologic evidence of previous measles infection.

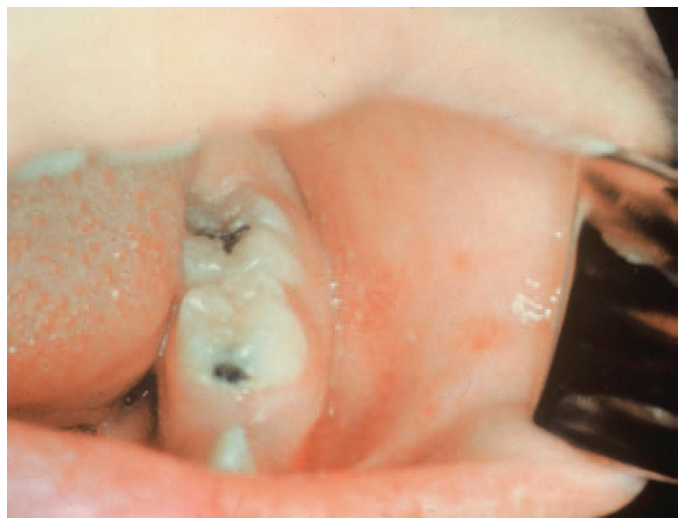

FIGURE 176-1 Koplik's spots, which manifest as white or bluish lesions with an erythematous halo on the buccal mucosa, usually occur in the first 2 days of measles symptoms and may briefly overlap the measles exanthem. The presence of the erythematous halo differentiates Koplik's spots from Fordyce's spots (ectopic sebaceous glands), which occur in the mouths of healthy individuals. *(Source: CDC. Photo selected by Dr. Kenneth Kaye.)*

After the live attenuated vaccine became available, the number of cases reported to the Centers for Disease Control and Prevention (CDC) fell, with a nadir of 1497 cases in 1983. After an upsurge to more than 27,000 cases (with 89 deaths) in 1990, the disease was once more brought under control, in part through the routine administration of two doses of vaccine. The foremost reason for the resurgence of measles was failure to immunize infants and young children, especially in inner-city areas. Primary vaccine failure (documented in about 5% of individuals) and secondary vaccine failure or waning immunity accounted for some cases.

In recent years, the majority of cases of measles have involved preschool children. Between 1993 and 1996, fewer than 1000 cases were reported annually in the United States; 309 cases were reported

in 1995 and 116 cases in 2001. Molecular studies indicated interruption of transmission of indigenous measles in 1993. Most cases have since resulted from international importations of the virus. Mortality is highest among children under 2 years of age and among adults. Patients with impaired cell-mediated immunity are at especially high risk for severe or even fatal measles. The measles-associated mortality rate in the United States is about 0.3%; in developing countries, mortality frequently exceeds 1% and sometimes approaches 10%.

Measles virus is transmitted by respiratory secretions, predominantly through exposure to aerosols but also through direct contact with larger droplets. Patients are contagious from 1 or 2 days before the onset of symptoms until 4 days after the appearance of the rash. Infectivity peaks during the prodromal phase. The mean intervals from infection to onset of symptoms and to appearance of rash are 10 and 14 days, respectively.

PATHOGENESIS, IMMUNITY, AND PATHOLOGY Measles virus invades the respiratory epithelium and spreads via the bloodstream to the reticuloendothelial system, from which it infects all types of white blood cells, thereby establishing infection of the skin, respiratory tract, and other organs. Both viremia and viruria develop. Multinucleated giant cells with inclusion bodies in the nucleus and cytoplasm (Warthin-Finkeldey cells) are found in respiratory and lymphoid tissues and are pathognomonic for measles. Direct invasion of T lymphocytes and increased levels of suppressive cytokines, such as interleukin 4, may play a role in the temporary depression of cellular immunity that accompanies and transiently follows measles. The major infected cell in the blood is the monocyte. Infection of the entire respiratory tract accounts for the characteristic cough and coryza of measles and for the less frequent manifestations of croup, bronchiolitis, and pneumonia. Generalized damage to the respiratory tract, with resultant loss of cilia, predisposes to secondary bacterial infections such as pneumonia and otitis media.

Specific antibodies are not detectable before the onset of rash. Cellular immunity (consisting of cytotoxic T cells and possibly natural killer cells) plays a prominent role in host defense, and patients who are deficient in cellular immunity are at high risk for severe measles. Children with isolated agammaglobulinemia are not at increased risk. Immune reactions to the virus in the endothelial cells of dermal capillaries play a substantial role in the development of Koplik's spots (the pathognomonic enanthem) as well as in that of rash; in immunodeficient hosts, measles may be severe despite the absence of these manifestations. Measles antigens have been demonstrated in involved skin during early stages of the illness.

Pathologic changes in measles encephalitis include focal hemorrhage, congestion, and perivascular demyelination. Measles virus is rarely isolated from cerebrospinal fluid (CSF) in cases of encephalitis, which are thought to be due to the interaction of virus-infected cells with local cellular immune factors.

CLINICAL MANIFESTATIONS Measles begins with a 2- to 4-day respiratory prodrome of malaise, cough, coryza, conjunctivitis with lacrimation, nasal discharge, and increasing fever [with temperatures as high as 40.6°C (105°F), probably reflecting secondary viremia]. At this stage of the illness, in which the rash has not yet developed, influenza may be suspected. Just before the onset of the rash, Koplik's spots appear as 1- to 2-mm blue-white spots on a bright red background (Fig. 176-1). Without adequate illumination for examination, they may be overlooked. Koplik's spots are typically located on the buccal mucosa alongside the second molars and may be extensive; they are not associated with any other infectious disease. The spots wane after the onset of rash and soon disappear. The entire buccal and inner labial mucosa may be inflamed, and the lips may be reddened.

The characteristic erythematous, nonpruritic, maculopapular rash of measles begins at the hairline and behind the ears, spreads down the trunk and limbs to include the palms and soles, and often becomes confluent (Fig. 176-2). At this time, the patient is at the most severe point of the illness. By the fourth day, the rash begins to fade in the order in which it appeared. Brownish discoloration of the skin and desquamation may occur later. Fever usually resolves by the fourth or fifth day after the onset of rash; prolonged fever suggests a complication of measles. Lymphadenopathy, diarrhea, vomiting, and splenomegaly are common features. The chest x-ray may be abnormal, even in uncomplicated measles, because of the propensity of this virus to invade the respiratory tract. The entire illness usually lasts about 10 days. The disease tends to be more severe in adults than in children, with higher fever, more prominent rash, and a higher incidence of complications.

FIGURE 176-2 In measles, discrete erythematous lesions become confluent as the rash spreads downward. *(Reprinted with permission from Fitzpatrick TB et al: Color Atlas & Synopsis of Clinical Dermatology, 4th ed. New York, McGraw-Hill, 2001, p 775.)*

Milder forms of the illness with less intense symptoms and a milder rash, termed *modified measles*, may occur in individuals with preexisting partial immunity induced by active or passive vaccination. These patients include infants under 1 year of age who retain some proportion of passively acquired maternal antibodies. On occasion, individuals with a history of immunization may develop modified measles.

COMPLICATIONS The complications of measles (Table 176-1) can conveniently be divided into three groups, according to the site involved: the respiratory tract, the central nervous system (CNS), and the gastrointestinal tract. Respiratory tract involvement, manifested as laryngitis, croup, or bronchitis, occurs in the majority of cases of uncomplicated measles. In young children, otitis media is the most common complication. Pneumonia is a frequent reason for hospitalization, especially of adults. The pneumonia is of viral origin in the majority of cases, but secondary bacterial infection (most commonly caused by streptococci, pneumococci, or staphylococci) also develops with some frequency. Primary giant cell (Hecht's) pneumonia is most often documented in immunocompromised and/or malnourished patients.

Encephalographic abnormalities in the absence of symptoms of CNS disease are extremely frequent in measles. Symptomatic CNS disease may present with fever, headache, drowsiness, coma, and/or seizures. Symptoms usually begin within days after the onset of rash but occasionally appear for the first time several weeks later. About 10% of patients do not survive acute measles encephalitis; a significant percentage of surviving patients develop permanent sequelae, such as mental retardation or epilepsy. Most cases appear to result from an immune-mediated response to myelin proteins (postinfectious encephalomyelitis) and not directly from viral infection of the CNS (Chap. 359). Rarely, transverse myelitis follows measles. Immunocompromised patients are at risk for progressive fatal encephalitis 1 to 6 months after measles; in some cases, even though prior measles has

TABLE 176-1 *Complications of Measles*

Complication	Comments
Otitis media	Very common in infants with measles
Pneumonia	May be primary viral pneumonia or bacterial superinfection; frequent reason for hospitalization of adults; measles rash sometimes lacking in immunocompromised patients with measles pneumonia
Croup	Occasionally severe, requiring intubation in infants
Gastroenteritis	Diarrhea can be life threatening in infants
Cervical adenitis	Due to lymphoid hyperplasia as host response to virus; common
Acute encephalitis	May be mild to severe/fatal; occurs in 1 in 1000 cases of measles; cerebral and cerebellar forms; immune-mediated pathogenesis
Subacute sclerosing panencephalitis (SSPE)	In 1 in 100,000 cases of measles, usually when measles occurred in infancy; seen 5–10 years later. In United States, most children with SSPE were born in another country where measles vaccine is not routinely used.

not been recognized, the virus is identified at autopsy. Subacute sclerosing panencephalitis (SSPE)—a protracted, chronic, extremely rare form of measles encephalitis—sometimes follows measles and is particularly common among children who have measles before the age of 2 years (Chap. 360). SSPE has virtually disappeared in the United States as a result of widespread vaccination. Typically, progressive dementia evolves over several months. SSPE is thought to be due to a complex interaction of the host with defective measles virus. It is associated with extremely high levels of antibodies to measles virus in the blood and CSF.

Gastrointestinal complications of measles include gastroenteritis, hepatitis, appendicitis, ileocolitis, and mesenteric adenitis. It is not uncommon to detect high levels of alanine and aspartate aminotransferases in the absence of gastrointestinal signs such as jaundice.

Other, rare complications include myocarditis, glomerulonephritis, and postinfectious thrombocytopenic purpura. Measles can exacerbate preexisting tuberculosis, presumably through depression of cellular immunity induced by the virus. Natural measles and immunization against measles can result in tuberculin skin-test anergy lasting for about 1 month.

ATYPICAL MEASLES An atypical form of measles has been reported in individuals who received formalin-inactivated measles vaccine (used in the United States from 1963 through 1967 and in Canada until 1970) and subsequently were exposed to measles virus. After a several-day prodrome of fever, myalgia, and headache, the rash appears (Fig. 176-3). Unlike the rash of typical measles, that of atypical measles begins peripherally and moves centrally; it can be urticarial, maculopapular, hemorrhagic, and/or vesicular. Fever is usually high and is accompanied by edema of the extremities, interstitial pulmonary infiltrates, hepatitis, and (on occasion) pleural effusion. The differential diagnosis often includes Rocky Mountain spotted fever, Henoch-Schönlein purpura, meningococcemia, drug allergy, toxic shock syndrome, and varicella. Despite the severity of atypical measles, patients invariably recover after a convalescence that may be prolonged. Measles virus is not isolated from these patients, and they do not spread the virus to others. This disease is believed to be due to hypersensitivity to measles virus induced by the inactivated vaccine. Formalin inactivation destroys the antigenicity of the F protein, antibodies to which are important in preventing spread of the virus from one cell to another. The role of cellular immunity in this process is unknown. Extremely high convalescent titers of antibody to measles virus (e.g., 1:1,000,000) are diagnostic of atypical measles. To prevent this syndrome, adults who received formalin-inactivated measles vaccine should be reimmunized with at least one dose of live attenuated measles vaccine. Because inactivated measles vaccine has not been available for more than 25 years, atypical measles has now virtually disappeared.

MEASLES IN THE IMMUNOCOMPROMISED HOST Patients with defects in cell-mediated immunity are at risk for severe protracted and fatal measles. Included in this category are patients with congenital cellular immune defects or malignancy, recipients of immunosuppressive therapy, or persons infected with HIV. In these patients, measles may not be accompanied by a rash. Complications are primary measles (giant cell) pneumonia, progressive encephalitis beginning weeks to months after initial infection, and (in HIV-infected patients) progression to AIDS.

MEASLES IN ADULTS Measles is naturally a disease of childhood and, like many other viral infections, is more severe in adults than in children. About 3% of young adults with measles develop primary viral pneumonia and require hospitalization. Hepatitis and bronchospasm are more common among adults with measles than among children, and the rash is more severe and more confluent in adults. Bacterial superinfection is more common among adults, more than one-third of whom develop respiratory complications such as otitis media, sinusitis, and pneumonia. Adults may develop measles because they were never immunized or (more rarely) because their vaccine-induced immunity has waned. Very low titers of antibody to measles virus have been associated with lack of protection.

LABORATORY FINDINGS Lymphopenia and neutropenia are common in measles and may be due to invasion of leukocytes by the virus, with subsequent cell death. Leukocytosis may herald a bacterial superinfection. Patients with measles encephalitis usually have an elevated protein concentration in CSF as well as lymphocytosis.

DIAGNOSIS A specific diagnosis of measles can be made quickly by immunofluorescent staining of a smear of respiratory secretions for measles antigen; monoclonal antibodies conjugated to fluorescein are commercially available for this purpose. Secretions can also be examined microscopically for multinucleated giant cells. Measles virus can be isolated from respiratory secretions or urine and rapidly identified in tissue culture with fluorescein-labeled monoclonal antibodies. The presence of measles virus RNA has been demonstrated by diagnostic reverse-transcription polymerase chain reaction. A number of serologic tests are available for the diagnosis of measles; however, a serologic diagnosis cannot necessarily be made quickly because both acute- and convalescent-phase sera are usually tested, ideally at the same time. The older hemagglutination inhibition test has been re-

FIGURE 176-3 Petechial lesions in a patient with atypical measles. *(Photo courtesy of Stephen E. Gellis, MD.)*

placed by enzyme immunoassay (EIA), which is more sensitive and simpler to perform. EIA can be used to measure specific IgM and thus to diagnose measles on the basis of an acute-phase serum sample alone. Specific IgM antibodies are detectable within 1 to 2 days after the appearance of rash, and the IgG titer rises significantly after 10 days. As already mentioned, atypical measles and SSPE are associated with extremely high titers of antibody.

DIFFERENTIAL DIAGNOSIS Classic measles—with Koplik's spots, cough, coryza, conjunctivitis, and a rash beginning on the head—is easily diagnosed on clinical grounds. Modified measles is more difficult to diagnose clinically because one or more characteristic signs may be lacking. The differential diagnosis of measles includes Kawasaki disease, scarlet fever, infectious mononucleosis, toxoplasmosis, drug eruption, and *Mycoplasma pneumoniae* infection. Most of these conditions can be identified by either culture or serologic assay. In the differential diagnosis of measles, attention should be paid to the current epidemiology of the disease in the community and to the patient's history of measles vaccination and foreign travel.

PREVENTION The development of live attenuated measles vaccine by Enders and colleagues was a milestone in American medicine. This vaccine, used in the United States for the routine immunization of children since 1963, induces seroconversion in about 95% of recipients and probably confers lifelong protection. Waning immunity to measles after immunization has been documented only on rare occasions. For the past three decades, measles vaccine has been available as the combination vaccine measles-mumps-rubella (MMR); MMR vaccine should be administered to children between the ages of 12 and 15 months. (Vaccination at 12 months is preferred for infants whose mothers were immunized against measles in childhood. These mothers have lower antibody titers than women who have had natural measles, and their infants correspondingly have transplacental antibodies of lower titer and shorter duration.) A second dose of MMR vaccine is recommended for school-age children at 4 to 12 years of age. This two-dose policy was developed in the late 1980s in response to measles outbreaks in the United States. Since the institution of the two-dose regimen and the increased effort to immunize all children, measles has again become an unusual disease in the United States. Regional guidelines that reflect the current local epidemiology of measles should be followed.

Older susceptible persons should also be immunized. Individuals should be considered susceptible to measles unless they have documentation of physician-diagnosed measles or of the receipt of two doses of vaccine, have laboratory evidence of measles immunity, or were born before 1957. Rarely, individuals born before 1957 develop measles, and those who are at risk of exposure to measles (e.g., health care workers, teachers, and international travelers) should be tested for measles antibody and immunized if necessary. Approximately 10% of healthy vaccinees develop a fever, with temperatures up to 39.4°C (103°F), 5 to 7 days after vaccination; this fever lasts 1 to 5 days and is accompanied by a transient rash. Individuals previously immunized only with killed vaccine are considered susceptible and should receive at least one dose—preferably two doses—of MMR vaccine. Transient adverse reactions in these individuals include fever, malaise, and redness and swelling at the injection site.

Because of the severity of measles in this group and the lack of reported problems following vaccination, children with asymptomatic HIV infection should receive MMR vaccine; those with severe immunosuppression (<15% CD4 lymphocytes) should not. A case of fatal measles due to vaccine-type virus was reported in a college student with AIDS. Measles vaccine is contraindicated for persons with impaired cell-mediated immunity, for pregnant women, and for persons with a history of anaphylaxis due to egg protein or neomycin. Minor illnesses, with or without fever and a history of convulsions, are not contraindications to vaccination. Vaccination should be deferred for 6 to 11 months after the receipt of immune globulin or of blood products containing antibodies and for at least 3 months after the discontinuation of immunosuppressive treatment. Vaccine failures have been ascribed to faulty storage of the preparation used, immunization of infants with preexisting (maternally derived) antibodies, and simultaneous administration of measles vaccine and immune globulin.

The only temporally related apparent complications of measles vaccination that are thought to be causal are febrile seizures, which rarely have long-term sequelae; thrombocytopenia, which is self-limited; and anaphylaxis, which is very rare. An exhaustive analysis conducted in 2000 by a number of official committees, including those of the American Academy of Pediatrics and the Institute of Medicine, found no causal relationship between MMR vaccination and development of autism.

Children and adults who are susceptible to measles and are exposed to the disease should receive postexposure prophylaxis. Standard immune globulin, given intramuscularly within 6 days of exposure, can exert a protective or modifying effect; the earlier it is given, the better the outcome. The dose is 0.25 mL/kg for healthy persons and 0.5 mL/kg for immunocompromised persons, with a maximum dose of 15 mL. Immune globulin is particularly strongly indicated for susceptible household contacts, especially those <1 year of age, and for immunocompromised persons. HIV-infected persons, particularly those with severe immunosuppression, should be given immune globulin after exposure, regardless of their measles immune status and whether or not they are receiving intravenous immune globulin. Vaccination within 72 h of exposure may also provide protection against clinical measles, but this strategy is contraindicated as postexposure prophylaxis for immunocompromised individuals. Vaccine and immune globulin should not be given concurrently.

TREATMENT

Therapy for measles is largely supportive and symptom based. Patients with otitis media and pneumonia should be given standard antibiotics. Patients with encephalitis need supportive care, including observation for increased intracranial pressure. Controlled trials suggest clinical benefit from high doses of vitamin A in severe or potentially severe measles, especially in children under the age of 2 years who are or may be malnourished. On the basis of limited data, a dose of 50,000 IU is used for infants 1 to 6 months old; a dose of 100,000 IU is recommended for infants 7 to 12 months old; and a dose of 200,000 IU is recommended for children >1 year old. A single dose is administered on two consecutive days. In the United States, vitamin A treatment is recommended for young children hospitalized for measles and for pediatric measles patients with immunodeficiency, clinical evidence of vitamin A deficiency, impaired intestinal absorption, moderate to severe malnutrition, or recent immigration from an area where there is high mortality from measles. Transient vomiting and headache may be associated with the administration of vitamin A. Ribavirin is effective against measles virus in vitro and may be considered for use in immunocompromised individuals.

177 RUBELLA (GERMAN MEASLES)

Anne Gershon

DEFINITION Rubella is an acute viral infection of children and adults that characteristically includes rash, fever, and lymphadenopathy and has a broad spectrum of other possible manifestations. However, a high percentage of rubella infections in both children and adults are subclinical. In addition, the illness can resemble a mild attack of measles (rubeola) and can cause arthritis, especially in adults. Rubella was formerly known as *German measles* because it was first described clinically as distinct from rubeola in Germany, where it generated much medical interest in the mid-eighteenth and early nineteenth centuries. Rubella during pregnancy can lead to fetal infection, with the production of a significant constellation of malformations (*congenital rubella syndrome*) in a high proportion of infected fetuses. Rubella virus was first isolated in cell culture just before the last pandemic of the disease began in 1962. Since the licensing of rubella vaccine in the United States in 1969, there have been no further epidemics in this country.

ETIOLOGIC AGENT Rubella virus, a togavirus, is the only member of the *Rubivirus* genus and is closely related to the alphaviruses. Unlike these agents, however, it does not require a vector for transmission. Moreover, there is no RNA sequence homology between rubella virus and the alphaviruses.

The rubella virion is composed of an inner icosahedral capsid of RNA and protein that is surrounded by a lipid-containing envelope with glycoprotein spikes and a diameter of about 60 nm. The structural proteins associated with rubella virus are E1 and E2 (transmembrane envelope glycoproteins) and C (the capsid protein that surrounds the viral RNA). Only one serotype has been identified.

EPIDEMIOLOGY In the United States during the prevaccine era, rubella was most common in the spring and most often affected school-age children; only 80 to 90% of adults were immune; and major epidemics occurred every 6 to 9 years. The most recent epidemic in the United States occurred in 1964 to 1965, when more than 12 million cases of postnatal rubella and more than 20,000 cases of the congenital rubella syndrome were reported. Although there have been no epidemics since the introduction of live attenuated rubella vaccine in 1969, limited outbreaks have been reported in settings where susceptible individuals come into close contact with one another (e.g., schools and workplaces). In 2001, only 23 cases of postnatally acquired rubella—most of them in young adults—and 3 confirmed cases of congenital rubella syndrome were reported to the Centers for Disease Control and Prevention (CDC).

Whether symptomatic or subclinical, rubella is contagious, albeit less so than measles. Its incubation period is 18 days on average, with a range of 12 to 23 days. The virus, which is spread in droplets shed in respiratory secretions, infects the respiratory tract and then the bloodstream. In postnatally acquired infections, rubella virus is shed during the prodromal phase of the illness, and shedding from the pharynx can continue for about a week after onset. Despite high titers of specific neutralizing antibodies, infants with congenital rubella may excrete rubella virus from the respiratory tract and in the urine until the age of 2 years. This excretion raises important issues related to infection control in hospital and day-care settings. Persons recently immunized with live attenuated rubella vaccine do not transmit the vaccine virus to others, although low titers of rubella virus may be detected transiently in the pharynx.

After an attack of rubella, specific antibodies and cell-mediated immunity develop and probably play a significant role in protection against future disease. Asymptomatic reinfection at the level of the respiratory tract is common upon re-exposure to the virus but is rarely, if ever, associated with viremia.

Rubella virus has been cultured from respiratory secretions during reinfection. Fetal infection may occur during maternal reinfection but is acknowledged to be extremely rare because of the absence of maternal viremia under these circumstances. Viremia following reinfection of individuals immunized against rubella is also rare. Thus the current level of congenital rubella in the United States is exceedingly low. Recently, however, it has been observed that young immigrants to the United States from countries in Latin America and the Caribbean, where rubella vaccine is not routinely given to children, are at increased risk for rubella susceptibility. Because infants with the congenital rubella syndrome have been born to immigrant Hispanic women, increasing efforts are being made to identify and vaccinate such women before they become pregnant.

PATHOGENESIS AND PATHOLOGY Little is known about the microscopic pathology of postnatally acquired rubella because the disease is invariably self-limited. Like that of measles, the rash of rubella is immunologically mediated; its onset coincides with the development of specific antibodies. Viremia can be demonstrated for about a week before and ends within a few days after the onset of rash.

The cause of the damage to cells and organs in congenital rubella is not well understood. Proposed mechanisms of fetal damage include mitotic arrest of cells, tissue necrosis without inflammation, and chromosomal damage. The growth of the fetus may be retarded. Other findings may include decreased numbers of megakaryocytes in the bone marrow, extramedullary hematopoiesis, and interstitial pneumonia.

CLINICAL MANIFESTATIONS ■ Postnatally Acquired Rubella Infection acquired after birth usually results in an extremely mild or subclinical illness. A prodromal phase is uncommon in children; adults may have more severe disease, with a brief prodrome of malaise, fever, and anorexia. The foremost symptoms of postnatally acquired rubella include posterior auricular, cervical, and suboccipital lymphadenopathy; fever; and rash. The rash often begins on the face (Fig. 177-1) and spreads down the body. It is maculopapular but not confluent, is sometimes accompanied by mild coryza and conjunctivitis, and generally lasts for 3 to 5 days. A petechial enanthem on the soft palate, designated *Forschheimer spots*, may occur but is not specific for rubella. Fever may be absent entirely or may be present for only several days in the early phase of the illness.

Complications of postnatally acquired rubella are uncommon; bacterial superinfection is rare. One particularly troublesome complication

FIGURE 177-1 In rubella, an erythematous exanthem spreads from the hairline downward and clears as it spreads. *(Photo courtesy of Stephen E. Gellis, MD.)*

is seen almost exclusively in women: arthritis, most frequently involving the fingers, wrists, and/or knees. Arthritis develops as the rash is appearing and may take several weeks to resolve. Chronic arthritis resulting from rubella is extremely rare. Rubella virus has been isolated from joint fluid during acute rubella arthritis and from peripheral blood in chronic rubella arthritis.

Another complication of postnatally acquired rubella is hemorrhage due to both thrombocytopenia and vascular damage; this complication occurs in 1 of every 3000 patients. Thrombocytopenia may last for weeks or months; it can have long-term consequences if there is bleeding into organs such as the eye or the brain.

Both children and adults may develop encephalitis after rubella; the incidence is about five times lower than that of encephalitis following measles. Adults are more likely than children to develop encephalitis; the mortality rate from this complication is 20 to 50%. Mild hepatitis is an unusual complication. Immunosuppressed patients are not at increased risk for rubella as they are for measles.

Congenital Rubella Maternal infection in early pregnancy can lead to fetal infection, with resultant congenital rubella. The classic signs of congenital rubella are cataract, heart disease, deafness, and myriad other defects (Table 177-1). The most important factor in the pathogenicity of rubella virus for the fetus is gestational age at the time of infection. Maternal infection during the first trimester leads to fetal infection in about 50% of cases; maternal infection early in the second trimester leads to fetal infection in about one-third of cases. Fetal malformations not only are more common after maternal infection in the first trimester but also tend to be more severe and to involve more organ systems. Whereas a fetus infected in the fourth week of gestation may develop many problems, one infected later (e.g., in the twentieth week) may have isolated deafness as the only symptom.

DIAGNOSIS Because postnatally acquired rubella is often a mild disease and because many cases are subclinical, diagnosis on clinical grounds can be difficult. Other diseases that may mimic rubella include toxoplasmosis, scarlet fever, modified measles, roseola, fifth disease (erythema infectiosum due to parvovirus B19), and enteroviral infection. Routine laboratory tests usually reveal leukopenia and atypical lymphocytes.

The isolation of rubella virus in cell cultures of throat samples, urine, or other secretions is difficult and expensive but is sometimes undertaken. This technique is most useful when congenital rubella is suspected. A laboratory diagnosis is more often made serologically. The most commonly used test is an enzyme-linked immunosorbent assay (ELISA) for IgG and IgM antibodies. Acute rubella is diagnosed by the documentation of a fourfold or greater rise in the titer of IgG antibodies in paired acute- and convalescent-phase serum specimens or by the detection of rubella-specific IgM antibodies in one serum specimen. However, false-negative and false-positive IgM reactions are sometimes obtained. Moreover, true-positive IgM reactions can occur in both primary infection and reinfection. Congenital rubella is diagnosed by the isolation of rubella virus, the detection of IgM antibodies in a single serum sample, and/or the documentation of either the persistence of rubella antibodies in serum beyond 1 year of age or a rising antibody titer anytime during infancy in an unvaccinated child. Biopsied tissues and/or blood and cerebrospinal fluid have also been used for the demonstration of rubella antigens with monoclonal antibodies and for the detection of rubella RNA by in situ hybridization and polymerase chain reaction.

TABLE 177-1 *Clinical Problems Associated with the Congenital Rubella Syndrome*

Transient Signs/Symptoms (at Birth Only)	*Permanent Signs/Symptoms (Developmental)*
Bony abnormalities	Autism
Cloudy cornea	Behavioral disorders
Hemolytic anemia	Congenital heart disease (patent ductus arteriosus, pulmonic stenosis)
Hepatitis	Cryptorchidism
Hepatosplenomegaly	Deafness
Jaundice	Degenerative brain disease
Low birth weight	Diabetes mellitus
Lymphadenopathy	Glaucoma
Meningoencephalitis	Inguinal hernia
Rubella viral pneumonia	Mental retardation
Thrombocytopenic purpura	Microcephaly
	Myopia
	Precocious puberty
	Retinopathy
	Seizures
	Spastic diplegia
	Thyroid disorders

PREVENTION Live attenuated rubella vaccine was licensed in 1969, 7 years after the virus was first isolated in culture. This vaccine was developed as a strategy to prevent congenital rubella by ensuring that very few pregnant women would be susceptible and that there would be little circulating wild-type virus. Rubella vaccine induces seroconversion in more than 95% of recipients. Since its licensure, there have been no major epidemics in the United States, and the number of cases has declined by 98%. The vaccine currently licensed in the United States, RA 27/3, is propagated in human diploid cells and is more immunogenic (particularly with regard to the stimulation of secretory immunity) than previously licensed vaccines. The present vaccination strategy, developed in part when measles was not being adequately controlled, is to immunize all infants at 12 to 15 months of age with measles-mumps-rubella (MMR) vaccine and to administer a second dose in early childhood. Rubella vaccine may also be administered to anyone who is thought to be susceptible to the infection and is not pregnant; it is particularly important that hospital workers of either sex be immune to rubella so that nosocomial transmission is avoided. Although there has been little change in the prevalence of immunity to rubella among women of childbearing age (about 80%), the incidence of congenital rubella is extremely low—fewer than 10 cases annually. It is likely that, although antibody may be undetectable years after immunization, protection against infection—possibly due to cell-mediated immunity—is the rule. At present, there is little if any evidence of significant waning of clinically important immunity to rubella with time.

On occasion, rubella vaccine may cause arthralgia or arthritis, especially in young women. Very rarely, rubella vaccination results in chronic arthritis; however, even cases of frank arthritis in vaccinees are self-limited, lasting only about 1 week.

After investigation of a series of more than 400 women who were inadvertently immunized during pregnancy and who carried their infants to term, the CDC has concluded that vaccine-type rubella virus either does not cause the congenital rubella syndrome at all or does so at an incidence too low to be detected. Nonetheless, rubella vaccine is contraindicated for use in pregnant women, and it is recommended that pregnancy be avoided for at least 3 months after rubella vaccination. It is acceptable for rubella-susceptible children whose mothers are also susceptible to be immunized, as vaccinated individuals do not shed rubella virus or transmit it to susceptible individuals. Although it is recommended that rubella vaccine not be given to immunosuppressed persons, the vaccine is given to children infected with HIV. No adverse effects of rubella vaccine have been reported in immunocompromised patients.

TREATMENT

There is no specific therapy for rubella. At one time, immune globulin was used in an effort to prevent congenital rubella when pregnant women became infected. However, because administration of immune globulin did not prevent maternal viremia, this approach was discarded. Symptom-based treatment is given for manifestations such as fever, arthralgia, and arthritis.

178 MUMPS

Anne Gershon

DEFINITION Mumps is an acute, systemic, communicable viral infection whose most distinctive feature is swelling of one or both parotid glands. Involvement of other salivary glands, the meninges, the pancreas, and the gonads is also common.

ETIOLOGIC AGENT Mumps virus, a paramyxovirus, is pleomorphic and has a diameter ranging from 100 to 300 nm. The virion is composed of RNA and seven proteins. The RNA is surrounded by an envelope with glycoprotein projections. There are two envelope glycoproteins—a hemagglutinin-neuraminidase (HN) and a hemolysis cell fusion antigen (F)—as well as a matrix envelope protein (M). A fourth protein (SH) may also be membrane-associated. There are three internal components: a nucleocapsid protein (NP), a phosphoprotein (P), and a large protein (L). There is only one antigenic type of mumps virus. The polymerase chain reaction (PCR) has detected geographic differences among mumps viruses from different locales.

EPIDEMIOLOGY After the introduction of mumps vaccine in 1967, the incidence of clinical mumps declined significantly in the United States. In 1968 (before widespread immunization), 185,691 cases of mumps were reported in this country. The 266 cases reported in 2001 represent a reduction in the number of cases by >99% from prevaccine levels; this is the lowest number of cases ever reported in a year. Before widespread vaccination, the incidence of mumps was highest in the winter and spring, with epidemics every 2 to 5 years. At that time, mumps was principally a disease of childhood, although today more than 50% of cases occur in young adults. Epidemics tended to occur in confined populations, such as those in schools and the military services.

The incubation period of mumps generally ranges from 14 to 18 days, with extremes of 7 and 23 days. However, because a contact may be shedding virus before the onset of clinical disease or (like one-third of patients) may have subclinical infection, the incubation period in individual cases is often uncertain. One attack of mumps usually confers lifelong immunity. Long-term immunity is also associated with immunization.

PATHOGENESIS Mumps virus is transmitted by droplet nuclei, saliva, and fomites. Replication of the virus in the epithelium of the upper respiratory tract leads to viremia, which is followed by infection of glandular tissues and/or the central nervous system (CNS).

Little is known of the pathology of mumps since the disease is rarely fatal. The affected glands contain perivascular and interstitial mononuclear cell infiltrates with prominent edema. Necrosis of acinar and epithelial duct cells is evident in the salivary glands and in the germinal epithelium of the seminiferous tubules.

CLINICAL MANIFESTATIONS The prodrome of mumps consists of fever, malaise, myalgia, and anorexia. Parotitis, if it develops, usually does so within the next 24 h but may be delayed for as long as a week; it is generally bilateral, although the onset on the two sides may not be synchronous and at times only one side is affected. The submaxillary and sublingual glands are involved less often than the parotid and are almost never involved alone. Swelling of the parotid is accompanied by tenderness and obliteration of the space between the ear lobe and the angle of the mandible. The patient frequently reports an earache and finds it difficult to eat, swallow, or talk. Glandular swelling increases for a few days and then gradually subsides, disappearing within a week. The orifice of Stensen's duct is commonly red and swollen. Presternal pitting edema has been described in about 5% of mumps cases, often in association with submandibular adenitis.

Other than parotitis, orchitis is the most common manifestation of mumps among postpubertal males, developing in about 20% of cases. The testis is painful and tender and is enlarged to several times its normal size; accompanying fever is common. Later, testicular atrophy develops in half of the affected men. Since orchitis is bilateral in fewer than 15% of cases, sterility after mumps is rare. Oophoritis in women—far less common than orchitis in men—may cause lower abdominal pain but does not lead to sterility.

Aseptic meningitis, which may develop before, during, after, or in the absence of parotitis, is a common manifestation of mumps in both children and adults. Symptoms include stiff neck, headache, and drowsiness. Pleocytosis of the cerebrospinal fluid (CSF), with up to 1000 cells/μL, may develop in up to 50% of cases of clinical mumps, but clinical signs of meningeal irritation are documented in only 5 to 25% of cases. Within the first 24 h, polymorphonuclear leukocytes may predominate in CSF, but by the second day nearly all the cells are lymphocytes. The glucose level in CSF may be abnormally low, and this finding may arouse suspicion of bacterial meningitis. Aseptic meningitis due to mumps without parotitis is indistinguishable clinically from that caused by other viruses. Mumps meningitis is almost invariably self-limited, although cranial nerve palsies have occasionally led to permanent sequelae, particularly deafness. More rarely, mumps virus may cause encephalitis, which presents as high fever with marked changes in the level of consciousness and frequently results in permanent sequelae in survivors. Other CNS problems occasionally associated with mumps include cerebellar ataxia, facial palsy, transverse myelitis, Guillain-Barré syndrome, and aqueductal stenosis leading to hydrocephalus.

Mumps pancreatitis, which may present as abdominal pain, is difficult to diagnose because an elevated serum amylase level can be associated with either parotitis or pancreatitis. Other unusual complications of mumps include myocarditis, mastitis, thyroiditis, nephritis, arthritis, and thrombocytopenic purpura. An excessive number of spontaneous abortions are associated with gestational mumps when the disease occurs during the first trimester. Mumps in pregnancy does not lead to premature birth or fetal malformations.

DIFFERENTIAL DIAGNOSIS The diagnosis of mumps is made easily in patients with acute bilateral parotitis and a history of recent exposure, but mumps is currently a rare disease in the United States due to widespread vaccination. When parotitis is unilateral or absent or when sites other than the parotid gland are involved, laboratory diagnosis may be required. The differential diagnosis of parotitis is presented in Table 178-1.

Other entities should be considered when manifestations consistent with mumps appear in organs other than the parotid. Testicular torsion may produce a painful scrotal mass resembling that seen in mumps

TABLE 178-1 *Differential Diagnosis of Parotitis*

Etiology	Comments
SYSTEMIC INFECTIONS	
Mumps	Rare in countries with vaccination programs
Coxsackievirus infection	Particularly likely in children
HIV infection	In HIV-positive children receiving no antiretroviral therapy; additional disease manifestations likely
Parainfluenza virus type 3 infection	Particularly likely in children, associated with acute respiratory tract symptoms
Influenza A virus infection	Seasonal (winter, spring), associated with acute respiratory tract symptoms
Cat-scratch disease	Unusual but described
Epstein-Barr virus infection	Unusual but described
SYSTEMIC NONINFECTIOUS CAUSES	
Sarcoidosis	Additional manifestations of disease likely
Sjögren's syndrome	Additional manifestations of disease likely
Uremia	Additional manifestations of disease likely
Diabetes mellitus	Additional manifestations of disease likely
Drugs	Phenylbutazone, thiouracil
UNILATERAL PAROTITIS	
Ductal obstruction due to stones or strictures	Unilateral, gradual onset, suppurative
Parotid cyst	Unilateral, gradual onset
Parotid tumor	Unilateral, gradual onset
ACUTE SUPPURATIVE PAROTITIS	
Staphylococcus aureus, *Streptococcus* species, and (rarely) gram-negative bacteria, anaerobes	

orchitis. Other viruses (e.g., enteroviruses) may cause aseptic meningitis that is clinically indistinguishable from that due to mumps virus.

Myocarditis as a severe but usually self-limited complication of mumps has been described. Molecular diagnostic assays have implicated mumps virus in some cases of endocardial fibroelastosis following myocarditis.

LABORATORY DIAGNOSIS Mumps virus is readily isolated after inoculation of appropriate clinical specimens into a variety of host systems, such as rhesus monkey kidney cells and human embryonic lung fibroblasts. The virus can be rapidly identified by inoculation of cells grown in shell vials and subsequent staining with fluorescein-labeled monoclonal antibodies to detect viral growth. Mumps virus may be recovered from saliva, throat, and urine during the first few days of illness and from the CSF of patients with mumps meningitis. Shedding of virus in the urine may persist for as long as 2 weeks. PCR is also used to detect mumps virus in clinical specimens. No particular peripheral blood cell count is characteristic of mumps.

Highly sensitive enzyme-linked immunosorbent assays are useful for serologic diagnosis of mumps and for determination of susceptibility to the disease. Acute mumps can be diagnosed either by the examination of acute- and convalescent-phase sera for a significant increase in IgG antibody titer or by the demonstration of specific IgM in one serum specimen. Use of a skin-test antigen to assess immunity to mumps has been replaced by serologic testing.

PREVENTION Live attenuated mumps vaccine (Jeryl Lynn strain) induces antibodies that protect the recipient against infection in more than 95% of cases. The subcutaneously administered vaccine may be given to children older than 1 year but is not recommended for younger infants because of the potential for interference by passive maternal antibodies. Mumps vaccine is usually administered as part of the measles-mumps-rubella (MMR) vaccine at the age of 12 to 15 months and again at 4 to 12 years of age. This MMR vaccine is also recommended for susceptible older children, adolescents, and adults, particularly adolescent males who have not had mumps. For these patients, either MMR or monovalent mumps vaccine may be given; two doses are preferred. Inadvertent immunization of individuals who are already immune is not associated with significant adverse reactions. Mumps vaccine is not recommended for pregnant women, for patients receiving glucocorticoids, or for other immunocompromised hosts. However, children with HIV infection who are not severely immunocompromised can safely be immunized against mumps; MMR vaccine is usually used for this purpose (Chap. 107). Occasionally, febrile reactions and parotitis have been reported soon after mumps vaccination. Allergic reactions after vaccination, such as rash and pruritus, occur uncommonly and are usually mild and self-limited. In the United States, the incidence of encephalitis during the month after mumps vaccination is no greater than the background incidence rate of encephalitis in the population.

TREATMENT

Therapy for parotitis and other manifestations of mumps is symptom-based. The administration of analgesics and the application of warm or cold compresses to the parotid area may be helpful. Mumps immune globulin is of no value in prophylaxis or treatment of established disease. Testicular pain may be minimized by the local application of cold compresses and gentle support for the scrotum. Anesthetic blocks may also be used. Neither the administration of glucocorticoids nor incision of the tunica albuginea is of proven value for the treatment of severe orchitis. Anecdotal information on a small number of patients with orchitis suggests that administration of interferon α may be helpful.

179 RABIES VIRUS AND OTHER RHABDOVIRUSES

Cathleen A. Hanlon, Lawrence Corey

RABIES VIRUS

DEFINITION Rabies is an invariably lethal, acute viral disease of the central nervous system (CNS) that affects all mammals and that is transmitted by infected secretions. Most commonly, transmission to humans takes place through exposure to saliva during a bite by an infected animal.

ETIOLOGY The rabies and rabies-related viruses are in the family Rhabdoviridae, with at least seven distinct types within the genus *Lyssa-*

virus. Isolates of rabies virus from different animal species and locales differ in their antigenic and biologic properties. These variations may account for differences in virulence between isolates. The bullet-shaped, enveloped viruses are single-strand RNA viruses of negative polarity. The rabies virus genome encodes five proteins: the nucleoprotein, the matrix protein, the glycoprotein, the phosphorylated protein, and a large polymerase protein. In immunofluorescence and complement fixation studies, broadly cross-reacting antigenic sites on the nucleoprotein are used to determine placement within the genus. The relatedness of a viral isolate to rabies and rabies-related viruses is determined by the comparison of specific antigenic sites or, more recently, by examination of RNA sequences. Cross-neutralization by rabies virus antisera ranges from moderate to very low. Only one serogroup is recognized within the genus. Recently, four new lyssaviruses have been described that expand current knowledge, classification, and taxonomy of rabies and rabies-related viruses.

EPIDEMIOLOGY An understanding of the epizootiology of rabies is necessary in evaluating the risk of exposure and the need for rabies post-exposure prophylaxis (PEP) in humans. Rabies is found in mammals in all regions of the world except Antarctica. The susceptibility of mammals varies greatly and most likely is related to differences in cell surface receptor characteristics (e.g., type and abundance) and the impact of these differences on receptor-virus interactions. Rabies exists in two forms: *urban rabies*, propagated chiefly by unimmunized domestic dogs, and *sylvatic rabies*, propagated by skunks, foxes, raccoons, mongooses, wolves, and bats. Infection in domestic animals usually represents a "spillover" from sylvatic reservoirs of infection. Human infection occurs through contact with unimmunized domestic animals or from exposure to wild animals in locales where rabies is enzootic or epizootic. The worldwide incidence of human rabies is estimated at more than 30,000 cases per year. Southeast Asia, the Philippines, Africa, the Indian subcontinent, and tropical South America are areas where the disease is especially common. In some endemic areas, 1 to 2% of autopsies yield evidence of rabies. Increased travel of humans, along with intentional and unintentional translocation of animals (including known potential rabies-reservoir species), has made the recognition of clinical rabies and its prevention of increasing importance.

Although there are island countries and whole continents that consider themselves rabies-free, the designation is relative and should take into account potential animal translocation events, the capacity of rabies reservoir hosts (e.g., bats) for long-distance flight, the lack of adequate rabies diagnostic capacity and expertise, and the reluctance of national authorities to change official designations despite the identification of lyssaviruses among volant hosts (i.e., those capable of flight) and the identification of associated human rabies deaths.

The main reservoir of rabies throughout the world is the domestic dog. In developed countries, control of stray dogs and mandatory vaccination of owned dogs have resulted in the virtual elimination of this problem across large geographic areas (e.g., most of North America). With the virtual elimination of dog rabies in the United States since the 1960s, a dog bite now poses a dramatically reduced risk of rabies exposure that is appropriately managed by a 10-day observation of the dog. Tremendous advances in the control of dog rabies have recently been made in Latin and South American countries. However, dog rabies remains largely uncontrolled in most of Asia and Africa.

In addition to rabies in dogs, diverse rabies virus variants occur among other mammalian hosts. For example, the disease is found in the several species of mongoose in Asia and Africa and has been translocated to several Caribbean Islands. In Canada, rabies occurs among skunks and foxes, and raccoon rabies has invaded Ontario from New York. In Eastern Europe, rabies occurs among raccoon dogs. Coyotes, jackals, and other wild canids may serve as reservoirs or vectors in North America, Asia, and Africa. The major rabies virus variants in the United States occur among raccoons, skunks, red and gray foxes, coyotes, and multiple insectivorous bat species. The most recent outbreak—and the most intense to date—affects raccoons in the eastern states from Florida to Maine and westward to the Appalachians and eastern Ohio. At the epizootic front in Ohio, New York, Pennsylvania, and West Virginia, the largest evaluation of oral rabies vaccination of free-ranging raccoons is in progress and represents an attempt to contain the westward spread of raccoon rabies. The vaccine, which is contained in baits and distributed primarily by air, is a vaccinia-rabies glycoprotein recombinant virus. Although highly attenuated by the lack of a critical enzyme (thymidine kinase), the vaccine is a live vaccinia virus and can infect humans, as demonstrated by at least one accidental human infection. In the United States, the domestic animal most commonly infected with rabies is the cat (~300 cases per year vs. ~100 cases in dogs). All other domestic animals combined (i.e., cattle, horses, sheep, goats, and pigs) account for a total of 150 to 200 cases per year.

Rabies in insectivorous bats occurs in the United States, Canada, Europe, Asia, Australia, and Africa—i.e., in essentially every locality where these bats are found. The epidemiology of rabies in bats is not well understood. In the United States, multiple rabies virus variants are generally associated with particular bat species, but variants may infect bat species other than their primary reservoir and may also infect terrestrial mammals, including other wildlife, domestic animals, and humans. Because migratory bat species travel widely and aggregate in large numbers, the rabies virus variants associated with these species are relatively homogeneous. In contrast, variants associated with non-migratory bat species may demonstrate more genetic variation, such that isolates from particular geographic areas form distinct lineages. In general, the rate of rabies among seemingly healthy captured bats is low (1 in 100 to 1000). However, the rate of rabies among dead and dying bats in high-density colonies may be >50%. Rabies cannot be ruled out definitively in an individual bat or in any other animal except by direct fluorescent antibody testing of brain tissue.

The "bat" category in rabies surveillance reports includes a wide variety of species as well as many individual bats whose species is never identified. For surveillance purposes, it is uninformative to lump all bats together by order, as is the current practice in many states. Nevertheless, the total of rabid bats is second only to the number of rabid raccoons and skunks. In contrast to a single human case due to the raccoon rabies virus variant, a single human case of skunk-associated rabies, and two human cases of dog/coyote-associated rabies since 1980, the 30 human rabies cases due to bats account for >90% of all human rabies cases in the United States since that date. It is intriguing that a particular bat-associated rabies virus is implicated in most human cases: Ln/Ps, which is associated with silver-haired and eastern pipistrelle bats. Several factors may be involved in this observation. One possibility is that the teeth of these bats are so small that a bite may be dismissed (e.g., if the victim is unaware of the potential for rabies in these animals) or even go unrecognized (e.g., if the victim is asleep or under the influence of drugs or alcohol). Another possibility is that this virus variant may be better than others at replicating in cells of epidermal origin and at cooler temperatures. Perhaps a unique viral adaptation coupled with a relatively nontraumatic bite introduction is facilitating the emergence of this source of rabies in humans in the United States.

Human rabies is rare in the United States. The disease can be prevented if the exposure is recognized and appropriate local wound care and human rabies PEP are administered. From 1980 to 2002, most human rabies cases in the United States were acquired indigenously, with no apparent geographic trends. Two indigenously acquired human cases were associated with a localized outbreak of rabies among coyotes and dogs at the U.S.–Mexico border; however, this was a small outbreak in terms of relative animal case numbers.

A comparison of the epidemiology of animal rabies, human rabies PEP, and human rabies cases in the United States presents an interesting conundrum. Raccoons are the leading rabies reservoir, but only one human death from the raccoon-associated rabies virus variant has been documented. Since human rabies PEP is not reportable, there are

few epidemiologic data on exposure to this reservoir. However, according to limited studies, most human rabies PEP is administered because of potential exposure to domestic cats and dogs in which rabies is suspected rather than because of direct exposure to raccoons or skunks—the first and second most commonly rabid animals in the United States.

PATHOGENESIS The first event in rabies is the inoculation of virus through the skin, usually through a bite that delivers virus-laden saliva. Initial viral replication appears to occur within striated muscle cells at the site of inoculation. The peripheral nervous system is exposed at the neuromuscular and/or neurotendinous spindles of unmyelinated sensory nerve cell endings, with neurotransmitter receptors such as acetylcholine implicated in viral attachment and internalization. The virus then spreads centripetally up the nerve to the CNS, probably via peripheral nerve axoplasm, at a rate of ~3 mm/h. Viremia has been documented in experimental conditions but is not thought to play a role in naturally acquired disease. Once the virus reaches the CNS, it replicates almost exclusively within the gray matter and then passes centrifugally along autonomic nerves to other tissues—the salivary glands, adrenal medulla, kidneys, lungs, liver, skeletal muscles, skin, and heart. Passage of the virus into the salivary glands and viral replication in mucinogenic acinar cells facilitate further transmission via infected saliva. The incubation period of rabies is exceedingly variable, ranging from 7 days to >1 year (mean, 1 to 2 months) and apparently depending on the amount of virus introduced, the amount of tissue involved, host defense mechanisms, and the actual distance that the virus has to travel from the site of inoculation to the CNS. Rates of infection and mortality are highest from bites on the face, intermediate from bites on the hands and arms, and lowest from bites on the legs. Cases of human rabies with an extended incubation period (2 to 7 years) have been reported, but they are rare. Host immune responses and viral strains also influence disease expression.

The neuropathology of rabies resembles that of other viral diseases of the CNS: hyperemia, varying degrees of chromatolysis, nuclear pyknosis, and neuronophagia of the nerve cells; infiltration by lymphocytes and plasma cells of the Virchow-Robin space; microglial infiltration; and parenchymal areas of nerve cell destruction. In experimental animal models, adenohypophyseal infection with rabies virus, with reduction in growth hormone and vasopressin release, is common. The most characteristic pathologic finding of rabies in the CNS is the formation of cytoplasmic inclusions called *Negri bodies* within neurons. Each eosinophilic mass measures ~10 nm and is made up of a finely fibrillar matrix and rabies virus particles. Negri bodies are distributed throughout the brain, particularly in Ammon's horn, the cerebral cortex, the brainstem, the hypothalamus, the Purkinje cells of the cerebellum, and the dorsal spinal ganglia. Negri bodies are not demonstrated in at least 20% of cases of rabies, and their absence from brain material does not rule out the diagnosis.

CLINICAL MANIFESTATIONS (See also Table 179-1) The clinical manifestations of rabies can be divided into four stages: (1) a nonspecific prodrome; (2) an acute encephalitis similar to other viral encephalitides; (3) a profound dysfunction of brainstem centers that produces the classic features of rabies encephalitis; and (4) death or, in rare cases, recovery.

The prodromal period usually lasts 1 to 4 days and is marked by fever, headache, malaise, myalgias, increased fatigability, anorexia, nausea and vomiting, sore throat, and a nonproductive cough. The prodromal symptom suggestive of rabies is the complaint of paresthesia and/or fasciculations at or around the site of inoculation of virus. These sensations, which may be related to the multiplication of virus in the dorsal root ganglion of the sensory nerve supplying the area of the bite, are reported by 50 to 80% of patients.

The encephalitic phase is usually ushered in by periods of excessive motor activity, excitation, and agitation. Confusion, hallucinations, combativeness, bizarre aberrations of thought, muscle spasms, meningismus, opisthotonic posturing, seizures, and focal paralysis soon appear. Characteristically, the periods of mental aberration are interspersed with completely lucid periods, but as the disease progresses the lucid periods get shorter until the patient lapses into coma. Hyperesthesia, with excessive sensitivity to bright light, loud noise, touch, and even gentle breezes, is very common. On physical examination, the temperature may be found to be as high as 40.6°C (105°F). Abnormalities of the autonomic nervous system include dilated irregular pupils; increased lacrimation, salivation, and perspiration; and postural hypotension. Evidence of upper motor neuron paralysis, with weakness, increased deep tendon reflexes, and extensor plantar responses, is the rule. Paralysis of the vocal cords is common. Unfortunately, the presenting signs and symptoms of rabies are indistinguishable from those of other viral and neurologic diseases. Thus delays in diagnosis are frequent. The presence of hydrophobia or aerophobia (seen in about two-thirds of recent cases) increases the likelihood of antemortem diagnosis.

TABLE 179-1 General Clinical Course of Human Rabies

Phase	Duration	Features/Comments
Exposure	—	Often unrecognized, particularly if of bat origin
Incubation period	3–4 weeks to 3–4 months in 95% of cases; 1–7 years in 1% of cases	—
Prodrome	1–2 days to 1 week	Fever, headache, anorexia, nausea, vomiting, malaise, lethargy, focal pain, paresthesia, anxiety, agitation, depression
Acute neurologic (encephalitic) phase	1–2 days to <1 week	Confusion, delirium, hallucinations, dysphagia, hypersalivation, aphasia, incoordination, marked hyperactivity, pharyngeal spasms, hydrophobia, aerophobia, hyperventilation, hypoxia, seizures
Coma, death	Several days to 1 week	Autonomic instability, hypoventilation, apnea, respiratory arrest, hypo-/hyperthermia, hypotension, pituitary dysfunction, rhabdomyolysis, cardiac arrhythmia, cardiac arrest

The manifestations of brainstem dysfunction begin shortly after the onset of the encephalitic phase. Cranial nerve involvement causes diplopia, facial palsies, optic neuritis, and the characteristic difficulty with deglutition. The combination of excessive salivation and difficulty in swallowing produces the traditional picture of "foaming at the mouth." Hydrophobia—the painful, violent, involuntary contraction of the diaphragmatic, accessory respiratory, pharyngeal, and laryngeal muscles initiated by swallowing liquids—is seen in ~50% of cases. Involvement of the amygdaloid nucleus may result in priapism and spontaneous ejaculation. The patient lapses into coma, and involvement of the respiratory center produces an apneic death. The prominence of early brainstem dysfunction distinguishes rabies from other viral encephalitides and accounts for the rapid downhill course. The median period of survival after the onset of symptoms is 4 days, with a maximum of 20 days, unless artificial supportive measures are instituted.

If intensive respiratory support is used, a number of late complications may appear. These include inappropriate secretion of antidiuretic hormone, diabetes insipidus, cardiac arrhythmias, vascular instability, adult respiratory distress syndrome, gastrointestinal bleeding, thrombocytopenia, and paralytic ileus. Recovery is very rare and, when it occurs, gradual.

Rabies may also present as an ascending paralysis resembling the Landry/Guillain-Barré syndrome (dumb rabies, *rage tranquille*). Ini-

tially, this clinical pattern was reported most frequently among persons given PEP after being bitten by vampire bats. Paralytic rabies also occurs in Southeast Asia among persons with canine exposures. The difficulty of diagnosing rabies associated with ascending paralysis is illustrated by cases of person-to-person transmission of the virus by tissue transplantation. Corneal transplants from donors who died of presumed Landry/Guillain-Barré syndrome produced clinical rabies in and caused the deaths of the recipients. Retrospective pathologic examinations of the brains of recipients demonstrated Negri bodies, and rabies virus was subsequently isolated from each donor's frozen eye.

LABORATORY FINDINGS During the early clinical period of rabies infection, laboratory findings—like signs and symptoms—are nonspecific. Complete blood cell counts and differentials are compatible with an acute viral illness. As with encephalitis or meningitis of any viral etiology, there is mild pleocytosis (>5 cells/μL) in the cerebrospinal fluid (CSF), with lymphocytosis. The CSF protein level may be mildly elevated, but the glucose level is generally normal. A decreased level of glucose in the CSF suggests the possibility of fungal, tuberculous, parasitic, leptospiral, syphilitic, sarcoid, or neoplastic meningitis. Severe pleocytosis (>1000 cells/μL) is compatible with nonviral and other inflammatory etiologies. The presence of large numbers of polymorphonuclear cells is indicative of bacterial infection, leptospirosis, amebic infection, and some noninfectious processes.

The most critical laboratory findings in suspected cases of human rabies are those that permit the exclusion of other etiologies (i.e., the most common sources of encephalitis) and that document a rapidly deteriorating clinical course compatible with rabies (see "Differential Diagnosis," below). Antemortem diagnosis of human rabies can be arranged through consultation with the relevant state health department and the Centers for Disease Control and Prevention (CDC). Such a diagnosis requires samples of the patient's CSF and serum (preferably paired), fresh saliva, and a full-thickness skin biopsy sample from the nape of the neck. If a patient dies during the effort to rule out rabies, fresh brain material is the optimal sample for a definitive postmortem diagnosis.

Rabies Virus–Specific Antibodies in Serum and CSF Since rabies virus remains in the "immunologically privileged" CNS (with no viremia), the infection is largely undetected by the immune system until late in the clinical course. Once encephalitis develops, immune surveillance within the CNS is substantially heightened and viral antigen is widespread, resulting in the development of an antibody response and the influx of cytotoxic T cells. Thus, rabies virus–specific antibodies in serum and CSF develop relatively late in the clinical course and, when the patient dies during the acute phase, may be undetectable.

Two laboratory methods are commonly used to detect rabies virus–specific antibodies. The *indirect fluorescent antibody test* involves the addition of dilutions of test serum to plates with wells containing rabies virus–infected cells. If rabies antigen–specific antibodies are present in the serum, they bind to infected cells. The bound antibody is then detected with fluorescein-tagged antihuman antibodies. This rapid test predominantly detects antibodies to the rabies virus nucleoprotein. The *rapid fluorescent focus inhibition test* (RFFIT) is a valuable but labor-intensive method that takes 1 day to complete. The RFFIT requires that a fixed amount of live rabies virus and dilutions of test serum be added to cell monolayers and allowed to incubate for 20 h. If neutralizing antibodies to the rabies virus glycoprotein are present in the patient's serum, few or no infected foci are seen when the direct fluorescent antibody (DFA) test is applied to the cell monolayer, because the viral particles will have been neutralized by antibodies and prevented from infecting cells. Rabies virus–specific antibodies may be found in serum as a result of previous vaccination against rabies. In contrast, the occurrence of rabies virus antibodies in the CSF is diagnostic for rabies (or, in extremely rare cases, indicative of previous exposure to and survival of rabies virus), since antibodies from vaccination do not cross an intact blood-brain barrier.

Reverse-Transcription Polymerase Chain Reaction (RT-PCR) on Fresh Saliva Viral shedding in the saliva directly precedes and accompanies the development of clinical signs in animals and probably in humans as well. During early CNS infection, the host may appear normal, but virus may already be present in the saliva as a result of centrifugal spread. With the exquisitely sensitive RT-PCR, the presence of rabies virus nucleic acid in fresh saliva can be confirmed or ruled out. If testing is performed very early in the clinical course, additional samples may need to be evaluated, because viral shedding may be intermittent at this time.

DFA Testing and RT-PCR on a Skin Biopsy Sample As a result of wide centrifugal spread, the rabies virus genome and antigen may be detectable in a skin biopsy from the nape of the patient's neck during the clinical course of suspected rabies. With the DFA test, viral antigen may be demonstrated in peripheral nerves associated with hair follicles in the skin sample. RT-PCR has shown greater sensitivity for detection of rabies genomic material in skin samples.

Other Tests Although patients with encephalitis are invariably evaluated with advanced tests (e.g., magnetic resonance imaging, computed tomography, electroencephalography, evoked response studies, electromyography, and nerve conduction studies), the results are nondiagnostic for rabies.

DIFFERENTIAL DIAGNOSIS The differential diagnosis in a case of suspected human rabies may initially include any cause of encephalitis, particularly infection with viruses such as herpesviruses, enteroviruses, and arboviruses (e.g., West Nile virus). The most important viruses to rule out are herpes simplex virus type 1, varicella-zoster virus, and (less commonly) enteroviruses, including coxsackieviruses, echoviruses, polioviruses, and human enteroviruses 68 to 71. A specific diagnosis may be made by a variety of diagnostic techniques, including CSF PCR testing, culture, and serology. In addition, consideration should be given to the local epidemiology of encephalitis caused by arboviruses belonging to several taxonomic groups, including eastern and western equine encephalitis viruses, St. Louis encephalitis virus, Powassan virus, the California encephalitis virus serogroup, and La Crosse virus.

New causes of viral encephalitis are also possible, as was evidenced by the recent outbreak in Malaysia of ~300 cases of encephalitis (mortality rate, 40%) caused by Nipah virus, a new paramyxovirus. Similarly, well-known viruses may be introduced into new locations, as is illustrated by the recent outbreak of encephalitis due to West Nile virus in the eastern United States. Epidemiologic factors (e.g., season, geographic location, and the patient's age, travel history, and possible exposure to animal bites, rodents, and ticks) may help direct the diagnostic workup.

TREATMENT

There is no specific treatment for clinical rabies. Death is virtually inevitable once clinical signs develop. Medical management is supportive and palliative.

POSTEXPOSURE PROPHYLAXIS When an exposure to rabies is recognized, immediate and thorough wound cleansing and the prompt administration of PEP (Table 179-2) are extremely effective in preventing infection. With regard to the prevention of human rabies in developed countries, recognition of a potential exposure and its distinction from circumstances in which no exposure has occurred are key steps in the judicious administration of rabies biologics. In developing countries, the prevention of rabies is hindered by economic conditions and inadequate access to modern biologics.

Unprovoked bites, especially if severe and multiple, by a confirmed rabid animal constitute the most obvious and highest-risk route of exposure to rabies. As stated in the recommendations of the Advisory Committee on Immunization Practices (ACIP, Table 179-2), simply touching a rabid animal (or person) does not constitute an exposure to rabies. Rabies virus forms an infectious aerosol only under intentional

TABLE 179-2 *Rabies Postexposure Prophylaxis Guide—United States*

Animal Type	Evaluation and Disposition of Animal	Postexposure Prophylaxis Recommendations
Dogs, cats, and ferrets	Healthy and available for 10 days observation	No treatment is necessary unless animal develops clinical signs of rabies.[a]
	Rabid or suspected rabid	Begin PEP.
	Unknown (e.g., escaped)	Consult public health officials.
Skunks, raccoons, foxes, and most other carnivores; bats	Regarded as rabid unless animal proven negative by laboratory tests[b]	Consider immediate vaccination.
Livestock, small rodents, lagomorphs (rabbits and hares), large rodents (woodchucks and beavers), and other mammals	Consider individually	Consult public health officials. Bites of squirrels, hamsters, guinea pigs, gerbils, chipmunks, rats, mice, other small rodents, small rodents, rabbits, and hares almost never require antirabies postexposure prophylaxis.

[a] During the 10-day observation period, begin postexposure prophylaxis at the first sign of rabies in a dog, cat, or ferret that has bitten someone. If the animal exhibits clinical signs of rabies, it should be euthanized immediately and tested.
[b] The animal should be euthanized and tested as soon as possible. Holding for observation is not recommended. Discontinue vaccine if immunofluorescence test results of the animal are negative.
Source: Human rabies prevention—United States, 1999. Recommendations of the Advisory Committee on Immunization Practices (ACIP). MMWR Recomm Rep 48(RR-1): 1-21, 1999; erratum in MMWR 48(1):16, 1999; MMWR 49(32):737, 2000.

or highly unnatural conditions. The only cases in which the aerosol route has been implicated are laboratory accidents and the Frio cave incidents of 50 years ago; in the latter situation, other routes of exposure for the bat biologists (e.g., bat bites or—in one person—contamination of an excoriated area of eczema) could not be ruled out. Contamination of mucous membranes with infectious material is considered an exposure to rabies because of observations in various species of occasional rabies cases resulting from intentional oral or intranasal exposure to high titers of virus; however, the majority of animals so exposed are unaffected, and a few such animals even develop immunity to rabies. Limited laboratory experiments with direct ocular exposure to rabies in one animal species did not result in viral infection; nevertheless, ocular contact with potentially contaminated material is considered an exposure because of the historic occurrence of human rabies cases after the transplantation of corneas from donors retrospectively diagnosed with rabies. Contamination of a fresh wound with infectious material (brain, salivary gland, or other innervated tissue from a rabid animal) constitutes an exposure to rabies.

Once the possibility of exposure has been identified, the wound should be thoroughly scrubbed with soap and then flushed with water. Both mechanical cleansing and chemical cleansing are important. Quaternary ammonium compounds such as 1 to 4% benzalkonium chloride, 1% cetrimonium bromide, or povidone-iodine solutions should be used. Tetanus toxoid and antibiotic prophylaxis should be administered as needed.

With an established exposure, the decision to administer human rabies biologics is straightforward if the animal is available for rabies diagnosis (i.e., euthanasia, brain removal, and laboratory testing). In dogs, cats, and ferrets in the United States, the potential shedding period indicates the adequacy of observation of the animal for 10 days after a bite to a human. If the animal remains clinically normal, laboratory and epidemiologic data indicate no risk of rabies exposure through the bite (although clearly, if unvaccinated, the animal may develop rabies in the future). If the animal develops signs suggestive of rabies, it should be euthanized and tested immediately, and the human victim should be treated according to the laboratory test result. If the animal is unavailable, the decision to treat depends upon the risk of rabies in the individual animal, the local epizootiology of rabies and the consequent risk to the individual animal, the potential route of exposure (i.e., multiple severe bites vs. potential contamination of mucous membranes with infectious material), and other factors. This decision may best be made in consultation with local, state, and federal public health professionals who have specialized knowledge of these variables.

Human rabies PEP consists of five doses of a modern cell culture vaccine, of which two types are commonly available for use in the United States (Table 179-3). The current cell culture vaccines are virtually equivalent in their unfailing potency and relative paucity of adverse effects. A reaction compatible with delayed-type hypersensitivity may occur in up to 12% of patients receiving human diploid cell vaccine; continuation of the pre- or postexposure series with an alternative vaccine may be sufficient for the resolution of this reaction. Doses are administered on a schedule of 0, 3, 7, 14, and 28 days. In addition to vaccine on day 0, one dose of human rabies immune globulin (20 IU/kg) should be given; as much of the dose as is anatomically feasible should be administered at the site of the bite, with any excess administered intramuscularly at a distant site—e.g., in the deltoid opposite the vaccine site. Periodically, human rabies immune globulin is in short supply. If it is not immediately available, the vaccine series should be initiated and the rabies immune globulin may be added at any point through day 7. After day 7, it is not necessary to add rabies immune globulin to the patient's regimen because endogenous antibodies are being produced and exogenous antibodies may actually be counterproductive. If a patient presents at a long interval after a potential exposure, it is not too late to initiate full human PEP unless clinical signs are present.

PREEXPOSURE RABIES VACCINATION Preexposure rabies vaccination is available to persons at risk of rabies exposure. The ACIP recommends a series of 1-mL doses of modern cell culture vaccine administered intramuscularly on days 0, 7, and 21 or 28. Once immunized against rabies with potent vaccines, individuals are primed against rabies for the rest of their lives. If an exposure occurs, a previously immunized

person should receive postexposure boosters consisting of two doses 3 days apart. Persons in the high-risk and moderate-risk rabies exposure categories should have their rabies virus–neutralizing antibody titers monitored every 6 months and every 2 years, respectively. Persons in the low-exposure category do not require serologic monitoring but, like all previously immunized persons, must receive the two booster vaccinations upon exposure to rabies. Moreover, appropriate wound care (i.e., copious flushing and the use of soap or detergent) remains critical.

MOKOLA VIRUS

Mokola virus was first isolated from wild shrews captured in Nigeria and was shown to be related morphologically and serologically to rabies virus. The subsequent isolation of the virus from cats in South Africa suggested a wider prevalence of the agent than had previously been expected. Only two cases of clinical infection have been reported; both were in children. One patient had a nonfatal illness characterized by fever, pharyngitis, and convulsions; Mokola virus was recovered from CSF. In the second patient, fever with cough and vomiting was followed within several days by drowsiness, confusion, and generalized flaccid weakness. The CSF was normal. The patient progressed to deep coma and died within 10 days of onset. Mokola virus was isolated from the brain, and examination of histopathologic sections revealed finely granular cytoplasmic inclusions that were distinguishable from Negri bodies in many neurons.

VESICULAR STOMATITIS VIRUS

Vesicular stomatitis is a viral illness of animals that occasionally affects humans. It presents as an acute, self-limited, influenza-like disease. The disease in animals is found in the United States and South America and affects chiefly domestic cattle, horses, swine, wild deer, raccoons, skunks, and bobcats.

In animals, vesicular stomatitis is characterized by the development of vesicles on the oral mucosa, particularly the tongue; the udders; and the heels. The mode of spread is probably by direct contact; however, epidemics tend to occur in warm weather, and isolation of the virus from *Phlebotomus* sandflies in Panama and *Aedes* mosquitoes in New Mexico suggests that these insects may be vectors. Two distinct types, New Jersey and Indiana, have been recognized, and most outbreaks in North America have been attributed to the New Jersey strain.

In humans, vesicular stomatitis is most common among laboratory workers. In one report, three-fourths of laboratory personnel handling experimentally infected animals or manipulating the virus developed neutralizing antibodies. The disease is also transmissible, however, under natural conditions among workers having direct contact with infected animals, especially cattle. An incubation period ranging from 1 to 6 days is followed by the sudden onset of fever [with temperatures of up to 40°C (104°F)], chills, profuse sweating, myalgias, malaise, headache, and pain on ocular movement. One-third to one-half of patients have a sore throat and cervical and/or submandibular adenopathy. Small raised vesicular lesions may appear on the buccal mucosa. Conjunctivitis and coryza are evident in ~20% of cases. Small subcorneal, intraepithelial vesicles occasionally appear on the fingers, usually in association with direct inoculation of the virus. Symptoms generally last 3 to 4 days, but occasionally the course is diphasic. Inapparent infection is common: among laboratory workers with serologic evidence of infection, only about one-half report symptoms. In some areas of Panama, 17 to 35% of the population have neutralizing antibodies to vesicular stomatitis virus.

The differential diagnosis includes hand-foot-and-mouth disease, herpangina, primary herpetic pharyngitis and other mucocutaneous syndromes, and influenza. The virus is not commonly isolated from patients. However, a rise in titer of complement-fixation and/or neutralizing antibody to vesicular stomatitis virus between acute- and convalescent-phase sera helps to confirm the diagnosis. Treatment is nonspecific.

180 INFECTIONS CAUSED BY ARTHROPOD- AND RODENT-BORNE VIRUSES

Clarence J. Peters

Some viruses are transmitted in nature without regard to humans and only incidentally infect and produce disease in humans; in addition, a few agents are regularly spread among humans by arthropods. Most of these viruses either are maintained by arthropods or chronically infect rodents. Obviously, the mode of transmission is not a rational basis for taxonomic classification. Indeed, zoonotic viruses from at least seven virus families act as significant human pathogens (Table 180-1). The virus families differ fundamentally from one another in terms of morphology, replication mechanisms, and genetics. Information on a virus's membership in a family or genus is enlightening with regard to maintenance strategies, sensitivity to antivirals, and some aspects of pathogenesis but does not necessarily predict which clinical syndromes—if any—the virus will cause in humans.

FAMILIES OF ARTHROPOD- AND RODENT-BORNE VIRUSES (Table 180-1)

The Arenaviridae

The Arenaviridae are spherical, 110- to 130-nm particles that bud from the cell's plasma membrane and utilize ambisense RNA genomes with two segments for replication. There are two main phylogenetic branches of Arenaviridae: the Old World viruses, such as Lassa fever and lymphocytic choriomeningitis (LCM) viruses, and the New World viruses, including those causing the South American hemorrhagic fevers (HFs). Arenaviruses persist in nature by chronically infecting rodents with a striking one-virus–one-rodent species relationship. These rodent infections result in long-term virus excretion and perhaps in lifelong viremia; vertical infection is common with some arenaviruses. Humans become infected through the inhalation of aerosols containing arenaviruses, which are then deposited in the terminal air passages, and probably also through close contact with rodents and their excreta, which results in the contamination of mucous membranes or breaks in the skin.

The Bunyaviridae

The family Bunyaviridae includes four medically significant genera. All of these spherical viruses have three negative-sense RNA segments maturing into 90- to 120-nm particles in the Golgi complex and exiting the cell by exocytosis. Viruses of the genus *Bunyavirus* are largely mosquito-borne and have a viremic vertebrate intermediate host; many are also transovarially transmitted in their specific mosquito host. One serologic group also uses biting midges as vectors. Sandflies or mosquitoes are the vectors for the genus *Phlebovirus* (named after phlebotomus fever or sandfly fever, the best-known disease associated with the genus), while ticks serve as vectors for the genus *Nairovirus*. Viruses of both of these genera are also associated with vertical transmission in the arthropod host and with horizontal spread through viremic vertebrate hosts. The genus *Hantavirus* is unique among the Bunyaviridae in that it is not transmitted by arthropods but is maintained in nature by rodent hosts that chronically shed virus. Like the arenaviruses, the hantaviruses usually display striking virus-rodent species specificity. Hantaviruses do not cause chronic viremia in their rodent hosts and are transmitted only horizontally from rodent to rodent.

Other Families

The Flaviviridae are positive-sense, single-strand RNA viruses that form particles of 40 to 50 nm in the endoplasmic reticulum. The flaviviruses discussed here are from the genus *Flavivirus* and make up two phylogenetically and antigenically distinct divisions transmitted among vertebrates by mosquitoes and ticks, respectively.

TABLE 180-1 *Major Zoonotic Virus Families and Some Characteristics of Typical Members*

Family	Genus or Group	Syndrome(s): Typical Viruses	Maintenance Strategy
Arenaviridae	Old World complex	FM, E: Lymphocytic choriomeningitis virus HF: Lassa fever virus	Chronic infection of rodents, often with persistent viremia; vertical transmission common
	New World or Tacaribe complex	HF: South American HF viruses (Machupo, Junin, Guanarito, Sabia)	Chronic infection of rodents, sometimes with persistent viremia; vertical infection may occur
Bunyaviridae	*Bunyavirus*	E: California serogroup viruses (La Crosse, Jamestown Canyon, California encephalitis) FM: Bunyamwera, group C, Tahyna viruses	Mosquito-vertebrate cycle; transovarial transmission in mosquito common
		FM: Oropouche virus	Transmitted by *Culicoides*
	Phlebovirus	FM: Sandfly fever, Toscana viruses FM: Punta Toro virus HF, FM, E: Rift Valley fever virus	Sandfly transmission between vertebrates, with prominent transovarial component in sandfly Mosquito-vertebrate transmission, with transovarial component in mosquito
	Nairovirus	HF: Crimean-Congo HF virus	Tick-vertebrate, with transovarial transmission in tick
	Hantavirus	HF: Hantaan, Dobrava, Puumala viruses	Rodent reservoir; chronic virus shedding, but chronic viremia unknown
		HF: Sin Nombre and related hantaviruses	Sigmodontine rodent reservoir
Filoviridae[a]		HF: Marburg viruses, Ebola viruses (4 subtypes)	Unknown
Flaviviridae	*Flavivirus* (mosquito-borne)	HF: Yellow fever virus FM, HF: Dengue viruses (4 subtypes) E: St. Louis, Japanese, West Nile, and Murray Valley encephalitis viruses; Rocio viruses	Mosquito-vertebrate; transovarial rare
	Flavivirus (tick-borne)	E: Central European tick-borne encephalitis, Russian spring-summer encephalitis, Powassan viruses HF: Omsk HF, Kyasanur Forest disease viruses	Tick-vertebrate
Reoviridae	*Coltivirus*	FM, E: Colorado tick fever virus	Tick-vertebrate
	Orbivirus	FM, E: Orungo, Kemerova viruses	Arthropod-vertebrate
Rhabdoviridae[b]	*Vesiculovirus*	FM: Vesicular stomatitis virus (Indiana, New Jersey); Chandipura, Piry viruses	Sandfly-vertebrate, with prominent transovarial component in sandfly
Togaviridae	*Alphavirus*	AR: Sindbis, chikungunya, Mayaro, Ross River, Barmah Forest viruses E: Eastern, western, and Venezuelan equine encephalitis viruses	Mosquito-vertebrate

[a] The Filoviridae are discussed in Chap. 181.
[b] The Rhabdoviridae are discussed in Chap. 179.

Note: Abbreviations refer to the disease syndrome most commonly associated with the virus: FM, fever, myalgia; AR, arthritis, rash; E, encephalitis; HF, hemorrhagic fever.

The mosquito-borne viruses fall into phylogenetic groups that include yellow fever virus, the four dengue viruses, and encephalitis viruses, while the tick-borne group encompasses a geographically varied spectrum of species, some of which are responsible for encephalitis or for hemorrhagic disease with encephalitis. The Reoviridae are double-strand RNA viruses with multisegmented genomes. These 80-nm particles are the only viruses discussed in this chapter that do not have a lipid envelope and thus are insensitive to detergents. The Togaviridae have a single positive-strand RNA genome and bud particles of ~60 to 70 nm from the plasma membrane. The togaviruses discussed here are all members of the genus *Alphavirus* and are transmitted among vertebrates by mosquitoes in their natural cycle. →***The Filoviridae and the Rhabdoviridae are discussed in Chaps. 181 and 179, respectively.***

PROMINENT FEATURES OF ARTHROPOD- AND RODENT-BORNE VIRUSES Although this chapter discusses the major features of selected arthropod- and rodent-borne viruses, it does not deal with >500 other distinct recognized zoonotic viruses, about one-fourth of which infect humans. Zoonotic viruses are undergoing genetic evolution, "new" zoonotic viruses are being discovered, and the epidemiology of zoonotic viruses is continuing to evolve through environmental changes affecting vectors, reservoirs, and humans. These zoonotic viruses are most numerous in the tropics but are also found in temperate and frigid climates. Their distribution and seasonal activity may be variable and often depend largely on ecologic conditions such as rainfall and temperature, which in turn affect the density of vectors and reservoirs and the development of infection therein.

Maintenance and Transmission Arthropod-borne viruses infect their vectors after the ingestion of a blood meal from a viremic vertebrate. The vectors then develop chronic, systemic infection as the viruses penetrate the gut and spread throughout the body. The viruses eventually reach the salivary glands during a period that is referred to as *extrinsic incubation* and that typically lasts 1 to 3 weeks in mosquitoes. At this point an arthropod is competent to continue the chain of transmission by infecting another vertebrate when a subsequent blood meal is taken. The arthropod generally is unharmed by the infection, and the natural vertebrate partner usually has only transient viremia with no overt disease. An alternative mechanism for virus maintenance in its arthropod host is transovarial transmission, which is common among members of the family Bunyaviridae.

Rodent-borne viruses such as the hantaviruses and arenaviruses are maintained in nature by chronic infection transmitted between rodents. As in arthropod-borne virus cycles, there is usually a high degree of rodent-virus specificity, and there is no overt disease in the reservoir/vector.

Epidemiology The distribution of arthropod- and rodent-borne viruses is restricted by the areas inhabited by their reservoir/vectors and provides an important clue in the differential diagnosis. Table 180-2 shows the approximate geographic distribution of the most important of these viruses. Members of each family, each genus, and even each serologically related group usually occur in each area but may not be pathogenic in all areas or may not be a commonly recognized cause of disease in all areas and so may not be included in the table.

Most of these diseases are acquired in a rural setting; a few have urban vectors. Seoul, sandfly fever, and Oropouche viruses are examples of urban viruses, but the most notable are yellow fever, dengue, and chikungunya viruses. A history of mosquito bite has little diagnostic significance in the individual; a history of tick bite is more diagnostically specific. Rodent exposure is often reported by persons infected with an arenavirus or a hantavirus but again has little specificity. Indeed, aerosols may infect persons who have no recollection of having even seen rodents.

Syndromes Human disease caused by arthropod- and rodent-borne viruses is often subclinical. The spectrum of possible responses to infection is wide, and our knowledge of the outcome of most of these infections is limited. The usual disease syndromes associated with these viruses have been grouped into four categories: fever and myalgia, arthritis and rash, encephalitis, and hemorrhagic fever. Although for the purposes of this discussion most viruses have been placed in a single group, the categories often overlap. For example, West Nile and Venezuelan equine encephalitis viruses are discussed as encephalitis viruses, but during epidemics they may cause many cases of milder

TABLE 180-2 *Geographic Distribution of Some Important and Commonly Encountered Human Zoonotic Viral Diseases*

Area	*Arenaviridae*	*Bunyaviridae*	*Flaviviridae*	*Rhabdoviridae*	*Togaviridae*
North America	Lymphocytic choriomeningitis	La Crosse, Jamestown Canyon, California encephalitis; hantavirus pulmonary syndrome	St. Louis, Powassan, West Nile encephalitis; dengue	Vesicular stomatitis	Eastern, western equine encephalitis
South America	Bolivian, Argentine, Venezuelan, and Brazilian HF; lymphocytic choriomeningitis	Oropouche, group C, Punta Toro infection; hantavirus pulmonary syndrome	Yellow fever, dengue, Rocio virus infection	Vesicular stomatitis, Piry virus infection	Mayaro virus infection, Venezuelan equine encephalitis
Europe	Lymphocytic choriomeningitis	Tahyna, Toscana, sandfly fever, HF with renal syndrome	West Nile, Central European tick-borne, Russian spring-summer encephalitis	—	Sindbis virus infection
Middle East	—	Sandfly fever, Crimean-Congo HF	West Nile encephalitis, dengue	—	—
Eastern Asia	—	Sandfly fever; Hantaan, Seoul virus infection	Dengue; Japanese, Russian spring-summer encephalitis; Omsk HF	Chandipura virus infection	—
Southwestern Asia	—	Sandfly fever, Crimean-Congo HF	West Nile, Japanese encephalitis; dengue; Kyasanur Forest disease	—	Chikungunya
Southeast Asia	—	Seoul virus infection	Japanese encephalitis, dengue	—	Chikungunya
Africa	Lassa fever	Bunyamwera virus infection, Rift Valley fever	Yellow fever, dengue	—	Sindbis virus infection, chikungunya
Australia	—	—	Murray Valley encephalitis, dengue	—	Ross River, Barmah Forest virus infection

Note: HF, hemorrhagic fever.

febrile syndromes and relatively uncommon cases of encephalitis. Similarly, Rift Valley fever virus is best known as a cause of HF, but the attack rates for febrile disease are far higher, and encephalitis is occasionally seen as well. LCM virus is classified as a cause of fever and myalgia because this syndrome is its most common disease manifestation and because, even when central nervous system (CNS) disease occurs, it is usually mild and is preceded by fever and myalgia. Dengue virus infection is considered as a cause of fever and myalgia (dengue fever) because this is by far the most common manifestation worldwide and is the syndrome most likely to be seen in the United States; however, dengue HF is also discussed in the HF section because of its complicated pathogenesis and importance in pediatric practice in certain areas of the world.

Diagnosis Laboratory diagnosis is required in any given case, although epidemics occasionally provide clinical and epidemiologic clues on which an educated guess as to etiology can be based. For most arthropod- and rodent-borne viruses, acute-phase serum samples (collected within 3 or 4 days of onset) have yielded isolates, and paired sera have been used to demonstrate rising antibody titers by a variety of tests. Intensive efforts to develop rapid tests for HF have resulted in an antigen-detection enzyme-linked immunosorbent assay (ELISA) and an IgM-capture ELISA that can provide a diagnosis based on a single serum sample within a few hours and are particularly useful in severe cases. More sensitive reverse-transcription polymerase chain reaction (RT-PCR) tests may yield diagnoses based on samples without detectable antigen and may also provide useful genetic information about the virus. Hantavirus infections differ from others discussed here in that severe acute disease is immunopathologic; patients present with serum IgM that serves as the basis for a sensitive and specific test.

At diagnosis, patients with encephalitis are generally no longer viremic or antigenemic and usually do not have virus in cerebrospinal fluid (CSF). In this situation, the value of serologic methods and RT-PCR is being validated. IgM capture is increasingly being used for the simultaneous testing of serum and CSF. IgG ELISA or classic serology is useful in the evaluation of past exposure to the viruses, many of which circulate in areas with a minimal medical infrastructure and sometimes cause mild or subclinical infection.

The remainder of this chapter offers general descriptions of the broad syndromes caused by arthropod- and rodent-borne viruses. Most of the diseases under consideration have not been studied in detail with modern medical approaches; thus available data may be incomplete or biased.

FEVER AND MYALGIA

Fever and myalgia constitute the syndrome most commonly associated with zoonotic virus infection. Many of the numerous viruses belonging to the families listed in Table 180-1 probably cause this syndrome, but several viruses have been selected for inclusion in the table because of their prominent associations with the syndrome and their biomedical importance.

The syndrome typically begins with the abrupt onset of fever, chills, intense myalgia, and malaise. Patients may also report joint pains, but no true arthritis is detectable. Anorexia is characteristic and may be accompanied by nausea or even vomiting. Headache is common and may be severe, with photophobia and retroorbital pain. Physical findings are minimal and are usually confined to conjunctival injection with pain on palpation of muscles or the epigastrium. The duration of symptoms is quite variable but generally is 2 to 5 days, with a biphasic course in some instances. The spectrum of disease varies from subclinical to temporarily incapacitating.

Less constant findings include a maculopapular rash. Epistaxis may occur but does not necessarily indicate a bleeding diathesis. A minority of the cases caused by some viruses are known or suspected to include aseptic meningitis, but this diagnosis is difficult in remote areas, given the patients' photophobia and myalgia as well as the lack of opportunity to examine the CSF. Although pharyngitis may be noted or radiographic evidence of pulmonary infiltrates found in some cases, these viruses are not primary respiratory pathogens. The differential diagnosis includes anicteric leptospirosis, rickettsial diseases, and the early stages of other syndromes discussed in this chapter. These diseases are often described as "flulike," but the usual absence of cough and coryza makes influenza an unlikely confounder except at the earliest stages.

Complete recovery is generally the outcome in this syndrome, although prolonged asthenia and nonspecific symptoms have been described in some cases, particularly after infection with LCM or dengue virus. Treatment is supportive, with aspirin avoided because of the potential for exacerbated bleeding and Reye's syndrome. Efforts at prevention are best based on vector control, which, however, may be expensive or impossible. For mosquito control, destruction of breeding sites is generally the most economically and environmentally sound approach. Measures taken by the individual to avoid the vector can be valuable. Avoiding the vector's habitat and times of peak activity, preventing the vector from entering dwellings by using screens or other barriers, judiciously applying arthropod repellents such as diethyltoluamide (DEET) to the skin, and wearing permethrin-impregnated clothing are all possible approaches, depending on the vector and its habits.

LYMPHOCYTIC CHORIOMENINGITIS LCM is transmitted from the common house mouse (*Mus musculus*) to humans by aerosols of excreta and secreta. LCM virus, an arenavirus, is maintained in the mouse mainly by vertical transmission from infected dams. The vertically infected mouse remains viremic for life, with high concentrations of virus in all tissues. Infected colonies of pet hamsters have also served as a link to humans. LCM virus is widely used in immunology laboratories as a model of T cell function and can silently infect cell cultures and passaged tumor lines, resulting in infections among scientists and animal caretakers. Patients with LCM may have a history of residence in rodent-infested housing or other exposure to rodents. An antibody prevalence of ~5 to 10% has been reported among adults from the United States, Argentina, and endemic areas of Germany.

LCM differs from the general syndrome of fever and myalgia in that its onset is gradual. Among the conditions occasionally associated with LCM are orchitis, transient alopecia, arthritis, pharyngitis, cough, and maculopapular rash. An estimated one-fourth of patients or fewer suffer a febrile phase of 3 to 6 days and then, after a brief remission, develop renewed fever accompanied by severe headache, nausea and vomiting, and meningeal signs lasting for about a week. These patients virtually always recover fully, as do the uncommon patients with clear-cut signs of encephalitis. Recovery may be delayed by transient hydrocephalus.

During the initial febrile phase, leukopenia and thrombocytopenia are common and virus can usually be isolated from blood. During the CNS phase of the illness, virus may be found in the CSF, but antibodies are present in blood. The pathogenesis of LCM is thought to resemble that following direct intracranial inoculation of the virus into adult mice; the onset of the immune response leads to T cell–mediated immunopathologic meningitis. During the meningeal phase, CSF mononuclear-cell counts range from the hundreds to the low thousands per microliter, and hypoglycorrhachia is found in one-third of cases. The IgM-capture ELISA of serum and CSF is usually positive; RT-PCR assays have been developed for application to CSF.

Infection with LCM virus should be suspected in acutely ill febrile patients with marked leukopenia and thrombocytopenia. In cases of aseptic meningitis, any of the following should suggest LCM: well-marked febrile prodrome, adult age, autumn seasonality, low CSF glucose levels, or CSF mononuclear cell counts of $>1000/\mu L$.

In pregnant women, LCM virus infection may lead to fetal invasion with consequent congenital hydrocephalus and chorioretinitis. Since the maternal infection may be mild, consisting of only a short febrile illness, antibodies to the virus should be sought in both the mother and the fetus in suspicious circumstances, particularly TORCH-negative neonatal hydrocephalus. [TORCH is a battery of tests encompassing

*t*oxoplasmosis, *o*ther conditions (congenital syphilis and viruses), *r*ubella, *c*ytomegalovirus, and *h*erpes simplex virus.]

SANDFLY FEVER The sandfly *Phlebotomus papatasi* transmits sandfly fever. Female sandflies may be infected by the oral route as they take a blood meal and may transmit the virus to offspring when they lay their eggs after a second blood meal. This prominent transovarial pattern was the first to be recognized among dipterans and complicates virus control. A previous designation for sandfly fever, "3-day fever," instructively describes the brief, debilitating course associated with this essentially benign infection. There is neither a rash nor CNS involvement, and complete recovery is the rule.

Sandfly fever is found in the circum-Mediterranean area, extending to the east through the Balkans into China as well as into the Middle East and southwestern Asia. The vector is found in both rural and urban settings and is known for its small size, which enables it to penetrate standard mosquito screens and netting, and for its short flight range. Epidemics have been described in the wake of natural disasters and wars. In parts of Europe, sandfly populations and virus transmission were greatly reduced by the extensive residual spraying conducted after World War II to control malaria, and the incidence continues to be low. A common pattern of disease in endemic areas consists of high attack rates among travelers and military personnel with little or no disease in the local population, who are protected after childhood infection. More than 30 related phleboviruses are transmitted by sandflies and mosquitoes, but most are of unknown significance in terms of human health.

DENGUE FEVER All four distinct dengue viruses (dengue 1–4) have *Aedes aegypti* as their principal vector, and all cause a similar clinical syndrome. In rare cases, second infection with a serotype of dengue virus different from that involved in the primary infection leads to dengue HF with severe shock (see below). Sporadic cases are seen in the settings of endemic transmission and epidemic disease. Year-round transmission between latitudes 25°N and 25°S has been established, and seasonal forays of the viruses to points as far north as Philadelphia are thought to have taken place in the United States. Dengue fever is seen in the Caribbean region, including Puerto Rico. With increasing spread of the vector mosquito throughout the tropics and subtropics, large areas of the world have become vulnerable to the introduction of dengue viruses, particularly through air travel by infected humans, and both dengue fever and the related dengue HF are becoming increasingly common. Conditions favorable to dengue transmission exist in the southern United States, and bursts of dengue fever activity are to be expected in this region, particularly along the Mexican border, where water may be stored in containers and *A. aegypti* numbers may therefore be greatest: this mosquito, which is also an efficient vector of the yellow fever and chikungunya viruses, typically breeds near human habitation, using relatively fresh water from sources such as water jars, vases, discarded containers, coconut husks, and old tires. *A. aegypti* usually inhabits dwellings and bites during the day.

After an incubation period of 2 to 7 days, the typical patient experiences the sudden onset of fever, headache, retroorbital pain, and back pain along with the severe myalgia that gave rise to the colloquial designation "break-bone fever." There is often a macular rash on the first day as well as adenopathy, palatal vesicles, and scleral injection. The illness may last a week, with additional symptoms usually including anorexia, nausea or vomiting, marked cutaneous hypersensitivity, and—near the time of defervescence—a maculopapular rash beginning on the trunk and spreading to the extremities and the face. Epistaxis and scattered petechiae are often noted in uncomplicated dengue, and preexisting gastrointestinal lesions may bleed during the acute illness.

Laboratory findings include leukopenia, thrombocytopenia, and, in many cases, serum aminotransferase elevations. The diagnosis is made by IgM ELISA or paired serology during recovery or by antigen-detection ELISA or RT-PCR during the acute phase. Virus is readily isolated from blood in the acute phase if mosquito inoculation or mosquito cell culture is used.

COLORADO TICK FEVER Several hundred cases of Colorado tick fever are reported annually in the United States. The infection is acquired between March and November through the bite of an infected *Dermacentor andersoni* tick in mountainous western regions at altitudes of 1200 to 3000 m (4000 to 10,000 ft). Small mammals serve as the amplifying host. The most common presentation consists of fever and myalgia; meningoencephalitis is not uncommon, and hemorrhagic disease, pericarditis, myocarditis, orchitis, and pulmonary presentations are also reported. Rash develops in a substantial minority of cases. The disease usually lasts 7 to 10 days and is often biphasic. The most important differential diagnostic considerations since the beginning of the twentieth century have been Rocky Mountain spotted fever and tularemia. In Colorado, Colorado tick fever is much more common than Rocky Mountain spotted fever.

Infection of erythroblasts and other marrow cells by Colorado tick fever virus results in the appearance and persistence (for several weeks) of erythrocytes containing the virus. This feature, detected in smears stained by immunofluorescence, can be diagnostically helpful. The clinical laboratory detects leukopenia and thrombocytopenia.

OTHER VIRUSES CAUSING FEVER AND MYALGIA For a discussion of additional zoonotic viral infections presenting with fever and myalgia, see Chap. 180 in *Harrison's Online* (*www.harrisonsonline.com*).

ENCEPHALITIS

Arboviral encephalitis is a seasonal disease, commonly occurring in the warmer months. Its incidence varies markedly with time and place, depending on ecologic factors. The causative viruses differ substantially in terms of case-infection ratio (i.e., the ratio of clinical to subclinical infections), mortality, and residua (Table 180-3). Humans are not an important amplifier of these viruses.

All the viral encephalitides discussed in this section have a similar pathogenesis as far as is known. An infected arthropod ingests a blood meal from a human and infects the host. The initial period of viremia is thought to originate most commonly from the lymphoid system. Viremia leads to CNS invasion, presumably through infection of olfactory neuroepithelium with passage through the cribriform plate or through infection of brain capillaries and multifocal entry into the CNS. During the viremic phase, there may be little or no recognized disease except in the case of tick-borne flaviviral encephalitis, in which there may be a clearly delineated phase of fever and systemic illness. The disease process in the CNS arises partly from direct neuronal infection and subsequent damage and partly from edema, inflammation, and other indirect effects. The usual pathologic picture is one of focal necrosis of neurons, inflammatory glial nodules, and perivascular lymphoid cuffing; the severity and distribution of these abnormalities vary with the infecting virus. Involved areas display the "luxury perfusion" phenomenon, with normal or increased total blood flow and low oxygen extraction.

The typical patient presents with a prodrome of nonspecific constitutional symptoms, including fever, abdominal pain, vertigo, sore throat, and respiratory symptoms. Headache, meningeal signs, photophobia, and vomiting follow quickly. Involvement of deeper structures may be signaled by lethargy, somnolence, and intellectual deficit (as disclosed by the mental status examination or failure at serial 7 subtraction); more severely affected patients will be obviously disoriented and may be comatose. Tremors, loss of abdominal reflexes, cranial nerve palsies, hemiparesis, monoparesis, difficulty in swallowing, and frontal lobe signs are all common. Spinal and motor neuron diseases are documented with West Nile and Japanese encephalitis viruses. Convulsions and focal signs may be evident early or may appear during the course of the disease. Some patients present with an abrupt onset of fever, convulsions, and other signs of CNS involvement. The results of human infection range from no significant symptoms through febrile headache to aseptic meningitis and finally to

TABLE 180-3 *Prominent Features of Arboviral Encephalitis*

Virus	Natural Cycle	Incubation Period, Days	Annual No. of Cases	Case-to-Infection Ratio	Age of Cases	Case-Fatality Rate, %	Residua
La Crosse	*Aedes triseriatus*–chipmunk (transovarial component in mosquito also important)	~3–7	70 (U.S.)	<1:1000	<15 years	<0.5	Recurrent seizures in ~10%; severe deficits in rare cases; decreased school performance and behavioral change suspected in small proportion
St. Louis	*Culex tarsalis*, *C. pipiens*, *C. quinquefasciatus*–birds	4–21	85, with hundreds to thousands in epidemic years (U.S.)	<1:200	Milder cases in the young; more severe cases in adults >40 years old, particularly the elderly	7	Common in the elderly
Japanese	*Culex tritaeniorhyncus*–birds	5–15	>25,000	1:200–300	All ages; children in highly endemic areas	20–50	Common (approximately half of cases); may be severe
West Nile	*Culex* mosquitoes–birds	3–6	?	Very low	Mainly the elderly	5–10	Uncommon
Central European	*Ixodes ricinus*–rodents, insectivores	7–14	Thousands	1:12	All ages; milder in children	1–5	20%
Russian spring-summer	*I. persulcatus*–rodents, insectivores	7–14	Hundreds	—	All ages; milder in children	20	Approximately half of cases; often severe; limb-girdle paralysis
Powassan	*I. cookei*–wild mammals	~10	~1 (U.S.)	—	All ages; some predilection for children	~10	Common (approximately half of cases)
Eastern equine	*Culiseta melanura*–birds	~5–10	5 (U.S.)	1:40 adult 1:17 child	All ages; predilection for children	50–75	Common
Western equine	*Culex tarsalis*–birds	~5–10	~20 (U.S.)	1:1000 adult 1:50 child 1:1 infant	All ages; predilection for children <2 years old (increased mortality in elderly)	3–7	Common only among infants <1 year old
Venezuelan equine (epidemic)	Unknown (multiple mosquito species and horses in epidemics)	1–5	?	1:250 adult 1:25 child (approximate)	All ages; predilection for children	~10	—

full-blown encephalitis; the proportions and severity of these manifestations vary with the infecting virus.

The acute encephalitis usually lasts from a few days to as long as 2 to 3 weeks, but recovery may be slow, with weeks or months required for the return of maximal recoupable function. Common complaints during recovery include difficulty concentrating, fatigability, tremors, and personality changes. The acute illness requires management of a comatose patient who may have intracranial pressure elevations, inappropriate secretion of antidiuretic hormone, respiratory failure, and convulsions. There is no specific therapy for these viral encephalitides. The only practical preventive measures are vector management and personal protection against the arthropod transmitting the virus; for Japanese encephalitis or tick-borne encephalitis, vaccination should be considered in certain circumstances (see relevant sections below).

The diagnosis of arboviral encephalitis depends on the careful evaluation of a febrile patient with CNS disease, with rapid identification of treatable herpes simplex encephalitis, ruling out of brain abscess, exclusion of bacterial meningitis by serial CSF examination, and performance of laboratory studies to define the viral etiology. Leptospirosis, neurosyphilis, Lyme disease, cat-scratch fever, and newer viral encephalitides such as Nipah virus infection from Malaysia should be considered. The CSF examination usually shows a modest cell count—in the tens or hundreds or perhaps a few thousand. Early in the process, a significant proportion of these cells may be polymorphonuclear leukocytes, but usually there is a mononuclear cell predominance. CSF glucose levels are usually normal. There are exceptions to this pattern of findings. In eastern equine encephalitis, for example, polymorphonuclear leukocytes may predominate during the first 72 h of disease and hypoglycorrhachia may be detected. In LCM, lymphocyte counts may be in the thousands, and the glucose concentration may be diminished. Experience with imaging studies is still evolving; clearly, however, both computed tomography (CT) and magnetic resonance imaging (MRI) may be normal, except for evidence of preexisting conditions, or sometimes may suggest diffuse edema. Several patients with eastern equine encephalitis have had focal abnormalities, and individuals with severe Japanese encephalitis have presented with bilateral thalamic lesions that have often been hemorrhagic. Electroencephalography usually shows diffuse abnormalities and is not directly helpful.

A humoral immune response is usually detectable at or near the onset of disease. Both serum and CSF should be examined for IgM antibodies. Virus generally cannot be isolated from blood or CSF, although Japanese encephalitis virus has been recovered from CSF in severe cases. Virus can be obtained from and viral antigen is present in brain tissue, although its distribution may be focal.

CALIFORNIA, LA CROSSE, AND JAMESTOWN CANYON VIRUS ENCEPHALITIS The isolation of California encephalitis virus established the California serogroup of viruses as a cause of encephalitis, and its use as a diagnostic antigen led to the description of many cases of "California encephalitis." In fact, however, this virus has been implicated in only a few cases of encephalitis, and the serologically related La Crosse virus is the major cause of encephalitis among viruses in the California serogroup. "California encephalitis" due to La Crosse virus infection is most commonly reported from the upper Midwest but is also found in other areas of the central and eastern United States, most often in West Virginia, Tennessee, North Carolina, and Georgia. The serogroup includes 13 other viruses, some of which may also be involved in human disease that is misattributed because of the complexity of the group's serology; these viruses include the Jamestown Canyon, snowshoe hare, Inkoo, and Trivittatus viruses, all of which have *Aedes* mosquitoes as

their vector and all of which have a strong element of transovarial transmission in their natural cycles.

The mosquito vector of La Crosse virus is *A. triseriatus*. In addition to a prominent transovarial component of transmission, a mosquito can also become infected through feeding on viremic chipmunks and other mammals as well as through venereal transmission from another mosquito. The mosquito breeds in sites such as tree holes and abandoned tires and bites during daylight hours; these findings correlate with the risk factors for cases: recreation in forested areas, residence at the forest's edge, and the presence of abandoned tires around the home. Intensive environmental modification based on these findings has reduced the incidence of disease in a highly endemic area in the Midwest. Most cases occur from July through September. The Asian tiger mosquito, *A. albopictus*, efficiently transmits the virus to mice and also transmits the agent transovarially in the laboratory; this aggressive anthropophilic mosquito has the capacity to urbanize, and its possible impact on transmission to humans is of concern.

An antibody prevalence of ≥20% in endemic areas indicates that infection is common, but CNS disease has been recognized primarily in children <15 years of age. The illness varies from a picture of aseptic meningitis accompanied by confusion to severe and occasionally fatal encephalitis. Although there may be prodromal symptoms, the onset of CNS disease is sudden, with fever, headache, and lethargy often joined by nausea and vomiting, convulsions (in one-half of patients), and coma (in one-third of patients). Focal seizures, hemiparesis, tremor, aphasia, chorea, Babinski's sign, and other evidence of significant neurologic dysfunction are common, but residua are not. Perhaps 10% of patients have recurrent seizures in the succeeding months. Other serious sequelae are rare, although a decrease in scholastic standing has been reported and mild personality change has occasionally been suggested. Treatment is supportive over a 1- to 2-week acute phase during which status epilepticus, cerebral edema, and inappropriate secretion of antidiuretic hormone are important concerns. Ribavirin has been used in severe cases, and a clinical trial of this drug is under way.

The blood leukocyte count is commonly elevated, sometimes reaching levels of 20,000/μL, and there is usually a left shift. CSF cell counts are typically 30 to 500/μL with a mononuclear cell predominance (although 25 to 90% of cells are polymorphonuclear in some cases). The protein level is normal or slightly increased, and the glucose level is normal. Specific virologic diagnosis based on IgM-capture assays of serum and CSF is efficient. The only human anatomical site from which virus has been isolated is the brain.

Jamestown Canyon virus has been implicated in several cases of encephalitis in adults; in these cases the disease was usually associated with a significant respiratory illness at onset. Human infection with this virus has been documented in New York, Wisconsin, Ohio, Michigan, Ontario, and other areas of North America where the vector mosquito, *A. stimulans*, feeds on its main host, the white-tailed deer.

ST. LOUIS ENCEPHALITIS St. Louis encephalitis virus is transmitted between *Culex* mosquitoes and birds. This virus causes low-level endemic infection among rural residents of the western and central United States, where *C. tarsalis* is the vector (see "Western Equine Encephalitis," below), but the more urbanized mosquito species *C. pipiens* and *C. quinquefasciatus* have been responsible for epidemics resulting in hundreds or even thousands of cases in cities of the central and eastern United States. Most cases occur in June through October. The urban mosquitoes breed in accumulations of stagnant water and sewage with high organic content and readily bite humans in and around houses at dusk. The elimination of open sewers and trash-filled drainage systems is expensive and may not be possible, but screening of houses and implementation of personal protective measures may be an effective approach for individuals. The rural vector is most active at dusk and outdoors; its bites can be avoided by modification of activities and use of repellents.

Disease severity increases with age: infections that result in aseptic meningitis or mild encephalitis are concentrated in children and young adults, while severe and fatal cases primarily affect the elderly. Infection rates are similar in all age groups; thus the greater susceptibility of older persons to disease is a biologic consequence of aging. The disease has an abrupt onset, sometimes following a prodrome, and begins with fever, lethargy, confusion, and headache. In addition, nuchal rigidity, hypotonia, hyperreflexia, myoclonus, and tremor are common. Severe cases can include cranial nerve palsies, hemiparesis, and convulsions. Patients often complain of dysuria and may have viral antigen in urine as well as pyuria. The overall mortality is generally ~7% but may reach 20% among patients over the age of 60. Recovery is slow. Emotional lability, difficulties in concentration and memory, asthenia, and tremor are commonly prolonged in older patients.

The CSF of patients with St. Louis encephalitis usually contains tens to hundreds of cells, with a lymphocytic predominance and a normal glucose level. Leukocytosis with a left shift is often documented.

JAPANESE ENCEPHALITIS Japanese encephalitis virus is found throughout Asia, including far eastern Russia, Japan, China, India, Pakistan, and Southeast Asia, and causes occasional epidemics on western Pacific islands. The virus has been detected in the Torres Strait islands, and a human encephalitis case has been identified on the nearby Australian mainland. This flavivirus is particularly common in areas where irrigated rice fields attract the natural avian vertebrate hosts and provide abundant breeding sites for mosquitoes such as *C. tritaeniorhyncus*, which transmit the virus to humans. Additional amplification by pigs, which suffer abortion, and horses, which develop encephalitis, may be significant as well. Vaccination of these additional amplifying hosts may reduce the transmission of the virus. An effective, formalin-inactivated vaccine purified from mouse brain is produced in Japan and licensed for human use in the United States. It is given on days 0, 7, and 30 or—with some sacrifice in serum neutralizing titer—on days 0, 7, and 14. Vaccination is indicated for summer travelers to rural Asia, where the risk of clinical disease may be 0.05 to 2.1/10,000 per week (Table 107-5). The severe and often fatal disease reported in expatriates must be balanced against the 0.1 to 1% chance of a late systemic or cutaneous allergic reaction. These reactions are rarely fatal but may be severe and have been known to begin 1 to 9 days after vaccination, with associated pruritus, urticaria, and angioedema. Live attenuated vaccines are being used in China but are not recommended in the United States at this time.

WEST NILE VIRUS INFECTION West Nile virus is transmitted among wild birds by *Culex* mosquitoes in Africa, the Middle East, southern Europe, and Asia. It is a frequent cause of febrile disease without CNS involvement, but it occasionally causes aseptic meningitis and severe encephalitis; these serious infections are particularly common among the elderly. The febrile-myalgic syndrome caused by West Nile virus differs from many others by the frequent appearance of a maculopapular rash concentrated on the trunk and lymphadenopathy. Headache, ocular pain, sore throat, nausea and vomiting, and arthralgia (but not arthritis) are common accompaniments. In addition, the virus has been implicated in severe and fatal hepatic necrosis in Africa.

In 1996 West Nile virus caused >300 cases of CNS disease, with 10% mortality, in the Danube flood plain, including Bucharest. In 1999 the virus appeared in New York City and other areas of the northeastern United States, causing >60 cases of aseptic meningitis or encephalitis among humans as well as die-offs among crows, exotic zoo birds, and other avians. The encephalitis was most severe among the elderly and was often associated with notable muscle weakness and even with flaccid paralysis. The virus, thought to have been transmitted in New York City by the ubiquitous *C. pipiens* mosquito, spread as far west as Minnesota and Texas as well as north into Canada by 2002. It seems likely that further spread will occur, and involvement of new vectors may enhance transmission to humans.

West Nile virus falls into the same phylogenetic group of flaviviruses as St. Louis and Japanese encephalitis viruses, as do Murray

Valley and Rocio viruses. The latter two viruses are both maintained in mosquitoes and birds and produce a clinical picture resembling that of Japanese encephalitis. Murray Valley virus has caused occasional epidemics and sporadic cases in Australia. Rocio virus caused recurrent epidemics in a focal area of Brazil in 1975 to 1977 and then virtually disappeared.

CENTRAL EUROPEAN TICK-BORNE ENCEPHALITIS AND RUSSIAN SPRING-SUMMER ENCEPHALITIS A spectrum of tick-borne flaviviruses has been identified across the Eurasian land mass. Many are known mainly as agricultural pathogens (e.g., louping ill virus in the United Kingdom). From Scandinavia to the Urals, central European tick-borne encephalitis is transmitted by *Ixodes ricinus*. Human cases occur between April and October, with a peak in June and July. A related and more virulent virus is that of Russian spring-summer encephalitis, which is associated with *I. persulcatus* and is distributed from Europe across the Urals to the Pacific Ocean. The ticks transmit the disease primarily in the spring and early summer, with a lower rate of transmission later in summer. Small mammals are the vertebrate amplifiers for both viruses. The risk varies by geographic area and can be highly localized within a given area; human cases usually follow outdoor activities or consumption of raw milk from infected goats or other infected animals.

After an incubation period of 7 to 14 days or perhaps longer, the central European viruses classically result in a febrile-myalgic phase that lasts for 2 to 4 days and is thought to correlate with viremia. A subsequent remission for several days is followed by the recurrence of fever and the onset of meningeal signs. The CNS phase varies from mild aseptic meningitis, which is more common among younger patients, to severe encephalitis with coma, convulsions, tremors, and motor signs lasting for 7 to 10 days before improvement begins. Spinal and medullary involvement can lead to typical limb-girdle paralysis and to respiratory paralysis. Most patients recover, only a minority with significant deficits. Infections with the far eastern viruses generally run a more abrupt course. The encephalitic syndrome caused by these viruses sometimes begins without a remission and has more severe manifestations than the European syndrome. Mortality is high, and major sequelae—most notably, lower motor neuron paralyses of the proximal muscles of the extremities, trunk, and neck—are common.

In the early stage of the illness, virus may be isolated from the blood. In the CNS phase, IgM antibodies are detectable in serum and/or CSF. Thrombocytopenia sometimes develops during the initial febrile illness, which resembles the early hemorrhagic phase of some other tick-borne flaviviral infections, such as Kyasanur Forest disease. Other tick-borne flaviviruses are less common causes of encephalitis, including louping ill virus in the United Kingdom and Powassan virus.

There is no specific therapy for infection with these viruses. However, effective alum-adjuvanted, formalin-inactivated vaccines are produced in Austria, Germany, and Russia. Two doses of the Austrian vaccine separated by an interval of 1 to 3 months appear to be effective in the field, and antibody responses are similar when vaccine is given on days 0 and 14. Other vaccines have elicited similar neutralizing antibody titers. Since rare cases of postvaccination Guillain-Barré syndrome have been reported, vaccination should be reserved for persons likely to experience rural exposure in an endemic area during the season of transmission. Cross-neutralization for the central European and far eastern strains has been established, but there are no published field studies on cross-protection of formalin-inactivated vaccines. Because 0.2 to 4% of ticks in endemic areas may be infected, tick bites raise the issue of immunoglobulin prophylaxis. Prompt administration of high-titered specific preparations should probably be undertaken, although no controlled data are available to prove the efficacy of this measure. Immunoglobulin should not be administered late because of the risk of antibody-mediated enhancement.

POWASSAN ENCEPHALITIS Powassan virus is a member of the tick-borne encephalitis virus complex and is transmitted by *I. cookei* among small mammals in eastern Canada and the United States, where it has been responsible for 20 recognized cases of human disease. Other ticks may transmit the virus in a wider geographic area, and there is some concern that *I. scapularis* (also called *I. dammini*), a competent vector in the laboratory, may become involved as it becomes more prominent in the United States. Patients with Powassan encephalitis—often children—present in May through December after outdoor exposure and an incubation period thought to be ~1 week. Powassan encephalitis is severe, and sequelae are common.

EASTERN EQUINE ENCEPHALITIS Eastern equine encephalitis is found primarily within endemic swampy foci along the eastern coast of the United States, with a few inland foci as far removed as Michigan. Human cases present from June through October, when the bird–*Culiseta* mosquito cycle spills over into other mosquito species such as *A. sollicitans* or *A. vexans*, which are more likely to bite mammals. There is concern over the potential role of the introduced anthropophilic mosquito species *A. albopictus*, which has been found to be naturally infected and is an effective vector in the laboratory. Horses are a common target for the virus; contact with unvaccinated horses may be associated with human disease, but horses probably do not play a significant role in amplification of the virus.

Eastern equine encephalitis is one of the most destructive of the arboviral conditions, with a brusque onset, rapid progression, high mortality, and frequent residua. This severity is reflected in the extensive necrotic lesions and polymorphonuclear infiltrates found at postmortem examination of the brain and the acute polymorphonuclear CSF pleocytosis often occurring during the first 1 to 3 days of disease. In addition, leukocytosis with a left shift is a common feature. A formalin-inactivated vaccine has been used to protect laboratory workers but is not generally available or applicable.

WESTERN EQUINE ENCEPHALITIS The primary maintenance cycle for western equine encephalitis virus in the United States is between *C. tarsalis* and birds, principally sparrows and finches. Equines and humans become infected, and both species suffer encephalitis without amplifying the virus in nature. St. Louis encephalitis is transmitted in a similar cycle in the same region but causes human disease about a month earlier than the period (July through October) in which western equine encephalitis virus is active. Large epidemics of western equine encephalitis took place in the western and central United States and Canada during the 1930s to 1950s, but in recent years the disease has been uncommon. There were 41 reported cases in the United States in 1987 but only 5 reported cases from 1988 to 2001. This decline in incidence may reflect in part the integrated approach to mosquito management that has been employed in irrigation projects and the increasing use of agricultural pesticides; it almost certainly reflects the increased tendency for humans to be indoors behind closed windows at dusk, the peak period of biting by the major vector.

Western equine encephalitis virus causes a typical diffuse viral encephalitis with an increased attack rate and increased morbidity in the young, particularly children <2 years old. In addition, mortality is high among the young and the very elderly. One-third of individuals who have convulsions during the acute illness have subsequent seizure activity. Infants <1 year old—particularly those in the first months of life—are at serious risk of motor and intellectual damage. Twice as many males as females develop clinical encephalitis after 5 to 9 years of age; this difference may be related to greater outdoor exposure of boys to the vector but is also likely to be due in part to biologic differences. A formalin-inactivated vaccine has been used to protect laboratory workers but is not generally available or applicable.

VENEZUELAN EQUINE ENCEPHALITIS There are six known types of virus in the Venezuelan equine encephalitis complex. An important distinction is between the "epizootic" viruses (subtypes IAB and IC) and the "enzootic" viruses (subtypes ID to IF and types II to VI). The epizootic viruses have an unknown natural cycle but periodically cause extensive epidemics in equines and humans in the Americas. These epidemics rely on the high-level viremia in horses and mules that results in the infection of several species of mosquitoes, which in turn infect

humans and perpetuate virus transmission. Humans also have high-level viremia but probably are not important in virus transmission. Enzootic viruses are found primarily in humid tropical forest habitats and are maintained between *Culex* mosquitoes and rodents; these viruses cause human disease but are not pathogenic for horses and do not cause epizootics.

Epizootics of Venezuelan equine encephalitis occurred repeatedly in Venezuela, Colombia, Ecuador, Peru, and other South American countries at intervals of ≤10 years from the 1930s until 1969, when a massive epizootic spread throughout Central America and Mexico, reaching southern Texas in 1972. Genetic sequencing of the virus from the 1969 to 1972 outbreak suggested that it originated from residual "un-inactivated" virus in veterinary vaccines. The outbreak was terminated in Texas with the use of a live attenuated vaccine (TC-83) originally developed for human use by the U.S. Army; this virus was then used for further production of inactivated veterinary vaccines. No further epizootic disease was identified until 1995 and subsequently, when additional epizootics took place in Colombia, Venezuela, and Mexico. The viruses involved in these epizootics as well as previously epizootic subtype IC viruses have been shown to be close phylogenetic relatives of known enzootic subtype ID viruses. This finding suggests that active evolution and selection of epizootic viruses are under way in northern South America.

During epizootics, extensive human infection is the rule, with clinical disease in 10 to 60% of infected individuals. Most infections result in notable acute febrile disease, while relatively few result in encephalitis. A low rate of CNS invasion is supported by the absence of encephalitis among the many infections resulting from exposure to aerosols in the laboratory or from vaccine accidents. The most recent large epizootic of Venezuelan equine encephalitis occurred in Colombia and Venezuela in 1995; of the >85,000 clinical cases, 4% (with a higher proportion among children than adults) included neurologic symptoms and 300 ended in death.

Enzootic strains of Venezuelan equine encephalitis virus are common causes of acute febrile disease, particularly in areas such as the Florida Everglades and the humid Atlantic coast of Central America. Encephalitis has been documented only in the Florida infections; the three cases were caused by type II enzootic virus, also called *Everglades virus*. All three patients had preexisting cerebral disease. Extrapolation from the rate of genetic change suggests that Everglades virus may have been introduced into Florida <200 years ago and that it is most closely related to the ID subtypes that appear to have given evolutionary rise to the epizootic strains active in South America.

The prevention of epizootic Venezuelan equine encephalitis depends on vaccination of horses with the attenuated TC-83 vaccine or with an inactivated vaccine prepared from that strain. Humans can be protected with similar vaccines, but the use of such products is restricted to laboratory personnel because of reactogenicity and limited availability. In addition, wild-type virus and perhaps TC-83 vaccine may have some degree of fetal pathogenicity. Enzootic viruses are genetically and antigenically different from epizootic viruses, and protection against the former with vaccines prepared from the latter is relatively ineffective.

ARTHRITIS AND RASH

True arthritis is a common accompaniment of several viral diseases, such as rubella (caused by a non-alphavirus togavirus), parvovirus B19 infection, and hepatitis B; it is an occasional accompaniment of infection due to mumps virus, enteroviruses, herpesviruses, and adenoviruses. It is not generally appreciated that the alphaviruses are also common causes of arthritis. In fact, the alphaviruses discussed below all cause acute febrile diseases accompanied by the development of true arthritis and a maculopapular rash. Rheumatic involvement includes arthralgia alone, periarticular swelling, and (less commonly) joint effusions. Most of these diseases are less severe and have fewer articular manifestations in children than in adults. In temperate climates, these are summer diseases. No specific therapy or licensed vaccines exist.

SINDBIS VIRUS INFECTION Sindbis virus is transmitted among birds by mosquitoes. Infections with the northern European strains of this virus (which cause, for example, Pogosta disease in Finland, Karelian fever in the independent states of the former Soviet Union, and Okelbo disease in Sweden) and with the genetically related southern African strains are particularly likely to result in the arthritis-rash syndrome. Exposure to a rural environment is commonly associated with this infection, which has an incubation period of <1 week.

The disease begins with rash and arthralgia. Constitutional symptoms are not marked, and fever is modest or lacking altogether. The rash, which lasts about a week, begins on the trunk, spreads to the extremities, and evolves from macules to papules that often vesiculate. The arthritis of this condition is multiarticular, migratory, and incapacitating, with resolution of the acute phase in a few days. Wrists, ankles, phalangeal joints, knees, elbows, and—to a much lesser extent—proximal and axial joints are involved. Persistence of joint pains and occasionally of arthritis is a major problem and may go on for months or even years despite a lack of deformity.

CHIKUNGUNYA VIRUS INFECTION It is likely that chikungunya virus ("that which bends up") is of African origin and is maintained among nonhuman primates on that continent by *Aedes* mosquitoes of the subgenus *Stegomyia* in a fashion similar to yellow fever virus. Like yellow fever virus, chikungunya virus is readily transmitted among humans in urban areas by *A. aegypti*. The *A. aegypti*–chikungunya virus transmission cycle has also been introduced into Asia, where it poses a prominent health problem. The disease is endemic in rural areas of Africa, and intermittent epidemics take place in towns and cities of Africa and Asia. Chikungunya is one more reason (in addition to dengue and yellow fever) that *A. aegypti* must be controlled.

Full-blown disease is most common among adults, in whom the clinical picture may be dramatic. The abrupt onset follows an incubation period of 2 to 3 days. Fever and severe arthralgia are accompanied by chills and constitutional symptoms such as headache, photophobia, conjunctival injection, anorexia, nausea, and abdominal pain. Migratory polyarthritis mainly affects the small joints of the hands, wrists, ankles, and feet, with lesser involvement of the larger joints. Rash may appear at the outset or several days into the illness; its development often coincides with defervescence, which takes place around day 2 or day 3 of disease. The rash is most intense on the trunk and limbs and may desquamate. Petechiae are occasionally seen, and epistaxis is not uncommon, but this virus is not a regular cause of the HF syndrome, even in children. A few patients develop leukopenia. Elevated levels of aspartate aminotransferase (AST) and C-reactive protein have been described, as have mildly decreased platelet counts. Recovery may require weeks. Some older patients continue to suffer from stiffness, joint pain, and recurrent effusions for several years; this persistence may be especially common in HLA-B27 patients. An investigational live attenuated vaccine has been developed but requires further testing.

A related virus, O'nyong-nyong, caused a major epidemic of arthritis and rash involving at least 2 million people as it moved across eastern and central Africa in the 1960s. After its mysterious emergence, the virus virtually disappeared, leaving only occasional evidence of its persistence in Kenya until a transient resurgence of epidemic activity in 1997.

EPIDEMIC POLYARTHRITIS (ROSS RIVER VIRUS INFECTION) Ross River virus has caused epidemics of distinctive clinical disease in Australia since the beginning of the twentieth century and continues to be responsible for thousands of cases in rural and suburban areas annually. The virus is transmitted by *A. vigilax* and other mosquitoes, and its persistence is thought to involve transovarial transmission. No definitive vertebrate host has been identified, but several mammalian species, including wallabies, have been suggested. Endemic transmission has also been documented in New Guinea, and in 1979 the virus swept through the eastern Pacific Islands, causing hundreds of thousands of illnesses.

The virus was carried from island to island by infected humans and was believed to have been transmitted among humans by *A. polynesiensis* and *A. aegypti*.

The incubation period is 7 to 11 days long, and the onset of illness is sudden, with joint pain usually ushering in the disease. The rash generally develops coincidentally or follows shortly but in some cases precedes joint pains by several days. Constitutional symptoms such as low-grade fever, asthenia, myalgia, headache, and nausea are not prominent and indeed are absent in many cases. Most patients are incapacitated for considerable periods by joint involvement, which interferes with sleeping, walking, and grasping. Wrist, ankle, metacarpophalangeal, interphalangeal, and knee joints are the most commonly involved, although toes, shoulders, and elbows may be affected with some frequency. Periarticular swelling and tenosynovitis are common, and one-third of patients have true arthritis. Only half of all arthritis patients can resume normal activities within 4 weeks, and 10% still must limit their activity at 3 months. Occasional patients are symptomatic for 1 to 3 years but without progressive arthropathy. Aspirin and nonsteroidal anti-inflammatory drugs are effective for the treatment of symptoms.

Clinical laboratory values are normal or variable in Ross River virus infection. Tests for rheumatoid factor and antinuclear antibodies are negative, and the erythrocyte sedimentation rate is acutely elevated. Joint fluid contains 1000 to 60,000 mononuclear cells per microliter, and Ross River virus antigen is demonstrable in macrophages. IgM antibodies are valuable in the diagnosis of this infection, although they occasionally persist for years. The isolation of the virus from blood by mosquito inoculation or mosquito cell culture is possible early in the illness. Because of the great economic impact of annual epidemics in Australia, an inactivated vaccine is being developed and has been found to be protective in mice.

Perhaps because of the local interest in arboviruses in general and in Ross River virus in particular, other arthritogenic arboviruses have been identified in Australia, including Gan Gan virus, a member of the family Bunyaviridae; Kokobera virus, a flavivirus; and Barmah Forest virus, an alphavirus. The last virus is a common cause of infection and must be differentiated from Ross River virus by specific testing.

HEMORRHAGIC FEVERS

The viral HF syndrome is a constellation of findings based on vascular instability and decreased vascular integrity. An assault, direct or indirect, on the microvasculature leads to increased permeability and (particularly when platelet function is decreased) to actual disruption and local hemorrhage. Blood pressure is decreased, and in severe cases shock supervenes. Cutaneous flushing and conjunctival suffusion are examples of common, observable abnormalities in the control of local circulation. The hemorrhage is inconstant and is in most cases an indication of widespread vascular damage rather than a life-threatening loss of blood volume. Disseminated intravascular coagulation (DIC) is occasionally found in any severely ill patient with HF but is thought to occur regularly only in the early phases of HF with renal syndrome, Crimean-Congo HF, and perhaps some cases of filovirus HF. In some viral HF syndromes, specific organs may be particularly impaired, such as the kidney in HF with renal syndrome, the lung in hantavirus pulmonary syndrome, or the liver in yellow fever, but in all these diseases the generalized circulatory disturbance is critically important.

The pathogenesis of HF is poorly understood and varies among the viruses regularly implicated in the syndrome, which number more than a dozen. In some cases direct damage to the vascular system or even to parenchymal cells of target organs is important, whereas in others soluble mediators are thought to play the major role. The acute phase in most cases of HF is associated with ongoing virus replication and viremia. Exceptions are the hantavirus diseases and dengue HF/dengue shock syndrome (DHF/DSS), in which the immune response plays a major pathogenic role.

The HF syndromes all begin with fever and myalgia, usually of abrupt onset. Within a few days the patient presents for medical attention because of increasing prostration that is often accompanied by severe headache, dizziness, photophobia, hyperesthesia, abdominal or chest pain, anorexia, nausea or vomiting, and other gastrointestinal disturbances. Initial examination often reveals only an acutely ill patient with conjunctival suffusion, tenderness to palpation of muscles or abdomen, and borderline hypotension or postural hypotension, perhaps with tachycardia. Petechiae (often best visualized in the axillae), flushing of the head and thorax, periorbital edema, and proteinuria are common. Levels of AST are usually elevated at presentation or within a day or two thereafter. Hemoconcentration from vascular leakage, which is usually evident, is most marked in hantavirus diseases and in DHF/DSS. The seriously ill patient progresses to more severe symptoms and develops shock and other findings typical of the causative virus. Shock, multifocal bleeding, and CNS involvement (encephalopathy, coma, convulsions) are all poor prognostic signs.

One of the major diagnostic clues is travel to an endemic area within the incubation period for a given syndrome (Table 180-4). Except for Seoul, dengue, and yellow fever virus infections, which have urban vectors, travel to a rural setting is especially suggestive of a diagnosis of HF.

Early recognition is important because of the need for virus-specific therapy and supportive measures, including prompt, atraumatic hospitalization; judicious fluid therapy that takes into account the patient's increased capillary permeability; administration of cardiotonic drugs; use of pressors to maintain blood pressure at levels that will support renal perfusion; treatment of the relatively common secondary bacterial infections; replacement of clotting factors and platelets as indicated; and the usual precautionary measures used in the treatment of patients with hemorrhagic diatheses. DIC should be treated only if clear laboratory evidence of its existence is found and if laboratory monitoring of therapy is feasible; there is no proven benefit of such therapy. The available evidence suggests that HF patients have a decreased cardiac output and will respond poorly to fluid loading as it is often practiced in the treatment of shock associated with bacterial sepsis. Specific therapy is available for several of the HF syndromes. In addition, several diseases considered in the differential diagnosis—malaria, shigellosis, typhoid, leptospirosis, relapsing fever, and rickettsial disease—are treatable and potentially lethal. Strict barrier nursing and other precautions against infection of medical staff and visitors are indicated in HF except that due to hantaviruses, yellow fever, Rift Valley fever, and dengue.

LASSA FEVER Lassa virus is known to cause endemic and epidemic disease in Nigeria, Sierra Leone, Guinea, and Liberia, although it is probably more widely distributed in West Africa. This virus and its relatives exist elsewhere in Africa, but their health significance is unknown. Like other arenaviruses, Lassa virus is spread to humans by small-particle aerosols from chronically infected rodents and may also be acquired during the capture or eating of these animals. It can be transmitted by close person-to-person contact. The virus is often present in urine during convalescence and is suspected to be present in seminal fluid early in recovery. Nosocomial spread has occurred but is uncommon if proper sterile parenteral techniques are used. Individuals of all ages and both sexes are affected; the incidence of disease is highest in the dry season, but transmission takes place year-round. In countries where Lassa virus is endemic, Lassa fever can be a prominent cause of febrile disease. For example, in one hospital in Sierra Leone, laboratory-confirmed Lassa fever is consistently responsible for one-fifth of admissions to the medical wards. There are probably tens of thousands of Lassa fever cases annually in West Africa alone.

The average case has a gradual onset (among the HF agents, only the arenaviruses are typically associated with a gradual onset) that gives way to more severe constitutional symptoms and prostration. Bleeding is seen in only ~15 to 30% of cases. A maculopapular rash is often noted in light-skinned Lassa patients. Effusions are common,

TABLE 180-4 *Viral Hemorrhagic Fever (HF) Syndromes and Their Distribution*

Disease	Incubation Period, Days	Case-Infection Ratio	Case-Fatality Rate, %	Geographic Range	Target Population
Lassa fever	5–16	Mild infections probably common	15	West Africa	All ages, both sexes
South American HF	7–14	Most infections (more than half) result in disease	15–30	Selected rural areas of Bolivia, Argentina, Venezuela, and Brazil	Bolivia: Men in countryside; all ages, both sexes in villages Argentina: All ages, both sexes; excess exposure and disease in men Venezuela: All ages, both sexes
Rift Valley fever	2–5	~1:100[a]	~50	Sub-Saharan Africa, Madagascar, Egypt	All ages, both sexes; more often diagnosed in men; preexisting liver disease may predispose
Crimean-Congo HF	3–12	≥1:5	15–30	Africa, Middle East, Balkans, southern region of former Soviet Union, western China	All ages, both sexes; men more exposed in some settings
HF with renal syndrome	9–35	Hantaan, >1:1.25; Puumala, 1:20	5–15, Hantaan; <1, Puumala	Worldwide, depending on rodent reservoir	Excess of male patients (partly due to greater exposure); mainly adults
Hantavirus pulmonary syndrome	~7–28	Very high	40–50	Americas	Excess of male patients due to some occupational exposure; mainly adults
Marburg or Ebola HF	3–16	High	25–90	Sub-Saharan Africa	All ages, both sexes; children less exposed
Yellow fever	3–6	1:2–1:20	20	Africa, South America	All ages, both sexes; adults more exposed in jungle setting; preexisting flavivirus immunity may cross-protect
Dengue HF/dengue shock syndrome	2–7	1:10,000, nonimmune; 1:100, heterologous immune	<1 with supportive treatment	Tropics and subtropics worldwide	Predominantly children; previous heterologous dengue infection predisposes to HF
Kyasanur Forest/ Omsk HF	3–8	Variable	0.5–10	Mysore State, India/ western Siberia	Variable

[a] Figure is for HF cases only. Most infections with Rift Valley fever virus result in fever and myalgia rather than HF.

and male-dominant pericarditis may develop late. The fetal death rate is 92% in the last trimester, when maternal mortality is also increased from the usual 15% to 30%; these figures suggest that interruption of the pregnancy of infected women should be considered. White blood cell counts are normal or slightly elevated, and platelet counts are normal or somewhat low. Deafness coincides with clinical improvement in ~20% of cases and is permanent and bilateral in some. Reinfection may occur but has not been associated with severe disease.

High-level viremia or a high serum concentration of AST statistically predicts a fatal outcome. Thus patients with an AST level of >150 IU/mL should be treated with intravenous ribavirin. This antiviral nucleoside analogue appears to be effective in reducing mortality from rates among retrospective controls, and its only major side effect is reversible anemia that usually does not require transfusion. The drug should be given by slow intravenous infusion in a dose of 32 mg/kg; this dose should be followed by 16 mg/kg every 6 h for 4 days and then by 8 mg/kg every 8 h for 6 days.

SOUTH AMERICAN HF SYNDROMES (ARGENTINE, BOLIVIAN, VENEZUELAN, AND BRAZILIAN) These diseases are similar to one another clinically, but their epidemiology differs with the habits of their rodent reservoirs and the interactions of these animals with humans (Table 180-4). Person-to-person or nosocomial transmission is rare but has occurred.

The basic disease resembles Lassa fever, with two marked differences. First, thrombocytopenia—often marked—is the rule, and bleeding is quite common. Second, CNS dysfunction is much more common than in Lassa fever and is often manifest by marked confusion, tremors of the upper extremities and tongue, and cerebellar signs. Some cases follow a predominantly neurologic course, with a poor prognosis. The clinical laboratory is helpful in diagnosis since thrombocytopenia, leukopenia, and proteinuria are typical findings.

Argentine HF is readily treated with convalescent-phase plasma given within the first 8 days of illness. In the absence of passive antibody therapy, intravenous ribavirin in the dose recommended for Lassa fever is likely to be effective in all the South American HF syndromes. The transmission of the disease from men convalescing from Argentine HF to their wives suggests the need for counseling of arenavirus HF patients concerning the avoidance of intimate contacts for several weeks after recovery. A safe, effective, live attenuated vaccine exists for Argentine HF. In experimental animals, this vaccine is cross-protective against the Bolivian HF virus.

RIFT VALLEY FEVER The mosquito-borne Rift Valley fever virus is also a pathogen of domestic animals such as sheep, cattle, and goats. It is maintained in nature by transovarial transmission in floodwater *Aedes* mosquitoes and presumably also has a vertebrate amplifier. Epizootics and epidemics occur when sheep or cattle become infected during particularly heavy rains; developing high-level viremia, these animals infect many different species of mosquitoes. Remote sensing via sat-

ellite can detect the ecologic changes associated with high rainfall that predict the likelihood of Rift Valley fever transmission; it can also detect the special depressions from which the floodwater *Aedes* mosquito vectors emerge. In addition, the virus is infectious when transmitted by contact with blood or aerosols from domestic animals or their abortuses. The slaughtered meat is not infectious; anaerobic glycolysis in postmortem tissues results in an acidic environment that rapidly inactivates Bunyaviridae such as Rift Valley fever virus and Crimean-Congo HF virus. The natural range of Rift Valley fever virus is confined to sub-Saharan Africa, where its circulation is markedly enhanced by substantial rainfall such as that which occurred during the El Niño phenomenon of 1997; subsequent spread to the Arabian Peninsula caused epidemic disease in 2000. The virus has also been found in Madagascar and has been introduced into Egypt, where it caused major epidemics in 1977 to 1979, 1993, and subsequently. Neither person-to-person nor nosocomial transmission has been documented.

Rift Valley fever virus is unusual in that it causes at least four different clinical syndromes. Most infections are manifested as the febrile-myalgic syndrome. A small proportion result in HF with especially prominent liver involvement. Perhaps 10% of otherwise mild infections lead to retinal vasculitis; funduscopic examination reveals edema, hemorrhages, and infarction, and some patients have permanently impaired vision. A small proportion of cases (<1 in 200) are followed by typical viral encephalitis. One of the complicated syndromes does not appear to predispose to another.

There is no proven therapy for any of the syndromes described above. The sensitivity of animal models of Rift Valley fever to antibody or ribavirin therapy suggests that either could be given intravenously to persons with HF. Both retinal disease and encephalitis occur after the acute febrile syndrome has ended and serum neutralizing antibody has developed—events suggesting that only supportive care need be given. Epidemic disease is best prevented by vaccination of livestock. The established ability of this virus to propagate after an introduction into Egypt suggests that other potentially receptive areas, including the United States, should have a response ready for such an eventuality. It seems likely that this disease, like Venezuelan equine encephalitis, can be controlled only with adequate stocks of an effective live attenuated vaccine, and there are no such global stocks. A formalin-inactivated vaccine confers immunity to humans, but quantities are limited and three injections are required; this vaccine is recommended for exposed laboratory workers and for veterinarians working in sub-Saharan Africa.

CRIMEAN-CONGO HF This severe HF syndrome has a wide geographic distribution, potentially being found wherever ticks of the genus *Hyalomma* occur (Table 180-4). The propensity of these ticks to feed on domestic livestock and certain wild mammals means that veterinary serosurveys are the most effective mechanism for the surveillance of virus circulation in a region. Human infection is acquired via a tick bite or during the crushing of infected ticks. Domestic animals do not become ill but do develop viremia; thus there is danger of infection at the time of slaughter and for a brief interval thereafter (through contact with hides or carcasses). Cases have followed sheep shearing. An epidemic in South Africa was associated with slaughter of tick-infested ostriches. Nosocomial epidemics are common and are usually related to extensive blood exposure or needle sticks.

Although generally similar to other HF syndromes, Crimean-Congo HF causes extensive liver damage, resulting in jaundice in some cases. Clinical laboratory values indicate DIC and show elevations in AST, creatine phosphokinase, and bilirubin. Patients with fatal cases generally have more marked changes, even in the early days of illness, and also develop leukocytosis rather than leukopenia. Thrombocytopenia is also more marked and develops earlier in cases with a fatal outcome.

No controlled trials have been performed with intravenous ribavirin, but clinical experience and retrospective comparison of patients with ominous clinical laboratory values suggest that ribavirin is efficacious and should be given. No human or veterinary vaccines are recommended.

HF WITH RENAL SYNDROME This disease, the first to be identified as an HF, is widely distributed over Europe and Asia; the major causative viruses and their rodent reservoirs on these two continents are Puumala virus (bank vole, *Clethrionomys glareolus*) and Hantaan virus (striped field mouse, *Apodemus agrarius*), respectively. Other potential causative viruses exist, including Dobrava virus (yellow-necked field mouse, *A. flavicollus*), which causes severe HF with renal syndrome in the Balkans. Seoul virus is associated with the Norway or sewer rat, *Rattus norvegicus*, and has a worldwide distribution through the migration of the rodent; it is associated with mild or moderate HF with renal syndrome in Asia, but in many areas of the world the human disease has been difficult to identify. Most cases occur in rural residents or vacationers; the exception is Seoul virus disease, which may be acquired in an urban or rural setting or from contaminated laboratory rat colonies. Classic Hantaan disease in Korea (Korean HF) and in rural China (epidemic HF) is most common in spring and fall and is related to rodent density and agricultural practices. Human infection is acquired primarily through aerosols of rodent urine, although virus is also present in saliva and feces. Patients with hantavirus diseases are not infectious. HF with renal syndrome is the most important form of HF today, with >100,000 cases of severe disease in Asia annually and milder Puumala infections numbering in the thousands as well.

Severe cases of HF with renal syndrome caused by Hantaan virus evolve in identifiable stages: the febrile stage with myalgia, lasting 3 to 4 days; the hypotensive stage, often associated with shock and lasting from a few hours to 48 h; the oliguric stage with renal failure, lasting 3 to 10 days; and the polyuric stage with diuresis and hyposthenuria.

The *febrile period* is initiated by the abrupt onset of fever, headache, severe myalgia, thirst, anorexia, and often nausea and vomiting. Photophobia, retroorbital pain, and pain on ocular movement are common, and the vision may become blurred with ciliary body inflammation. Flushing over the face, the V area of the neck, and the back are characteristic, as are pharyngeal injection, periorbital edema, and conjunctival suffusion. Petechiae often develop in areas of pressure, the conjunctivae, and the axillae. Back pain and tenderness to percussion at the costovertebral angle reflect massive retroperitoneal edema. Laboratory evidence of mild to moderate DIC is present. Other laboratory findings include proteinuria and an active urinary sediment.

The *hypotensive phase* is ushered in by falling blood pressure and sometimes by shock. The relative bradycardia typical of the febrile phase is replaced by tachycardia. Kinin activation is marked. The rising hematocrit reflects increasing vascular leakage. Leukocytosis with a left shift develops, and thrombocytopenia continues. Atypical lymphocytes—which in fact are activated CD8+ and to a lesser extent CD4+ T cells—circulate. Proteinuria is marked, and the urine's specific gravity falls to 1.010. The renal circulation is congested and compromised from local and systemic circulatory changes resulting in necrosis of tubules, particularly at the corticomedullary junction, and oliguria.

During the *oliguric phase*, hemorrhagic tendencies continue, probably in large part because of uremic bleeding defects. The oliguria persists for 3 to 10 days before renal function returns and marks the onset of the *polyuric stage*, which carries the danger of dehydration and electrolyte abnormalities.

Mild cases of HF with renal syndrome may be much less stereotypical. The presentation may include only fever, gastrointestinal abnormalities, and transient oliguria followed by hyposthenuria.

HF with renal syndrome should be suspected in patients with rural exposure in an endemic area. Prompt recognition of the disease will permit rapid hospitalization and expectant management of shock and

renal failure. Useful clinical laboratory parameters include leukocytosis, which may be leukemoid and is associated with a left shift; thrombocytopenia; and proteinuria. Mainstays of therapy are the management of shock, reliance on pressors, modest crystalloid infusion, intravenous use of human serum albumin, and treatment of renal failure with prompt dialysis for the usual indications. Hydration may result in pulmonary edema, and hypertension should be avoided because of the possibility of intracranial hemorrhage. Use of intravenous ribavirin has reduced mortality and morbidity in severe cases provided treatment is begun within the first 4 days of illness. The case-fatality ratio may be as high as 15% but with proper therapy should be <5%. Sequelae have not been definitely established, but there is a correlation in the United States between chronic hypertensive renal failure and the presence of antibodies to Seoul virus.

Infections with Puumala virus, the most common cause of HF with renal syndrome in Europe, result in a much attenuated picture but the same general presentation. The syndrome may be referred to by its former name, *nephropathia epidemica*. Bleeding manifestations are found in only 10% of cases, hypotension rather than shock is usually seen, and oliguria is present in only about half of patients. The dominant features may be fever, abdominal pain, proteinuria, mild oliguria, and sometimes blurred vision or glaucoma followed by polyuria and hyposthenuria in recovery. Mortality is <1%.

The diagnosis is readily made by IgM-capture ELISA, which should be positive at admission or within 24 to 48 h thereafter. The isolation of virus is difficult, but RT-PCR of a blood clot collected early in the clinical course or of tissues obtained postmortem will give positive results. Such testing is usually undertaken only if definitive identification of the infecting viral species is required or if molecular epidemiologic questions exist.

HANTAVIRUS PULMONARY SYNDROME Hantavirus pulmonary syndrome was discovered in 1993, but retrospective identification of cases by immunohistochemistry (1978) and serology (1959) support the idea that it is a recently discovered rather than a truly new disease. The causative viruses are hantaviruses of a distinct phylogenetic lineage that is associated with the rodent subfamily Sigmodontinae. Sin Nombre virus chronically infects the deer mouse (*Peromyscus maniculatus*) and is the most important virus causing hantavirus pulmonary syndrome in the United States. The disease is also caused by a Sin Nombre virus variant from the white-footed mouse (*P. leucopus*), by Black Creek Canal virus (*Sigmodon hispidus*, the cotton rat), and by Bayou virus (*Oryzomys palustris*, the rice rat). Several other related viruses cause the disease in South America, but Andes virus is unusual in that it, alone among hantaviruses, has been implicated in human-to-human transmission. The disease is linked to rodent exposure and particularly affects rural residents living in dwellings permeable to rodent entry or working at occupations that pose a risk of rodent exposure. Each rodent species has its own particular habits; in the case of the deer mouse, these behaviors include living in and around human habitation.

The disease begins with a prodrome of about 3 to 4 days (range, 1 to 11 days) comprising fever, myalgia, malaise, and often gastrointestinal disturbances such as nausea, vomiting, and abdominal pain. Dizziness is common and vertigo occasional. Severe prodromal symptoms bring some individuals to medical attention, but patients are usually recognized as the cardiopulmonary phase begins. Typically, there is slightly lowered blood pressure, tachycardia, tachypnea, mild hypoxemia, and early radiographic signs of pulmonary edema. Physical findings in the chest are often surprisingly scant. The conjunctival and cutaneous signs of vascular involvement seen in other types of HF are absent. During the next few hours, decompensation may progress rapidly to severe hypoxemia and respiratory failure. Most patients surviving the first 48 h of hospitalization are extubated and discharged within a few days, with no apparent residua.

Management during the first few hours after presentation is critical. The goal is to prevent severe hypoxemia by oxygen therapy and, if needed, intubation and intensive respiratory management. During this period, hypotension and shock with increasing hematocrit invite aggressive fluid administration, but this intervention should be undertaken with great caution. Because of low cardiac output with myocardial depression and increased pulmonary vascular permeability, shock should be managed expectantly with pressors and modest infusion of fluid guided by the pulmonary capillary wedge pressure. Mild cases can be managed by frequent monitoring and oxygen administration without intubation. Many patients require intubation to manage hypoxemia and also develop shock. Mortality remains at ~30 to 40% with good management. The antiviral drug ribavirin inhibits the virus in vitro but did not have a marked effect on patients treated in an open-label study.

During the prodrome, the differential diagnosis of hantavirus pulmonary syndrome is difficult, but by the time of presentation or within 24 h thereafter, a number of diagnostically helpful clinical features become apparent. Cough is not usually present at the outset but may develop later. Interstitial edema is evident on the chest x-ray. Later, bilateral alveolar edema with a central distribution develops in the setting of a normal-sized heart; occasionally, the edema is initially unilateral. Pleural effusions are often visualized. Thrombocytopenia, circulating atypical lymphocytes, and a left shift (often with leukocytosis) are almost always evident; thrombocytopenia has been a particularly important early clue. Hemoconcentration, proteinuria, and hypoalbuminemia should also be sought. Although thrombocytopenia virtually always develops and prolongation of the partial thromboplastin time is the rule, clinical evidence for coagulopathy or laboratory indications of DIC are found in only a minority of cases, usually in severely ill patients. Severely ill patients also have acidosis and elevated serum levels of lactate. Mildly increased values in renal function tests are common, but patients with severe cases often have markedly elevated concentrations of serum creatinine; some of the viruses other than Sin Nombre virus have been associated with more kidney involvement, but few such cases have been studied. The differential diagnosis includes abdominal surgical conditions and pyelonephritis as well as rickettsial disease, sepsis, meningococcemia, plague, tularemia, influenza, and relapsing fever.

A specific diagnosis is best made by IgM testing of acute-phase serum, which has yielded positive results even in the prodrome. Tests using a Sin Nombre virus antigen detect the related hantaviruses causing the pulmonary syndrome in the Americas. Occasionally, heterologous viruses will react only in the IgG ELISA, but this finding is highly suspicious given the very low seroprevalence of these viruses in normal populations. RT-PCR is usually positive when used to test blood clots obtained in the first 7 to 9 days of illness as well as tissues; this test is useful in identifying the infecting virus in areas outside the home range of the deer mouse and in atypical cases.

YELLOW FEVER Yellow fever virus caused major epidemics in the Americas, Africa, and Europe before the discovery of mosquito transmission in 1900 led to its control through attacks on its urban vector, *A. aegypti*. Only then was it found that a jungle cycle also existed in Africa, involving other *Aedes* mosquitoes and monkeys, and that colonization of the New World with *A. aegypti*, originally an African species, had established urban yellow fever as well as an independent sylvatic yellow fever cycle in American jungles involving *Haemagogus* mosquitoes and New World monkeys. Today, urban yellow fever transmission occurs only in some African cities, but the threat exists in the great cities of South America, where reinfestation by *A. aegypti* has taken place and dengue transmission by the same mosquito is common. As late as 1905, New Orleans suffered >3000 cases with 452 deaths from "yellow jack." Despite the existence of a highly effective and safe vaccine, several hundred jungle yellow fever cases occur annually in South America, and thousands of jungle and urban cases occur each year in Africa.

Yellow fever is a typical HF accompanied by prominent hepatic necrosis. A period of viremia, typically lasting 3 or 4 days, is followed by a period of "intoxication." During the latter phase in severe cases,

the characteristic jaundice, hemorrhages, black vomit, anuria, and terminal delirium occur, perhaps related in part to extensive hepatic involvement. Blood leukocyte counts may be normal or reduced and are often high in terminal stages. Albuminuria is usually noted and may be marked; as renal function fails in terminal or severe cases, the level of blood urea nitrogen rises proportionately. Abnormalities detected in liver function tests range from modest elevations of AST levels in mild cases to severe derangement.

Urban yellow fever can be prevented by the control of *A. aegypti*. The continuing sylvatic cycle requires vaccination of all visitors to areas of potential transmission. With few exceptions (in the very young and the elderly), reactions to vaccine are minimal; immunity is provided within 10 days and lasts for at least 10 years. An egg allergy dictates caution in vaccine administration. Although there are no documented harmful effects of the vaccine on the fetus, pregnant women should be immunized only if they are definitely at risk of yellow fever exposure. Since vaccination has been associated with several cases of encephalitis in children <6 months of age, it should be delayed until after 12 months of age unless the risk of exposure is very high. Timely information on changes in yellow fever distribution and yellow fever vaccine requirements can be obtained from Health Information for Travelers, Centers for Disease Control and Prevention, Atlanta, GA 30333; by fax request (404-332-4565; document number 220022#); by phone (404-332-4559); or via the Internet (*www.cdc.gov*).

DENGUE HEMORRHAGIC FEVER/DENGUE SHOCK SYNDROME A syndrome of HF noted in the 1950s among children in the Philippines and Southeast Asia was soon associated with dengue virus infections, particularly those occurring against a background of previous exposure to another serotype. The transient heterotypic protection after dengue virus infection is replaced within several weeks by the potential for heterotypic infection resulting in typical dengue fever (see above) or—uncommonly—for enhanced disease (secondary DHF/DSS). In rare instances, primary dengue infections lead to an HF syndrome, but much less is known about pathogenesis in this situation. In the past 20 years, *A. aegypti* has progressively reinvaded Latin America and other areas, and frequent travel by infected individuals has introduced multiple strains of dengue virus from many geographic areas. Thus the pattern of hyperendemic transmission of multiple dengue serotypes has now been established in the Americas and the Caribbean and has led to the emergence of DHF/DSS as a major problem there as well. Millions of dengue infections, including many thousands of cases of DHF/DSS, occur annually. The severe syndrome is unlikely to be seen in U.S. citizens since few children have the dengue antibodies that can trigger the pathogenetic cascade when a second infection is acquired.

Macrophage/monocyte infection is central to the pathogenesis of dengue fever and to the origin of DHF/DSS. Previous infection with a heterologous dengue-virus serotype may result in the production of nonprotective antiviral antibodies that nevertheless bind to the virion's surface and through interaction with the Fc receptor focus secondary dengue viruses on the target cell, the result being enhanced infection. The host is also primed for a secondary antibody response when viral antigens are released and immune complexes lead to activation of the classic complement pathway, with consequent phlogistic effects. Cross-reactivity at the T cell level results in the release of physiologically active cytokines, including interferon γ and tumor necrosis factor α. The induction of vascular permeability and shock depends on multiple factors, including the following:

1. *Presence of enhancing and nonneutralizing antibodies*—Transplacental maternal antibody may be present in infants <9 months old, or antibody elicited by previous heterologous dengue infection may be present in older individuals. T cell reactivity is also intimately involved.
2. *Age*—Susceptibility to DHF/DSS drops considerably after 12 years of age.
3. *Sex*—Females are more often affected than males.
4. *Race*—Caucasians are more often affected than blacks.
5. *Nutritional status*—Malnutrition is protective.
6. *Sequence of infection*—For example, serotype 1 followed by serotype 2 seems to be more dangerous than serotype 4 followed by serotype 2.
7. *Infecting serotype*—Type 2 is apparently more dangerous than other serotypes.

In addition, there is considerable variation among strains of a given serotype, with Southeast Asian serotype 2 strains having more potential to cause DHF/DSS than others.

Dengue HF is identified by the detection of bleeding tendencies (tourniquet test, petechiae) or overt bleeding in the absence of underlying causes such as preexisting gastrointestinal lesions. Dengue shock syndrome, usually accompanied by hemorrhagic signs, is much more serious and results from increased vascular permeability leading to shock. In mild DHF/DSS, restlessness, lethargy, thrombocytopenia (<100,000/μL), and hemoconcentration are detected 2 to 5 days after the onset of typical dengue fever, usually at the time of defervescence. The maculopapular rash that often develops in dengue fever may also appear in DHF/DSS. In more severe cases, frank shock is apparent, with low pulse pressure, cyanosis, hepatomegaly, pleural effusions, ascites, and in some cases severe ecchymoses and gastrointestinal bleeding. The period of shock lasts only 1 or 2 days, and most patients respond promptly to close monitoring, oxygen administration, and infusion of crystalloid or—in severe cases—colloid. The case-fatality rates reported vary greatly with case ascertainment and the quality of treatment; however, most DHF/DSS patients respond well to supportive therapy, and overall mortality in an experienced center in the tropics is probably as low as 1%.

A virologic diagnosis can be made by the usual means, although multiple flavivirus infections lead to a broad immune response to several members of the group, and this situation may result in a lack of virus specificity of the IgM and IgG immune responses. A secondary antibody response can be sought with tests against several flavivirus antigens to demonstrate the characteristic wide spectrum of reactivity.

The key to control of both dengue fever and DHF/DSS is the control of *A. aegypti*, which also reduces the risk of urban yellow fever and chikungunya virus circulation. Control efforts have been handicapped by the presence of nondegradable tires and long-lived plastic containers in trash repositories, insecticide resistance, urban poverty, and an inability of the public health community to mobilize the populace to respond to the need to eliminate mosquito breeding sites. Live attenuated dengue vaccines are in the late stages of development and have produced promising results in early tests. Whether vaccines can provide safe, durable immunity to an immunopathologic disease such as DHF/DSS in endemic areas is an issue that will have to be tested, but it is hoped that vaccination will reduce transmission to negligible levels.

181 EBOLA AND MARBURG VIRUSES

Clarence J. Peters

DEFINITION Both Marburg virus and Ebola virus cause an acute febrile illness associated with high mortality. This illness is characterized by multisystem involvement that begins with the abrupt onset of headache, myalgias, and fever and proceeds to prostration, rash, and shock and often to bleeding manifestations. Epidemics usually begin with a single case acquired from an unknown reservoir in nature and spread mainly through close contact with sick persons or their body fluids, either in the home or at the hospital.

ETIOLOGY The family Filoviridae comprises two antigenically and genetically distinct viruses: Marburg virus and Ebola virus. Ebola virus has four readily distinguishable subtypes named for their original sites of recognition (Zaire, Sudan, Cote d'Ivoire, and Reston). Except for Ebola virus subtype Reston, all the Filoviridae are African viruses that cause severe and often fatal disease in humans. The Reston virus, which has been exported from the Philippines on several occasions, has caused fatal infections in monkeys but only subclinical infections in humans. Different isolates of the four Ebola subtypes made over time and space exhibit remarkable sequence conservation, indicating marked genetic stability in their selective niche. Typical filovirus particles contain a single linear, negative-sense, single-stranded RNA arranged in a helical nucleocapsid. The virions are 790 to 970 nm in length; they may also appear in elongated, contorted forms. The lipid envelope confers sensitivity to lipid solvents and common detergents. The viruses are largely destroyed by heat (60°C, 30 min) and by acidity but may persist for weeks in blood at room temperature. The surface glycoprotein self-associates to form the virion surface spikes, which presumably mediate attachment to cells and fusion. The glycoprotein's high sugar content may contribute to its low capacity to elicit neutralizing antibodies. A smaller form of the glycoprotein, bearing many of its antigenic determinants, is produced by in vitro–infected cells and is found in the circulation in human disease; it has been speculated that this circulating soluble protein may suppress the immune response to the virion surface protein or block antiviral effector mechanisms. Both Marburg virus and Ebola virus are biosafety level 4 pathogens because of their high associated mortality rate and aerosol infectivity.

EPIDEMIOLOGY Marburg virus was first identified in Germany in 1967, when infected African green monkeys (*Cercopithecus aethiops*) imported from Uganda transmitted the agent to vaccine-laboratory workers. Of the 25 human cases acquired from monkeys, 7 ended in death. The six secondary cases were associated with close contact or parenteral exposure. Secondary spread to the wife of one patient was documented, and virus was isolated from the husband's semen despite the presence of circulating antibodies. Subsequently, isolated cases of Marburg virus infection have been reported from eastern and southern Africa, with limited spread.

In 1999, repeated transmission of Marburg virus to workers in a gold mine in eastern Democratic Republic of Congo was documented. The secondary spread of the virus among patients' families was more extensive than previously noted, resembling that of Ebola virus and emphasizing the importance of hygiene and proper barrier nursing in the epidemiology of these viruses in Africa.

In 1976, epidemics of severe hemorrhagic fever (550 human cases) occurred simultaneously in Zaire and Sudan, and Ebola virus was found to be the etiologic agent. Later, it was shown that different subtypes of virus—associated with 90 and 50% mortality, respectively—caused the two epidemics. Both epidemics were associated with interhuman spread (particularly in the hospital setting) and the use of unsterilized needles and syringes, a common practice in developing-country hospitals. The epidemics dwindled as the clinics were closed and people in the endemic area increasingly shunned affected persons and avoided traditional burial practices.

The Zaire subtype of Ebola virus recurred in a major epidemic (317 cases, 88% mortality) in Democratic Republic of Congo in 1995 and in smaller epidemics in Gabon in 1994–1996. Mortality was high, transmission to caregivers and others who had direct contact with body fluids was common, and poor hygiene in hospitals exacerbated spread. In the Congo epidemic, an index case was infected in Kikwit in January 1995. The epidemic smoldered until April, when intense nosocomial transmission forced closure of the hospitals; samples were finally sent to the laboratory for Ebola testing, which yielded positive results within a few hours. International assistance, with barrier nursing instruction and materials, was provided; nosocomial transmission ceased, hospitals reopened, and patients were segregated to prevent intrafamilial spread. The last case was reported in June 1995.

Separate emergences of Ebola virus (subtype Zaire) were detected in Gabon from 1994 through 2003, usually in association with deep forest exposure and subsequent familial and nosocomial transmission. Nonhuman primates sometimes exhibited die-offs, and Ebola infection was confirmed in at least some animals. In a 1996 episode, a physician exposed to Ebola-infected patients traveled to South Africa with a fever; a nurse who assisted in a cutdown on the physician developed Ebola hemorrhagic fever and died despite intensive care. The index patient was identified retrospectively on the basis of serum antibodies and virus isolation from semen. Thus, distant transport of Ebola virus is an established risk, but limited nosocomial spread occurs under proper hygienic conditions.

In 2000–2001, an indolent outbreak of the Sudan subtype claimed the lives of 224 (53%) of 425 patients with presumptive cases in Uganda.

The Reston subtype of Ebola virus was first seen in the United States in 1989, when it caused a fatal, highly transmissible disease among cynomolgus macaques imported from the Philippines and quarantined in Reston, VA, pending distribution to biomedical researchers. This and other appearances of the Reston virus have been traced to a single export facility in the Philippines, but no source in nature has been established.

Epidemiologic studies (including a specific search in the Kikwit epidemic) have failed to yield evidence for an important role of airborne particles in human disease. This lack of epidemiologic evidence is surprising and seems to conflict with the viruses' classification as biosafety level 4 pathogens based in part on their aerosol infectivity and with formal laboratory assessments showing a high degree of aerosol infectivity for monkeys. Sick humans apparently do not usually generate sufficient amounts of infectious aerosols to pose a significant hazard to those around them.

Available evidence points to a nonprimate reservoir for these viruses, but an intensive search has failed to elucidate what this reservoir might be. Speculation has centered on a possible role for bats, but that

hypothesis has risen in part merely because of the ubiquity of bats when sought in affected areas and the frustration of researchers in identifying a source of virus.

PATHOLOGY AND PATHOGENESIS In humans and in animal models, Ebola and Marburg viruses replicate well in virtually all cell types, including endothelial cells, macrophages, and parenchymal cells of multiple organs. The earliest involvement is that of the mononuclear phagocyte system, and this is responsible for initiation of the disease process. Viral replication is associated with cellular necrosis both in vivo and in vitro. Significant findings at the light-microscopic level include liver necrosis with Councilman bodies (intracellular inclusions that correlate with extensive collections of viral nucleocapsids), interstitial pneumonitis, cerebral glial nodules, and small infarcts. Antigen and virions are abundant in fibroblasts, interstitium, and (to a lesser extent) the appendages of the subcutaneous tissues in fatal cases; escape through small breaks in the skin or possibly through sweat glands may occur and, if so, may be correlated with the established epidemiologic risk of close contact with patients and the touching of the deceased. Inflammatory cells are not prominent, even in necrotic areas.

In addition to sustaining direct damage from viral infection, patients infected with Ebola virus (Zaire subtype) have high circulating levels of proinflammatory cytokines, which presumably contribute to the severity of the illness. In fact, the virus interacts intimately with the cellular cytokine system. It is resistant to the antiviral effects of interferon α, although this mediator is amply induced. Viral infection of endothelial cells selectively inhibits the expression of MHC class I molecules and blocks the induction of several genes by the interferons. In addition, glycoprotein expression inhibits αV integrin expression, an effect that has been shown in vitro to lead to detachment and subsequent death of endothelial cells.

Acute infection is associated with high levels of circulating virus and viral antigen. Clinical improvement takes place when viral titers decrease concomitantly with the onset of a virus-specific immune response, as detected by enzyme-linked immunosorbent assay (ELISA) or fluorescent antibody test. In fatal cases, there is usually little evidence of an antibody response and there is extensive depletion of spleen and lymph nodes. Recovery is apparently mediated by the cellular immune response: convalescent-phase plasma has little in vitro virus-neutralizing capacity and is not protective in passive transfer experiments in monkey and guinea pig models.

CLINICAL MANIFESTATIONS After an incubation period of ~7 to 10 days (range, 3 to 16 days), the patient abruptly develops fever, severe headache, malaise, myalgia, nausea, and vomiting. Continued fever is joined by diarrhea (often severe), chest pain (accompanied by cough), prostration, and depressed mentation. In light-skinned patients (and less often in dark-skinned individuals), a maculopapular rash appears around day 5 to 7 and is followed by desquamation. Bleeding may begin about this time and is apparent from any mucosal site and into the skin. In some epidemics, fewer than half of patients have had overt bleeding, and this manifestation has been absent even in some fatal cases. Additional findings include edema of the face, neck, and/or scrotum; hepatomegaly; flushing; conjunctival injection; and pharyngitis. Around 10 to 12 days after the onset of disease, the sustained fever may break, with improvement and eventual recovery of the patient. Recrudescence of fever may be associated with secondary bacterial infections or possibly with localized virus persistence. Late hepatitis, uveitis, and orchitis have been reported, with isolation of virus from semen or detection of polymerase chain reaction (PCR) products in vaginal secretions for several weeks.

LABORATORY FINDINGS Leukopenia is common early on; neutrophilia has its onset later. Platelet counts fall below (sometimes much below) 50,000/μL. Laboratory evidence of disseminated intravascular coagulation may be found, but its clinical significance and the need for therapy are controversial. Serum levels of alanine and aspartate aminotransferases (particularly the latter) rise progressively, and jaundice develops in some cases. The serum amylase level may be elevated, and this elevation may be associated with abdominal pain suggesting pancreatitis. Proteinuria is usual; decreased kidney function is proportional to shock.

DIAGNOSIS Most patients acutely ill as a result of infection with Ebola or Marburg viruses have high concentrations of virus in blood. Antigen-detection ELISA is a sensitive, robust diagnostic modality. Virus isolation and reverse-transcriptase PCR are also effective and provide additional sensitivity in some cases. Patients who are recovering develop IgM and IgG antibodies that are best detected by ELISA but are also reactive in the less specific fluorescent antibody test. Skin biopsies are an extremely useful adjunct in postmortem diagnosis of Ebola (and, to a lesser extent, Marburg) virus infections because of the presence of large amounts of viral antigen, the relative safety of obtaining the sample, and the freedom from cold-chain requirements for formalin-fixed tissues.

℞ TREATMENT

No virus-specific therapy is available, and, given the extensive viral involvement in fatal cases, supportive treatment may not be as useful as was once hoped. However, recent studies in rhesus monkeys have shown improved survival among animals treated with an inhibitor of factor VIIa/tissue factor. Vigorous treatment of shock should take into account the likelihood of vascular leak in the pulmonary and systemic circulation and of myocardial functional compromise. The membrane fusion mechanism of Ebola resembles that of retroviruses, and the identification of "fusogenic" sequences suggests that inhibitors of cell entry may be developed. Despite the poor neutralizing capacity of polyclonal convalescent-phase sera, phage display of immunoglobulin mRNA from convalescent bone marrow has produced monoclonal antibodies that have in vitro neutralizing capacity and mediate protection in guinea pig—but, unfortunately, not in monkey—models.

PREVENTION No vaccine or antiviral drug is currently available, but barrier nursing precautions in African hospitals can greatly decrease the spread of the virus beyond the index case and thus prevent epidemics of filoviruses and other agents as well. An adenovirus-vectored Ebola glycoprotein gene has proved protective in nonhuman primates and is undergoing phase 1 trials in humans.

182 DIAGNOSIS AND TREATMENT OF FUNGAL INFECTIONS

John E. Bennett

MYCOLOGY FUNDAMENTALS

Fungi can appear microscopically as either rounded, budding forms (yeastlike organisms) or hyphae (molds). Yeastlike colonies are smooth, while mold colonies are fuzzy; fungi that grow as yeasts include species of *Candida* and *Cryptococcus*, while fungi that grow as molds include species of *Aspergillus*, *Rhizopus*, and dermatophytes (ringworm fungi). The fungi that cause histoplasmosis, blastomycosis, sporotrichosis, coccidioidomycosis, and paracoccidioidomycosis are called *dimorphic* ("having two forms") because they are spherical in tissue but grow like molds when cultured at room temperature. *Candida* species other than *Candida glabrata* appear in tissue as both budding yeasts and tubular elements called *pseudohyphae*. Pseudohyphae, unlike true hyphae, have constrictions in the cell wall where septa are located and have septa at branching points. *Pneumocystis* (Chap. 191) is closer to fungi than to parasites by ribosomal sequences. Because the drugs used to treat *Pneumocystis* pneumonia are also used to treat parasitic or bacterial infections (see Chaps. 118 and 193), those drugs will not be discussed in this chapter.

Many fungi can form two different types of spores and are given different names, depending on the spore-bearing structures. When the spores are produced by mitosis, the fungus is said to be an *anamorph*, or to be in the imperfect state. Many fungi can have different sporulating structures in which genetic recombination occurs, often as a result of coculture with a strain of the opposite mating type. A fungus producing those distinctive spores is said to be a *teleomorph*, or to be in the perfect state. Diagnostic laboratories usually use the name of the anamorph because they do not use culture conditions that would produce the teleomorph. One exception is *Scedosporium apiospermum*, which is often observed as a teleomorph in the diagnostic laboratory and identified as *Pseudallescheria boydii*.

Most fungi that are pathogenic for humans are saprophytes in nature; they cause infection when airborne spores reach the lung or paranasal sinus or when hyphae or spores are accidentally inoculated into the skin or cornea. Acquisition of infection from another person or an animal has been reported in the case of ringworm but is very rare in other mycoses. Thus, hospitalized patients with fungal infections do not require special isolation. Most fungi infect hosts preferentially by one route and only infrequently by other routes. For example, the agents of ringworm, pityriasis versicolor, and piedra infect the epidermis and its appendages. Sporotrichosis and mycetoma usually arise from subcutaneous inoculation. Inhalation is the route of inoculation for the agents of most deep mycoses. Ingestion of fungi rarely causes infection; *Candida albicans*, a normal commensal in the mouth and intestine, reaches deeper tissues only when mucosal or cutaneous barriers are breached by disease, surgery, trauma, or catheterization. Histoplasmosis, blastomycosis, coccidioidomycosis, and paracoccidioidomycosis have been called "endemic" mycoses to emphasize their restricted geographic distribution. Some fungi, such as *Aspergillus* and *Fusarium*, are said to be opportunists in that they usually infect hosts with compromised immunity. This distinction is relative, not absolute.

Immunity after exposure to fungi may confer partial protection against reinfection. Residents of areas in which mycoses are endemic are less subject to infection than are newcomers. Predisposing factors are helpful in defining host defense. Immunoglobulin deficiencies do not appear to predispose to any mycosis, whereas neutropenia is common among patients who develop invasive mold infections or deep candidiasis. Cell-mediated immunity appears to be of paramount importance in cryptococcosis, histoplasmosis, and coccidioidomycosis.

DIAGNOSIS

Many fungi can be identified to the genus or even the species level by microscopic examination of smears or biopsy specimens. Calcofluor white staining with fluorescence microscopy is a sensitive technique for smears of sputum, bronchoalveolar lavage fluid, or pus. India ink smear remains the method of choice for detecting cryptococci in cerebrospinal fluid (CSF). *Candida* yeast cells and pseudohyphae are the only fungi that are usually gram-positive on smears. For other fungi, Gram's staining is distinctly suboptimal. For histopathology slides, Gomori methenamine silver and a neutral counterstain are preferred.

The method used has a marked effect on the rapidity and sensitivity of blood cultures for fungi except in the case of *Candida* species, which are relatively easy to grow. For most other fungi, concentration of the blood by lysis centrifugation and culture on solid medium constitute the optimal technique. Commercially available nucleic acid hybridization techniques can speed the identification of slow-growing molds, such as *Histoplasma capsulatum* and *Coccidioides immitis*. Serology has limited value, but testing of serum or CSF for cryptococcal antigen or antibody to *C. immitis* can be diagnostic. Detection of *Histoplasma* antigen in urine or serum is helpful in diagnosis and in following the results of treatment for disseminated histoplasmosis. Skin testing with fungal antigens is not useful in detecting active infection.

ANTIFUNGAL THERAPY

TOPICAL AGENTS ■ Imidazoles and Triazoles (See also "Systemic Antifungals") These synthetic compounds act by inhibiting ergosterol synthesis in the fungal cell wall and, when given topically, may cause direct damage to the fungal cytoplasmic membrane. The imidazoles available for cutaneous application include clotrimazole, econazole, ketoconazole, sulconazole, oxiconazole, and miconazole. Vaginal formulations include four imidazoles (miconazole, clotrimazole, tioconazole, and butoconazole) and one triazole (terconazole). As yet, no substantial differences in the efficacy of or local intolerance to the various topical azoles have become apparent. All are effective in the treatment of cutaneous candidiasis, tinea (pityriasis) versicolor, and mild to moderately severe ringworm of the glabrous skin. Vaginal formulations are effective for vulvovaginal candidiasis. Clotrimazole is poorly absorbed from the gastrointestinal tract, but the oral troche is useful as a topical treatment for oral and esophageal candidiasis.

Polyene Macrolide Antibiotics These broad-spectrum antifungal agents combine with sterol in the fungal cytoplasmic membrane, increasing membrane permeability. Topically, they are not active against ringworm but are effective against candidiasis of the skin and mucous membranes. Nystatin and amphotericin B suspensions are effective in oral thrush, and vaginal troches are effective in vulvovaginal candidiasis. Both nystatin and amphotericin B are available in topical preparations for cutaneous candidiasis.

Other Topical Antifungals Ciclopirox olamine, haloprogin, terbinafine, and naftifine have the same clinical spectrum among the cutaneous mycoses as the imidazoles. Tolnaftate and undecylenic acid are effective against ringworm but not candidiasis. Keratolytic agents, such as salicylic acid, are helpful as accessory drugs for some hyperkeratotic skin lesions.

SYSTEMIC ANTIFUNGALS ■ Griseofulvin Griseofulvin is a useful drug in the treatment of certain kinds of ringworm; however, it is ineffective in the treatment of candidiasis. The microcrystalline and ultramicrocrystalline preparations differ in dose but not in efficacy. Absorption of both is enhanced when the drug is ingested with fat-containing foods. Griseofulvin interacts with phenobarbital and warfarin.

Terbinafine Oral terbinafine (250 mg once daily) is at least as effective as itraconazole and more effective than griseofulvin in onychomycosis and ringworm. Treatment duration ranges from 3 months for fingernails to 6 months for toenails. Gastrointestinal distress is the most common side effect. Rash, hepatitis, and pancytopenia have occurred, but serious adverse effects have been uncommon. Terbinafine decreases cyclosporine levels. Cimetidine increases and rifampin decreases terbinafine levels in blood.

Imidazoles and Triazoles ■ *GENERAL FEATURES* The azole antifungals include imidazoles and triazoles. Fluconazole, itraconazole, voriconazole, and the investigational azoles posaconazole and ravuconazole are all triazoles, so named because they have three nitrogens in the ring structure. This class has less impact on human hormonal synthesis and less hepatotoxicity than the only widely used systemic imidazole, ketoconazole. Itraconazole has many structural features in common with ketoconazole; however, it has a broader spectrum of activity and has largely replaced ketoconazole.

Interactions between azoles and other drugs can increase the plasma concentrations of the other drugs to toxic levels or decrease the azole plasma concentrations to subtherapeutic levels. A few drugs can increase the plasma concentrations of azoles, but the effect is modest. Drug-drug interactions are most numerous with itraconazole and ketoconazole; some drugs are contraindicated for concomitant use with these agents. Azole interactions with any one class of drugs, such as benzodiazepines, HMG-CoA reductase inhibitors, or drugs that decrease gastric acidity, should be considered to apply to all drugs of that class until proven otherwise. Fluconazole differs substantially from itraconazole: unlike that of itraconazole, the absorption of fluconazole is independent of food or gastric acid, and fluconazole has much less effect on the hepatic metabolism of other drugs than does itraconazole. High fluconazole blood levels engendered by azotemia or by dosages above those used in pharmacologic studies may lead to new and profound drug interactions.

All azoles have the potential for embryotoxicity and teratogenicity. In fact, it seems likely that azoles should not be given during pregnancy without a discussion of the serious risks and possible benefits with the mother. Four infants born to mothers taking at least 400 mg of fluconazole daily for coccidioidal meningitis have had severe bone, craniofacial, or cardiac abnormalities. Similarity of these abnormalities to those in pregnant animals given fluconazole suggests that fluconazole caused the defects.

ITRACONAZOLE Itraconazole is useful in the treatment of blastomycosis, histoplasmosis, cutaneous candidiasis, coccidioidomycosis, sporotrichosis, pseudallescheriasis, onychomycosis, ringworm, tinea versicolor, and indolent cases of aspergillosis. The drug is metabolized in the liver, with the hydroxy metabolite accounting for at least half of the antifungal activity in serum. The sum of the blood levels of the native drug and its hydroxylated metabolite is usually at least 2 μg/mL a few hours after oral administration. Almost no bioactive drug appears in urine or CSF.

Itraconazole is available as a 100-mg capsule, an oral solution, and an intravenous formulation. Although itraconazole capsules are less expensive and cause less gastrointestinal distress than the oral solution, their absorption is sometimes problematic. Cyclodextrin, which is used to formulate both the oral solution and the intravenous formulation, is renally excreted but is not absorbed from the gastrointestinal tract. Food increases the absorption of itraconazole capsules by about threefold but substantially reduces the absorption of the cyclodextrin suspension.

The oral solution is effective in oropharyngeal and esophageal candidiasis at a dose of 100 mg (10 mL) twice daily and has also been used at twice that dose for the treatment of deep mycoses in patients who absorb itraconazole capsules poorly. The efficacy of itraconazole in mycoses of the central nervous system has been modest at best, given the drug's inability to reach the CSF. For deep infections, itraconazole capsules are given at an initial dosage of 600 to 800 mg daily for 3 days and a subsequent dosage of 200 to 400 mg once daily continued for 6 to 12 months. Itraconazole blood levels (see above) are helpful in documenting absorption when the oral drug is used for the treatment of deep mycoses. The commercially available intravenous formulation should be considered for initial therapy in hospitalized patients whose itraconazole absorption from the gastrointestinal tract may be suboptimal and whose creatinine clearance rate exceeds 30 mL/min. The dose is 200 mg twice daily for four doses followed by 200 mg daily for up to 2 weeks. Intravenous itraconazole, followed by the oral solution, is approved for the treatment of fever of unknown origin in neutropenic patients not responding to at least 96 h of therapy with antibacterial antibiotics.

Except for gastrointestinal distress from the oral solution, the toxicity of itraconazole is generally low, although life-threatening hepatotoxicity, congestive heart failure, edema, cardiac dysrhythmias, and peripheral neuropathy have been reported.

FLUCONAZOLE This triazole can be administered in tablet form, as a suspension, or as an intravenous infusion. With a half-life of about 31 h, fluconazole can be given once a day. Approximately 80% of the drug is excreted unchanged in the urine. Patients with creatinine clearance rates of 21 to 50 mL/min and 11 to 20 mL/min should have their fluconazole doses reduced by 50 and 75%, respectively. The drug penetrates the CSF and other body fluids very well.

Nausea and abdominal distress are the most common forms of dose-limiting fluconazole toxicity. An allergic rash may develop and is particularly common among patients infected with HIV. Fatal cases of Stevens-Johnson syndrome have been described in the HIV-infected population. Alopecia commonly follows prolonged administration of $\geq$400 mg daily but resolves when therapy is discontinued. Rare cases of anaphylaxis, hepatic necrosis, and neutropenia have been described.

Fluconazole is useful in the treatment of oropharyngeal and esophageal candidiasis in adults. A single 150-mg tablet is effective in vulvovaginal candidiasis. Catheter-acquired candidemia in the immunocompetent host responds to 400 mg of fluconazole daily in conjunction with the removal of the infected catheter. Treatment should be continued for 10 to 14 days after the patient has become afebrile. Fluconazole is also effective in initial and maintenance therapy for cryptococcal meningitis in patients with AIDS, although most of these patients should initially receive a 2-week course of intravenous amphotericin B. Fluconazole is the drug of choice for coccidioidal meningitis.

The incidence of deep candidiasis among recipients of allogeneic bone marrow transplants can be reduced by the administration of fluconazole (400 mg daily) for 75 days after initiation of the transplantation-preparative regimen. Prophylaxis in other neutropenic patients has not appeared useful. Fluconazole (200 mg daily) reduced the incidence of cryptococcosis and mucosal candidiasis among AIDS patients whose CD4+ cell counts were $<$200/μL and was particularly effective among those with counts of $<$50/μL. However, this regimen is not recommended because it does not reduce mortality, is expensive, and can lead to drug resistance.

Fluconazole is less effective than itraconazole in blastomycosis, histoplasmosis, and sporotrichosis. The drug is not active in aspergillosis, pseudallescheriasis, or mucormycosis.

VORICONAZOLE This recently marketed triazole is available as 50- and 200-mg tablets and as vials of 200 mg for intravenous administration. The average-sized adult is given 6 mg/kg intravenously every 12 h for two doses followed by maintenance doses of 4 mg/kg intravenously every 12 h. In patients whose condition is improving, the regimen can be changed to 200 mg twice daily by mouth. Up to 300 mg twice daily by mouth can be given to patients who do not respond adequately to the lower dose.

Voriconazole is well absorbed from the gastrointestinal tract and is metabolized completely by the liver by way of CYP2C9, CYP2C19, and CYP3A4. Genetic polymorphisms in CYP2C19 activity cause substantial variation in voriconazole metabolism. Dose adjustment for azotemia is not necessary, but the dose should be reduced by half in

patients with moderate liver disease. Because the cyclodextrin used in the intravenous formulation is renally excreted, oral—not intravenous—voriconazole should be used in patients with creatinine clearance rates below 50 mL/min. Penetration into the CSF is good. Concurrent use of sirolimus is contraindicated because its serum levels are markedly increased in the presence of voriconazole. Until more complete data are available, the drug interactions for voriconazole should be considered to be similar to those for itraconazole. The toxic effects of voriconazole include transient visual disturbances (color changes, blurring) in 30% of patients, hepatotoxicity in 10%, and rash in 5%.

The spectrum of voriconazole includes all the fungi against which itraconazole and fluconazole are active. Voriconazole is indicated for initial treatment of invasive aspergillosis, pseudallescheriasis, and fusariosis. The drug is also useful as empirical therapy in febrile neutropenic patients who do not respond to at least 96 h of treatment with antibacterial antibiotics and who are at high risk of invasive mold infections.

INVESTIGATIONAL TRIAZOLES Posaconazole and ravuconazole, which are undergoing early clinical trials, have antifungal spectra similar to that of voriconazole. Ravuconazole is notable for a half-life of ~1 week.

Echinocandins One echinocandin (caspofungin) is on the market, and two others (micafungin and anidulafungin) are being assessed in clinical trials. All are administered intravenously and act by inhibiting synthesis of (1,3)β-D-glucan in the cell wall. The in vitro activity of these drugs against nearly all *Candida* species is similar and is independent of azole resistance. The possible exception is *Candida parapsilosis*, a species whose susceptibility varies with the isolate and the particular echinocandin. Activity against *Aspergillus* species is more obvious in experimentally infected animals than in vitro, where changes in hyphal shape are more obvious than decreased growth. The recommended regimen is a 70-mg loading dose followed by 50 mg daily. Toxicity is low and includes histamine-like acute infusion reactions and hepatotoxicity. Cyclosporine elevates caspofungin blood levels, but other drug-drug interactions have been minor so far. No dosage adjustment is needed in patients with azotemia or hemodialysis, but the dose should be reduced for moderate hepatic insufficiency. Penetration into CSF is negligible. On the basis of an open trial in 63 patients, caspofungin has been approved for salvage therapy in aspergillosis. Data on candidemia in nonneutropenic patients indicate an efficacy equivalent to that of fluconazole or amphotericin B.

Amphotericin B A colloidal deoxycholate complex of the polyene drug amphotericin B is available for intravenous or intrathecal administration. The catabolism of amphotericin B is extremely slow and is not influenced by renal failure, hepatic failure, or hemodialysis. The drug's penetration into CSF and vitreous humor is poor; however, the concentrations in pleural, peritoneal, and articular exudates are adequate for many mycoses. Histoplasmosis, blastomycosis, paracoccidioidomycosis, candidiasis, and cryptococcosis are the most responsive mycoses; coccidioidomycosis, extraarticular sporotrichosis, aspergillosis, and mucormycosis are less responsive; and chromoblastomycosis, mycetoma, and pseudallescheriasis respond little, if at all. The usual course is 0.5 to 0.7 mg/kg daily for 8 to 10 weeks. Infusions are generally given in 5% dextrose over 2 to 4 h.

Initial doses of amphotericin B occasionally cause marked febrile reactions that may be poorly tolerated by adult patients with limited cardiac or pulmonary function. It may be prudent to give such patients an initial 1-mg test dose followed by rapidly escalating doses, depending on tolerance. Premedication with aspirin or acetaminophen or the addition of hydrocortisone (25 mg) to the infusion decreases chills and fever. Azotemia during treatment is usual, the extent depending on the daily dose, underlying renal disease, and concomitant nephrotoxic agents. Saline infusions have been advocated to reduce azotemia. Continuous amphotericin B infusions may reduce nephrotoxicity, but the impact on efficacy is unknown. Other side effects include anemia, hypokalemia, renal tubular acidosis, nausea, anorexia, weight loss, phlebitis, and occasionally hypomagnesemia. Intrathecal amphotericin B has been used in coccidioidal meningitis and refractory cryptococcal meningitis, although this therapy is associated with transient fever, headache, nausea, and vomiting.

Three lipid formulations of intravenous amphotericin B are commercially available in the United States. These formulations and their usual once-daily doses are amphotericin B lipid complex (ABLC), 5 mg/kg; amphotericin B colloidal dispersion (ABCD), 6 mg/kg; and liposomal amphotericin B (L-AB), 4–5 mg/kg. The most nephrotoxic lipid formulation is ABLC; ABCD causes less azotemia; and L-AB is the least nephrotoxic. Acute, febrile, infusion-related reactions occur with all amphotericin B formulations; their degree of severity is greatest with ABCD and lesser with ABLC and L-AB. The recommended duration for initial infusions of ABCD is 6 h for 6 mg/kg, slower than the 2-h duration of ABLC or L-AB infusions. Infusions of ABCD given more rapidly than 1 mg/kg per hour have caused severe reactions with fever and hypoxia. Use of these remarkably expensive formulations should be restricted to patients who cannot tolerate the nephrotoxicity of the deoxycholate formulation (ABD). Although the lipid formulations are also approved for patients with mycoses failing to respond to ABD, there is no indication that these formulations are more effective than ABD for any mycosis. ABLC and L-AB are probably equivalent in efficacy to ABD for most mycoses. Data on the efficacy of ABCD are largely confined to aspergillosis, in which the efficacy of this lipid formulation was equivalent to that of conventional amphotericin B.

Flucytosine Flucytosine (5-fluorocytosine) is a synthetic oral drug useful in cryptococcosis, candidiasis, and chromoblastomycosis. Within the fungal cell, flucytosine is converted to the antimetabolite 5-fluorouracil. Drug resistance appears rather rapidly when flucytosine is used alone. For this reason, the drug is generally used in combination with amphotericin B. The usual dose of flucytosine is 25 to 37.5 mg/kg every 6 h. Flucytosine is well absorbed from the gastrointestinal tract. The drug penetrates well into the CSF and is excreted unchanged in the urine. Even modest reductions in renal function may elevate flucytosine blood levels into the toxic range ($\geq$100 to 125 μg/mL). Elevated levels are associated with a significant incidence of neutropenia and thrombocytopenia and also seem to predispose to colitis, the other major toxic effect of this drug. Hepatotoxicity is idiosyncratic and uncommon. An allergic rash may develop.

183 HISTOPLASMOSIS

John E. Bennett

ETIOLOGIC AGENT *Histoplasma capsulatum* var. *capsulatum* is a dimorphic fungus that grows as a mold in nature or on Sabouraud's agar at room temperature. Hyphae bear both large and small spores, which are used for identification. Nucleic acid hybridization can also be used to identify the organism in culture. *H. capsulatum* var. *capsulatum* grows as a small budding yeast in host tissue and on enriched agar, such as blood cysteine glucose, at 37°C. Despite its name, the fungus is unencapsulated. Coculture of isolates with opposite mating types can produce different sporulating structures in which genetic recombination occurs. When these structures, referred to as a *teleomorph* or the *perfect state*, are seen in culture, the name *Ajellomyces capsulatus* is used. *H. capsulatum* var. *duboisii* is a rare cause of infection, with most cases originating in Africa. The yeast cells of the *duboisii* variant are larger than those of *H. capsulatum* var. *capsulatum*, but the mold forms of the two appear identical.

EPIDEMIOLOGY Infection with *H. capsulatum* has been encountered in many areas of the world but is much more frequent in certain areas. Within the United States, infection is most common in the southeastern, mid-Atlantic, and central states. Infection has been reported in travelers returning from Latin America and other endemic areas overseas. Endemicity is contingent on the availability of proper conditions in nature for growth of the fungus. *H. capsulatum* prefers moist surface soil, particularly soil enriched by droppings of certain birds and bats. The fungus persists in contaminated soil for years and becomes airborne when the soil is disturbed. Acute infection is usually recognized as case clusters occurring 5 to 18 days after the exposure of groups of people to dust while (for example) cleaning dirt-floored chicken coops; raking or rototilling soil; exploring caves; and cleaning, remodeling, or demolishing old buildings. Skin-test reactivity in many endemic areas indicates that ≥80% of residents over age 16 have been exposed.

PATHOGENESIS AND PATHOLOGY Microconidia, or small spores, of *H. capsulatum* are small enough to reach the alveoli on inhalation and are transformed there to budding forms. With time, an intense granulomatous reaction occurs. Caseation necrosis or calcification may mimic tuberculosis. In children, the primary infection usually heals completely but may leave spotty calcification in the hilar nodes or lung. Transient dissemination may leave calcified granulomas in the spleen. In adults, a rounded mass of scar tissue, with or without central calcification, may remain in the lung. This mass has been called a *histoplasmoma*. Previous exposure is thought to confer some protection against reinfection, but infection in persons with prior positive skin tests clearly has occurred.

In a small proportion of patients, histoplasmosis becomes a progressive, potentially fatal infection. The disease occurs either as chronic fibrocavitary pneumonia or, less commonly, as disseminated infection. Patients with either form lack a history of acute primary pulmonary histoplasmosis. Chronic pulmonary infection favors otherwise-healthy males over the age of 40. A history of cigarette use or the presence of emphysema is elicited from nearly all patients with chronic progressive pulmonary histoplasmosis. An acute, rapidly fatal disseminated infection is most likely to be encountered among young children and immunosuppressed patients, including those with AIDS. Use of tumor necrosis factor α antagonists, particularly infliximab, also appears to predispose to severe disseminated histoplasmosis. A more chronic but equally lethal disseminated infection is more common among previously healthy adults.

CLINICAL MANIFESTATIONS The vast majority of infections are either asymptomatic or mild, and the diagnosis is elusive. Cough, fever, malaise, and chest x-ray findings of hilar adenopathy with or without one or more areas of pneumonitis are typical features. Erythema nodosum and erythema multiforme have been reported in a few outbreaks. Hilar adenopathy may cause temporary compression of the right-middle-lobe bronchus in children and young adults. Subacute pericarditis may develop, probably by extension from contiguous lymph nodes. Rarely, hilar nodes undergo a caseous, granulomatous reaction with perinodal fibrosis. Mediastinal structures become encased by progressive fibrosis, and compression of the pulmonary veins, superior vena cava, pulmonary arteries, and esophagus may take place over many years. Late in mediastinal disease, only rare nonviable *Histoplasma* cells can be found in caseous residua of lymph nodes.

Chronic pulmonary histoplasmosis is characterized by a gradual onset (over weeks or months) of increasing productive cough, weight loss, and sometimes night sweats. Chest x-ray reveals uni- or bilateral fibronodular apical infiltrates. Approximately one-third of cases stabilize or improve spontaneously early in the course. The remainder progress insidiously. Retraction and cavitation of the upper lobes occur, with spread to the apex of the lower lobes and other areas of the lung. Emphysema and bulla formation further compromise pulmonary function. Death from cor pulmonale, bacterial pneumonia, or histoplasmosis occurs after months or years.

Disseminated histoplasmosis has many features in common with hematogenously disseminated tuberculosis (Chap. 150). Common findings include fever, emaciation, hepatosplenomegaly, lymphadenopathy, abnormal liver function, anemia, leukopenia, and thrombocytopenia. Although skin lesions are uncommon in histoplasmosis, patients with far-advanced HIV infection may present with one or more discrete erythematous skin papules. Diffuse pulmonary disease may be mistaken for *Pneumocystis* pneumonia in patients infected with HIV. HIV-infected patients responding to highly active antiretroviral therapy may experience a return of the symptoms of histoplasmosis as a result of immune reconstitution. Previously normal patients usually have a much more indolent disease that progresses over weeks or months. Disease tends to be more focal, with one or more indurated ulcers of the mouth, tongue, nose, or larynx in about one-fourth of cases. Other focal findings include granulomatous hepatitis, Addison's disease, gastrointestinal ulcers, endocarditis, and chronic meningitis. Chest x-ray abnormalities are evident in half of cases and characteristically have a miliary pattern.

Infection with *H. capsulatum* var. *duboisii* is rare but should be considered in previous residents of Africa. Clinical manifestations resemble those of blastomycosis more than those of histoplasmosis in that skin and bone lesions are very common.

Presumed ocular histoplasmosis syndrome (POHS) is a clinical syndrome characterized by discrete atrophic choroidal scars in the macula or midperiphery, peripapillary atrophy, and choroidal neovascularization. These changes lead to a severe loss of central vision. It is unclear whether POHS represents an immune response to prior histoplasmosis, but there is no evidence of active infection. Susceptibility may be correlated with certain HLA types.

DIAGNOSIS Culture of the etiologic organism is the preferred method for diagnosis of histoplasmosis but is often difficult. Blood cultures are best performed by the lysis-centrifugation technique, with plates held at 30°C for at least 2 weeks. Approximately 15 mL of blood should be cultured from adults. Routine blood cultures in broth are generally unsuitable. Cultures of bone marrow, mucosal lesions, liver, and bronchoalveolar lavage fluid are diagnostically useful in disseminated histoplasmosis. Sputum culture is the preferred method for the diagnosis of chronic pulmonary histoplasmosis. However, growth may require 2 to 4 weeks to become visible, and other organisms may overgrow the plate. Diagnosis based on Giemsa-stained smears of blood or bronchoalveolar lavage fluid or on methenamine silver staining of infected lung, bone marrow, lymph node, or mucosal lesions requires considerable expertise, although these techniques yield results rapidly and provide specimens that can easily be sent to a referral laboratory. Organisms may be very scanty in lesions with marked caseous necrosis. An assay for *Histoplasma* antigen in blood or urine is commercially available and is useful both for diagnosis and for monitoring the response to therapy in patients with disseminated infection.

Antigen is detected occasionally in acute pulmonary histoplasmosis but rarely in chronic pulmonary disease. Diagnosis by antigen detection requires confirmation by culture or histopathology because false-positive results have occasionally been obtained. Tests for antibody to *H. capsulatum* have been of limited value in diagnosis. Histoplasmin skin testing has proven useful in epidemiologic studies but is no longer commercially available.

TREATMENT

See also Table 183-1. Acute pulmonary histoplasmosis requires no therapy. Oral itraconazole (200 mg/d) can be given in the hope of shortening the course of illness, although this effect has not been proven. Patients with mediastinal fibrosis may benefit from vascular stent placement, but their ultimate prognosis is poor. All patients with disseminated or chronic pulmonary histoplasmosis should receive antifungal therapy. Intravenous amphotericin B (conventional or lipid formulation) is the drug of choice for the initial treatment of patients with disseminated histoplasmosis who are severely ill or immunosuppressed or whose infection involves the central nervous system; the regimen can be changed to itraconazole (200 mg twice daily) once clinical improvement is evident, and the latter regimen can be used as the initial therapy in less severely ill patients. Fluconazole at doses up to 400 mg/d has been less effective. Patients with AIDS whose disseminated histoplasmosis has responded to 10 weeks of therapy should receive itraconazole (200 mg/d) for life to prevent relapse. Lifelong maintenance therapy may not be necessary for HIV-infected patients who have received prolonged itraconazole treatment, have had a sustained response to highly active antiretroviral therapy, and no longer have detectable *Histoplasma* antigen in serum.

Immunocompetent patients with disseminated or chronic pulmonary histoplasmosis are given itraconazole (200 mg twice daily) and are generally treated for 6 to 12 months. Alternatively, immunocompetent patients can be given a 10-week course of amphotericin B (0.5 mg/kg daily).

Long-term maintenance therapy with an azole is not recommended for patients other than those with AIDS. However, relapse of chronic pulmonary and disseminated histoplasmosis is not rare and warrants careful follow-up for 1 year after therapy.

TABLE 183-1 *Treatment of Histoplasmosis*[a]

Type of Disease	Preferred Treatment	Alternatives
Acute pulmonary	None	. . .
Chronic pulmonary	Itraconazole	Amphotericin B
Disseminated		
Immunocompetent patient, less severe illness	Itraconazole	Amphotericin B
Rapid progression, severe illness, CNS involvement, HIV infection or other immunocompromise	Amphotericin B	Switch to itraconazole after 2 weeks if patient is improved and clinically stable.

[a] Amphotericin B is given as 0.5 mg/kg daily for 10 to 12 weeks. Liposomal amphotericin B (3–5 mg/kg daily) can also be used. Itraconazole is given as 200 mg twice daily for 6 to 12 months except in AIDS patients, in whom therapy is lifelong.

184 COCCIDIOIDOMYCOSIS

John E. Bennett

ETIOLOGIC AGENT *Coccidioides immitis* has two forms, growing as a white fluffy mold on most culture media but as a nonbudding spherical form (a spherule) in host tissue or under special conditions. Solely on the basis of DNA evidence, isolates from outside the San Joaquin Valley of California have been designated *Coccidioides posadasii* by some authorities. *C. immitis* reproduces in host tissue by forming small endospores within mature spherules. After rupture of the spherule, the released endospores enlarge, become spherules, and repeat the cycle. The fungus is identified by its appearance and by the formation of thick-walled, barrel-shaped spores, called *arthrospores*, in the hyphae of the mold form. Nucleic acid hybridization is a highly accurate and relatively safe way to identify this biohazard level 3 fungus.

EPIDEMIOLOGY, PATHOGENESIS, AND PATHOLOGY *C. immitis* is a soil saprophyte found in certain arid regions of the United States, Mexico, Central America, and South America. Within the United States, most cases of infection with *C. immitis* are acquired in California, Arizona, and western Texas (Fig. 184-1). A few cases are acquired by exposure to fomites from endemic areas (e.g., in cotton bales). Use of *C. immitis* by bioterrorists should be kept in mind should large outbreaks occur (Chap. 205).

Infection in humans and animals results from inhalation of windborne arthrospores from soil sites. This primary pulmonary infection is symptomatic in only 40% of cases, with symptoms ranging from a mild influenza-like illness to severe pneumonia. Mild self-limited infections may come to medical attention because of case clusters or hypersensitivity reactions: erythema nodosum, erythema multiforme, toxic erythema, arthralgia, arthritis, conjunctivitis, or episcleritis. Case clusters occur 10 to 14 days after a group of susceptible individuals is exposed to dust in an endemic area through such activities as archaeologic excavation, rock hunting, military maneuvers, model airplane contests, or construction work. Windstorms can carry spores to adjacent nonendemic areas and cause case clusters. The usual course of primary pneumonia is complete healing, although an area of pneumonitis (detected on radiographs) may heal by the formation of a coin-like lesion called a *coccidioidoma*. Less commonly, a single thin-walled cavity remains as a chronic sequela in the area of consolidation. Alternatively, an area of consolidation may persist as chronic pneumonia or progress to fibronodular cavitary disease.

Pleural effusion may be the only manifestation of primary infection. Spontaneous healing of this form is common.

An uncommon but dreaded complication of coccidioidomycosis is dissemination beyond the lung and hilar lymph nodes. Dissemination is especially frequent among blacks, Filipinos, Native Americans, Mexican Americans, pregnant women, and immunosuppressed patients, including those with AIDS.

C. immitis incites a chronic pyogranuloma in host tissue, often with areas of caseation necrosis. Lung and hilar node lesions may show

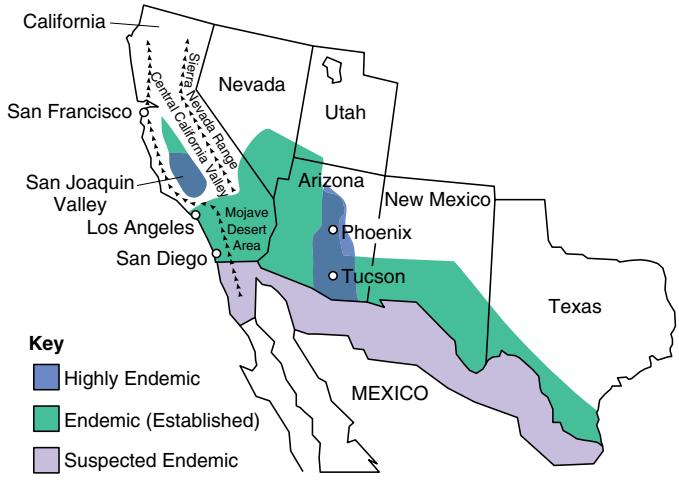

FIGURE 184-1 Geographic distribution of coccidioidomycosis. *(From Emerg Infect Dis 2:192, 1996)*

calcification. Both IgM and IgG antibodies to *C. immitis* are induced by infection, but neither type of antibody appears to be protective. The amount of specific IgG antibody is a rough measure of the antigenic mass (i.e., of the intensity of infection), and a high titer is a poor prognostic sign. Appearance of delayed hypersensitivity to antigens of *C. immitis* is most common in clinical forms of disease with a good prognosis, such as self-limited primary pulmonary disease.

CLINICAL MANIFESTATIONS Symptomatic primary pulmonary infection begins 10 to 14 days after exposure and is manifested by fever, cough, chest pain, malaise, and sometimes the hypersensitivity reactions listed above. Chest radiographs may show an infiltrate, hilar adenopathy, or pleural effusion. Mild peripheral-blood eosinophilia may be found. Spontaneous improvement begins after several days to 2 weeks of illness and usually culminates in complete recovery.

The symptoms of a chronic thin-walled cavity include cough or hemoptysis in half of cases; the other half are asymptomatic. The cavity contracts to a nodule during the first year in about half of cases. Chronic fibrocavitary pulmonary coccidioidomycosis causes cough, sputum production, variable degrees of fever, and weight loss. The first indications of dissemination usually appear during primary infection. Reactivation with dissemination in later years occurs occasionally, especially if Hodgkin's disease, non-Hodgkin's lymphoma, renal transplantation, AIDS, or immunosuppression of some other etiology has supervened. Dissemination should be suspected when fever, malaise, hilar or paratracheal lymphadenopathy, elevated sedimentation rate, and high complement fixation titers signal abnormal persistence in patients with primary pulmonary coccidioidomycosis. With time, lesions appear in the bone, skin, subcutaneous tissue, meninges, joints, and other sites. Chronic meningitis presents as headache of indolent onset, with or without other signs of disseminated coccidioidomycosis. Cultures and smears of cerebrospinal fluid (CSF) are most often negative, but antibody is usually detectable in CSF by complement fixation. Skin lesions are indolent and maculopapular. Soft tissue and bony lesions contain pus and may present as a draining sinus. Without treatment, disseminated coccidioidomycosis progresses to death over weeks to years.

Disseminated coccidioidomycosis can progress rapidly in patients with advanced HIV infection. Fever with skin or bone lesions may be the first sign. Those who present with diffuse pulmonary infiltrates have a poor prognosis. Blood cultures are positive late in the disease, if at all.

DIAGNOSIS When coccidioidomycosis is suspected, sputum, urine, and pus should be examined for *C. immitis* by wet smear and culture. *The laboratory request should indicate clearly that coccidioidomycosis is suspected, because the mold form must be handled with extreme care to prevent infection of laboratory personnel*. On biopsy, smaller spherules must be distinguished from nonbudding forms of *Blastomyces* and *Cryptococcus*, but the appearance of the mature spherule is diagnostic.

Serologic tests are very helpful in the diagnosis of coccidioidomycosis. Latex agglutination and agar gel diffusion tests are useful in screening sera for antibody to *Coccidioides*. The complement fixation test is used for CSF determinations and for the confirmation and quantitation of serum antibody detected by screening tests. The number of cases with a positive complement fixation test depends on the severity of disease and on the laboratory performing the test. Positive tests are least common among patients with solitary pulmonary cavities or primary pulmonary infection, while sera from patients with disseminated disease in multiple organs are nearly all positive. Seroconversion is helpful in diagnosing primary pulmonary coccidioidomycosis but may not occur for up to 8 weeks after onset. A positive complement fixation test of unconcentrated CSF is diagnostic of meningitis. Rarely, a parameningeal focus causes a positive complement fixation testof CSF.

Conversion of the skin test from negative to positive (≥5 mm of induration at 24 or 48 h) with spherulin may take place between days 3 and 21 of symptoms in primary pulmonary coccidioidomycosis. Spherulin is not currently available commercially, but skin testing can be helpful in epidemiologic studies, such as investigations of case clusters or the definition of endemic areas. The utility of skin testing as a diagnostic tool is limited by the persistence of positive tests resulting from remote exposures to *Coccidioides* and by the frequency of negative skin tests among patients with either thin-walled cavities or disseminated coccidioidomycosis. A positive skin test has not predicted dissemination in HIV-infected patients. The presence of complement-fixing antibody to *C. immitis* in AIDS patients should prompt a search for active infection.

TREATMENT

See also Table 184-1. Primary pulmonary coccidioidomycosis usually resolves spontaneously. Some physicians give a few weeks of treatment with intravenous amphotericin B followed by oral itracon-

TABLE 184-1 Treatment of Coccidioidomycosis

Type of Disease	Preferred Treatment	Alternatives
Asymptomatic pulmonary nodule	None	. . .
Solitary pulmonary cavity	None; excision with persistence for >1 year	Itraconazole or fluconazole
Chronic fibrocavitary pneumonia	Itraconazole or fluconazole[a]	Amphotericin B[b]; excision if refractory
Acute pneumonia		
No risk factors[c]	Itraconazole or fluconazole	Observation
Risk factors, severe illness, rapid progression, or diffuse pulmonary infiltrates	Amphotericin B	Switch to itraconazole or fluconazole after 2–3 months if patient's condition improves.
Chronic dissemination (no CNS disease)	Itraconazole or fluconazole[d]	Amphotericin B
Meningitis	Fluconazole[e]	Intrathecal amphotericin B

[a] Itraconazole is given as 200 mg twice daily by mouth and fluconazole as 400 mg/d by mouth.
[b] Amphotericin B is given as 0.5–0.7 mg/kg daily or as a lipid formulation (5 mg/kg daily).
[c] Risk factors include HIV infection, organ transplantation, treatment with high-dose glucocorticoids, and pregnancy.
[d] The optimal duration of therapy for disseminated infection is unclear but should probably be lifelong in both immunocompetent and immunocompromised patients.
[e] Patients in whom fluconazole therapy fails at the 400-mg dose may be advanced to 600 or 800 mg daily. Lifelong therapy for meningitis is recommended.

azole or fluconazole to patients with unusually severe or protracted primary infection in the hope of aborting disseminated or chronic pulmonary disease. Solitary pulmonary cavities that do not close spontaneously over the first year can be excised electively, particularly if complicated by hemoptysis or recurrent bacterial infection. Response to systemic antifungal therapy is poor.

Patients with severe or rapidly progressing disseminated coccidioidomycosis are first given intravenous amphotericin B at a dose of 0.5 to 0.7 mg/kg daily. Patients whose condition improves after 2 to 3 months of amphotericin B treatment or who have more indolent disseminated infection are given itraconazole (200 mg twice daily) or fluconazole (400 mg/d). These oral agents are useful for long-term suppression of infection, and treatment should be continued for years. Patients with coccidioidal meningitis usually are initially given fluconazole (400 to 800 mg/d) but may require intrathecal amphotericin B. Hydrocephalus is a frequent complication of uncontrolled meningitis. Surgical debridement of bone lesions or drainage of abscesses can be helpful. The prognosis for ultimate cure of disseminated coccidioidomycosis is guarded.

Resection of chronic progressive pulmonary lesions is a helpful adjunct to chemotherapy when infection is confined to the lung and to one lobe.

185 BLASTOMYCOSIS

John E. Bennett

ETIOLOGIC AGENT *Blastomyces dermatitidis* is a dimorphic fungus that grows at room temperature as a white or tan mold but grows within the host or at 37°C as budding, round yeastlike cells. The fungus can be identified on the basis of its appearance, its dimorphism, the small spores borne on hyphae of the mold form, or the results of nucleic acid hybridization. When isolates of the two opposite mating types are grown close together on special culture medium, such as yeast extract or soil extract agar, sporulating structures that characterize the perfect state (*teleomorph*), called *Ajellomyces dermatitidis*, appear.

EPIDEMIOLOGY The infection is restricted by geography and age. Blastomycosis is uncommon in any locality, but most cases occur in the southeastern, central, and mid-Atlantic areas of the United States and in the Canadian provinces of Ontario and Manitoba. Mississippi, Kentucky, Arkansas, Tennessee, North Carolina, Wisconsin, and Illinois typically report the most cases. Cases have also been encountered in Africa, Mexico, Central America, and (rarely) South America. Most patients are between 20 and 69 years old. The male-to-female ratio is about 10:1. There is no occupational predisposition to the development of blastomycosis.

PATHOGENESIS AND PATHOLOGY Infection with *B. dermatitidis* appears to be acquired by inhalation of the fungus from soil, decomposed vegetation, or rotting wood. Several case clusters have resulted from participation in recreational activities in wooded areas along waterways. Infection is not transmissible from person to person. The initial pulmonary infection may either heal spontaneously or become chronic. Spread to other portions of the lung, cavitation, or endobronchial lesions may be found in patients with chronic disease. Whether or not the lung lesion resolves spontaneously, infection commonly spreads hematogenously to the skin, subcutaneous tissue, bone, prostate, epididymis, or mucosa of the nose, mouth, or larynx. Less commonly, infection spreads to the brain, meninges, liver, lymph nodes, or spleen. Dissemination may not be evident for weeks or years after the appearance of the lung lesion. Progressive infection is only rarely attributable to an underlying disease, to HIV infection, or to immunosuppressive treatment. The inflammatory response includes lymphocytes, giant cells, and neutrophils. Pseudoepitheliomatous hyperplasia may be striking and may lead to a mistaken diagnosis of squamous cell carcinoma of the skin, lung, or larynx.

CLINICAL MANIFESTATIONS A few patients have acute, self-limited pneumonia. Fever, productive cough, myalgia, and malaise usually resolve within a month. Pulmonary infiltrates clear slowly as *B. dermatitidis* disappears from the sputum.

In the vast majority of patients, blastomycosis has an indolent onset and a chronically progressive course. Fever, cough, weight loss, lassitude, skin lesions, and chest ache are common. Skin lesions favor exposed areas and enlarge over many weeks from pimples to well-circumscribed, verrucous, crusted, or ulcerated lesions. Pain and regional lymphadenopathy are minimal. Large chronic lesions may undergo central healing with scarring and contracture. Mucous membrane and laryngeal lesions present as an indurated, nontender, sharply circumscribed hypertrophic plaque, often mistaken for squamous cell carcinoma. Chest x-ray findings are abnormal in two-thirds of patients, with one or more densely consolidated areas of pneumonia or nodular infiltrates that occasionally include areas of cavitation. Pleural thickening or small pleural effusions develop occasionally, but large pleural effusions are rare, as is calcification of the lung or hilar nodes. Patients may present with an acute respiratory distress syndrome (ARDS), although indolent symptoms usually precede this syndrome. The lungs of ARDS patients are filled with myriad organisms, and the patient often dies within a few days of admission to the hospital. Calcification, hilar adenopathy, and large pleural effusions are rare. Osteolytic lesions occur in one-fourth of patients and may involve nearly any bone. Osseous lesions, which appear radiologically as circumscribed osteolytic areas, present clinically as a cold abscess or a draining sinus or extend to a contiguous joint and cause an indolent arthritis yielding pus on aspiration. Prostatic and epididymal lesions present as an indurated nontender mass. Hydrocele or a draining sinus may accompany blastomycotic epididymitis.

DIAGNOSIS The diagnosis of blastomycosis is made by demonstration of the fungus in a culture of sputum, pus, or urine. An expert can diagnose blastomycosis by the appearance of the organism in wet smear or histopathologic section. The fungus may be visible in a sputum cytology smear but is easily overlooked.

Rx TREATMENT

See also Table 185-1. A few patients have developed only transitory lung lesions, but no guidelines are known to distinguish these patients from those whose disease will progress locally or disseminate. Therefore, every patient should receive treatment. Intravenous amphotericin B is the drug of choice for patients with rapidly progressive infections, severe illness, or central nervous system lesions. Because the clinical

TABLE 185-1 *Treatment of Blastomycosis*

Type of Disease	Preferred Treatment[a]	Alternatives
Rapid progression or severe illness	Amphotericin B for 10–12 weeks	Switch to itraconazole (400 mg/d) when condition stabilizes; continue for 6–12 months.
CNS disease	Amphotericin B for 10–12 weeks	Give fluconazole (800 mg/d) if patient improves and cannot tolerate amphotericin B; continue for 6–12 months.
Indolent infection, mild to moderate illness, no CNS disease	Itraconazole (400 mg/d) for 6–12 months	. . .

[a] See text for dosage of amphotericin B.

response to amphotericin B is more rapid than that to an azole, intravenous itraconazole is less appropriate. However, therapy may be switched to itraconazole when the patient's condition stabilizes. Skin and noncavitary lung lesions should be treated for about 8 to 10 weeks when amphotericin B alone is used. The recommended total dose for an adult is ~2 g. Cavitary lung disease or infection extending beyond the lung and skin is more likely to relapse after 10 weeks of amphotericin B administration at this total dose; thus it should be treated for about 10 to 12 weeks with a total dose of ≥2.5 g, or the patient should be switched to itraconazole for prolonged therapy. Experience with lipid amphotericin B formulations is limited, but they are likely to prove effective.

Oral itraconazole (200 mg twice daily with food) is the drug of choice for the treatment of patients who have indolent nonmeningeal blastomycosis of mild to moderate severity and who take the drug reliably. Therapy with itraconazole is continued for 6 to 12 months, whether given initially or after a short course of amphotericin B. HIV-infected patients should probably receive lifelong therapy, but relevant experience is limited. Fluconazole is less effective than itraconazole; however, because of its good penetration into the central nervous system, treatment with 400 to 800 mg daily may be considered to follow amphotericin B therapy in CNS blastomycosis. The mortality rate in appropriately treated cases of blastomycosis is ≤15% but exceeds 50% in cases presenting as ARDS.

186 CRYPTOCOCCOSIS

John E. Bennett

ETIOLOGIC AGENT Cryptococcosis is an infection caused by the yeastlike fungus *Cryptococcus neoformans*. This fungus reproduces by budding and forms round, yeastlike cells. Within the host and on certain culture media, a large polysaccharide capsule surrounds each yeast cell. The fungus grows well in smooth, creamy-white colonies on Sabouraud's or other simple media at 20° to 37°C. Identification of the organism is based on gross and microscopic appearance, biochemical test results, and growth at 37°C. The results of nucleic acid hybridization or the formation of brown pigment on Niger seed agar can also be used for identification.

The fungus has four capsular serotypes, designated A, B, C, and D. There are also two mating types. Coculture of opposite mating types creates a transient diploid state called *Filobasidiella neoformans* var. *neoformans* for serotypes A and D and *F. neoformans* var. *bacillispora* for serotypes B and C. Organisms not cultured under mating conditions are designated *C. neoformans* var. *neoformans* for serotypes A and D and *C. neoformans* var. *gattii* for serotypes B and C; a simple color medium distinguishes the two varieties. Some authorities have called serotype A *C. neoformans* var. *grubii*.

EPIDEMIOLOGY Weathered pigeon droppings commonly contain serotype A or D (*C. neoformans* var. *neoformans*). *C. neoformans* var. *gattii* has been isolated from the litter around trees of the species *Eucalyptus camaldulensis* and *E. tereticornis*. Eucalyptus isolates have so far typed as serotype B. The distribution of these eucalyptus species in Australia corresponds to the distribution of infections due to *C. neoformans* var. *gattii* in that country. The high prevalence of these trees in other subtropical climates has been postulated to explain the relative restriction of such infections to warm climates. A notable exception is the cluster of clinical cases and environmental isolates *not* from eucalyptus trees on the eastern coast of Vancouver Island in British Columbia, Canada.

The most common predisposing factor to cryptococcosis worldwide is currently AIDS. CD4+ cell counts are usually below 200/μL in AIDS patients who develop cryptococcal infection. The incidence of cryptococcosis has been declining in the United States since the advent of highly active antiretroviral therapy (HAART). More than half of non-AIDS patients with cryptococcosis have been receiving glucocorticoids or other immunosuppressive drugs prior to the onset of the fungal infection. Solid organ transplantation, lymphoma, sarcoidosis, and idiopathic CD4+ lymphocytopenia also predispose to infection by *C. neoformans* var. *neoformans*. Most infections in immunocompromised patients are caused by serotype A, although serotype D occurs in up to 20% of cases in Western Europe. Infections with var. *gattii* have been rare among AIDS patients and other immunocompromised patients, even in subtropical climates where var. *gattii* infection occurs in previously healthy individuals.

Animals, particularly cats, can acquire cryptococcosis but have not been known to transmit the infection to other animals or to humans. The source from which humans acquire the infection is unknown, with the rare exception of cases acquired through a transplanted cornea, kidney, or other solid organ. Cryptococcosis is rare before puberty.

PATHOGENESIS AND PATHOLOGY Cryptococcal infection is thought to be acquired by inhalation of the fungus into the lungs, although rare cases of cutaneous cryptococcosis appear to arise by minor trauma. Pulmonary infection has a tendency toward spontaneous resolution and is frequently asymptomatic. Silent hematogenous spread to the brain leads to clusters of cryptococci in the perivascular areas of cortical gray matter, in the basal ganglia, and, to a lesser extent, in other areas of the central nervous system. The inflammatory response around these foci is usually scant. In the more chronic cases, a dense basilar arachnoiditis is typical. Lung lesions are characterized by intense granulomatous inflammation. Cryptococci are best seen in tissue by staining

with methenamine silver or periodic acid–Schiff. Although a strongly positive result on mucicarmine staining of tissue is diagnostic, staining varies from intense to absent.

CLINICAL MANIFESTATIONS Most patients have *meningoencephalitis* at the time of diagnosis. This form of cryptococcosis is invariably fatal without appropriate therapy; death occurs anytime from 2 weeks to several years after the onset of symptoms. Early manifestations include headache, nausea, staggering gait, dementia, irritability, confusion, and blurred vision. Both fever and nuchal rigidity are often mild or lacking. Papilledema is evident in one-third of cases at the time of diagnosis. Rapid and permanent loss of vision may occur, leaving a central scotoma or optic atrophy. Cranial nerve palsies, typically asymmetric, occur in about one-fourth of cases. Other lateralized signs are rare. With progression of the infection, deepening coma and signs of brainstem compression appear. Autopsy often reveals cerebral edema in more acute cases and hydrocephalus in more chronic cases. Neuroimaging is most often normal. Focal lesions called *cryptococcomas* are more common in previously normal patients, particularly those with var. *gattii* infections, than in immunosuppressed patients. These lesions are commonly located in the basal ganglia or the head of the caudate nucleus. Cryptococcomas are best seen on magnetic resonance imaging (MRI) with T2 or FLARE imaging and gadolinium enhancement. Edema around the mass disappears with successful therapy, but the cryptococcoma can persist for years.

Pulmonary cryptococcosis causes chest pain in ~40% of patients and cough in ~20%. Fever is modest or absent. The chest x-ray shows one or more dense infiltrates, which are often well circumscribed. Cavitation, pleural effusions, and hilar adenopathy are infrequent. Calcification is not evident, and fibrotic stranding is rarely noticeable.

Some 10% of patients with cryptococcosis have skin lesions, and the vast majority of patients with skin lesions have disseminated infection (Fig. 186-1). One or a few asymptomatic tiny papular lesions appear and slowly enlarge; they display a tendency toward central softening leading to ulceration. Osteolytic lesions occur in 4% of cases and usually present as a cold abscess. Rare manifestations of cryptococcosis include prostatitis, endophthalmitis, hepatitis, pericarditis, endocarditis, and renal abscess.

Cryptococcosis in AIDS patients is notable for the relative paucity of symptoms and signs, even in severe disease. Headache is present in ~90% of cases and fever in ~75%. Blurred vision, cranial nerve palsies, lethargy, and confusion signal advanced infection. Cerebrospinal fluid (CSF) abnormalities in protein and glucose levels and in cell count are modest (see "Diagnosis"). A CSF leukocyte count of $<10/\mu L$ and an opening pressure of >250 mm are bad prognostic signs. Immune reconstitution during a response to HAART can lead to a return of fever and headache, suppuration of mediastinal lymph nodes, or meningeal enhancement on MRI.

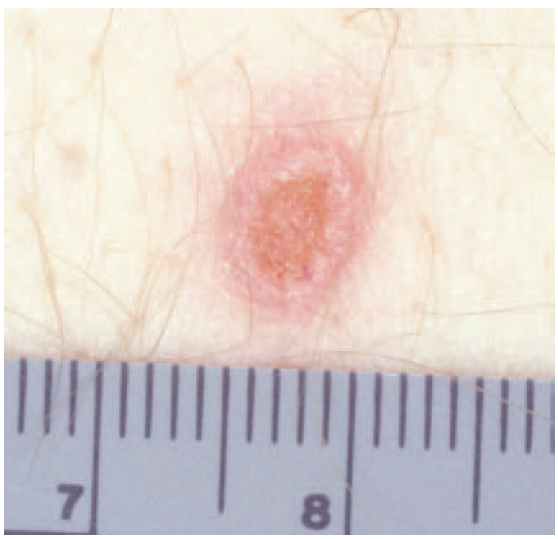

FIGURE 186-1 Disseminated fungal infection. A liver transplant recipient developed six cutaneous lesions similar to the one shown. Biopsy and serum antigen testing demonstrated *Cryptococcus*. Important features of the lesion include a benign-appearing fleshy papule with central umbilication resembling molluscum contagiosum. (*Photo courtesy of Dr. Lindsey Baden.*)

DIAGNOSIS Fever and headache in a patient with AIDS or with risk factors for HIV infection suggest the possibility of cryptococcosis, toxoplasmosis, or central nervous system lymphoma. Evidence of a focal lesion on MRI is unusual in cryptococcosis. Most cryptococcal cerebral mass lesions occur in patients infected with *C. neoformans* var. *gattii* who also have meningitis. In patients without AIDS, meningitis due to *C. neoformans* resembles that due to *Mycobacterium tuberculosis*, *Histoplasma capsulatum*, *Coccidioides immitis*, or metastatic cancer. Lumbar puncture is the single most useful diagnostic test. An india ink smear of centrifuged CSF sediment reveals encapsulated yeast in more than half of cases, although artifacts can cause confusion. In patients without AIDS, levels of glucose in CSF are reduced in half of all cases; protein levels are usually increased; and lymphocytic pleocytosis is usually found. CSF abnormalities are less pronounced in patients with AIDS, although india ink smear and serum antigen tests are more often positive.

Approximately 90% of patients with cryptococcal meningoencephalitis, including all those with a positive CSF smear and nearly all AIDS patients, have capsular antigen detectable in CSF or serum by latex agglutination. An enzyme immunoassay for cryptococcal antigen does not offer useful quantitative results but more clearly establishes positivity. Occasional false-positive results in both antigen tests make culture the definitive diagnostic test and have prevented serum antigen from being a useful screening test in asymptomatic patients with AIDS. Testing for serum antigen in AIDS patients with headache or fever is helpful. *C. neoformans* can often be cultured from the urine of patients with meningoencephalitis. Fungemia occurs in 10 to 30% of non-AIDS patients and in 60% of AIDS patients.

Pulmonary cryptococcosis appears on computed tomography (CT) as nodules with smooth or relatively undefined margins and homogeneous attenuation. In rare instances, ground-glass opacification is seen. Sputum culture is positive in only 10% of cases, and serum antigen tests are positive in only one-third. Occasionally, *C. neoformans* appears in one or more sputum specimens as an endobronchial saprophyte. Biopsy is usually required for diagnosis.

Cutaneous cryptococcosis may be mistaken for a comedo, basal cell carcinoma, or sarcoidosis. In patients with AIDS, skin lesions may be numerous and are sometimes mistaken for molluscum contagiosum (as shown for a liver transplant recipient in Fig. 186-1). Biopsy reveals myriad cryptococci. Osseous cryptococcosis is diagnosed by examination of bone or an adjacent soft tissue abscess.

Rx TREATMENT

See also Table 186-1. Patients with AIDS and cryptococcosis are treated initially with intravenous amphotericin B (0.7 to 1.0 mg/kg daily) for at least 2 weeks and until their clinical condition is stable; thereafter, they receive fluconazole. The addition of flucytosine (25 mg/kg every 6 h) to amphotericin B for 2 weeks has minimal impact on morbidity and mortality. After treatment with amphotericin B, fluconazole (400 mg) is given once daily; daily doses of 800 mg have been used with marginal changes in toxicity or efficacy. The addition of flucytosine to fluconazole increases gastrointestinal intolerance. Serum and CSF antigen have not been helpful in determining the efficacy of therapy, but CSF cultures should convert to negative. After at least 10 weeks of treatment and when the patient is asymptomatic, treatment with fluconazole (200 mg/d) is continued indefinitely. Itraconazole is less effective than fluconazole in cryptococcal meningitis but can be used. Patients with incapacitating symptoms of immune reconstitution improve with glucocorticoid therapy; it is unclear whether amphotericin B should be restarted until the glucocorticoid dose has been ta-

pered. AIDS patients who have negative antigen and fungal cultures of CSF after prolonged fluconazole treatment and who have a sustained (≥6-month) CD4+ response to HAART (with counts of at least 100 to 200/μL) may be candidates for discontinuation of maintenance therapy. Should CD4+ cell counts fall again, resumption of maintenance therapy would be reasonable.

TABLE 186-1 *Treatment of Cryptococcosis*

Type of Disease	Preferred Treatment	Alternatives
Disease in AIDS patient	Amphotericin B (0.7–1.0 mg/kg daily) or liposomal amphotericin B (4–5 mg/kg daily) for 2 weeks and until symptoms improve; then fluconazole (400 mg/d) for 8 weeks; then fluconazole (200 mg/d) for life	Itraconazole (400 mg/d) for 8 weeks after amphotericin B; then 200 mg/d maintenance
Disease in non-AIDS patient		
Meningitis	Amphotericin B (0.6–0.7 mg/kg daily) or liposomal amphotericin B (4–5 mg/kg daily) for 10 weeks[a]	Switch to fluconazole (400 mg/d) when patient's condition has improved; continue for 6–12 months
Pulmonary disease	Treat immunosuppressed patients as for meningitis; previously normal patients may respond to fluconazole (400 mg/d) for 6–12 months.	Itraconazole (400 mg/d) for previously normal patients

[a] CSF culture should be negative, antigen titer falling, and glucose level normal.

In patients without AIDS, the therapeutic goal is to cure cryptococcal meningitis, not merely to control its symptoms. A single intensive course of amphotericin B is given for at least 10 weeks until cultures from all previously positive sites (particularly CSF) become convincingly negative. Normalization of the glucose level in lumbar CSF is important. The CSF antigen titer should fall by the end of therapy, but complete clearance of CSF or serum antigen during therapy is not essential. Amphotericin B (0.6 to 0.7 mg/kg daily for 10 weeks) is the best-studied regimen, but liposomal amphotericin B (4 to 5 mg/kg daily) is probably equivalent. Amphotericin B lipid complex and amphotericin B colloidal dispersion are not recommended pending further study. Flucytosine has been added to amphotericin B to accelerate the culture response, but grave toxicity can result unless flucytosine blood levels are kept below 100 μg/mL. Fluconazole (400 mg daily), given initially or begun after a course of amphotericin B, has cured cryptococcal meningitis or pulmonary cryptococcosis in some less immunosuppressed patients. Useful parameters for deciding when to discontinue therapy are unknown, but culture conversion, normalization of CSF glucose levels, and a fall in CSF antigen titer are minimal end points. A 6- to 12-month course of treatment is often used. Routine follow-up CSF cultures for the next year are useful in detecting relapse before symptoms supervene. Lung lesions on CT may take 6 weeks to improve and many months to resolve, if they ever do. Some immunosuppressed patients are treated as described above for AIDS patients, with indefinite fluconazole maintenance therapy.

Hydrocephalus may be the presenting manifestation or a later complication of cryptococcosis. Blindness, dementia, and personality change are among the other sequelae. Cerebral edema (in the absence of a cryptococcoma) causing headache, confusion, or blurred vision should be treated by daily lumbar puncture or CSF shunting to avert blindness. The shunt does not act as a nidus of persistent infection.

PROPHYLAXIS Fluconazole (200 mg/d) has been shown to decrease the incidence of cryptococcosis in HIV-infected patients with CD4+ cell counts of <200/μL and particularly in those with counts of <50/μL. Weekly fluconazole has not provided this protection. Daily fluconazole has not conferred a survival advantage; in light of its cost and the currently low incidence of cryptococcosis in patients with AIDS in the United States, prophylaxis is strongly discouraged.

187 CANDIDIASIS

John E. Bennett

ETIOLOGIC AGENTS *Candida albicans* is the most common cause of mucosal candidiasis and is responsible for about half of all cases of candidemia in hospitalized patients. A small proportion of isolates previously identified as *C. albicans* have been transferred to a new species, *C. dubliniensis*. *C. tropicalis*, *C. parapsilosis*, *C. guilliermondii*, *C. glabrata* (formerly *Torulopsis glabrata*), *C. krusei*, and a few other *Candida* species account for the other half of candidemia cases; all can cause potentially lethal septic shock. The majority of these non-*albicans* species enter the bloodstream through intravascular catheters. *Candida* species, taken together, are the fourth or fifth most common cause of nosocomial bloodstream infections in the United States.

All *Candida* species pathogenic for humans are also encountered as commensals of humans, particularly in the mouth, stool, and vagina. These species grow rapidly at 25° to 37°C on simple media as oval, budding cells. In tissue, both yeasts and pseudohyphae are present. The latter are elongated branching structures with constrictions at the septae. Budding yeasts may be seen as separate structures or as projections from pseudohyphae. *C. glabrata* differs from other members of the genus in that it forms no true hyphae or pseudohyphae in vitro or in infected tissue. *C. albicans* and *C. dubliniensis* can be identified preliminarily by their ability to form germ tubes in serum—a test that requires only a few hours. These two species can be more accurately identified by the formation in special culture medium of thick-walled large spores called *chlamydospores*. Culture media now available for primary inoculation allow preliminary identification of *Candida* species by colony color. Accurate identification of *Candida* species other than *C. albicans* requires biochemical tests.

PATHOGENESIS Deeply invasive candidiasis is often preceded by increased colonization of the mouth, vagina, and stool with *Candida* due to broad-spectrum antibiotic therapy. Additional local and systemic factors favor infection. Oropharyngeal thrush is particularly likely to occur in neonates and in patients with diabetes mellitus, HIV infection, or dentures. Vulvovaginal candidiasis (Chap. 115) is especially common in the third trimester of pregnancy. *Candida* from the perineum can enter the urinary tract via an indwelling bladder catheter. Cuta-

neous candidiasis most often involves macerated skin, such as that in the diapered area of infants, under pendulous breasts, or on hands constantly in water or covered by occlusive gloves. *Candida* can pass from the colonized surface into deep tissue when the integrity of the mucosa or skin is violated, as, for example, by perforation of the gastrointestinal tract through trauma, surgery, or peptic ulceration or by mucosal damage due to cytotoxic agents used for cancer chemotherapy. Although *Candida* is not normally a resident of the skin, secretions from the mouth, rectum, or vagina as well as drainage from surgical wounds or tracheostomy sites can contaminate the hub or skin site of a catheter in an umbilical or central vein. Intravenous drug abuse or third-degree burns can also provide a skin portal for *Candida* that can lead to deep candidiasis. Once *Candida* has passed the integumentary barrier, very low birth weight (in neonates) and neutropenia or glucocorticoid therapy (in any patient) markedly compromise host defense. Hematogenous seeding is particularly evident in the retina, kidney, spleen, and liver.

CLINICAL MANIFESTATIONS ■ Mucocutaneous Candidiasis *Oral thrush* presents as discrete and confluent adherent white plaques on the oral and pharyngeal mucosa, particularly in the mouth and on the tongue. These lesions are usually painless, but fissuring at the corners of the mouth can be painful. Unexplained oropharyngeal thrush raises the possibility of HIV infection. Oral thrush is common in acute HIV infection and becomes increasingly common late in disease as the CD4+ cell count falls. At CD4+ counts of $<50/\mu L$, esophageal thrush also becomes common. HIV infection appears not to be an independent risk factor for vulvovaginal thrush.

Cutaneous candidiasis presents as red macerated intertriginous areas, paronychia, balanitis, or pruritus ani. Candidiasis of the perineal and scrotal skin may be accompanied by discrete pustular lesions on the inner aspects of the thighs. *Chronic mucocutaneous candidiasis* (*CMC*) or *candidal granuloma* typically presents as circumscribed hyperkeratotic skin lesions, crumbling dystrophic nails, partial alopecia in areas of scalp lesions, and both oral and vaginal thrush. Other findings may include chronic ringworm, dental dysplasia, and hypofunction of the parathyroid, adrenal, or thyroid gland. CMC is a major component of the immune polyendocrinopathy syndrome caused by a mutation in the autoimmune regulator gene (*AIRE*) on chromosome 21q22,3 (Chap. 330). CMC can begin in childhood as an autosomal dominant or recessive disorder or in association with Job's syndrome and can occur in adults in association with thymoma. Systemic infection is very rare in CMC, but permanent alopecia and disfigurement of the face and hands can be severe. Vulvovaginal thrush (Chap. 115) causes pruritus, discharge, and sometimes pain on intercourse or urination. Speculum examination reveals an inflamed mucosa and a thin exudate, often with white curds. Excessive colonization of the gastrointestinal tract has been associated with diarrhea and with chronic fatigue syndrome, but the linkage is unconvincing.

Esophageal candidiasis is often asymptomatic but can cause substernal pain or a sense of obstruction on swallowing. The pain of esophageal candidiasis may be mistaken for pain of cardiac origin. Most lesions are in the distal third of the esophagus and appear on endoscopy as areas of redness and edema, focal white patches, or ulcers. Biopsy or brushing is required for diagnosis and for detection of concomitant infections, particularly herpes simplex in patients with hematologic malignancies and cytomegalovirus infection in AIDS patients. *Candida* esophagitis can cause bleeding and impaired alimentation. Hematogenous dissemination from the esophagus probably occurs in some neutropenic patients but is rarely reported in HIV-infected patients.

Deeply Invasive Candidiasis In the obstructed *urinary tract*, *Candida* can cause cystitis, pyelitis, or renal papillary necrosis. When a colonized urinary tract is operated on or instrumented, candidemia may result. However, most patients with *Candida* cultured from the urine simply have bladder colonization from a Foley catheter or a sizable volume of residual urine. Contamination of a voided midstream specimen by vaginal *Candida* is also common.

Candidemia originating from an intravascular catheter may clear in the immunocompetent patient when the catheter is removed. Focal seeding of the retina can take place even if candidemia clears and the patient becomes afebrile. Unilateral or bilateral small white retinal exudates appear within 2 weeks of the onset of candidemia. Lesions may regress spontaneously or enlarge slowly. The vitreous humor becomes cloudy, and the patient notices blurring, ocular pain, or a scotoma. Retinal detachment, vitreous abscess, and extension to the anterior chamber can occur over the ensuing weeks. These retinal lesions, present in ~10% of nonneutropenic patients with candidemia, are the principal reason that systemic antifungal therapy is recommended for all patients with candidemia. Funduscopy should be performed to ensure that retinal lesions, if present, resolve completely. Most cases with ocular involvement have occurred in nonneutropenic patients. In contrast, so-called *hepatosplenic candidiasis* is usually recognized in patients with acute leukemia who are recovering from profound neutropenia. This entity, better called *chronic disseminated candidiasis*, originates from intestinal seeding of the portal and venous circulation. Fever, modestly elevated serum concentrations of alkaline phosphatase, and multiple small abscesses evident on ultrasonography, magnetic resonance imaging, or computed tomography (CT) of the liver, spleen, or kidney suggest the diagnosis. During acute candidemia in neutropenic patients, small erythematous papules may appear anywhere on the skin (Fig. 187-1). If the patient does not expire promptly from disseminated candidiasis, the lesions will develop a necrotic center. Painful muscle lesions may also be found. Punch biopsy of a skin lesion helps distinguish this extremely grave condition from *Malassezia* folliculitis, a similar-appearing but benign condition that can involve the cape area of the chest or the extremities of a sweaty febrile patient.

Hematogenous seeding in the neutropenic patient is occasionally visible radiologically as tiny pulmonary nodules. *Candida pneumonia*, apart from hematogenous candidiasis, is very rare. *Candida endocarditis* can be caused by any *Candida* species and favors previously damaged or prosthetic heart valves. The source is often an intravascular catheter or contaminated equipment used for illicit intravenous drug injection. An interval of weeks or even months between candidemia and discovery of endocarditis is common. Emboli to large arteries, such as the iliac or femoral artery, are characteristic. Intravenous injection of impure brown heroin has caused a clinical syndrome consisting of *Candida endophthalmitis* and purulent *folliculitis*, sometimes accompanied by vertebral *osteomyelitis*.

Candida can cause indolent *arthritis*, most commonly of the knee, in patients who have received glucocorticoid injections into the joint, in patients who are immunosuppressed, and in low-birth-weight neonates. Prosthetic joints may become infected during implantation. Scanty growth of *Candida* from joint fluid can cause the laboratory to

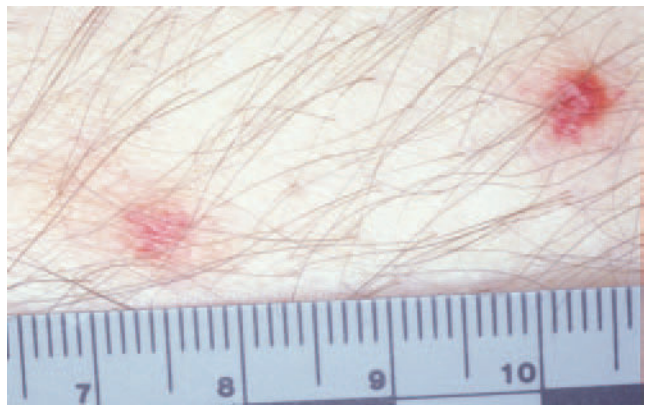

FIGURE 187-1 Disseminated candidiasis. Tender, erythematous, nodular lesions developed in a neutropenic patient with leukemia who was undergoing induction chemotherapy. (Photo courtesy of *Dr. Lindsey Baden.*)

incorrectly dismiss the organism as a contaminant. *Candida* can cause subacute *peritonitis* arising either from a perforated viscus or from a peritoneal dialysis catheter.

Hematogenous dissemination can lead to *brain abscess* or chronic *meningitis*. Diagnosis of infections of ventriculoperitoneal shunts is difficult because symptoms are indolent and cultures of lumbar fluid are usually sterile.

DIAGNOSIS Demonstration of pseudohyphae on wet smear with confirmation by culture is the procedure of choice for diagnosing superficial candidiasis. Scrapings for the smear may be obtained from skin, nails, and oral and vaginal mucosa. A culture of urine, sputum, existing abdominal drains, endotracheal aspirates, or the vagina is not diagnostic; however, recovery of *Candida* species from multiple superficial sites has been identified as a risk factor for deeply invasive candidiasis in some studies of patients with prolonged neutropenia or complicated abdominal surgery.

Deeper lesions due to *Candida* may be diagnosed by histologic section of biopsies or by culture of cerebrospinal fluid, blood, joint fluid, CT-guided needle aspirates, or surgical specimens. Blood cultures are useful in the diagnosis of *Candida* endocarditis and intravenous catheter–induced sepsis but are positive less often in other forms of disseminated disease. Serologic tests for antibody or antigen are not useful.

TABLE 187-1 *Treatment of Candidiasis*

Type of Disease	*Preferred Treatment*[a]	*Alternatives*
Mucocutaneous		
Cutaneous	Topical azole	Topical nystatin
Vulvovaginal	Azole cream or suppository or oral fluconazole (150 mg)	Nystatin suppository
Oropharyngeal	Clotrimazole troche or fluconazole tablet (100 mg/d) or itraconazole solution (200 mg/d)	Nystatin suspension; for azole-unresponsive disease: caspofungin (50 mg/d) or amphotericin B (0.3–0.5 mg/kg daily)
Esophageal	Fluconazole tablet (100–200 mg/d) or itraconazole solution (200 mg/d)	For azole-unresponsive disease: caspofungin (70 mg once, then 50 mg/d) or amphotericin B (0.3–0.5 mg/kg daily)
Deeply invasive		
Nonneutropenic	Fluconazole (400 mg/d) or amphotericin B[b] or caspofungin (70 mg once, then 50 mg/d)	
Neutropenic	Amphotericin B[b]	

[a] Removal of foreign bodies is critical, including plastic catheters for intravenous fluids, peritoneal dialysis or cerebrospinal fluid shunts, prosthetic cardiac valves, and prosthetic joints.
[b] The dosage of amphotericin B for deeply invasive candidiasis is 0.5 mg/kg daily, although initial doses of 0.7–1.0 mg/kg daily may be appropriate for severely immunosuppressed patients. Amphotericin B lipid complex and liposomal amphotericin B are given as 5 mg/kg daily.

TREATMENT

(See also Table 187-1.) Cutaneous candidiasis of macerated areas responds to measures that reduce moisture and chafing plus topical application of an antifungal agent in a nonocclusive base. Nystatin powder or a cream containing ciclopirox or an azole is useful. Clotrimazole, miconazole, econazole, ketoconazole, sulconazole, and oxiconazole are available as creams or lotions. *Candida* vulvovaginitis responds better to an azole than to nystatin suppositories. There is little difference in efficacy among miconazole, clotrimazole, tioconazole, butoconazole, and terconazole vaginal formulations. Systemic treatment of *Candida* vulvovaginitis with a single 150-mg capsule of fluconazole is more convenient than topical treatment; however, this option is contraindicated in pregnancy, is less effective in patients with multiple relapses, and poses a higher risk of adverse effects. Clotrimazole troches, used five times a day, are more effective in oral candidiasis than nystatin suspension and are approximately as effective as oral fluconazole (100 mg daily). Oral fluconazole (100 to 200 mg once daily) is more convenient and more effective in esophagitis than clotrimazole troches. Esophagitis not responding to fluconazole may warrant repeat endoscopy to exclude other conditions. Itraconazole suspension (100 mg twice daily) alleviates *Candida* esophagitis in some patients in whom fluconazole treatment fails. Nearly all patients with azole-resistant oropharyngeal or esophageal candidiasis respond to a 2-week course of intravenous amphotericin B (0.3 to 0.5 mg/kg daily) or caspofungin (70 mg for one dose, then 50 mg daily). Relapse is usual.

Management of recurrent oropharyngeal candidiasis in the HIV-infected patient presents special problems. Patients with CD4+ cell counts of $<100/\mu L$ who have received prolonged fluconazole therapy are at risk of developing azole resistance, requiring an increased dose to mount a response, relapsing early, and eventually failing to respond well to any dose of fluconazole. The increasing azole resistance in this population suggests that HIV-infected patients with oropharyngeal or esophageal candidiasis should be treated for each individual episode and that only when episodes become intolerably frequent or severe should prophylaxis be given.

Bladder thrush responds to bladder irrigations with amphotericin B (50 μg/mL for 5 days). If no bladder catheter is in place, oral fluconazole can be used to control candiduria. Most patients with candiduria do not have unrelieved urinary tract obstruction and do not benefit from therapy.

Intravenous amphotericin B is the drug of choice for deeply invasive candidiasis in neutropenic or seriously immunosuppressed patients. The deoxycholate formulation is usually given at a dosage of 0.5 to 0.7 mg/kg daily. Open, noncomparative studies of amphotericin B lipid complex and liposomal amphotericin B indicate that either preparation is effective in deeply invasive candidiasis. The usual dose of either formulation is 5 mg/kg daily by the intravenous route.

Candida endocarditis on prosthetic or native valves usually relapses unless the valve is replaced. Long-term fluconazole administration has been used to prevent recurrence after valve replacement.

In immunocompetent patients with intravenous catheter–acquired *C. albicans* fungemia, the catheter should be removed in conjunction with the administration of fluconazole (400 mg/d), amphotericin B (0.5 mg/kg daily), or caspofungin (one 70-mg dose followed by 50 mg daily by the intravenous route). Amphotericin B (0.7 to 1.0 mg/kg daily) may be appropriate as initial therapy in severely neutropenic patients. Candidemia from suppurative phlebitis of a peripheral vein may not respond until the infected portion of the vein is excised. Therapy for candidemia is continued for 2 weeks after the patient becomes afebrile. The *Candida* species involved should be considered in choosing a drug for candidemia. *C. krusei* and *C. inconspicua* are rare causes of candidemia but are resistant to fluconazole in vitro. *C. glabrata* exhibits intermediate susceptibility to fluconazole. Thus either increasing the daily fluconazole dose to 800 mg or using amphotericin B or caspofungin may be appropriate. Caspofungin displays approximately equal activity in vitro against all *Candida* species, including azole-resistant strains. Strains of *C. lusitaniae* resistant to amphotericin B but susceptible to azoles or caspofungin have been encountered. Intravenous amphotericin B, with or without flucytosine, is the preferred treatment for *Candida* endophthalmitis, although cures have been reported with fluconazole. Pars plana vitrectomy may facilitate diagnosis and cure when a *Candida* vitreous abscess is present. Injection of amphotericin B into the vitreous humor can also be helpful.

Because amphotericin B and fluconazole penetrate reasonably well into an infected joint, the pleural cavity, and the peritoneum, local injection is not indicated. Removal of prostheses (including prosthetic joints and cardiac valves), peritoneal dialysis catheters, and central venous catheters is usually essential. Debridement, along with anti-

fungal therapy, is beneficial in *Candida* osteomyelitis. All collections of pus, such as those in the postoperative abdomen, need to be drained surgically or by percutaneous, CT-guided catheterization; an exception relates to the numerous small abscesses in liver, spleen, or kidney in chronic disseminated candidiasis, which cannot be drained effectively and require prolonged antifungal therapy. In general, treatment should continue until the patient with chronic disseminated candidiasis has been afebrile and nonneutropenic for at least 2 weeks. Defects may persist on imaging studies long after cure. Relapse during another episode of neutropenia is common unless the patient is receiving amphotericin B. Repeat cytotoxic therapy or even bone marrow transplantation can be undertaken in patients with prior chronic disseminated candidiasis, but amphotericin B should be given empirically during neutropenia.

PROPHYLAXIS Fluconazole can decrease the incidence of deeply invasive candidiasis in recipients of allogeneic bone marrow transplants when 400 mg is given daily. Some centers continue such prophylaxis for 70 days; others discontinue it after engraftment. Studies of leukemic and other neutropenic patients have found no significant reduction in the incidence of deeply invasive candidiasis associated with prophylactic use of fluconazole or itraconazole oral suspension, although this topic remains controversial. Prophylaxis against recurrent oropharyngeal or esophageal candidiasis in HIV-infected patients is no longer recommended unless recurrences are very frequent or severe. Fluconazole (3 to 6 mg/kg) or itraconazole solution (5 mg/kg) is the recommended daily oral dose. Fluconazole prophylaxis at 400 mg daily may be useful in preventing deeply invasive candidiasis in some high-risk postoperative patients. Definition of groups at sufficient risk to benefit from fluconazole depends on the intensive care unit but likely includes patients undergoing repeat, complicated abdominal surgery and patients who are both heavily colonized with *Candida* and immunosuppressed at the time of complicated surgery. The presence of intravenous catheters, prolonged stays in the intensive care unit, and renal failure increase the risk of candidemia.

188 ASPERGILLOSIS

John E. Bennett

ETIOLOGIC AGENTS *Aspergillus fumigatus* is the most common cause of aspergillosis, but *A. flavus*, *A. niger*, *A. nidulans*, *A. terreus*, and several other species can also cause disease. *Aspergillus* is a mold with septate branching hyphae ~2 to 4 μm in diameter. The fungus is identified by its gross and microscopic appearance in culture.

PATHOGENESIS AND PATHOLOGY All the common species of *Aspergillus* that cause disease in humans are ubiquitous in the environment, growing on dead leaves, stored grain, compost piles, hay, and other decaying vegetation. The fungus can also be isolated from potable water, although the clinical significance of this observation is unknown. Inhalation of *Aspergillus* spores must be extremely common, but disease is rare. Invasion of lung tissue is confined almost entirely to immunosuppressed patients, in roughly 90% of whom two of the following three conditions will be operative: a granulocyte count in peripheral blood of $<500/\mu$L, treatment with supraphysiologic doses of adrenal glucocorticoids, and a history of treatment with other immunosuppressive drugs such as cyclosporine. Invasive aspergillosis is an occasional complication of AIDS. *Aspergillus* infection in the neutropenic patient is characterized by hyphal invasion of blood vessels, thrombosis, necrosis, and hemorrhagic infarction. Chronic granulomatous disease of childhood also predisposes to invasive pulmonary aspergillosis, but in that situation the inflammatory response is a pyogranuloma and blood vessel invasion is rare.

Massive inhalation of *Aspergillus* spores by healthy persons can lead to acute, diffuse, self-limited pneumonitis. Epithelioid granulomas with giant cells and central pyogenic areas containing hyphae are detected in these cases. Spontaneous recovery taking several weeks is the usual course. Such patients should be tested for underlying chronic granulomatous disease.

Aspergillus can colonize the damaged bronchial tree, pulmonary cysts, or cavities of patients with underlying lung disease. Balls of hyphae within cysts or cavities (aspergillomas), usually in the upper lobe, may reach several centimeters in diameter and may be visible on chest x-ray. Tissue invasion does not occur.

CLINICAL MANIFESTATIONS *Allergic bronchopulmonary aspergillosis* occurs in patients with preexisting asthma (particularly glucocorticoid-dependent asthma) or cystic fibrosis and causes intermittent episodes of wheezing, pulmonary infiltrates from transient bronchial plugging, sputum and blood eosinophilia, low-grade fever, and brownish or greenish flecks in the sputum. These flecks contain *Aspergillus* hyphae, thick mucus, eosinophils, and Charcot-Leyden crystals. Some patients with repeated exacerbations develop central bronchiectasis and progressive loss of pulmonary function.

Endobronchial saprophytic pulmonary aspergillosis presents as chronic productive cough, often with hemoptysis, in a patient with prior chronic lung disease, such as tuberculosis, sarcoidosis, bronchiectasis, or histoplasmosis. *Aspergillus* may be spread from its endocavitary or endobronchial site to the pleura during the course of bacterial lung abscess or surgery. Patients reported to have chronic necrotizing *Aspergillus* pneumonia appear in most instances to have had saprophytic endobronchial colonization and a pulmonary process attributable to another disease, with or without superimposed bacterial infections. Patients with chronic pneumonia and *Aspergillus* in the sputum should be assumed to have either pneumonia of a different etiology (e.g., histoplasmosis) or *Aspergillus* pneumonia with underlying immunosuppression (e.g., chronic granulomatous disease or infection with HIV).

Invasive aspergillosis in the immunocompromised host presents as an acute, rapidly progressive, densely consolidated pulmonary infiltrate and is most common among patients with acute leukemia and recipients of tissue transplants. Infection progresses by direct extension across tissue planes and by hematogenous dissemination to lung, brain, and other organs. Computed tomography (CT) has been particularly valuable in suggesting the diagnosis of invasive pulmonary aspergillosis in patients with neutropenia. The earliest CT finding is one or more small pulmonary nodules. As a nodule enlarges, the dense

central core of infarcted tissue becomes surrounded by edema or hemorrhage, forming a hazy rim called the *halo sign*. This rim disappears in a few days as the dense core enlarges. When bone marrow function recovers, the infarcted central core cavitates, creating the *crescent sign*. *Aspergillus* may invade immunosuppressed patients through the skin at a site of minor trauma or through the upper airway mucosa. Early lesions in the nose should be sought in patients with neutropenia who have fever and minimal epistaxis. Scarlet-red patches of the mucosa rapidly become necrotic and white, then black. Rapid extension into the adjacent paranasal sinus, orbit, or face is usual, with or without the appearance of lung lesions.

Aspergillus sinusitis in immunocompetent patients may take three forms. A ball of hyphae may form in a chronically obstructed paranasal sinus, without tissue invasion. Much less commonly, a chronic, fibrosing granulomatous inflammation associated with *Aspergillus* hyphae within tissue may begin in the sinus and spread slowly to the orbit and the brain. *Aspergillus* is also a cause of allergic fungal sinusitis, but dark-walled fungi (e.g., *Curvularia*, *Alternaria*) are more common in this setting. Patients usually have a history of chronic allergic rhinitis, sometimes with nasal polyps, but are otherwise healthy, presenting with painless proptosis, nasal obstruction, or dull aching pain. On CT or magnetic resonance imaging, a solid soft-tissue mass pushing out the lateral wall of the ethmoid sinus or the medial wall of the maxillary sinus may be detected. On sinus exploration, the mucosa is found to be thickened and inflamed but intact. Within the sinus cavity, sticky mucopus with strands of neutrophils, eosinophils, Charcot-Leyden crystals, and occasional hyphae can be found.

Aspergillosis in HIV-infected patients most commonly involves the lung, presenting as fever, cough, and dyspnea. Typically, the CD4+ cell count is $<50/\mu L$. Roughly half of these patients have neutropenia or have recently been treated with glucocorticoids. Bilateral diffuse or focal pulmonary infiltrates with a tendency to cavitate constitute the most common radiologic manifestation. Well-localized, white, necrotic pseudomembranes full of hyphae or ulcers may develop in the trachea or the major bronchi. Progression of bronchitis to pneumonia is usual, but hematogenous dissemination is uncommon. Either allergic or invasive *Aspergillus* sinusitis can occur in HIV-infected patients; the allergic form can develop even at CD4+ cell counts of $>50/\mu L$.

The growth of *Aspergillus* on cerumen and detritus within the external auditory canal is termed *otomycosis*. Trauma to the cornea may cause *Aspergillus* keratitis. Endophthalmitis follows the introduction of *Aspergillus* into the globe by trauma or surgery. *Aspergillus* may infect intracardiac or intravascular prostheses.

DIAGNOSIS The repeated isolation of *Aspergillus* from sputum or the demonstration of hyphae in sputum or bronchoalveolar lavage fluid suggests endobronchial colonization or infection. Even a single isolation of *Aspergillus* from the sputum of a neutropenic patient or a hematopoietic stem-cell transplant recipient with pneumonia, particularly a child or a nonsmoker, suggests the diagnosis of invasive aspergillosis. In patients with advanced AIDS, fever, and cough, the isolation of *Aspergillus* from respiratory secretions raises the possibility of aspergillosis and thus should prompt bronchoscopy. Fungus ball of the lung is usually detectable by chest x-ray. IgG antibody to *Aspergillus* antigens is demonstrable in the serum of many colonized patients and of virtually all patients with fungus ball. Patients with allergic bronchopulmonary aspergillosis have specific serum IgE antibody to *Aspergillus* antigens and often have IgG antibody as well. No standardized test for these antibodies exists. Serum IgE concentrations are often >1000 ng/mL.

Biopsy is usually required for the diagnosis of invasive aspergillosis of the lung, nose, paranasal sinus, bronchi, or sites of dissemination. Blood cultures are rarely positive, even in patients with infected cardiac valves (native or prosthetic). Detection of galactomannan antigen in serum suggests the diagnosis, but sensitivity is low early in the disease and false-positive results occur, particularly in children. *Aspergillus* hyphae can be identified presumptively by histology, but culture is required for confirmation and for identification of the species. Only culture can reliably distinguish aspergillosis from pseudallescheriasis; drug therapy for these two diseases differs.

Rx TREATMENT

(See also Table 188-1.) Patients with severe hemoptysis due to fungus ball of the lung may benefit from lobectomy. Poor pulmonary function in residual lung and dense pleural adhesions around the lesion can complicate the resection. Bead embolization directed to the bronchial arterial supply has been used as a temporizing measure. Systemic chemotherapy is of no value in endobronchial or endocavitary aspergillosis. Short courses of oral adrenal glucocorticoids have been used to treat acute bronchial plugging in patients with allergic bronchopulmonary aspergillosis. Two small studies have indicated that patients with allergic bronchopulmonary aspergillosis require less glucocorticoid therapy and have fewer exacerbations when given prophylaxis with oral itraconazole (200 mg twice daily). Itraconazole has also been used with glucocorticoids to treat exacerbations.

Treatment with intravenous amphotericin B (1.0 to 1.5 mg/kg daily) has elicited a response in 30 to 40% of patients with invasive aspergillosis. Intravenous voriconazole (6 mg/kg every 12 h for two doses, then 4 mg/kg every 12 h) is better tolerated and more efficacious than a regimen starting with conventional amphotericin B. Once the patient has begun to respond, voriconazole can be given orally as 200 mg twice daily. Liposomal amphotericin B at daily doses of 5 mg/kg is probably comparable to voriconazole, but no comparative study is available. Compared with conventional amphotericin B, amphotericin B colloidal dispersion shows equivalent efficacy in aspergillosis, is less nephrotoxic, and more often causes infusion-related chills and fever. Itraconazole (200 mg twice daily) is useful in some less immunosuppressed patients with indolent or slowly progressive invasive aspergillosis. Over the first 2 weeks, itraconazole can be given intravenously as 200 mg twice daily for four doses and then 200 mg daily to patients who are unable to take or unlikely to absorb oral itraconazole. The intravenous formulation is contraindicated in patients with a creatinine clearance rate of <30 mL/min. Itraconazole capsules are given as 200 mg twice daily. Intravenous caspofungin (70 mg once, then 50 mg daily) can be considered for patients in whom therapy with other drugs fails. Surgery is the only treatment needed for fungus ball of the sinus and for allergic fungal sinusitis. Antifungal therapy has little effect on either entity if used alone, but chronic suppressive therapy has been begun postoperatively for relapse of allergic fungal si-

TABLE 188-1 *Treatment of Aspergillosis*

Type of Disease	Preferred Treatment	Alternatives
Fungus ball of the lung	Surgical resection	Bead embolization for hemoptysis
Allergic bronchopulmonary aspergillosis	Short courses of glucocorticoids	Itraconazole prophylaxis
Invasive aspergillosis[a]	Voriconazole, liposomal or conventional amphotericin B	Amphotericin B colloidal dispersion or lipid complex, itraconazole, or caspofungin

[a] Voriconazole dose: 6 mg/kg twice daily for two doses; then 4 mg/kg twice daily; for later oral administration, 200 mg twice daily. Liposomal amphotericin B dose: 5 mg/kg daily. Conventional amphotericin B dose: 1.0 to 1.5 mg/kg daily. Amphotericin B colloidal dispersion dose: 6 mg/kg daily. Amphotericin B lipid complex dose: 5 mg/kg daily. Intravenous itraconazole dose: 200 mg twice daily for four doses, then 200 mg daily. Intravenous caspofungin dose: 70 mg once, then 50 mg daily.

nusitis. The prognosis for cure of invasive aspergillosis in the paranasal sinus is very poor when the patient has profound and unremitting neutropenia. The prognosis is better in less immunosuppressed patients.

189 MUCORMYCOSIS

John E. Bennett

ETIOLOGIC AGENTS Species of *Rhizopus*, *Rhizomucor*, and *Cunninghamella* are the most common causes of mucormycosis, but species of *Apophysomyces*, *Saksenaea*, *Mucor*, and *Absidia* also are occasionally responsible for this infection. The etiologic organism in tissue is composed of broad, rarely septate hyphae of uneven diameter (6 to 15 μm). The organisms are inexplicably difficult to grow from infected tissue. When growth does take place, it is rapid and profuse on most media at room temperature. Identification is based on the gross and microscopic appearance of the mold.

Zygomycosis is a term that includes mucormycosis and entomophthoramycosis. The latter is a tropical infection of the subcutaneous tissue or paranasal sinuses caused by species of *Basidiobolus* and *Conidiobolus*, respectively.

EPIDEMIOLOGY AND PATHOLOGY *Rhizopus* and *Rhizomucor* species are ubiquitous, appearing on decaying vegetation, dung, and foods of high sugar content. Mucormycosis is uncommon and is largely confined to patients with serious preexisting diseases. Mucormycosis originating in the paranasal sinuses and nose predominantly affects patients with poorly controlled diabetes mellitus. Patients who have undergone organ transplantation, who have a hematologic malignancy, or who are receiving long-term deferoxamine therapy are predisposed to mucormycosis of either sinus or lung. Deferoxamine chelates iron in a form that the fungus can utilize. Gastrointestinal mucormycosis occurs in a variety of conditions, including uremia, severe malnutrition, and diarrheal diseases. The infection is acquired from nature, with no person-to-person spread. In all forms of mucormycosis, vascular invasion by hyphae is a prominent feature. Ischemic or hemorrhagic necrosis is the foremost histologic finding.

CLINICAL MANIFESTATIONS Mucormycosis originating in the nose and paranasal sinuses produces a characteristic clinical picture. Low-grade fever, dull sinus pain, and sometimes nasal congestion or a thin, bloody nasal discharge are followed in a few days by double vision, increasing fever, and obtundation. Examination reveals a unilateral generalized reduction of ocular motion, chemosis, and proptosis. The nasal turbinates on the involved side may be dusky red or necrotic. A sharply delineated area of necrosis, strictly respecting the midline, may appear in the hard palate. Facial skin adjacent to paranasal sinuses may be invaded by direct extension, turning progressively red, purple, and black. Fungal invasion of the globe or ophthalmic artery leads to blindness. Opacification of one or more sinuses is detected by computed tomography (CT) or magnetic resonance imaging (MRI). Magnetic resonance angiography (MRA) with gadolinium enhancement may show invasion or obstruction of the carotid siphon. Coma is due to direct invasion of the frontal lobe. Early symptoms mimic those of bacterial sinusitis. Clouding of the sensorium may be attributed to diabetic acidosis. Cavernous sinus thrombosis may be considered when orbital invasion occurs. Without treatment, the patient may die after an interval ranging from a few days to a few weeks.

Pulmonary mucormycosis manifests as progressive severe pneumonia accompanied by high fever and toxicity. The necrotic center of large infiltrates may cavitate. Fatal hemoptysis may occur from cavities formed near the hilum. Hematogenous spread to other areas of the lung, as well as to the brain and other organs, is common. Survival beyond 2 weeks is unusual. Gastrointestinal invasion presents as one or more ulcers that tend to perforate. Hematogenous dissemination can originate from the gastrointestinal tract, lung, or paranasal sinuses. Sometimes no portal of entry can be found. Primary cutaneous inoculation is uncommon but occurs in burn eschars, underneath occlusive dressings, and at sites of minor trauma in immunocompromised adults and low-birth-weight neonates. Several reported infections with *Apophysomyces elegans* have manifested as cellulitis in diabetics or previously normal patients.

DIAGNOSIS CT or MRI is very helpful in assessing the extent of sinusitis before surgery and in evaluating the patient afterward. CT is better for detecting bony erosion; MRI better visualizes extension into the frontal lobe or carotid artery in the siphon. Lesions of the lung and craniofacial structures are best diagnosed by biopsy and histologic section. Cultural confirmation should be attempted. Wet smear of crushed tissue can provide a rapid diagnosis. Cultures of blood and cerebrospinal fluid are negative. Smear and culture of sputum may be positive during cavitation of a lung lesion.

℞ TREATMENT

Regulation of diabetes mellitus and a decrease in the dose of immunosuppressive drugs facilitate the treatment of mucormycosis. Extensive debridement of craniofacial lesions appears to be very important. Orbital exenteration may be required. Intravenous amphotericin B is clearly of value in craniofacial mucormycosis and should be employed in the other forms of mucormycosis as well. The maximal tolerated doses are given until progression is halted. Endoscopic examination of paranasal sinuses can help assess progression. With the deoxycholate formulation, a dosage of 1 to 1.5 mg/kg daily is indicated. Amphotericin B lipid complex or liposomal amphotericin B, each at 5 mg/kg daily, appears to be as effective as and less toxic than conventional amphotericin B. Therapy is continued for a total of 10 to 12 weeks. Voriconazole and itraconazole are of no value. Results of hyperbaric oxygen therapy have been unimpressive. Appropriate management results in cure of about half of craniofacial infections. Primary cutaneous lesions benefit from debridement; extensive plastic surgical repair may be required, but the prognosis is good. Survival is rare among patients who have received deferoxamine and among those with pulmonary, gastrointestinal, or disseminated mucormycosis.

190 MISCELLANEOUS MYCOSES AND ALGAL INFECTIONS

John E. Bennett

CHROMOBLASTOMYCOSIS (CHROMOMYCOSIS) This chronic subcutaneous mycosis, rarely seen in the United States, presents as nodular or verrucoid, ulcerated, or crusted skin lesions on exposed areas of skin, particularly on the lower extremities. Over months and years, lesions extend to contiguous skin; they may be tender or itchy. Pain is not a prominent symptom. The disease, which in fact causes few symptoms, follows the introduction of any of several fungi into subcutaneous tissue by thorns or bits of vegetation. The appearance of thick-walled, dark-colored, rounded forms ("copper pennies") in a histopathologic section of the dermis is diagnostic. Dark-walled hyphae may be seen in the stratum corneum. Surgical excision is the treatment of choice for small lesions. Cryotherapy and itraconazole with or without flucytosine have ameliorated larger lesions. Repeated treatments may be necessary.

DERMATOPHYTOSIS ■ Definition Dermatophytosis, also known as ringworm or tinea, is a chronic fungal infection of the skin, hair, or nails.

Etiology Species of *Trichophyton*, *Microsporum*, and *Epidermophyton* are called *dermatophytes*. These organisms grow in and remain confined to the keratinous structures of the body. Other mycoses, such as candidiasis, pityriasis versicolor, and tinea nigra, may include fungal invasion of keratinous structures but traditionally are not called dermatophytoses.

Pathology and Pathogenesis Dermatophyte species are referred to as *anthropophilic*, *zoophilic*, or *geophilic*, depending on whether their usual reservoir in nature appears to be humans, animals, or soil, respectively. The infectivity of organisms from all these sources is low, and outbreaks are largely confined to occasional clusters of cases of scalp infection in children. Acquisition of a dermatophytosis appears to be favored by minor trauma (including that incurred during wrestling), maceration, and poor hygiene of the skin. Infection does not seem to confer solid immunity: repeated infection with the same species is common, particularly with anthropophilic species. The infrequency of scalp infection among adults has been attributed to local factors rather than immunity.

Invasion of the stratum corneum by dermatophytes may cause inflammation that is either mild or (particularly with zoophilic fungi) intense. Shedding of the stratum corneum is increased by inflammation. To the extent that fungal growth cannot keep up with shedding, inflammation may help terminate infection. Conversely, infection is probably favored when shedding is reduced by treatment with glucocorticoids and cytotoxic drugs. Antifungal drugs interfere with the ability of fungal growth to keep up with shedding.

Clinical Manifestations The disease varies with the site of infection and the fungal species involved. Foot infection (athlete's foot, tinea pedis) may present as fissuring of the toe webs, scaling of the plantar surfaces, or vesicles around the toe webs and soles. Interdigital lesions may be pruritic or, when bacterial superinfection occurs, may be painful. Hand infection is less common but resembles foot infection.

Scalp dermatophytosis (tinea capitis) is characterized by areas of alopecia and scaling. In so-called endothrix infection, the hair shaft breaks off at the skin surface, leaving the hairs visible as black dots in the scalp. Some forms of scalp infection include an area of intense boggy suppuration called a *kerion*.

Dermatophytosis of the glabrous skin (Fig. 190-1) presents as circumscribed lesions with a wide variety of appearances, including scales, vesicles, and pustules. Inflammation may be minimal or intense. Central healing of less inflamed lesions may take place. The serpiginous border of inflammation is the source of the name *ringworm*.

Dermatophytosis of the bearded area (tinea barbae) appears as a pustular folliculitis. Onychomycosis (tinea unguium) presents as a white discoloration of the nails or as thickening, chalkiness, and crumbling of the nails. Peeling and fissuring of paronychial nail folds or keratotic debris under the nail edge also may be evident.

Diagnosis Discolored hairs, scales, and keratotic debris under infected nails should be collected for KOH or calcofluor smear and culture. In the scraping of skin lesions, a drop of water on the skin site may keep the removed scales from flying off and thus may aid in their collection. Culture is important in distinguishing dermatophytes from *Candida* and fungal saprophytes growing in keratinaceous debris.

℞ TREATMENT

Noninflammatory lesions of the trunk, groin, hands, and feet usually respond to twice-daily applications of clotrimazole, miconazole, ketoconazole, econazole, naftifine, terbinafine, or ciclopirox olamine cream. Hyperkeratotic lesions of the palms and soles respond slowly to these agents and may benefit from the initial application of Whitfield's ointment to thin the keratin. Ointment should not be used between the toes, in the groin, or in the gluteal crease because maceration promotes bacterial infection.

Ringworm that is moderately severe, that is unresponsive to topical

FIGURE 190-1 Tinea corporis is a superficial fungal infection, seen here as an erythematous annular scaly plaque with central clearing.

therapy, or that involves the scalp, nails, or bearded area should be treated systemically. Once-daily therapy with itraconazole (200 mg), terbinafine (250 mg), microcrystalline griseofulvin (500 mg), or ultramicrocrystalline griseofulvin (375 mg) is effective. Treatment must be continued until all infected keratin is gone. Cutting off infected hair and cleansing interdigital webs can expedite cure. Secondary bacterial infection of the foot may require soaks or antibacterial agents. The likelihood of relapse of dermatophyte foot infections may be decreased by keeping the feet clean and dry. For nail infections, itraconazole or terbinafine is preferred. In distal subungual onychomycosis, a single course of either drug results in initial improvement in half of patients, of whom half relapse. Results are better with fingernails than with toenails and for more distal rather than proximal nail involvement. To save money, itraconazole can be given as a double dose (400 mg) for 1 week each month with only marginal loss of efficacy. The rare but life-threatening complications of itraconazole must be weighed against the patient's desire to have normal-appearing nails. The duration of therapy with itraconazole or terbinafine is 2 to 3 months for fingernails and 4 to 6 months for toenails.

PROTOTHECOSIS *Prototheca* species are ubiquitous achlorophyllic algae that enter exposed areas of skin through contaminated wounds and cause localized infections in the skin, olecranon bursa, and, rarely, tendon sheaths or deeper tissue. Diagnosis is based on culture or histopathologic demonstration of morula-like sporangia containing endospores in tissue. *Prototheca wickerhamii*, the usual agent, grows readily on fungal culture medium. Surgical debridement and treatment with itraconazole or intravenous amphotericin B are useful.

FUSARIOSIS *Fusarium* species can cause localized or hematogenously disseminated infection. Indolent cellulitis or soft-tissue necrosis can occur in immunocompetent patients at the site of trauma (including burns) or adjacent to onychomycosis. Immunocompromised patients may develop skin lesions at the site of minor trauma or, more often, as a result of hematogenous dissemination. Two-thirds of patients with disseminated infection who are severely immunosuppressed, particularly those who are profoundly neutropenic, develop skin lesions. One or more tender erythematous papules enlarge rapidly, may develop a surrounding rim of erythema, and may become necrotic or ulcerated in the center. A portal of infection is not usually apparent. Blood cultures have been positive in 59% of cases. The presence of a mold growing in a culture of blood from a neutropenic patient suggests fusariosis. Blood cultures are rarely positive in aspergillosis or mucormycosis. Voriconazole or amphotericin B is the drug of choice for fusariosis, but survival from disseminated infection depends on the diminution of neutropenia. Debridement of localized lesions in immunocompetent patients is useful.

***MALASSEZIA* INFECTION (PITYRIASIS)** *Malassezia furfur* is part of the normal flora of the human skin but can cause tinea (pityriasis) versicolor or catheter-acquired sepsis. Tinea versicolor appears as asymptomatic, well-delineated, hyperpigmented or hypopigmented macules centered on the upper trunk and upper arms. Confluent lesions may cover large areas, making the border difficult to find. A fine "branny" scale or folliculitis is sometimes visible. When examined microscopically by KOH mount, skin sections are seen to contain characteristic round and elongated cells. On inspection with Wood's light, lesions either do not fluoresce or appear yellow-green. *Erythrasma* resembles tinea versicolor but is characterized by gram-positive bacilli on smear and coral-red fluorescence. Azole creams are effective for the treatment of small areas of tinea versicolor; however, the application of selenium sulfide shampoo (Selsun) for 10 min daily, followed by showering to remove the shampoo, is more practical for large areas. Itraconazole is also effective. Catheter-acquired sepsis due to *M. furfur* develops in patients (particularly neonates) receiving intravenous lipid. The organism requires special culture conditions for growth, and the infection is cured by catheter removal.

MYCETOMA ■ Etiology *Actinomycetoma* refers to infection by actinomycetes of the genera *Nocardia* (Chap. 146), *Nocardiopsis*, *Streptomyces*, and *Actinomadura*. *Eumycetoma* is caused by true fungi of many different genera. The predominant agent varies with the locality.

Pathogenesis and Pathology The pathogens live in the soil and enter the skin through minor trauma. The most common site of infection is the foot. The infection runs a relentless course over many years, with destruction of contiguous bone and fascia. Grains are found in purulent foci surrounded by fibrosis and a mononuclear cell inflammatory response.

Clinical Manifestations Mycetoma is a chronic suppurative infection originating in subcutaneous tissue and characterized by the presence of grains, which are tightly clumped colonies of the causative agent. The infected site is characterized by painless swelling, woody induration, and sinus tracts that discharge pus intermittently. Systemic symptoms do not develop, and spread to distant sites in the body does not take place.

Diagnosis Although the clinical picture is characteristic, mycetoma is sometimes confused with chronic osteomyelitis or botryomycosis. The diagnosis requires demonstration of grains in pus from the draining sinus or in biopsy sections. Many histologic sections may need to be examined to locate a grain.

℞ TREATMENT

Actinomycetoma may respond to prolonged combination chemotherapy—e.g., with streptomycin and either dapsone or trimethoprim-sulfamethoxazole. Eumycetoma rarely responds to chemotherapy; some cases caused by *Madurella mycetomatis* have appeared to respond to ketoconazole or itraconazole.

PARACOCCIDIOIDOMYCOSIS ■ Etiology Formerly called *South American blastomycosis*, this mycosis is caused by *Paracoccidioides brasiliensis*. A dimorphic fungus, *P. brasiliensis* grows as a budding yeast in tissue and as either a yeast or a mold on culture medium. The organism is identified by its gross and microscopic appearance.

Pathogenesis and Pathology Infection is thought to be acquired by inhalation of spores from environmental sources, possibly soil. Pulmonary infection produces few symptoms initially. Hematogenous spread to the mucous membranes of the mouth and nose, the lymph nodes, and other sites causes patients to seek medical attention. In fatal cases, the infection spreads to the adrenals, the gastrointestinal tract, and many other viscera.

Clinical Manifestations Common signs include indurated ulcers of the mouth, oropharynx, larynx, and nose; enlarged and draining lymph nodes; lesions of the skin and genitalia; and productive cough, weight loss, dyspnea, and sometimes fever. Paracoccidioidomycosis is acquired only in South America, Central America, and Mexico, but its extreme indolence may delay its recognition until many years after the patient has left the endemic area. Chest radiography most often shows bilateral patchy pneumonia.

Diagnosis Cultures of sputum, pus, and mucosal lesions are often diagnostic. The diagnosis can be made by smear or histologic section, although confirmation by culture is preferable. Serologic tests are useful in suggesting the diagnosis and monitoring the response to therapy.

℞ TREATMENT

Relatively mild cases of paracoccidioidomycosis may be cured by 1 year of treatment with oral itraconazole (200 to 400 mg daily). More advanced cases are treated with intravenous amphotericin B followed by itraconazole.

PENICILLIOSIS MARNEFFEI *Penicillium marneffei* has emerged as a leading cause of opportunistic infection in patients in the late stages of HIV infection in Southeast Asia—notably, northern Thailand and southern China. Infection is probably acquired by the inhalation of spores from an unknown site in nature. At the time of diagnosis, in-

fection has usually disseminated to bone marrow, liver, spleen, skin, or bone. Clinical manifestations and histopathologic findings resemble those of histoplasmosis. Both *P. marneffei* and *Histoplasma* are dimorphic fungi, appearing as small yeast cells in tissue and as a mold in culture. Unlike *Histoplasma*, the yeastlike cells of *P. marneffei* do not bud but divide by longitudinal fission. During growth as a mold, a red pigment forming in the agar underneath *P. marneffei* colonies can aid in the organism's identification. Treatment consists of amphotericin B administration for 2 weeks or until improvement is documented, with subsequent administration of itraconazole (400 mg daily for 8 weeks, then 200 mg daily as maintenance therapy). A few patients with a sustained response to highly active antiretroviral therapy and prolonged maintenance therapy have had itraconazole discontinued, with no subsequent relapse.

PHAEOHYPHOMYCOSIS This is the name given to infections caused by fungi with dark-walled hyphae, excluding those given conventional names like chromoblastomycosis. Although an extraordinary variety of fungi and clinical syndromes are encompassed by this definition, most patients have brain abscess, subcutaneous abscess, or allergic fungal sinusitis. Most of the brain abscesses are due to *Cladophialophora bantiana*, *Ochroconis gallopavum*, *Exophiala dermatitidis*, *Bipolaris* species, and *Ramichloridium mackenziei (obovoideum)*. Patients are previously healthy. Subcutaneous abscesses are usually single, arise at the site of minor trauma, and occur in both immunosuppressed and immunocompetent individuals. A large number of dematiaceous (dark-walled) mold species cause subcutaneous phaeohyphomycosis as well as allergic fungal sinusitis. The latter entity develops in patients with allergic rhinitis and presents as an expanding mucoid mass in one or more paranasal sinuses. The tenacious mucus contains eosinophils, Charcot-Leyden crystals, and occasional hyphae. Surgical excision of phaeohyphomycotic lesions is important. Antifungal therapy may retard recurrences but is of little value without surgical excision.

PSEUDALLESCHERIASIS ■ Etiology Also called *Petriellidium boydii*, *Pseudallescheria boydii* is a mold frequently found in soil. When isolated in the imperfect state, the anamorph is called *Scedosporium apiospermum*. *Scedosporium prolificans* is a closely related species.

Pathogenesis and Pathology Wind-borne spores of *P. boydii*, arising from the soil, are the presumed source of infection. The fungus grows as a mold within tissue, causing necrosis and abscess formation.

Clinical Manifestations *P. boydii* resembles *Aspergillus* in its ability to colonize the endobronchial tree, to form fungus balls in the lungs or paranasal sinuses, and to invade the cornea or globe of the eye, the soft tissues, the joints, or the bones after trauma or surgery and in its propensity to invade the lungs and paranasal sinuses of immunosuppressed hosts, including patients with AIDS. Hematogenous dissemination to the eye, brain, soft tissues, and other sites is common. Severe pneumonia, often with hematogenous dissemination and brain abscesses, has followed near-drowning in stagnant water. Hyphae of *P. boydii* in tissue may be difficult to distinguish from those of *Aspergillus*. Intravascular hyphae, a hallmark of invasive aspergillosis, are also found in pseudallescheriasis in neutropenic patients.

S. prolificans has caused infections in bones, joints, and soft tissue, usually after trauma.

Diagnosis Demonstration of hyphae in tissue and culture confirmation are required for diagnosis.

℞ TREATMENT

Soft-tissue infections in previously normal patients respond well to surgical debridement and treatment with itraconazole or voriconazole. Immunosuppressed patients respond poorly, and those with disseminated infection usually die. Surgical drainage is useful in brain abscesses. Voriconazole is the drug of choice for immunosuppressed individuals, and itraconazole is a suitable alternative. *P. boydii* appears to be unresponsive to systemic amphotericin B therapy, although injection of amphotericin B into an infected joint has been helpful in a few cases. In previously normal patients with *S. prolificans* soft-tissue infection, surgical debridement has been useful. The response to all antifungal agents has been poor in immunosuppressed patients, but voriconazole treatment has resulted in cure in a few cases.

SPOROTRICHOSIS ■ Etiology *Sporothrix schenckii* lives as a saprophyte on plants in many areas of the world. In nature and on culture at room temperature, the fungus grows as a mold; within host tissue or at 37°C on enriched media, it grows as a budding yeast. It is identified by its appearance in mold and yeast forms.

Pathogenesis and Pathology Infection results from the inoculation of *S. schenckii* into subcutaneous tissue through minor trauma. Nursery workers, florists, and gardeners acquire the illness from roses, sphagnum moss, and other plants. Infection may be limited to the site of inoculation (plaque sporotrichosis) or extend along proximal lymphatic channels (lymphangitic sporotrichosis). Spread beyond an extremity—the usual site of infection—is rare, and hematogenous dissemination from the skin remains unproven. The portal for osteoarticular, pulmonary, and other extracutaneous forms of sporotrichosis is unknown but is probably the lung. Untreated sporotrichosis persists for months. The inflammatory response includes neutrophil clustering and a marked granulomatous response with epithelioid and giant cells.

Clinical Manifestations In lymphangitic sporotrichosis, which is by far the most common manifestation, a nearly painless red papule forms at the site of inoculation. Over the next several weeks, similar nodules form along proximal lymphatic channels. The nodules intermittently discharge small amounts of pus. Ulceration may occur. The proximal extension of these lesions, often with skip areas, is quite distinctive but may be mimicked by lesions of *Nocardia brasiliensis*, *Mycobacterium marinum*, or (in rare cases) *Leishmania brasiliensis* or *Mycobacterium kansasii*.

Plaque sporotrichosis manifests as a nontender red maculopapular granuloma confined to the site of inoculation. Osteoarticular sporotrichosis presents as mono- or polyarticular arthritis of indolent onset and progression over months or years, involving the elbows, knees, wrists, ankles, and (rarely) smaller joints of the extremities. Periarticular bone develops areas of demineralization detectable on x-ray, and draining sinuses may appear over joints and bursae. Hematogenous spread to the skin may take place during polyarticular disease, but none of the skin lesions shows lymphangitic spread. Immunosuppression, including that due to advanced infection with HIV, predisposes to hematogenous spread. Pulmonary sporotrichosis usually presents as a single chronic cavitary upper-lobe lung lesion. Chronic meningitis can develop in the absence of skin or lung lesions. *S. schenckii* is difficult to recover from cerebrospinal fluid.

Diagnosis Culture of pus, joint fluid, sputum, or a skin biopsy specimen is preferred. The appearance of *S. schenckii* in tissue is variable. In skin lesions, the organisms are hard to find.

℞ TREATMENT

Itraconazole (100 to 200 mg daily) is the drug of choice for the treatment of cutaneous sporotrichosis. A saturated solution of potassium iodide given orally is also effective, but side effects often prevent the effective use of this regimen. Therapy should be continued for 1 month after the resolution of all lesions. Fluconazole is less effective. Extracutaneous sporotrichosis may be cured by itraconazole (200 mg twice daily), but the response is slow and may be incomplete. Prolonged courses of intravenous amphotericin B are more effective. Cavitary pulmonary sporotrichosis may require resection for cure.

TRICHOSPORONOSIS A change in the taxonomy of the genus *Trichosporon* moved most of the agents causing deep infections from *T. beigelii* into the species *T. asahii*, with a few categorized as *T. mucoides*. White piedra of the scalp is caused by *T. ovoides* and that of the pubic hair by *T. inkin*. *T. cutaneum* and *T. asteroides* cause su-

perficial infections. Most of what is currently known about *Trichosporon* infections is not species specific, so the following description refers to *T. beigelii*. *T. capitatum*, which causes disseminated infection in patients with neutropenia, was previously reclassified as *Blastoschizomyces capitatus* and will not be covered here.

T. beigelii can be isolated from soil, the human gastrointestinal tract, and skin. The organism can enter the bloodstream of patients with severe neutropenia through an inapparent source. Hematogenously disseminated infection is manifested by fever and often by the development of several erythematous or purpuric tender papules anywhere on the body. Lesions can form large, tense hemorrhagic bullae. In some patients, native or prosthetic cardiac valves become infected. In tissue, hyphae and yeastlike cells are seen. Amphotericin B is probably the drug of choice for treatment, but recovery depends on the return of bone marrow function.

191 *PNEUMOCYSTIS* INFECTION

Peter D. Walzer

DEFINITION AND DESCRIPTION *Pneumocystis* is an opportunistic fungal pulmonary pathogen that is an important cause of pneumonia (pneumocystosis) in the immunocompromised host. The taxonomic classification of *Pneumocystis* as a fungus is based on factors such as analysis of gene sequences for ribosomal RNA, mitochondrial proteins, and major enzymes; the presence of β-1,3 glucan in the cell wall; and the efficacy of antifungal drugs that inhibit β-glucan synthesis in animal models. However, in contrast to most fungi, *Pneumocystis* lacks ergosterol and is not susceptible to antifungal drugs that inhibit ergosterol synthesis.

Although *Pneumocystis* organisms obtained from different sources are morphologically very similar, they are genetically diverse and host specific. New nomenclature, which is still evolving, has established that organisms derived from rats and humans are separate species termed *P. carinii* and termed *P. jiroveci*, respectively. For the purpose of clarity, only the genus designation, *Pneumocystis*, will be used in this chapter.

Research on *Pneumocystis* has been limited by the lack of a reliable in vitro culture system. Developmental stages of the organism include the small (1- to 4-μm) pleomorphic trophic form; the 5- to 8-μm cyst, which has a thick cell wall and contains up to eight intracystic bodies; and the precyst, an intermediate stage. The life cycle of *Pneumocystis* probably involves sexual and asexual reproduction. *Pneumocystis* contains several different antigen groups, the most prominent of which is the 95- to 140-kDa major surface glycoprotein (MSG). MSG represents a multigene family of proteins, and the ability of MSG to undergo antigenic variation may represent a mechanism by which *Pneumocystis* evades host defenses. MSG is highly immunogenic, contains protective epitopes, and facilitates adherence of the organism to host cells via extracellular matrix proteins, surfactant proteins, and the mannose receptor.

EPIDEMIOLOGY Serologic surveys have demonstrated that *Pneumocystis* has a worldwide distribution and that most healthy children have been exposed to the organism by 3 to 4 years of age. Airborne transmission of *Pneumocystis* has been documented in animal studies; person-to-person transmission has been suggested by hospital outbreaks of pneumocystosis and by molecular analysis of isolates from patients and their close contacts. Geography has also emerged as a contributory factor in the epidemiology of *Pneumocystis* infection.

PATHOGENESIS AND PATHOLOGY The host factors that predispose to the development of pneumocystosis include defects in cellular and humoral immunity. The risk of developing *Pneumocystis* pneumonia among HIV patients rises markedly when circulating CD4+ cell counts fall below 200/μL. The frequency of serum antibodies to a specific segment of MSG is significantly higher in HIV patients who have recovered from an episode of pneumocystosis than in HIV patients who have never had the disease. Other persons at risk for *Pneumocystis* pneumonia are patients receiving immunosuppressive therapy (particularly glucocorticoids) for cancer, organ transplantation, and other disorders; children with primary immunodeficiency diseases; and premature malnourished infants.

The principal host effector cells against *Pneumocystis* are alveolar macrophages, which ingest and kill the organism, releasing a variety of inflammatory mediators. Tumor necrosis factor α and interleukin (IL) 1, interferon γ, and granulocyte-macrophage colony-stimulating factor contribute to host defenses against *Pneumocystis*. HIV reduces the mannose receptor–mediated binding and phagocytosis of *Pneumocystis* and alters the cytokine responses to the organism.

After being inhaled, *Pneumocystis* takes up residence in the alveoli, where it attaches tightly to type I cells but maintains an extracellular existence. It was formerly thought that the organism remains latent in the host for long periods, but more recent data suggest that pneumonia can arise from a new bout of infection. As the immune system of the host becomes compromised, *Pneumocystis* organisms propagate and gradually fill the alveoli. This scenario is accompanied by a complex series of events that result in increased alveolar-capillary permeability and damage to alveolar type I cells. Surfactant abnormalities include a fall in bronchoalveolar lavage (BAL) fluid phospholipids and an increase in surfactant proteins A and D. Contributions of the host inflammatory response to lung injury are suggested by the correlation of increased IL-8 levels and neutrophil counts in BAL fluid from patients with severe disease. In addition, immune reconstitution with the start of highly potent anti-HIV drugs and treatment of pneumocystosis is sometimes associated with new pulmonary infiltrates.

On lung sections stained with hematoxylin and eosin, the alveoli are filled with a typical foamy, vacuolated exudate. Severe disease may include interstitial edema, fibrosis, and hyaline membrane formation. The host inflammatory changes usually consist of hypertrophy of alveolar type II cells, a typical reparative response, and a mild mononuclear cell interstitial infiltrate. Malnourished infants display an intense plasma cell infiltrate that gave the disease its early name: interstitial plasma cell pneumonia.

CLINICAL FEATURES Patients with pneumocystosis develop dyspnea, fever, and nonproductive cough. Symptoms in non-HIV-infected patients often begin after the glucocorticoid dose has been tapered and typically last 1 to 2 weeks. HIV-infected patients are usually ill for several weeks or longer and have relatively subtle manifestations. The clinical picture in individual patients is variable. A high index of suspicion and a thorough history are key factors in early detection.

Physical findings include tachypnea, tachycardia, and cyanosis, but

lung auscultation reveals few abnormalities. The white blood cell count is variable and is usually governed by the patient's underlying disease. Reduced arterial oxygen pressure (Pa_{O_2}), increased alveolar-arterial oxygen gradient ($PA_{O_2} - Pa_{O_2}$), and respiratory alkalosis are evident. There also may be changes in pulmonary function test values (diffusing capacity) and heightened uptake with nonspecific nuclear imaging techniques (gallium scan). Elevated serum concentrations of lactate dehydrogenase (LDH) have been reported; the increase probably reflects lung parenchymal damage but is not specific to *Pneumocystis* infection. In general, laboratory abnormalities are less severe in HIV-infected patients than in non-HIV-infected patients.

The classic findings on chest radiography consist of bilateral diffuse infiltrates beginning in the perihilar regions (Fig. 191-1), but various atypical manifestations (nodular densities, cavitary lesions) have also been reported. Patients who receive aerosolized pentamidine have an increased frequency of upper-lobe infiltrates. Pneumothorax also occurs, and management is often difficult. Early in the course of pneumocystosis, the chest radiograph may be normal.

Although *Pneumocystis* usually remains confined to the lungs, cases of disseminated infection have occurred in both HIV-infected and non-HIV-infected patients. One risk factor for extrapulmonary spread in patients with HIV is the administration of aerosolized pentamidine. The most common sites of involvement are the lymph nodes, spleen, liver, and bone marrow. Eye lesions (choroiditis) also occur and must be distinguished from retinitis caused by cytomegalovirus. Clinical manifestations range from incidental findings at autopsy to specific organ involvement. Histopathologic examination reveals *Pneumocystis* and the characteristic associated foamy material.

DIAGNOSIS Because the clinical picture of *Pneumocystis* infection can be produced by many other infectious and noninfectious agents, the diagnosis must be based on specific identification of the organism. A definitive diagnosis is made by histopathologic staining. Traditional stains have included reagents such as methenamine silver, toluidine blue, and cresyl echt violet, which selectively stain the wall of *Pneumocystis* cysts, and reagents such as Wright-Giemsa, which stain the nuclei of all developmental stages. Other reagents include nonspecific fluorochrome stains (calcofluor white) and Papanicolaou's stain. Immunofluorescence with monoclonal antibodies is more sensitive than histologic staining but is also more expensive. DNA amplification by the polymerase chain reaction (PCR) is most sensitive and should be part of routine diagnosis if commercial kits become available.

The successful diagnosis of pneumocystosis depends upon the collection of proper specimens. In general, the yield from different diagnostic procedures is higher in HIV-infected patients than in non-HIV-infected patients because of the higher organism burden in the former group. Sputum induction has gained popularity as a simple, noninvasive technique; this procedure requires trained and dedicated personnel, and its success has varied at different institutions. Oral washes, combined with PCR, have also shown promise. Fiberoptic bronchoscopy with BAL, which is more sensitive than sputum induction, remains the mainstay of *Pneumocystis* diagnosis. This procedure also provides information about the organism burden, the host inflammatory response, and the presence of other opportunistic infections. Transbronchial biopsy and open lung biopsy, the most invasive procedures, are used only when a diagnosis cannot be made by BAL.

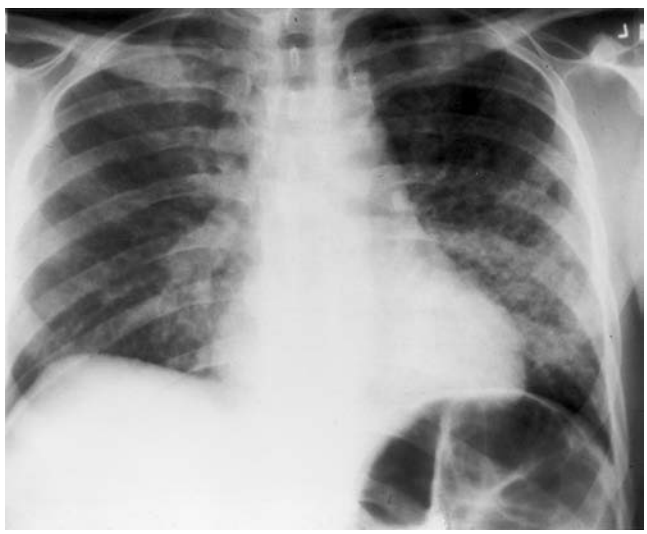

FIGURE 191-1 Chest radiograph depicting diffuse infiltrates in an HIV-infected patient with pneumocystosis.

COURSE AND PROGNOSIS In the typical case of untreated *Pneumocystis* pneumonia, progressive respiratory embarrassment leads to death. Therapy is most effective when instituted early in the course of the disease, before there is extensive alveolar damage. If induced sputum is nondiagnostic and BAL cannot be performed in a timely manner, it is reasonable to begin empirical therapy with drugs active against *Pneumocystis*. However, this practice does not obviate a specific etiologic diagnosis. With improved management of HIV and its complications, mortality from pneumocystosis is 15 to 20% at 1 month and 50 to 55% at 1 year. Rates of early death remain high among people who require mechanical ventilation (60%) and among non-HIV patients (40%). The most widely used prognostic factor is the degree of hypoxemia. Other factors include pneumocystosis history, age, CD4+ count, neutrophil and IL-8 levels in BAL fluid, albumin and LDH levels in serum, and the degree of expertise with which HIV infection is managed.

TREATMENT

For decisions about therapy (see also Chaps. 118 and 193), pneumocystosis has been classified as mild (a Pa_{O_2} of >70 mmHg or a $PA_{O_2} - Pa_{O_2}$ of <35 mmHg) or as moderate to severe (a Pa_{O_2} of ≤ 70 mmHg or a $PA_{O_2} - Pa_{O_2}$ of ≥ 35 mmHg) on breathing room air. Trimethoprim-sulfamethoxazole (TMP-SMX), which acts by inhibiting folic acid synthesis, is considered the drug of choice for all forms of pneumocystosis (Table 191-1). Treatment for extrapulmonary disease is the same as that for pneumonia. Therapy is continued for 14 days in non-HIV-infected patients and for 21 days in persons infected with HIV. Since HIV-infected patients respond more slowly than non-HIV-infected patients, it is prudent to wait at least 7 days after the initiation of treatment before concluding that therapy has failed. Adding drugs to an existing regimen is no more effective than switching regimens and may increase the risk of toxicity. TMP-SMX is well tolerated by non-HIV-infected patients, whereas more than half of HIV-infected patients experience serious adverse reactions.

Several alternative regimens are available for the treatment of mild to moderate cases of pneumocystosis. TMP plus dapsone and clindamycin plus primaquine are about as effective as TMP-SMX. Dapsone and primaquine should not be used in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency. Atovaquone is less effective than TMP-SMX but is better tolerated. Atovaquone should be given with food to enhance absorption.

One alternative regimen for the treatment of moderate to severe *Pneumocystis* pneumonia is parenteral pentamidine. Pentamidine is about as effective as TMP-SMX but is highly toxic to both HIV-infected and non-HIV-infected patients. Other regimens include parenteral clindamycin plus primaquine and trimetrexate plus leucovorin (with leucovorin administered to prevent bone marrow suppression).

In recent years, molecular evidence of resistance to sulfonamides—and, to a lesser extent, atovaquone—has emerged among human *Pneumocystis* isolates. Although prior sulfonamide exposure has been a risk factor, this resistance has also occurred in HIV-infected patients who never used sulfonamides. Some studies have found an association of sulfonamide resistance with a poor response to therapy, whereas other studies have not.

Patients infected with HIV frequently experience deterioration in

respiratory function shortly after receiving anti-*Pneumocystis* drugs. The adjunctive administration of tapering doses of glucocorticoids to patients with HIV infection and moderate to severe pneumocystosis can prevent this problem and improve the rate of survival (Table 191-1). For maximal benefit, this adjunctive therapy should be started early in the course of the illness (usually when antimicrobial drugs are begun). This regimen has generally proved to be safe despite concern about its effects on other opportunistic infections. The use of steroids as adjunctive therapy in HIV-infected patients with mild pneumocystosis or in non-HIV-infected patients remains to be evaluated.

PREVENTION Primary prophylaxis is indicated for HIV-infected patients with CD4+ cell counts of $<200/\mu L$ or a history of oropharyngeal candidiasis. Primary prophylaxis guidelines for other immunocompromised hosts are less clear. Secondary prophylaxis is indicated for both HIV-infected and non-HIV-infected patients who have recovered from pneumocystosis. Primary and secondary prophylaxis may be discontinued in HIV-infected persons once CD4+ counts have risen to $>200/\mu L$ and remained at that level for ≥ 3 months.

TABLE 191-1 *Treatment of Pneumocystosis*

Drug(s), Dose, Route	Adverse Effects
FIRST CHOICE[a]	
TMP-SMX (5 mg/kg TMP, 25 mg/kg SMX[b]) q6–8 h PO or IV	Fever, rash, cytopenias, hepatitis, hyperkalemia, GI disturbances
OTHER AGENTS[a]	
TMP, 5 mg/kg q6–8h, plus dapsone, 100 mg qd PO	Hemolysis (G6PD deficiency), methemoglobinemia, fever, rash, GI disturbances
Atovaquone, 750 mg bid PO	Rash, fever, GI and hepatic disturbances
Clindamycin, 300–450 mg q6h PO or 600 mg q6–8h IV, plus primaquine, 15–30 mg qd PO	Hemolysis (G6PD deficiency), methemoglobinemia, rash, colitis, neutropenia
Pentamidine, 3–4 mg/kg qd IV	Hypotension, azotemia, cardiac arrhythmias, pancreatitis, dysglycemias, hypocalcemia, neutropenia, hepatitis
Trimetrexate, 45 mg/m^2 qd IV, plus leucovorin[c], 20 mg/kg q6h PO or IV	Cytopenias, peripheral neuropathy, hepatic disturbances
ADJUNCTIVE AGENT	
Prednisone, 40 mg bid × 5 d, 40 mg qd × 5 d, 20 mg qd × 11 d; PO or IV	Immunosuppression, peptic ulcer, hyperglycemia, mood changes, hypertension

[a] Therapy is administered for 14 days to non-HIV-infected patients and for 21 days to HIV-infected patients.
[b] Equivalent of 2 double-strength (DS) tablets. (One DS tablet contains 160 mg of TMP and 800 mg of SMX.)
[c] Leucovorin prevents bone marrow toxicity from trimetrexate.
Note: GI, gastrointestinal; G6PD, glucose-6-phosphate dehydrogenase; TMP-SMX, trimethoprim-sulfamethoxazole.

TABLE 191-2 *Prophylaxis of Pneumocystosis*[a]

Drug, Dose, Route	Comments
FIRST CHOICE	
TMP-SMX, 1 DS tablet or 1 SS tablet qd PO[b]	TMP-SMX can be safely reintroduced in some patients who have experienced mild to moderate side effects.
OTHER AGENTS	
Dapsone, 50 mg bid or 100 mg qd PO	—
Dapsone, 50 mg qd PO, plus pyrimethamine, 50 mg weekly PO, plus leucovorin, 25 mg weekly PO	Leucovorin prevents bone marrow toxicity from pyrimethamine.
Dapsone, 200 mg weekly PO, plus pyrimethamine, 75 mg weekly PO, plus leucovorin, 25 mg weekly PO	Leucovorin prevents bone marrow toxicity from pyrimethamine.
Pentamidine, 300 mg monthly via Respirgard II nebulizer	Adverse reactions include cough, bronchospasm.
Atovaquone, 1500 mg qd PO	—
TMP-SMX, 1 DS tablet three times weekly PO	TMP-SMX can be safely reintroduced in some patients who have experienced mild to moderate side effects.

[a] For list of adverse effects, see Table 191-1.
[b] One DS tablet contains 160 mg of TMP and 800 mg of SMX.
Note: DS, double-strength; SS, single-strength; TMP-SMX, trimethoprim-sulfamethoxazole.

TMP-SMX is the drug of choice for primary and secondary prophylaxis (Table 191-2). This agent also provides protection against toxoplasmosis and some bacterial infections. Alternative regimens include dapsone, dapsone plus pyrimethamine plus leucovorin, aerosolized pentamidine, and atovaquone. Although there are no specific recommendations for preventing the spread of *Pneumocystis* infection in health care facilities, it seems prudent to prevent direct contact between patients with pneumocystosis and other susceptible hosts.

192 LABORATORY DIAGNOSIS OF PARASITIC INFECTIONS

Charles E. Davis

The cornerstone for the diagnosis of parasitic infections is a thorough history of the patient's illness. Epidemiologic aspects of the illness are especially important because the risks of acquiring many parasites are closely related to occupation, recreation, or travel to areas of high endemicity. Without a basic knowledge of the epidemiology and life cycles of the major parasites, it is difficult to approach the diagnosis of parasitic infections systematically. Accordingly, the medical classification of important human parasites in this chapter emphasizes their

Strongyloides stercoralis (strongyloidiasis)	Moist tropics and subtropics	Soil→skin	Humans	Larvae	Feces, sputum, duodenal fluid	EIA	Dissemination in immunodeficiency
TISSUE ROUNDWORMS							
Trichinella spiralis (trichinosis)	Worldwide	Swine/humans	Swine/humans	Larvae	Muscle	EIA	Muscle biopsy
Wuchereria bancrofti (filariasis)	Coastal areas in tropics and subtropics	Mosquitoes	Humans	Microfilariae	Blood, lymph nodes	EIA	Nocturnal periodicity[a]
Brugia malayi (filariasis)	Asia, Indian subcontinent	Mosquitoes	Humans	Microfilariae	Blood	EIA	Nocturnal
Loa loa (African eye worm)	West and Central Africa	Mango flies (*Chrysops*)	Humans	Microfilariae	Blood	—	May be visible in eye, diurnal
Onchocerca volvulus (river blindness)	Africa, Mexico, Central and South America	Blackflies	Humans	Adults/larvae	Skin/eye	—	Examine nodules or skin snips
Dracunculus medinensis (guinea worm)	Africa	*Cyclops*	Humans	Adults/larvae	Skin	—	May be visible in lesion
LARVA MIGRANS SYNDROMES							
Ancylostoma braziliense (creeping eruption)	Tropical and temperate zones	Soil→skin	Dogs/cats, humans	Larvae	Skin	—	Dog and cat hookworm
Toxocara canis and *cati* (visceral larva migrans)	Tropical and temperate zones	Soil, fecal-oral	Dogs/cats, humans	Larvae	Viscera, CNS, eye	EIA[b]	Also caused by roundworms of other species

[a] Blood should be drawn at midnight, except for infection acquired in the South Pacific.
[b] The presence of hemagglutinins is a useful clue.

Note: Sx, signs/symptoms; EIA, enzyme immunoassay; CNS, central nervous system.

geographic distribution, their transmission, and the anatomic location and stages of their life cycle in humans. The text and tables are intended to serve as a guide to the correct diagnostic procedures for the major parasitic infections and to direct the reader to other chapters that contain more comprehensive information about each infection. Tables 192-1, 192-2, and 192-3 summarize the geographic distributions, the anatomic locations, and the methods employed for the diagnosis of flatworm, roundworm, and protozoal infections, respectively.

In addition to selecting the correct diagnostic procedures, physicians must counsel their patients to ensure that specimens are collected properly and arrive at the laboratory promptly. For example, the diagnosis of bancroftian filariasis is unlikely to be confirmed by the laboratory unless blood is drawn near midnight, when the nocturnal microfilariae are active. Laboratory personnel and surgical pathologists should be notified in advance when a parasitic infection is suspected. Continuing interaction with the laboratory staff and the surgical pathologists increases the likelihood that parasites in body fluids or biopsy specimens will be examined carefully by the most capable individuals.

INTESTINAL PARASITES Most helminths and protozoa exit the body in the fecal stream. The patient should be instructed to collect feces in a clean cardboard container and to record the time of collection on the container. Contamination with water (which could contain free-living protozoa) or with urine should be avoided. Fecal samples should be collected before ingestion of barium or other contrast agents for radiologic procedures and before treatment with antidiarrheal agents and antacids, because these substances change the consistency of the feces and interfere with microscopic detection of parasites. Because of the cyclic shedding of most parasites in the feces, a minimum of three samples collected on alternate days should be examined. When delays in transport to the laboratory are unavoidable, fecal samples should be kept in polyvinyl alcohol to preserve protozoal trophozoites. Refrig-

TABLE 192-3 *Protozoal Infections*

Parasite	Geographic Distribution	Life-Cycle Hosts: Intermediate (Transmission)	Life-Cycle Hosts: Definitive	Diagnosis: Parasite Stage	Diagnosis: Body Fluid or Tissue	Diagnosis: Serologic Tests	Diagnosis: Other
INTESTINAL PROTOZOANS							
Entamoeba histolytica (amebiasis)	Worldwide, especially tropics	Fecal-oral	Humans	Troph, cyst	Feces, liver	EIA, antigen detection	Ultrasound, liver CT, PCR
Giardia lamblia (giardiasis)	Worldwide	Fecal-oral	Humans	Troph, cyst	Feces	Antigen detection	String test
Isospora belli	Worldwide	Fecal-oral	Humans	Oocyst	Feces	—	Acid-fast
Cryptosporidium	Worldwide	Fecal-oral	Humans, other animals	Oocyst	Feces	Antigen detection	Acid-fast, biopsy, PCR
Cyclospora cayetanensis	Worldwide?	Fecal-oral	Humans, other animals?	Oocyst	Feces	—	Modified safranin, epifluorescence, PCR
Enterocytozoon bieneusi (microsporidiosis)	Worldwide?	?	Animals, humans	Spore	Feces	—	Modified trichrome, biopsy, PCR
FREE-LIVING AMEBAS							
Naegleria	Worldwide	Warm water	Humans	Troph, cyst	CNS, nares	—	Biopsy, nasal swab
Acanthamoeba	Worldwide	Soil, water	Humans	Troph, cyst	CNS, skin, cornea	—	Biopsy, scrapings
BLOOD AND TISSUE PROTOZOANS							
Plasmodium spp. (malaria)	Subtropics and tropics	Mosquitoes	Humans	Asexual	Blood	Limited use	PCR
Babesia microti (babesiosis)	U.S., especially New England	Ticks	Rodents, humans	Asexual	Blood	IIF	Animal spp. in asplenia, PCR
Trypanosoma rhodesiense (African sleeping sickness)	Sub-Saharan East Africa	Tsetse flies	Humans, herbivores	Tryp	Blood, CSF	Card agglutination, IIF[a]	Also chancre, lymph nodes
T. gambiense (African sleeping sickness)	Sub-Saharan West Africa	Tsetse flies	Humans, swine	Tryp	Blood, CSF	Card agglutination, IIF[a]	Also chancre, lymph nodes
T. cruzi (Chagas' disease)	Mexico→ South America	Reduviid bugs (triatomes)	Humans, dogs, wild animals	Amastigote, tryp	Multiple organs/ blood	IIF, EIA	Reactivation in immunosuppression
Leishmania tropica, etc.	Widespread in tropics and subtropics	Sandflies (*Phlebotomus*)	Humans, dogs, rodents	Amastigote	Skin	IFA, EIA[b]	Biopsy, scraping, culture
L. braziliensis (mucocutaneous)	Mexico→ South America	Sandflies (*Lutzomyia*)	Humans, dogs, rodents	Amastigote	Skin, mucous membranes	IFA[b], EIA	Biopsy, scraping, culture
L. donovani (kala-azar)	Widespread in tropics and subtropics	Sandflies (*Phlebotomus*)	Humans, dogs, wild animals	Amastigote	RE system	IFA[b], EIA	Biopsy, culture, PCR
Toxoplasma gondii (toxoplasmosis)	Worldwide	Humans, other mammals	Cats	Cyst, troph	CNS, eye, muscles, other	EIA, IIF	PCR

[a] Card agglutination provided to endemic countries by the World Health Organization; contact the CDC at 770-488-7760.
[b] Limited specificity. Most sensitive for *L. donovani* (kala-azar).
Note: CT, computed tomography; troph, trophozoite; tryp, trypomastigote form; IIF, indirect immunofluorescence; RE, reticuloendothelial; PCR, polymerase chain reaction; EIA, enzyme immunoassay; CNS, central nervous system; IFA, indirect fluorescent antibody; CSF, cerebrospinal fluid.

eration will also preserve trophozoites for a few hours and protozoal cysts and helminthic ova for several days.

Analysis of fecal samples consists of both a macroscopic and a microscopic examination. Watery or loose stools are more likely to contain protozoal trophozoites, but protozoal cysts and all stages of helminths may be found in formed feces. If adult worms or tapeworm segments are observed, they should be transported promptly to the laboratory or washed and preserved in fixative for later examination. The only tapeworm with motile segments is *Taenia saginata*, the beef tapeworm, which patients sometimes bring to the physician. Motility is an important distinguishing characteristic, because the ova of *T. saginata* and *Taenia solium*, the cause of cysticercosis, are morphologically indistinguishable.

Microscopic examination of feces (Table 192-4) is not complete until direct wet mounts have been evaluated and concentration techniques as well as permanent stains have been applied. Before accepting a report of negativity for ova and parasites as final, the physician should insist that the laboratory undertake each of these procedures. Some intestinal parasites are more readily detected in material other than feces. For example, use of the string test to sample duodenal contents is sometimes necessary to detect *Giardia lamblia*, *Cryptosporidium*, and *Strongyloides* larvae. Use of the "Scotch tape" technique to detect pinworm ova on the perianal skin sometimes also reveals ova of *T. saginata* deposited perianally when the motile segments disintegrate (Table 192-4).

Two routine solutions are used to make wet mounts for the identification of the various life stages of helminths and protozoa: physiologic saline for trophozoites, cysts, ova, and larvae and dilute iodine solution for protozoal cysts and ova. Iodine solution must never be used to examine specimens for trophozoites because it kills the parasites and thus eliminates their characteristic motility.

The two most common concentration procedures for detecting small numbers of cysts and ova are formalin-ether sedimentation and zinc sulfate flotation. The formalin-ether technique is preferable, be-

TABLE 192-4 *Alternative Procedures for Laboratory Diagnosis of Parasites Found in Feces*[a]

Parasites and Fecal Stages	Alternative Diagnostic Procedures
TAPEWORMS (CESTODES)	
Taenia saginata ova and segments	Perianal "Scotch tape" test for ova
T. solium ova and segments	Serology; brain biopsy for neurocysticercosis
FLUKES (TREMATODES)	
Clonorchis (Opisthorchis) sinensis ova	Examination of bile for ova and adults in cholangitis
Fasciola hepatica ova	Examination of bile for ova and adults in cholangitis
Paragonimus spp. ova	Serology; sputum; biopsy of lung or brain for ova
Schistosoma ova	Serology for all; rectal snips (especially for *S. mansoni*), urine (*S. haematobium*), liver biopsy and liver ultrasound
ROUNDWORMS	
Enterobius vermicularis ova and adults	Perianal "Scotch tape" test for ova and adults
Trichuris trichiura ova	None
Ascaris lumbricoides ova and adults	Examination of sputum for larvae in lung disease
Hookworm ova and occasional larvae	Examination of sputum for larvae in lung disease
Strongyloides larvae	Duodenal aspirate or jejunal biopsy; serology; sputum or lung biopsy for filariform larvae in disseminated disease
PROTOZOANS	
Entamoeba histolytica trophozoites and cysts	Serology; liver biopsy for trophozoites
Giardia lamblia trophozoites and cysts	Duodenal aspirate or jejunal biopsy[b]
Isospora belli oocysts	Duodenal aspirate or jejunal biopsy[b]
Cryptosporidium oocysts	Duodenal aspirate or jejunal biopsy[b]
Enterocytozoon bieneusi spores	Duodenal aspirate or jejunal biopsy[b]

[a] Stains and concentration techniques are discussed in the text.
[b] Commercial string test is satisfactory; *Isospora* and *Cryptosporidium* are acid-fast.

cause all parasites sediment but not all float. Slides permanently stained for trophozoites should be prepared before concentration. Additional slides stained for cysts and ova may be made from the concentrate.

In many instances, especially in the differentiation of *Entamoeba histolytica* from other amebas, identification of parasites from wet mounts or concentrates must be considered tentative. Permanently stained smears allow study of the cellular detail necessary for definitive identification. The iron-hematoxylin stain is excellent for critical work, but trichrome staining, which can be completed in 1 h, is a satisfactory alternative that also reveals parasites in specimens preserved in polyvinyl alcohol fixative.

BLOOD AND TISSUE PARASITES Invasion of tissue by protozoa and helminths renders the choice of diagnostic techniques more difficult. For example, physicians must understand that aspiration of an amebic liver abscess rarely reveals *E. histolytica* because the trophozoites are located primarily in the abscess wall. They must remember that the urine sediment offers the best opportunity to detect *Schistosoma haematobium* in the Ethiopian youngster or the American traveler who returns from Africa with hematuria (Table 192-5). Tables 192-1, 192-2, and 192-3, which offer a quick guide to the geographic distribution and anatomic locations of the major tissue parasites, should help the physician to select the appropriate body fluid or biopsy site for microscopic examination. Tables 192-5 and 192-6 provide additional information about the identification of parasites in samples from specific anatomic locations. The laboratory procedures for detection of parasites in other body fluids are similar to those used in the examination of feces. The physician should insist on wet mounts, concentration techniques, and permanent stains for all body fluids. The trichrome or iron-hematoxylin stain is satisfactory for all tissue helminths in body fluids other than blood, but microfilarial worms and blood protozoa are more easily visualized when stained with Giemsa or Wright's stain.

TABLE 192-5 *Identification of Parasites in Blood and Other Body Fluids*

Body Fluid, Parasite	Enrichment/Stain	Culture Technique
BLOOD		
Plasmodium spp.	Thick and thin smears/Giemsa or Wright's	Not useful for diagnosis
Leishmania spp.	Buffy coat/Giemsa	Media available from CDC
African trypanosomes[a]	Buffy coat, anion column/wet mount and Giemsa	Mouse or rat inoculation[b]
Trypanosoma cruzi[c]	As for African species	As above and xenodiagnosis
Toxoplasma gondii	Buffy coat/Giemsa	Fibroblast cell lines
Microfilariae[d]	Nuclepore filtration/wet mount and Giemsa	None
URINE		
Schistosoma haematobium	Centrifugation/wet mount	None
Microfilariae (in chyluria)	As for blood	None
SPINAL FLUID		
African trypanosomes	Centrifugation, anion column/wet mount and Giemsa	As for blood
Naegleria fowleri	Centrifugation/wet mount and Giemsa or trichrome	Nonnutrient agar overlaid with *Escherichia coli*

[a] *Trypanosoma rhodesiense* and *T. gambiense*.
[b] Inject mice intraperitoneally with 0.2 mL of whole heparinized blood (0.5 mL for rats). After 5 days, tail blood should be checked daily for trypanosomes as described above.
[c] Detectable in blood by conventional techniques only during acute disease. Xenodiagnosis is successful in ~ 50% of patients with chronic Chagas' disease.
[d] Day (1000–1400 h) and night (2200–0200 h) blood should be drawn to maximize the chance of detecting *Wuchereria* (nocturnal except for Pacific strains), *Brugia* (nocturnal), and *Loa loa* (diurnal).

The most common parasites detected in Giemsa-stained blood smears are the plasmodia, microfilariae, and African trypanosomes (Table 192-5). Most patients with Chagas' disease present in the chronic phase, when *Trypanosoma cruzi* is no longer microscopically detectable in blood smears. Wet mounts are sometimes more sensitive than stained smears for the detection of microfilariae and African trypanosomes because these active parasites cause noticeable movement of the erythrocytes in the microscopic field. Nuclepore filtration of blood facilitates the detection of microfilariae. The intracellular amastigote forms of *Leishmania* spp. and *T. cruzi* can sometimes be visualized in stained smears of peripheral blood, but aspirates of the bone marrow, liver, and spleen are the best sources for microscopic detection and culture of *Leishmania* in kala-azar and of *T. cruzi* in chronic Chagas' disease. The diagnosis of malaria and the critical distinction among the various *Plasmodium* species are made by microscopic examination of stained thick and thin blood films (Chap. 195).

Although most tissue parasites stain with the traditional hematoxylin and eosin, surgical biopsy specimens should also be stained with appropriate special stains. The surgical pathologist who is accustomed to applying silver stains for *Pneumocystis carinii* to induced sputum and transbronchial biopsies may have to be reminded to examine wet mounts and iron-hematoxylin–stained preparations of pulmonary specimens for helminthic ova and *E. histolytica*. The clinician should also be able to advise the surgeon and pathologist about optimal techniques for the identification of parasites in specimens obtained by certain specialized minor procedures (Table 192-6). For example, the excision of skin snips for the diagnosis of onchocerciasis, the collection of rectal snips for the diagnosis of schistosomiasis, and punch biopsy of skin lesions for the identification and culture of cutaneous and mucocutaneous species of *Leishmania* are simple procedures, but the diagnosis can be missed if the specimens are improperly obtained or processed.

TABLE 192-6 *Minor Procedures for Diagnosis of Parasitic Infections*

Parasite(s) and Stage	Procedure
Onchocerca volvulus and *Mansonella streptocerca* microfilariae	*Skin snips:* Lift skin with a needle and excise ~ 1 mg to a depth of 0.5 mm from several sites. Weigh each sample, place it in 0.5 mL of saline for 4 h, and examine wet mounts and Giemsa stains of the saline either directly or after filtration. Count microfilariae.[a]
Loa loa adults and *O. volvulus* adults and microfilariae	*Biopsies of subcutaneous nodules:* Stain routine histopathologic sections and impression smears with Giemsa.
Trichinella spiralis larvae (and perhaps *Taenia solium* cysticerci)	*Muscle biopsies:* Excise about 1.0 g of deltoid or gastrocnemius muscle and squash between two glass slides for direct microscopic examination.
Schistosoma ova of all species, but especially *S. mansoni*	*Rectal snips:* From four areas of mucosa, take 2-mg snips, tease onto a glass slide, and flatten with a second slide before examining directly at 10×. Preparations may be fixed in alcohol or stained.
Trypanosoma gambiense and *T. rhodesiense* trypomastigotes	*Aspirate of chancre or lymph node*[b]: Aspirate center with 18-gauge needle, place a drop on a slide, and examine for motile forms. An otherwise insufficient volume of material may be stained with Giemsa.
Acanthamoeba spp. trophozoites or cysts	*Corneal scrapings:* Obtain sample from ophthalmologist for immediate Giemsa staining and culture on nutrient agar overlaid with *Escherichia coli*.
Cutaneous and mucocutaneous *Leishmania* spp.	*Swabs, aspirates, or punch biopsies of skin lesions:* Obtain specimen from margin of lesion for Giemsa staining of impression smears, and section and culture on special media from CDC.

[a] Counts of >100/mg are associated with significant risk of complications.
[b] Lymph node aspiration is contraindicated in some infections and should be used judiciously.

NONSPECIFIC TESTS Eosinophilia is a common accompaniment of infections with most of the tissue helminths; absolute numbers of eosinophils may be high in trichinosis and the migratory phases of filariasis (Table 192-7). Intestinal helminths provoke eosinophilia only during pulmonary migration of the larval stages. Eosinophilia is not a manifestation of protozoal infections, with the possible exceptions of those due to *Isospora* and *Dientamoeba fragilis*.

Like the hypochromic, microcytic anemia of heavy hookworm infections, other nonspecific laboratory abnormalities may suggest parasitic infection in patients with appropriate geographic and/or environmental exposures. Biochemical evidence of cirrhosis or an abnormal urine sediment in an African immigrant certainly raises the possibility of schistosomiasis, and anemia and thrombocytopenia in a febrile traveler or immigrant are among the hallmarks of malaria. Computed tomography and magnetic resonance imaging also contribute to the diagnosis of infections with many tissue parasites and have become invaluable adjuncts in the diagnosis of neurocysticercosis and cerebral toxoplasmosis.

ANTIBODY AND ANTIGEN DETECTION Useful antibody assays for many of the important tissue parasites are available; most of those listed in Table 192-8 can be obtained from the Centers for Disease Control and Prevention (CDC) in Atlanta. The results of serologic tests not listed in the tables should be interpreted with caution.

The value of antibody assays is limited by several factors. For example, the preparation of thick and thin blood smears remains the procedure of choice for the diagnosis of malaria in individual patients because diagnostic titers to plasmodia develop slowly. Filarial antigens cross-react with those from other nematodes; as in assays for antibody to most parasites, the presence of antibody in the filarial assay fails to distinguish between past and current infection. Despite these specific limitations, the restricted geographic distribution of many tropical parasites increases the diagnostic usefulness of both the presence and the absence of antibody in travelers from industrialized countries. In contrast, a large proportion of the world's population has been exposed to *Toxoplasma gondii*, and the presence of IgG antibody to *T. gondii* does not constitute proof of active disease.

Fewer antibody assays are available for the diagnosis of infection with intestinal parasites. *E. histolytica* is the major exception. Sensitive, specific serologic tests are invaluable in the diagnosis of amebiasis. Commercial kits for the detection of antigen by enzyme-linked immunosorbent assay or of whole organisms by fluorescent antibody assay are now available for several protozoan parasites (Table 192-8).

MOLECULAR TECHNIQUES DNA hybridization with probes that are repeated many times in the genome of a specific parasite and amplifi-

TABLE 192-7 *Parasites Frequently Associated with Eosinophilia*[a]

Parasite	Comment
TAPEWORMS (CESTODES)	
Echinococcus granulosus	When hydatid cyst leaks
Taenia solium	During muscle encystation and in CSF with neurocysticercosis
FLUKES (TREMATODES)	
Paragonimus spp.	Uniformly high in acute stage
Fasciola hepatica	May be high in acute stage
Clonorchis (Opisthorchis) sinensis	Variable
Schistosoma mansoni	50% of infected travelers
S. haematobium	25% of infected travelers
S. japonicum	Up to 6000/μL in acute infection
ROUNDWORMS	
Ascaris lumbricoides	During larval migration
Hookworm species	During larval migration
Strongyloides stercoralis	Profound during migration and early years of infection
Trichinella spiralis	Up to 7000/μL
Filarial species[b]	Varies but can reach 5000 to 8000/μL
Toxocara spp.	>3000/μL
Ancylostoma braziliense	With extensive cutaneous eruption
Gnathostoma spinigerum	In visceral larva migrans and eosinophilic meningitis
Angiostrongylus cantonensis	In eosinophilic meningitis
A. costaricensis	During larval migration in mesenteric vessels

[a] Virtually every helminth has been associated with eosinophilia. This table includes both common and uncommon parasites that frequently elicit eosinophilia during infection.
[b] *Wuchereria bancrofti*, *Brugia* spp., *Loa loa*, and *Onchocerca volvulus*.

[a] Commercial laboratories only.
[b] Available at the NIH (301-496-5398) and commercially.
[c] Of limited use for management of acute disease.
Note: WB, western blot; EIA, enzyme immunoassay; IIF, indirect immunofluorescence; DFA, direct fluorescent antibody; PCR, polymerase chain reaction. Unless specified, antibody tests listed are available from the CDC. Antigen and parasite detection kits are available commercially. The PCRs listed are available in commercial or research laboratories. The CDC currently uses PCRs as research tools and in selected diagnostic situations (contact Dr. Alexandre da Silva 770-488-4072).

cation of a specific DNA fragment by the polymerase chain reaction (PCR) are promising techniques for the diagnosis of parasitic infections. Although molecular techniques for the detection of many parasites are already being used in insect vectors, animal models, and human trials, relatively few are available for routine use in patients at this time. Several commercial laboratories now perform PCRs for detection of the nucleic acid of a few specific parasites in stool, biopsy, bronchoalveolar lavage, and blood samples (Table 192-8). Because their roles in the diagnosis and management of individual patients are still being defined, the CDC currently uses PCRs as research tools and in selected diagnostic situations (contact Dr. Alexandre da Silva, 770-488-4072).

193 AGENTS USED TO TREAT INFECTIONS DUE TO PARASITES AND *PNEUMOCYSTIS*

Thomas A. Moore

Parasitic infections afflict more than half of the world's population and impose a substantial health burden, particularly in underdeveloped nations, where they are most prevalent. The remarkable success of global campaigns aimed at controlling or eliminating ancient scourges such as dracunculiasis and onchocerciasis has been offset by the spread of other diseases such as trypanosomiasis due to crumbling infrastructures in settings of HIV infection, civil war, and unstable government. The reach of some parasitic diseases, including malaria, has expanded over the past few decades as a result of factors such as deforestation, population shifts, global warming, and other climatic events. Despite major efforts at vaccine development, chemotherapy remains the single most effective means of controlling parasitic infections. However, efforts to combat the spread of some diseases are hindered by the development and spread of drug resistance and the limited introduction of new antiparasitic agents. Since the last edition of this text was published, new and significant obstacles have arisen. The most serious problems include the discontinued production of inexpensive agents that appear on the essential medicine list of the World Health Organization (WHO)—e.g., amphotericin B deoxycholate, eflornithine, metrifonate, and praziquantel—and the introduction in some areas of counterfeit antiparasitic agents.

Significant advances toward the reduction of the burden of parasitic disease have nevertheless been made. The continued generous donation of ivermectin and albendazole for global eradication programs has improved the health of countless individuals and offers the promise of eradication of some diseases (e.g., the filariases). Shortages of some drugs have prompted a fresh look at currently available agents (e.g., high-dose metronidazole for schistosomiasis). The broader use of newer agents, either alone (e.g., fumagillin, metrifonate, nitazoxanide) or in combination (e.g., lumefantrine with artemether), also appears promising.

This chapter deals exclusively with the agents used to treat infections due to parasites and the fungus *Pneumocystis* (Chap. 191). Specific treatment recommendations for the parasitic diseases of humans are listed in subsequent chapters. Table 193-1 presents a brief overview of each agent (including some that are not discussed in the text but are covered in other chapters), along with its major toxicities, spectrum of activity, and safety for use during pregnancy and lactation. Many of the agents are approved by the U.S. Food and Drug Administration (FDA) but are considered investigational for the treatment of certain infections; these drugs are marked accordingly in Table 193-1. Drugs marked in the text with an asterisk (*) are available only through the Centers for Disease Control and Prevention (CDC) Drug Service (telephone: 404-639-3670 or 404-639-2888; *www.cdc.gov/ncidod/dpd/professional/drug_service.htm*). Other drugs, marked with a dagger (†), are available only through their manufacturers; contact information for these manufacturers may be available from the CDC.

Albendazole Like all benzimidazoles, albendazole acts by binding to free β-tubulin, inhibiting the polymerization of tubulin and the microtubule-dependent uptake of glucose. This fundamental disruption of

TABLE 193-1 *Overview of Agents Used for the Treatment of Parasitic and Pneumocystis Infections*

Drug	Infection(s)	Adverse Effects	Major Drug Interactions	Pregnancy Class[a]	Breast Milk
Albendazole	Ascariasis, capillariasis, clonorchiasis, cutaneous larva migrans, cysticercosis,[b] echinococcosis,[b] enterobiasis, eosinophilic enterocolitis, gnathostomiasis, hookworm, microsporidiosis, strongyloidiasis, trichinellosis, trichostrongyliasis, trichuriasis, visceral larva migrans	Occasional: nausea, vomiting, abdominal pain, headache, reversible alopecia, elevated aminotransferases. Rare: leukopenia, rash	Dexamethasone, praziquantel: increase plasma level of albendazole sulfoxide by ~50%	C	Yes[c]
Amphotericin B [amphotericin B deoxycholate, Amphotec (InterMune), amphotericin B lipid complex (ABLC, Abelcet), liposomal amphotericin B (AmBisome)]	Leishmaniasis,[d] amebic meningoencephalitis	Frequent: fever, chills, hypokalemia, hypomagnesemia, nephrotoxicity. Occasional: vomiting, dyspnea, hypotension	Antineoplastic agents: renal toxicity, bronchospasm, hypotension. Glucocorticoids, ACTH, digitalis: hypokalemia. Zidovudine: increased myelo- and nephrotoxicity (ABLC only)	B	No information
Antimonials [pentavalent antimony (Pentostam), meglumine antimonate (Glucantime)]	Leishmaniasis	Frequent: arthralgias/myalgias, pancreatitis, ECG changes (QT prolongation, T wave flattening or inversion)	Antiarrhythmics and tricyclic antidepressants: increased risk of cardiotoxicity (meglumine antimonate only)	Not assigned	Yes (pentavalent antimony); unknown (meglumine antimonate)
Artemisinin derivatives	Malaria	Occasional: neurotoxicity (ataxia, convulsions), nausea, vomiting, anorexia, contact dermatitis	Mefloquine: levels decreased and clearance accelerated by artesunate	Not assigned	Yes
Atovaquone	Malaria,[b] pneumocystosis,[b] babesiosis	Frequent: nausea, vomiting. Occasional: abdominal pain, headache	Plasma levels decreased by rifampin, tetracycline; bioavailability decreased by metoclopramide	C	No information
Azithromycin	Babesiosis	Occasional: nausea, vomiting, diarrhea, abdominal pain. Rare: angioedema, cholestatic jaundice	Cyclosporine and digoxin: levels increased by azithromycin. Nelfinavir: increases levels of azithromycin	B	
Azoles (fluconazole, itraconazole, ketoconazole)	Leishmaniasis	Occasional: hepatotoxicity. Rare: exfoliative skin disorders, anaphylaxis	Warfarin, oral hypoglycemics, phenytoin, cyclosporine, theophylline, digoxin, dofetilide, quinidine, carbamazepine, rifabutin, busulfan, docetaxel, vinca alkaloids, pimozide, alprazolam, diazepam, midazolam, triazolam, verapamil, atorvastatin, cerivastatin, lovastatin, simvastatin, tacrolimus, sirolimus, indinavir, ritonavir, saquinavir, alfentanil, buspirone, methylprednisolone, trimetrexate: plasma levels increased by azoles. Carbamazepine, phenobarbital, phenytoin, isoniazid, rifabutin, rifampin, antacids, H2-receptor antagonists, proton pump inhibitors, nevirapine: decrease plasma levels of azoles. Clarithromycin, erythromycin, indinavir, ritonavir: increase plasma levels of azoles	C	Yes
Benznidazole	Chagas' disease	Frequent: rash, pruritus, nausea, leukopenia, paresthesias	No major interactions	Not assigned	No information

(continued)

TABLE 193-1 *Overview of Agents Used for the Treatment of Parasitic and Pneumocystis Infections—(Continued)*

Drug	Infection(s)	Adverse Effects	Major Drug Interactions	Pregnancy Class[a]	Breast Milk
Chloroquine	Malaria[b]	Occasional: pruritus, nausea, vomiting, headache, hair depigmentation, exfoliative dermatitis, reversible corneal opacity. Rare: irreversible retinal injury, nail discoloration, blood dyscrasias	Antacids and kaolin: reduce absorption of chloroquine. Ampicillin: bioavailability reduced by chloroquine. Cimetidine: increases serum levels of chloroquine. Cyclosporine: serum levels increased by chloroquine	Not assigned[e]	Yes
Ciprofloxacin	Cyclosporiasis, isosporiasis	Occasional: nausea, diarrhea, vomiting, abdominal pain/discomfort, headache, restlessness, rash. Rare: myalgias/arthralgias, tendon rupture, CNS symptoms (nervousness, agitation, insomnia, anxiety, nightmares, or paranoia), convulsions	Probenecid: increases serum levels of ciprofloxacin. Theophylline, warfarin: serum levels increased by ciprofloxacin	C	Yes
Clindamycin	Babesiosis, malaria, toxoplasmosis, pneumocystosis	Occasional: pseudomembranous colitis, abdominal pain, diarrhea, nausea/vomiting. Rare: pruritus, skin rashes	No major interactions	B	Yes[c]
Dapsone	Leishmaniasis, malaria, pneumocystosis, toxoplasmosis	Frequent: rash, anorexia. Occasional: hemolysis, methemoglobinemia, neuropathy, allergic dermatitis, anorexia, nausea, vomiting, tachycardia, headache, insomnia, psychosis, hepatitis. Rare: agranulocytosis	Rifampin: lowers plasma levels of dapsone	C	Yes
Diethylcarbamazine	Lymphatic filariasis, loiasis	Frequent: dose-related nausea, vomiting. Rare: fever, chills, arthralgias, headaches	None reported	Not assigned[e]	No information
Diloxanide furoate	Amebiasis	Frequent: flatulence. Occasional: nausea, vomiting, diarrhea. Rare: pruritus	None reported	Contraindicated	No information
Eflornithine (difluoromethylornithine, DFMO)	Trypanosomiasis	Frequent: pancytopenia. Occasional: diarrhea, seizures. Rare: transient hearing loss	No major interactions	Contraindicated	No information
Fumagillin	Microsporidiosis	Rare: neutropenia, thrombocytopenia	None reported	No information	No information
Furazolidone	Giardiasis	Frequent: nausea/vomiting, brown urine. Occasional: rectal itching, headache. Rare: hemolytic anemia, disulfiram-like reactions, MAO-inhibitor interactions	Risk of hypertensive crisis when administered >5 days with MAO inhibitors	No information	No information
Halofantrine	Malaria[b]	Frequent: abdominal pain, diarrhea. Occasional: ECG disturbances (dose-related prolongation of QTc and PR interval), nausea, pruritus. Contraindicated in persons who have cardiac disease or who have taken mefloquine in preceding 3 weeks	Concomitant use of agents that prolong QTc interval contraindicated	C	No information
Iodoquinol	Amebiasis,[b] balantidiasis, *Dientamoeba fragilis* infection	Occasional: headache, rash, pruritus, thyrotoxicosis, nausea, vomiting, abdominal pain, diarrhea. Rare: optic neuritis, peripheral neuropathy, seizures, encephalopathy	No major interactions	No information	No information
Ivermectin	Ascariasis, cutaneous larva migrans, enterobiasis, gnathostomiasis, loiasis, lymphatic filariasis, onchocerciasis,[b] scabies, strongyloidiasis[b]	Occasional: fever, pruritus, headache, myalgias. Rare: hypotension	No major interactions	C	Yes[c]

(continued)

TABLE 193-1—*(Continued)*

Drug	Infection(s)	Adverse Effects	Major Drug Interactions	Pregnancy Class[a]	Breast Milk
Lumefantrine	Malaria	Occasional: nausea, vomiting, diarrhea, abdominal pain, anorexia, headache, dizziness	No major interactions	Not assigned	No information
Mebendazole	Ascariasis,[b] capillariasis, eosinophilic enterocolitis, enterobiasis,[b] hookworm,[b] trichinellosis, trichostrongyliasis, trichuriasis,[b] visceral larva migrans	Occasional: diarrhea, abdominal pain, elevated aminotransferases. Rare: agranulocytosis, thrombocytopenia, alopecia	Cimetidine: inhibits mebendazole metabolism	C	No information
Mefloquine	Malaria[b]	Frequent: light-headedness, nausea, headache. Occasional: confusion, nightmares, insomnia, visual disturbances, transient and clinically silent ECG abnormalities (including sinus bradycardia, sinus arrhythmia, first-degree AV block, prolongation of QTc interval, and abnormal T waves). Rare: psychosis, convulsions, hypotension	Administration of halofantrine <3 weeks after mefloquine use may produce fatal QTc prolongation. Mefloquine may lower plasma levels of anticonvulsants. Mefloquine levels decreased and clearance accelerated by artesunate	C	Yes
Melarsoprol	Trypanosomiasis	Frequent: myocardial injury, encephalopathy, peripheral neuropathy, hypertension. Occasional: G6PD-induced hemolysis, erythema nodosum leprosum. Rare: hypotension	No major interactions	Not assigned	No information
Metrifonate	Schistosomiasis	Frequent: abdominal pain, nausea, vomiting, diarrhea, headache, vertigo, bronchospasm. Rare: cholinergic symptoms	No major interactions	Not assigned	No information
Metronidazole	Amebiasis,[b] balantidiasis, dracunculiasis, giardiasis, trichomoniasis,[b] *D. fragilis* infection	Frequent: nausea, headache, anorexia, metallic aftertaste. Occasional: vomiting, insomnia, vertigo, paresthesias, disulfiram-like effects. Rare: seizures, peripheral neuropathy	Warfarin: effect enhanced by metronidazole. Disulfiram: psychotic reaction. Phenobarbital, phenytoin: accelerate elimination of metronidazole. Lithium: serum levels elevated by metronidazole. Cimetidine: prolongs half-life of metronidazole	B	Yes
Miltefosine	Leishmaniasis	Frequent: mild and transient (1-2 days) gastrointestinal disturbances within first 2 weeks of therapy (resolve after treatment completion), motion sickness. Occasional: reversible elevations of creatinine and aminotransferases	No major interactions	Not assigned	No information
Niclosamide	Intestinal cestodes[b]	Occasional: nausea, vomiting, dizziness, pruritus	No major interactions	Not assigned	No information
Nifurtimox	Chagas' disease	Frequent: nausea, vomiting, abdominal pain, insomnia, paresthesias, weakness, tremors. Rare: seizures. All effects reversible and dose-related	No major interactions	Not assigned	No information
Nitazoxanide	Cryptosporidiosis,[b] giardiasis[b]	Occasional: abdominal pain, diarrhea. Rare: vomiting, headache	No major interactions	B	No information
Oxamniquine	Schistosomiasis	Occasional: dizziness, drowsiness, headache, orange urine, elevated aminotransferases. Rare: seizures	No major interactions	Not assigned	No information

(continued)

TABLE 193-1 *Overview of Agents Used for the Treatment of Parasitic and Pneumocystis Infections—(Continued)*

Drug	Infection(s)	Adverse Effects	Major Drug Interactions	Pregnancy Class[a]	Breast Milk
Paromomycin	Amebiasis,[b] *D. fragilis* infection, giardiasis, leishmaniasis	Frequent: gastrointestinal disturbances (oral dosing only). Occasional: nephrotoxicity, ototoxicity, vestibular toxicity (parenteral dosing only)	No major interactions	Not assigned[e]	No information
Pentamidine isethionate	Pneumocystosis,[b] leishmaniasis, trypanosomiasis	Frequent: hypotension, hypoglycemia, pancreatitis, sterile abscesses at intramuscular injection sites, gastrointestinal disturbances, reversible renal failure. Occasional: hepatotoxicity, cardiotoxicity, delirium. Rare: pancreatitis, anaphylaxis	No major interactions	C	No information
Praziquantel	Clonorchiasis,[b] cysticercosis, diphyllobothriasis, hymenolepiasis, taeniasis, opisthorchiasis, intestinal trematodes, paragonimiasis, schistosomiasis[b]	Frequent: abdominal pain, diarrhea, dizziness, headache, malaise. Occasional: fever, nausea. Rare: pruritus, singultus	No major interactions	B	Yes
Primaquine phosphate	Malaria,[b] pneumocystosis	Frequent: hemolytic anemia in patients with G6PD deficiency. Occasional: methemoglobinemia, gastrointestinal disturbances. Rare: CNS symptoms	Quinacrine: potentiates toxicity of primaquine	Contraindicated	No information
Proguanil (chloroguanide)	Malaria	Occasional: urticaria. Rare: hematuria, gastrointestinal disturbances	No major interactions	C	Yes
Pyrantel pamoate	Ascariasis, eosinophilic enterocolitis, enterobiasis,[b] hookworm, trichostrongyliasis	Occasional: gastrointestinal disturbances, headache, dizziness, elevated aminotransferases	No major interactions	C	No information
Pyrimethamine	Malaria,[b] pneumocystosis, toxoplasmosis[b]	Occasional: folate deficiency. Rare: rash, seizures, severe skin reactions (toxic epidermal necrolysis, erythema multiforme, Stevens-Johnson syndrome)	Sulfonamides, proguanil, zidovudine: increased risk of bone marrow suppression when used concomitantly	C	Yes
Quinacrine	Giardiasis[b]	Frequent: headache, nausea, vomiting, bitter taste. Occasional: yellow-orange discoloration of skin, sclerae, urine (begins after 1 week of treatment and lasts up to 4 months after drug discontinuation). Rare: psychosis, exfoliative dermatitis, retinopathy, G6PD-induced hemolysis, exacerbation of psoriasis, disulfiram-like effects	Primaquine: toxicity potentiated by quinacrine	Contraindicated	No information
Quinine and quinidine	Malaria, babesiosis	Frequent: cinchonism (tinnitus, high-tone deafness, headache, dysphoria, nausea, vomiting, abdominal pain, visual disturbances, postural hypotension), hyperinsulinemia resulting in life-threatening hypoglycemia. Occasional: deafness, hemolytic anemia, arrhythmias, hypotension due to rapid intravenous infusion	Carbonic-anhydrase inhibitors, thiazide diuretics: reduce renal elimination of quinidine. Amiodarone, cimetidine: increase quinidine levels. Nifedipine: decreases quinidine levels; quinidine slows metabolism of nifedipine. Phenobarbital, phenytoin, rifampin: accelerate hepatic elimination of quinidine. Verapamil: reduces hepatic clearance of quinidine. Diltiazem: decreases clearance of quinidine	X	Yes[c]

(continued)

TABLE 193-1—*(Continued)*

Drug	Infection(s)	Adverse Effects	Major Drug Interactions	Pregnancy Class[a]	Breast Milk
Spiramycin	Toxoplasmosis	Occasional: gastrointestinal disturbances, transient skin eruptions. Rare: thrombocytopenia, QT prolongation in an infant, cholestatic hepatitis	No major interactions	Not assigned[e]	Yes[c]
Sulfonamides	Malaria,[b] pneumocystosis,[b] toxoplasmosis[b]	Frequent: gastrointestinal disturbances, allergic skin reactions. Rare: severe skin reactions (toxic epidermal necrolysis, erythema multiforme, Stevens-Johnson syndrome), agranulocytosis, aplastic anemia, hypersensitivity of respiratory tract, hepatitis, interstitial nephritis, hypoglycemia, aseptic meningitis	Thiazide diuretics: increased risk of thrombocytopenia in elderly patients. Warfarin: effect prolonged by sulfonamides. Methotrexate: levels increased by sulfonamides. Phenytoin: metabolism impaired by sulfonamides	B	Yes
Suramin	Trypanosomiasis	Frequent, immediate: fever, urticaria, nausea, vomiting, hypotension. Frequent, delayed (up to 24 h): exfoliative dermatitis, stomatitis, paresthesias, photophobia, renal dysfunction. Occasional: nephrotoxicity, adrenal toxicity, optic atrophy, anaphylaxis	No major interactions	Not assigned	No information
Tetracyclines	Balantidiasis, *D. fragilis* infection, malaria	Frequent: gastrointestinal disturbances. Occasional: photosensitivity dermatitis. Rare: exfoliative dermatitis, esophagitis, hepatotoxicity	Warfarin: effect prolonged by tetracyclines	D	Yes
Thiabendazole	Strongyloidiasis,[b] cutaneous larva migrans,[b] visceral larva migrans[b]	Frequent: anorexia, nausea, vomiting, diarrhea, headache, dizziness, asparagus-like urine odor. Occasional: drowsiness, giddiness, crystalluria, elevated aminotransferases, psychosis. Rare: hepatitis, seizures, angioneurotic edema, Stevens-Johnson syndrome, tinnitus	Theophylline: serum levels increased by thiabendazole	C	No information
Tinidazole	Amebiasis,[b] giardiasis, trichomoniasis	Occasional: nausea, vomiting, metallic taste	See metronidazole	Not assigned	No information
Triclabendazole	Fascioliasis, paragonimiasis	Occasional: abdominal cramps, diarrhea, biliary colic, transient headache	No information	Not assigned	Yes
Trimethoprim-sulfamethoxazole	Cyclosporiasis, isosporiasis, pneumocystosis	See sulfonamides	See sulfonamides	C	Yes

[a] Based on U.S. Food and Drug Administration (FDA) pregnancy categories A through D and X.
[b] Approved by the FDA for this indication.
[c] Not believed to be harmful.
[d] Only AmBisome has been approved for this indication.
[e] Use in pregnancy is recommended by international organizations outside the United States.
Abbreviations: ACTH, adrenocorticotropic hormone; AV, atrioventricular; CNS, central nervous system; ECG, electrocardiogram; G6PD, glucose 6-phosphate dehydrogenase; MAO, monoamine oxidase.

cellular metabolism offers treatment for a wide range of parasitic diseases.

Albendazole is poorly absorbed from the gastrointestinal tract. Administration with a fatty meal increases its absorption by two- to six-fold. While poor absorption may be advantageous for the treatment of intestinal helminths, successful treatment of tissue helminth infections such as hydatid disease or neurocysticercosis requires that a sufficient quantity of active drug reach the site of infection. The metabolite albendazole sulfoxide is responsible for the drug's therapeutic effect outside the gut lumen. Significant quantities of this metabolite are measurable in lung and liver tissues and in hydatid cyst fluid obtained at surgery. Cyst concentrations are considerably higher than those obtained with mebendazole. Albendazole sulfoxide crosses the blood-brain barrier, reaching a level significantly higher than that achieved in plasma. The high concentrations of albendazole sulfoxide attained in cerebrospinal fluid (CSF) probably explain the efficacy of albendazole in the treatment of neurocysticercosis.

Albendazole is extensively metabolized in the liver, but there are few data regarding the drug's use in patients with significant hepatocellular disease. Prolonged therapy with full-dose albendazole (800 mg/d) should be approached cautiously in patients also receiving drugs with known effects on the cytochrome P450 system. A single dose of 400 mg is generally recommended for clearance of gastrointestinal nematode infection in both adults and children >2 years of age.

Single-dose albendazole therapy in humans is largely without side effects (overall frequency, ≤1%). More prolonged courses (e.g., as administered for cystic and alveolar echinococcal disease) have been associated with liver function abnormalities and bone marrow toxicity. Thus, when prolonged use is anticipated, the drug should be administered in treatment cycles of 28 days interrupted by 14 days off therapy.

Amphotericin B See Table 193-1 and Chap. 182.

Antimonials* Despite associated adverse reactions and the need for prolonged parenteral treatment, the pentavalent antimonial compounds (designated Sb^v) have remained the first-line therapy for all forms of leishmaniasis throughout the world, primarily because they are affordable, are effective, and have survived the test of time. Although they have been used for almost 100 years, their mechanism of action against *Leishmania* spp. remains unknown. Presumably, the compounds interfere with parasite metabolism. The drugs are taken up by the reticuloendothelial system, and their activity against *Leishmania* spp. may be enhanced by this localization. Sodium stibogluconate is the only pentavalent antimonial available in the United States; meglumine antimonate is principally used in francophone countries.

Resistance is a major problem in some areas. Although low-level unresponsiveness to Sb^v was identified in India in the 1970s, incremental increases in both the recommended daily dosage (to 20 mg/kg) and the duration of treatment (to 28 days) satisfactorily compensated for the growing resistance until around 1990. Since that time, there has been steady erosion in the capacity of Sb^v to induce long-term cure in patients with kala-azar who live in eastern India. Foremost among the many factors that have probably contributed to this failure is the provision of suboptimal treatment for years, which led to the development of drug resistance among parasites. Co-infection with HIV impairs the response to therapy.

Sodium stibogluconate is available in aqueous solution and is administered parenterally. Antimony appears to have two elimination phases. When administered intravenously, the mean half-life of the first phase is <2 h; the mean half-life of the terminal elimination phase is nearly 36 h. This slower phase may be due to conversion of pentavalent antimony to a trivalent form that is the likely cause of the side effects often seen with prolonged therapy.

Artemisinin Derivatives Artesunate, artemether, arteether, and the parent compound artemisinin are sesquiterpene lactones derived from the wormwood plant *Artemisia annua*. These agents are at least ten-fold more potent in vivo than other antimalarial drugs and presently show no cross-resistance with known antimalarials; thus they have become first-line treatments for severe falciparum malaria in some areas where multidrug resistance is a major problem. They are rapidly effective against the asexual blood forms of *Plasmodium* spp., including multidrug-resistant *Plasmodium falciparum*, but they are not active against intrahepatic forms. A combined formulation of artemether and lumefantrine has been developed for the treatment of acute uncomplicated falciparum malaria in areas where *P. falciparum* is resistant to chloroquine and antifolates. Artemether appears to be effective for the treatment of schistosomiasis and is being evaluated for community-based treatment programs.

The antimalarial effect of artemisinin compounds results primarily from dihydroartemisinin, a compound to which artemether and artesunate are both converted. In the presence of antiparasitic iron, dihydroartemisinin produces superoxide radicals, resulting in damage to parasite proteins. Long treatment courses are required. When these agents are used alone, recrudescence may occur. The compounds are available for oral, rectal, intravenous, or intramuscular administration, depending on the derivative. Artemisinin and its derivatives are cleared rapidly from the circulation. Their short half-lives limit their value for prophylaxis. These drugs are not available in the United States.

Atovaquone Atovaquone is a hydroxynaphthoquinone that exerts broad-spectrum antiprotozoal activity via selective inhibition of parasite mitochondrial electron transport. Atovaquone is an alternative to trimethoprim-sulfamethoxazole for the treatment of *Pneumocystis* pneumonia. This agent exhibits potent activity against toxoplasmosis when used with pyrimethamine. It is active against the erythrocytic and exoerythrocytic stages of *Plasmodium* spp.; when combined with proguanil or doxycycline, it is effective for both treatment and prophylaxis of malaria. Malarone is a fixed-dose combination of atovaquone and proguanil used for malaria prophylaxis as well as for the treatment of acute, uncomplicated *P. falciparum* malaria. Malarone has been shown to be effective in regions with multidrug-resistant *P. falciparum*. Resistance to atovaquone has yet to be reported, although strains of *P. falciparum* with diminished susceptibility to atovaquone alone can be selected both in vitro and in vivo. The drug does not eradicate hypnozoites from the liver; thus patients with *P. vivax* or *P. ovale* infections must be given radical prophylaxis.

The bioavailability of atovaquone varies considerably. Absorption after a single oral dose is slow, increases two- to three-fold with a fatty meal, and is dose-limited above 750 mg. The elimination half-life is increased in patients with moderate hepatic impairment. Because of the potential for drug accumulation, the use of atovaquone is contraindicated in persons with severe renal impairment (creatinine clearance rate <30 mL/min). No dosage adjustments are needed in patients with mild to moderate renal impairment. It is unknown if atovaquone is dialyzable.

Azithromycin See Table 193-1 and Chap. 118.

Azoles See Table 193-1 and Chap. 182.

Benznidazole This oral nitroimidazole derivative is used to treat Chagas' disease, with cure rates of 80 to 90% recorded in acute infections. Benznidazole exerts its trypanocidal effects by generating oxygen radicals to which the parasite is more sensitive than mammalian cells because of a relative deficiency in antioxidant enzymes. Benznidazole also appears to alter the balance between pro- and anti-inflammatory mediators by downregulating the synthesis of nitrite, interleukin (IL) 6, and IL-10 in macrophages.

Benznidazole is highly lipophilic and readily absorbed. The drug is extensively metabolized; only 5% of the dose is excreted unchanged in the urine. Benznidazole is currently unavailable in the United States.

Chloroquine This 4-aminoquinoline has marked, rapid schizontocidal and gametocidal activity against blood forms of *P. ovale* and *Plasmodium malariae* and against susceptible strains of *P. vivax* and *P. falciparum*. It is not active against intrahepatic forms (*P. vivax* and *P. ovale*). Chloroquine is concentrated in the acidic food vacuoles of intraerythrocytic parasites, reaching levels at this site that are 600-fold higher than plasma levels. The drug inhibits a parasite heme polymerase; as a result, the parasite is effectively killed with its own metabolic waste. Compared with susceptible strains, chloroquine-resistant plasmodia transport chloroquine out of intraparasitic compartments more rapidly and maintain lower chloroquine concentrations in their acid vesicles. Hydroxychloroquine, a congener of chloroquine, is equivalent to chloroquine in its antimalarial efficacy but is preferred to chloroquine for the treatment of autoimmune disorders because it produces less ocular toxicity when used in high doses.

Chloroquine is well absorbed. However, because it exhibits extensive tissue binding, a loading dose is required to yield effective plasma concentrations. A therapeutic drug level in plasma is reached 2 to 3 h after oral administration (the preferred route). Chloroquine can be administered intravenously, but excessively rapid parenteral administration can result in seizures and death from cardiovascular collapse. The mean half-life of chloroquine is 4 days, but the rate of excretion decreases as plasma levels decline, making once-weekly administration possible for prophylaxis in areas with sensitive strains. About half of the parent drug is excreted in urine, but the dose should not be reduced for persons with acute malaria and renal insufficiency.

Ciprofloxacin See Table 193-1 and Chap. 118.

Clindamycin See Table 193-1 and Chap. 118.

Dapsone See Table 193-1 and Chap. 149.

Diethylcarbamazine* A derivative of the antihelminthic agent piperazine with a long history of successful use, diethylcarbamazine (DEC) remains the treatment of choice for lymphatic filariasis and loiasis and has also been used for visceral larva migrans. While piperazine itself has no antifilarial activity, the piperazine ring of DEC is essential for activity of the drug. DEC exerts various effects on helminths, including immobilization due to a decrease in muscle activity, disruption of microtubule formation, and alteration of helminthic surface membranes resulting in enhanced killing by the host's immune system. In addition, this agent enhances adherence properties of eosinophils. The development of resistance under drug pressure (i.e., a progressive decrease in efficacy when the drug is used widely in human populations) has not been observed, although the drug's effect is variable when administered to persons with filariasis. Monthly administration provides effective prophylaxis against both bancroftian filariasis and loiasis.

DEC is well absorbed after oral administration, with peak plasma concentrations reached within 1 to 2 h. No parenteral form is available. The drug is eliminated largely by renal excretion, with <5% found in feces. If more than one dose is to be administered to an individual with renal dysfunction, the dose should be reduced commensurate with the reduction in creatinine clearance rate. Alkalinization of the urine prevents renal excretion and increases the half-life of the drug. Use in patients with onchocerciasis can precipitate a Mazzotti reaction, with pruritus, fever, and arthralgias.

Diloxanide Furoate Diloxanide furoate, a substituted acetanilide, is a luminally active agent used to eradicate the cysts of *Entamoeba histolytica*. After ingestion, diloxanide furoate is hydrolyzed by enzymes in the lumen or mucosa of the intestine, releasing furoic acid and the ester diloxanide, the latter of which acts directly as an amebicide.

Diloxanide furoate is given alone in asymptomatic cyst passers. For patients with active amebic infections, diloxanide is generally administered in combination with a 5-nitroimidazole such as metronidazole or tinidazole. Diloxanide furoate is rapidly absorbed after oral administration. When coadministered with a 5-nitroimidazole, only diloxanide appears in the systemic circulation; levels peak within 1 h and disappear within 6 h. About 90% of an oral dose is excreted in the urine within 48 h, chiefly as the glucuronide metabolite. Diloxanide furoate is contraindicated in pregnant and breast-feeding women and in children <2 years of age. The drug is not currently available in the United States.

Eflornithine† Eflornithine (difluoromethylornithine, or DFMO) is a fluorinated analogue of the amino acid ornithine. Although originally designed as an antineoplastic agent, eflornithine has proven effective against some trypanosomatids as well as *Pneumocystis*. At one point, the production of this effective agent ceased despite the increasing incidence of human African trypanosomiasis; however, production resumed after eflornithine was discovered to be an effective cosmetic depilatory agent.

Eflornithine has specific activity against all stages of infection with *Trypanosoma brucei gambiense*; however, it is inactive against *T. b. rhodesiense*. The drug acts by irreversibly inhibiting ornithine decarboxylase—an enzyme critical to the formation of polyamines, which are essential to the growth, differentiation, and replication of the trypanosomatids. The diminished effectiveness of eflornithine against *T. b. rhodesiense* appears to be due to the parasite's ability to replace the inhibited enzyme more rapidly than *T. b. gambiense*. Eflornithine is less toxic but more costly than conventional therapy. Supplies of the drug are very limited due to the aforementioned halt in production.

Eflornithine HCl can be administered intravenously or orally; however, its bioavailability after oral administration is only 54%. Eflornithine readily crosses the blood-brain barrier; CSF levels are highest in persons with the most severe central nervous system involvement. The kidney excretes >80% of the drug; therefore, the dosage should be reduced in patients with renal failure.

Fumagillin Fumagillin, an antibiotic derived from the fungus *Aspergillus fumigatus*, has been used to treat microsporidiosis in honeybees and has been effective against other microsporidia in vitro. This agent was used >40 years ago for the treatment of intestinal amebiasis, and it is effective when used topically in the treatment of microsporidial keratoconjunctivitis.

Fumagillin is being investigated as an angiogenesis inhibitor for the treatment of solid tumors.

Fumagillin exerts its antineoplastic action by inhibiting endothelial cell proliferation and angiogenesis. However, the mechanisms by which fumagillin inhibits microsporidial replication are poorly understood. Fumagillin is not yet available in the United States.

Furazolidone This nitrofuran derivative is an effective alternative agent for the treatment of giardiasis and exhibits activity against *Isospora belli*. Like other nitrofurans, it acts by damaging DNA. Since it is the only agent active against *Giardia* that is available in liquid form, it is often used to treat young children. Although furazolidone had been thought to be largely unabsorbed when administered orally, the occurrence of systemic adverse reactions indicates that this is not the case. More than 65% of the drug can be recovered from the urine as colored metabolites.

Furazolidone is a monoamine oxidase (MAO) inhibitor; thus caution should be used in its concomitant administration with other drugs (especially indirectly acting sympathomimetic amines) and in the consumption of food and drink containing tyramine during treatment. However, hypertensive crises have not been reported in patients receiving furazolidone, and it has been suggested that—since furazolidone inhibits MAO gradually over several days—the risks are small if treatment is limited to a 5-day course. Because hemolytic anemia can occur in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency and glutathione instability, furazolidone treatment is contraindicated in mothers who are breast-feeding and in neonates.

Halofantrine This 9-phenanthrenemethanol is one of three classes of arylaminoalcohols first identified as potential antimalarial agents by the World War II Malaria Chemotherapy Program. Its activity is believed to be similar to that of chloroquine, although it is an oral alternative for the treatment of malaria due to chloroquine-resistant *P. falciparum*. The mechanism of action is poorly understood.

Halofantrine exhibits erratic bioavailability, but its absorption is significantly enhanced when it is taken with a fatty meal. The elimination half-life of halofantrine is 1 to 2 days; it is excreted mainly in feces. Halofantrine is metabolized into *N*-debutyl-halofantrine by the cytochrome P450 enzyme CYP3A4. Grapefruit juice should be avoided during treatment because it increases both halofantrine's bioavailability and halofantrine-induced QT interval prolongation by inhibiting CYP3A4 at the enterocyte level. Halofantrine is currently unavailable in the United States.

Iodoquinol Iodoquinol (diiodohydroxyquin), a hydroxyquinoline, is an effective luminal agent for the treatment of amebiasis, balantidiasis, and infection with *Dientamoeba fragilis*. Its mechanism of action is unknown. It is poorly absorbed. Because the drug contains 64% organically bound iodine, it should be used with caution in patients with thyroid disease. Iodine dermatitis occurs occasionally during iodoquinol treatment. Protein-bound serum iodine levels may be increased during treatment and can interfere with certain tests of thyroid function. These effects may persist for as long as 6 months after discontinuation of therapy. Iodoquinol is contraindicated in patients with liver disease. Most serious are the reactions related to prolonged high-dose therapy (optic neuritis, peripheral neuropathy), which should not occur if the recommended dosage regimens are followed.

Ivermectin Ivermectin (22,23 dihydroavermectin) is a derivative of the macrocyclic lactone avermectin produced by the soil-dwelling acti-

nomycete *Streptomyces avermitilis*. Ivermectin is active at low doses against a wide range of helminths and ectoparasites. It is the drug of choice for the treatment of onchocerciasis, strongyloidiasis, cutaneous larva migrans, and scabies. Ivermectin is highly active against microfilariae of the lymphatic filariases but has no macrofilaricidal activity. When ivermectin is used in combination with other agents such as diethylcarbamazine or albendazole for treatment of lymphatic filariasis, synergistic activity is seen. While active against the intestinal helminths *Ascaris lumbricoides* and *Enterobius vermicularis*, ivermectin is only variably effective in trichuriasis and is ineffective against hookworms. Widespread use of ivermectin for treatment of intestinal nematode infections in sheep and goats has led to the emergence of drug resistance in veterinary practice; this development may portend problems in human medical use.

Recent data suggest that ivermectin acts by opening the neuromuscular membrane-associated, glutamate-dependent chloride channels that are unique to nematodes and arthropods. In this proposed scenario, the result is an influx of chloride ions followed by worm paralysis and subsequent death (via immune or other mechanisms).

Because of its low water solubility, ivermectin is available only as an oral formulation. The drug is highly protein bound; it is almost completely excreted in feces. The effect of food on bioavailability is unknown. Ivermectin is distributed widely throughout the body; animal studies indicate that it accumulates at the highest concentration in adipose tissue and liver, with little accumulation in the brain. Few data exist to guide therapy in hosts with conditions that may influence drug pharmacokinetics.

Ivermectin is generally administered as a single dose of 150 to 200 μg/kg. In the absence of parasitic infection, the adverse effects of ivermectin in therapeutic doses are minimal. Adverse effects in patients with filarial infections include fever, myalgia, malaise, lightheadedness, and (occasionally) postural hypotension. The severity of such side effects is related to the intensity of parasite infection, with more symptoms in individuals with a heavy parasite burden. In onchocerciasis, skin edema, pruritus, and mild eye irritation may also occur. The adverse effects are generally self-limiting and only occasionally require symptom-based treatment with antipyretics or antihistamines. More severe complications of ivermectin therapy for onchocerciasis include encephalopathy in patients heavily infected with *Loa loa*. This reaction has led to the suspension of ivermectin distribution for this indication in regions where the two filarial infections are coendemic.

Lumefantrine Lumefantrine (benflumetol), a fluorene (benzindene) derivative synthesized in the 1970s by the Chinese Academy of Military Medical Sciences (Beijing), has marked blood schizontocidal activity against a wide range of plasmodia. This agent conforms structurally and in mode of action to the arylaminoalcohol group of antimalarial drugs, including quinine, mefloquine, and halofantrine. Lumefantrine exerts its antimalarial effect as a consequence of its interaction with heme, a degradation product of hemoglobin metabolism. Its antimalarial activity is slower than that of the artemisinin-based drugs, but at the recommended dose regimen the recrudescence rate with lumefantrine is lower. The pharmacokinetic properties of lumefantrine are reminiscent of those of halofantrine, with variable oral bioavailability, considerable augmentation of oral bioavailability by concomitant fat intake, and a terminal elimination half-life of ~4 to 5 days in patients with malaria.

Artemether and lumefantrine have synergistic activity, and clinical studies in China on several hundred patients show the combination to be safe and well tolerated. The combined formulation of artemether and lumefantrine has been developed for the treatment of falciparum malaria in areas where *P. falciparum* is resistant to chloroquine and antifolates. Neither drug is available in the United States.

Mebendazole This benzimidazole is a broad-spectrum antiparasitic agent widely used to treat intestinal helminthiases. Its mechanism of action is similar to that of albendazole.

Mebendazole is available only in oral form but is poorly absorbed from the gastrointestinal tract; only 5 to 10% of a standard dose is measurable in plasma. The proportion absorbed from the gastrointestinal tract is extensively metabolized in the liver. Metabolites appear in the urine and bile; impaired liver or biliary function results in higher plasma mebendazole levels in treated patients. No dose reduction is warranted in patients with renal function impairment. Because mebendazole is poorly absorbed, its incidence of side effects is low. Transient abdominal pain and diarrhea sometimes occur, usually in persons with massive parasite burdens.

Mefloquine Like quinine and chloroquine, this quinoline is active only against the asexual erythrocytic stages of malarial parasites. It is the preferred drug for prophylaxis of chloroquine-resistant malaria; high doses can be used for treatment. Despite the recent development of drug-resistant strains of *P. falciparum* in parts of Africa and Southeast Asia, mefloquine is an effective drug throughout most of the world. Cross-resistance of mefloquine with halofantrine and with quinine has been documented in limited areas. Mefloquine's mode of action is similar to that of chloroquine, but mefloquine is not concentrated so extensively in the food vacuole and may act on alternative targets in the parasite.

Mefloquine HCl is available as 250-mg tablets (equivalent to 228.0 mg of the free base). The presence of food significantly enhances the rate and extent of absorption. About 98% of the drug binds to protein. Mefloquine is excreted mainly in the bile and feces; therefore, no dose adjustment is needed in persons with renal insufficiency. The drug and its main metabolite are not appreciably removed by hemodialysis. No special chemoprophylactic dosage adjustments are indicated for dialysis patients to achieve plasma concentrations similar to those in healthy persons. Pharmacokinetic differences have been detected between various ethnic populations. In practice, however, these are of minor importance compared with host immune status and parasite sensitivity. In patients with impaired liver function, the elimination of mefloquine may be prolonged, leading to higher plasma levels.

Mefloquine should be used with caution in individuals participating in activities requiring alertness and fine-motor coordination (e.g., driving, piloting aircraft, operating machinery, and deep-sea diving). If the drug is to be administered for a prolonged period, periodic evaluations are recommended, including liver function tests and ophthalmic examinations. Sleep abnormalities (insomnia, abnormal dreams) have occasionally been reported. Psychosis and seizures occur rarely; mefloquine should not be prescribed to patients with neuropsychiatric conditions, including depression, generalized anxiety disorder, psychosis, schizophrenia, and seizure disorder. If acute anxiety, depression, restlessness, or confusion develops during prophylaxis, these psychiatric symptoms may be considered prodromal to a more serious event, and the drug should be discontinued.

Concomitant use of quinine, quinidine, or drugs producing β-adrenergic blockade may cause significant electrocardiographic abnormalities or cardiac arrest. Halofantrine must not be given simultaneously with or $<$3 weeks after mefloquine because a potentially fatal prolongation of the QTc interval on electrocardiography may occur. No data exist on mefloquine use after halofantrine use. Administration of mefloquine with quinine or chloroquine may increase the risk of convulsions. Mefloquine may lower plasma levels of anticonvulsants. Caution should be exercised with regard to concomitant antiretroviral therapy, since mefloquine has been shown to exert variable effects on ritonavir pharmacokinetics that are not explained by hepatic CYP3A4 activity or ritonavir protein binding. Vaccinations with attenuated live bacteria should be completed at least 3 days before the first dose of mefloquine.

Women of childbearing age who are traveling to areas where malaria is endemic should be warned against becoming pregnant and encouraged to practice contraception during malaria prophylaxis with mefloquine and for up to 3 months thereafter. However, in the case of unplanned pregnancy, use of mefloquine is not considered an indication for pregnancy termination.

Melarsoprol* This trivalent arsenical compound has been used outside the United States since 1949 for the treatment of human African trypanosomiasis (HAT). It is considered investigational in the United States and is indicated for the treatment of HAT with neurologic involvement and for the treatment of early HAT that is resistant to suramin or pentamidine. The drug enters the parasite via an adenosine transporter; resistant strains lack this transport system. Arsenicals react avidly with sulfhydryl groups on proteins, inhibiting their function. This is the likely mechanism of action and the cause of the severe adverse reactions that commonly occur. Resistance to melarsoprol is attributed to the expression of an unusual purine transporter, resulting in altered drug uptake.

Melarsoprol is always administered intravenously. The most common treatment protocol consists of three or four series of three or four injections each (one intravenous injection per day) separated by rest periods. A recently proposed alternative protocol for *T. b. gambiense* HAT appears to be similarly efficacious and consists of 10 consecutive injections of 2.2 mg/kg per day. A small but therapeutically significant amount of the drug enters the CSF. The compound is excreted rapidly, with ~80% of the arsenic found in feces.

Melarsoprol is highly toxic. The most serious adverse reaction is reactive encephalopathy, which affects 6% of treated individuals and usually develops within 4 days of the start of therapy, with an average case-fatality rate of 50%. Glucocorticoids are administered with melarsoprol to prevent this development. Because melarsoprol is intensely irritating, care must be taken to avoid infiltration of the drug.

Metrifonate This organophosphorous compound has selective activity against *Schistosoma haematobium*. Metrifonate is a prodrug; it is converted nonenzymatically to dichlorvos (2,2-dichlorovinyl dimethylphosphate, DDVP), a highly active chemical that irreversibly inhibits the acetylcholinesterase enzyme. Schistosomal cholinesterase is more susceptible to dichlorvos than is the corresponding human enzyme. The exact mechanism of action of metrifonate is uncertain, but it is believed to inhibit tegumental acetylcholine receptors that mediate glucose transport.

Metrifonate is administered in a series of three doses at 2-week intervals. After a single oral dose, metrifonate produces a 95% decrease in plasma cholinesterase activity within 6 h, with a fairly rapid return to normal. However, 2.5 months are required for erythrocyte cholinesterase levels to return to normal. Treated persons should not be exposed to neuromuscular blocking agents or organophosphate insecticides for at least 48 h after treatment. Metrifonate is currently unavailable in the United States.

Metronidazole and Other Nitroimidazoles See Table 193-1 and Chap. 118.

Miltefosine Miltefosine (hexadecylphosphocholine), originally developed as an antineoplastic agent, was discovered to have significant antiproliferative activity against *Leishmania* spp., *Trypanosoma cruzi*, and *T. brucei* parasites in vitro and in experimental animal models in the early 1990s. In 1995, Tropical Disease Research, a program sponsored by the WHO and other international groups, entered into an agreement with the company now known as ASTA Medica/Zentaris to develop miltefosine for the treatment of visceral leishmaniasis in India. Miltefosine is the first oral drug that has proved to be highly effective and comparable to amphotericin B against visceral leishmaniasis in India, where antimonial-resistant cases are now prevalent. Miltefosine exerts activity in both previously untreated and pentavalent antimonial–unresponsive visceral infections. A recently concluded study in Colombia demonstrated miltefosine cure rates comparable to those for antimony against cutaneous leishmaniasis.

The activity of miltefosine is attributed to interaction with cell signal transduction pathways and inhibition of phospholipid and sterol biosynthesis.

Resistance to miltefosine has not been observed clinically.

Miltefosine is readily absorbed from the gastrointestinal tract, is widely distributed, and accumulates in several tissues. The efficacy of a 28-day treatment course in Indian visceral leishmaniasis is equivalent to that of amphotericin B therapy; however, it appears that a shortened course of 21 days may be equally efficacious.

General recommendations for the use of miltefosine are limited by the exclusion of specific groups from the published clinical trials: persons <12 or >65 years of age, persons with the most advanced disease, breast-feeding women, HIV-infected patients, and individuals with significant renal or hepatic insufficiency. Miltefosine is currently unavailable in the United States.

Niclosamide Niclosamide is active against a wide variety of adult tapeworms but not against tissue cestodes. It is also a molluscacide and is used in snail-control programs. The drug acts by inhibiting oxidative phosphorylation in worm mitochondria, with consequent energy depletion. Use of the drug is limited by side effects, necessary duration of therapy, the recommended use of purgatives, and—most important—limited availability (i.e., availability on a named-patient basis from the manufacturer).

Niclosamide is poorly absorbed. Tablets are given on an empty stomach in the morning after a liquid meal the night before, and this dose is followed by another 1 h later. For treatment of hymenolepiasis, the drug is administered for 7 days. A second course is often prescribed. The scolex and proximal segments of the tapeworms are killed on contact with niclosamide and may be digested in the gut. However, disintegration of the adult tapeworm results in the release of viable ova, which theoretically can result in autoinfection. Although fears of the development of cysticercosis in patients with *Taenia solium* infections have proved unfounded, it is still recommended that a brisk purgative be given 2 h after the first dose. Niclosamide is no longer approved for use in the United States.

Nifurtimox* This nitrofuran compound is a cheap and effective oral agent for the treatment of acute Chagas' disease. Intracellular reduction followed by auto-oxidation yielding oxygen radicals has been suggested as the mode of action of nifurtimox on *T. cruzi* and as the basis of the drug's toxicity to humans. Prolonged use is required, but the course may have to be interrupted because of drug toxicity, which develops in 40 to 70% of recipients.

Nifurtimox is well absorbed and undergoes rapid and extensive biotransformation: <0.5% of the original drug is excreted in urine.

Nitazoxanide† Nitazoxanide is a 5-nitrothiazole compound used for the treatment of cryptosporidiosis and giardiasis; it is active against other intestinal protozoa as well. The drug is approved for use in children 1 through 11 years of age.

The antiprotozoal activity of nitazoxanide is believed to be due to interference with the pyruvate-ferredoxin oxidoreductase (PFOR) enzyme–dependent electron transfer reaction that is essential to anaerobic energy metabolism. Studies have shown that the PFOR enzyme from *Giardia lamblia* directly reduces nitazoxanide by transfer of electrons in the absence of ferredoxin. The DNA-derived PFOR protein sequence of *Cryptosporidium parvum* appears to be similar to that of *G. lamblia*. Interference with the PFOR enzyme–dependent electron transfer reaction may not be the only pathway by which nitazoxanide exerts antiprotozoal activity.

Nitazoxanide is currently available only as an oral suspension. After oral administration, nitazoxanide is rapidly hydrolyzed to an active metabolite, tizoxanide (desacetyl-nitazoxanide). Tizoxanide then undergoes conjugation, primarily by glucuronidation. It is recommended that nitazoxanide be taken with food; however, no studies have been conducted to determine whether the pharmacokinetics of tizoxanide and tizoxanide glucuronide differ in fasted versus fed subjects. Tizoxanide is excreted in urine, bile, and feces, and tizoxanide glucuronide is excreted in urine and bile. The pharmacokinetics of nitazoxanide in patients with impaired hepatic and/or renal function have not been studied. Tizoxanide is highly bound to plasma protein (>99.9%). Therefore, caution should be used when administering this agent concurrently with other highly plasma protein–bound drugs with narrow therapeutic indices, as competition for binding sites may occur.

Oxamniquine This tetrahydroquinoline derivative is an effective alternative agent for the treatment of *Schistosoma mansoni*, although susceptibility to this drug exhibits regional variation. Oxamniquine exhibits anticholinergic properties, but its primary mode of action seems to rely on ATP-dependent enzymatic drug activation generating an intermediate that alkylates essential macromolecules, including DNA. In treated adult schistosomes, oxamniquine produces marked tegumental alterations similar to those seen with praziquantel but developing less rapidly (i.e., evident 4 to 8 days after treatment).

Oxamniquine is administered orally as a single dose and is well absorbed. Food retards absorption and reduces bioavailability. About 70% of an administered dose is excreted in urine as a mixture of pharmacologically inactive metabolites. Patients should be warned that their urine might have an intense orange-red color. Side effects are uncommon and usually mild, although hallucinations and seizures have been reported. Oxamniquine remains unavailable in the United States.

Paromomycin (Aminosidine) First isolated in 1956, this aminoglycoside is an effective oral agent for the treatment of infections due to intestinal protozoa. Parenteral paromomycin appears to be effective against visceral leishmaniasis in India.

Paromomycin inhibits protozoan protein synthesis by binding to the 30S ribosomal RNA in the aminoacyl-tRNA site, causing misreading of mRNA codons. Paromomycin is less active against *G. lamblia* than standard agents; however, like other aminoglycosides, paromomycin is poorly absorbed from the intestinal lumen, and the high levels of drug in the gut compensate for this relatively weak activity. If absorbed or administered systemically, paromomycin can cause ototoxicity and nephrotoxicity. However, systemic absorption is very limited, and toxicity should not be a concern in persons with normal kidneys. Topical formulations are not generally available.

Pentamidine Isethionate This diamidine is an effective alternative agent for *Pneumocystis* pneumonia and for some forms of leishmaniasis and trypanosomiasis. It is available for parenteral and aerosolized administration. While its mechanism of action remains undefined, it is known to exert a wide range of effects, including interaction with trypanosomal kinetoplast DNA; interference with polyamine synthesis by a decrease in the activity of ornithine decarboxylase; and inhibition of RNA polymerase, ribosomal function, and the synthesis of nucleic acids and proteins.

Pentamidine isethionate is well absorbed, is highly tissue bound, and is excreted slowly over several weeks, with an elimination half-life of 12 days. No steady-state plasma concentration is attained in persons given daily injections; the result is extensive accumulation of pentamidine in tissues, primarily the liver, kidney, adrenal, and spleen. Pentamidine does not penetrate well into the central nervous system. Pulmonary concentrations of pentamidine are increased when delivered in aerosolized form.

Praziquantel This heterocyclic pyrazinoisoquinoline derivative is highly active against a broad spectrum of trematodes and cestodes. It is the mainstay of treatment for schistosomiasis and is a critical part of community-based control programs.

All of the effects of praziquantel can be attributed either directly or indirectly to an alteration of intracellular calcium concentrations. Although the exact mechanism of action remains unclear, the major mechanism is disruption of the parasite tegument, causing tetanic contractures with loss of adherence to host tissues and, ultimately, disintegration or expulsion. Praziquantel induces changes in the antigenicity of the parasite by causing the exposure of concealed antigens. Praziquantel also produces alterations in schistosomal glucose metabolism, including decreases in glucose uptake, lactate release, glycogen content, and ATP levels.

Praziquantel exerts its parasitic effects directly and does not need to be metabolized to be effective. It is well absorbed but undergoes extensive first-pass hepatic clearance. Levels of the drug are increased when it is taken with food, particularly carbohydrates, or with cimetidine. Serum levels are reduced by glucocorticoids, chloroquine, carbamazepine, and phenytoin. Praziquantel is completely metabolized in humans, with 80% of the dose recovered as metabolites in urine within 4 days. It is not known to what extent praziquantel crosses the placenta.

Patients with schistosomiasis who have heavy parasite burdens may develop abdominal discomfort, nausea, headache, dizziness, and drowsiness. Symptoms begin 30 min after ingestion, may require spasmolytics for relief, and usually disappear spontaneously after a few hours.

Primaquine Phosphate This drug is the only agent available for eradication of the hepatic stage of malarial parasites. Primaquine must be metabolized by the host to be effective. It is, in fact, rapidly metabolized; only a small fraction of the dose of the parent drug is excreted unchanged. Although the parasiticidal activity of the three oxidative metabolites remains unclear, they are believed to affect both pyrimidine synthesis and the mitochondrial electron transport chain. The metabolites appear to have significantly less antimalarial activity than primaquine; however, their hemolytic activity is greater than that of the parent drug.

Primaquine causes marked hypotension after parenteral administration and therefore is given only by the oral route. It is rapidly and almost completely absorbed from the gastrointestinal tract.

Patients should be tested for G6PD deficiency before they receive primaquine. Primaquine is otherwise well tolerated.

Proguanil (Chloroguanide) Proguanil inhibits plasmodial dihydrofolate reductase and is used with atovaquone for oral treatment of uncomplicated malaria or with chloroquine for malaria prophylaxis in parts of Africa without widespread chloroquine-resistant *P. falciparum*.

Proguanil primarily exerts its effect by means of the metabolite cycloguanil, whose inhibition of dihydrofolate reductase in the parasite disrupts deoxythymidylate synthesis, thus interfering with a key pathway involved in the biosynthesis of pyrimidines required for nucleic acid replication. There are no clinical data indicating that folate supplementation diminishes drug efficacy; women of childbearing age for whom atovaquone/proguanil is prescribed should continue taking folate supplements to prevent neural-tube birth defects.

Proguanil is extensively absorbed regardless of food intake. The drug is 75% protein-bound. The main routes of elimination are hepatic biotransformation and renal excretion. Between 40 and 60% of proguanil is excreted by the kidneys. Drug levels are increased and elimination is impaired in patients with hepatic impairment. Proguanil is not available in the United States.

Pyrantel Pamoate Pyrantel is a tetrahydropyrimidine formulated as pamoate. This safe, well-tolerated, inexpensive drug is used to treat a variety of intestinal nematode infections but is ineffective in trichuriasis. Pyrantel pamoate is usually effective in a single dose. It depolarizes the neuromuscular junctions of most intestinal nematodes, resulting in their irreversible paralysis and allowing natural expulsion of the worms with the host's feces.

Pyrantel pamoate is poorly absorbed from the intestine; >85% of the dose is passed unaltered in feces. The absorbed portion is metabolized and excreted in urine. Piperazine, which produces hyperpolarization of muscle cells in intestinal helminths, is antagonistic to pyrantel pamoate and should not be used concomitantly.

Pyrantel pamoate has minimal toxicity at the oral doses used to treat intestinal helminthic infection. It is not recommended for pregnant women or children <12 months old.

Pyrimethamine When combined with short-acting sulfonamides, this diaminopyrimidine is effective in malaria, toxoplasmosis, and isosporiasis. Unlike mammalian cells, the parasites that cause these infections cannot utilize preformed pyrimidines obtained through salvage pathways but rather rely completely on de novo pyrimidine synthesis, for which folate derivatives are essential cofactors. The efficacy of pyrimethamine is increasingly limited by the development of

resistant strains of *P. falciparum* and *P. vivax*. Single amino acid substitutions to parasite dihydrofolate reductase confer resistance to pyrimethamine by decreasing the enzyme's binding affinity for the drug.

Pyrimethamine is well absorbed; the drug is 87% bound to human plasma proteins. In healthy volunteers, drug concentrations remain at therapeutic levels for up to 2 weeks; drug levels are lower in patients with malaria. Pyrimethamine is extensively metabolized; <3% is excreted unchanged in urine.

At the usual dosage, pyrimethamine alone causes little toxicity except for occasional skin rashes and blood dyscrasias. Bone marrow suppression sometimes occurs at the higher doses used for toxoplasmosis; at these doses, the drug should be administered with folinic acid.

Quinacrine* First introduced as an antimalarial agent in 1930, quinacrine is the only drug approved by the FDA for the treatment of giardiasis. Its production was discontinued in 1992. Although not commercially available, quinacrine can be obtained from alternative sources through the CDC Drug Service. The antiprotozoal mechanism of quinacrine has not been fully elucidated. Quinacrine, a substituted acridine, intercalates into parasite DNA, and it is this interaction that is thought to cause an inhibition of nucleic acid synthesis. The drug inhibits NADH oxidase—the same enzyme that activates furazolidone. The differing relative quinacrine uptake rate between human cells and *G. lamblia* may explain the selective toxicity of the drug. Resistance correlates with decreased drug uptake.

Quinacrine is rapidly absorbed from the intestinal tract and is widely distributed in body tissues. Alcohol is best avoided due to a disulfiram-like effect.

Quinine and Quinidine When combined with another agent, the cinchona alkaloid quinine is effective for the oral treatment of both uncomplicated, chloroquine-resistant malaria and babesiosis. Quinine acts rapidly against the asexual blood stages of all forms of human malaria. For severe malaria, only quinidine (the dextroisomer of quinine) is available in the United States. Quinine concentrates in the acidic food vacuoles of *Plasmodium* spp. The drug inhibits the nonenzymatic polymerization of the highly reactive, toxic heme molecule into a nontoxic polymer pigment called *hemozoin*.

Quinine is readily absorbed when given orally. In patients with malaria, the elimination half-life of quinine increases according to the severity of the infection. However, toxicity is avoided by an increase in the concentration of plasma glycoproteins. The cinchona alkaloids are extensively metabolized, particularly by CYP3A4; only 20% of the dose is excreted unchanged in urine. The drug's metabolites are also excreted in urine and may be responsible for toxicity in patients with renal failure. Renal excretion of quinine is decreased when cimetidine is taken and increased when the urine is acidic. The drug readily crosses the placenta.

Quinidine is both more potent as an antimalarial and more toxic than quinine. Its use requires cardiac monitoring. Dose reduction is necessary in persons with severe renal impairment.

Spiramycin† This macrolide is used to treat acute toxoplasmosis in pregnancy and congenital toxoplasmosis. While the mechanism of action is similar to that of other macrolides, the efficacy of spiramycin in toxoplasmosis appears to stem from its rapid and extensive intracellular penetration, resulting in macrophage drug concentrations 10 to 20 times greater than serum concentrations.

Spiramycin is rapidly and widely distributed throughout the body and reaches concentrations in the placenta up to five times those in serum. This agent is excreted mainly in bile. Indeed, in humans, the urinary excretion of active compounds represents only 20% of the administered dose.

Serious reactions to spiramycin are rare. Of the available macrolides, spiramycin appears to have the lowest risk of drug interactions. Complications of treatment are rare but, in neonates, can include life-threatening ventricular arrhythmias that disappear with drug discontinuation. Although not yet licensed in the United States, spiramycin is available through the FDA.

Sulfonamides See Table 193-1 and Chap. 118.

Suramin* This derivative of urea is the drug of choice for the early stage of African trypanosomiasis. The drug is polyanionic and acts by forming stable complexes with proteins, inhibiting multiple enzymes essential to parasite energy metabolism.

Suramin is parenterally administered. It binds to plasma proteins and persists at low levels for several weeks after infusion. Its metabolism is negligible. This drug does not penetrate the central nervous system.

Tetracyclines See Table 193-1 and Chap. 118.

Thiabendazole Discovered in 1961, thiabendazole remains one of the most potent of the numerous benzimidazole derivatives. However, its use has declined significantly because of a higher frequency of adverse effects than is seen with other, equally effective agents.

Thiabendazole is available in tablet form and as an oral suspension. The drug is rapidly absorbed from the gastrointestinal tract but can also be absorbed through the skin. Thiabendazole should be taken after meals. This agent is extensively metabolized in the liver before ultimately being excreted, principally as glucuronide or sulfate conjugates of 5-hydroxythiabendazole. Within 48 h, 87% of an oral dose of thiabendazole is excreted in urine, and 5% is excreted in feces; most of the dose is excreted within the first 24 h. The usual dose of thiabendazole is determined by the patient's weight, but some treatment regimens are parasite-specific. No specific adjustments are recommended in patients with renal or hepatic failure; only cautious use is advised.

Thiabendazole is active against most intestinal nematodes that infect humans. Although the exact mechanism of its antihelminthic activity has not been fully elucidated, it is likely to be similar to that of other benzimidazole drugs: namely, inhibition of polymerization of parasite β-tubulin. The drug also inhibits the helminth-specific enzyme fumarate reductase. In animals, thiabendazole has anti-inflammatory, antipyretic, and analgesic effects, which may explain its usefulness in dracunculiasis and trichinosis. Thiabendazole also suppresses egg and/or larval production by some nematodes and may inhibit the subsequent development of eggs or larvae passed in feces. Despite the emergence and global spread of thiabendazole-resistant trichostrongyliasis among sheep, there have been no reports of drug resistance in humans.

Coadministration of thiabendazole in patients taking theophylline can result in an increase in theophylline levels by >50%. Therefore, serum levels of theophylline should be monitored closely in this situation.

Tinidazole This nitroimidazole is effective for the treatment of amebiasis, giardiasis, and trichomoniasis. Its mechanism of action and side effects are similar to those of metronidazole, but adverse events appear to be less frequent and severe with tinidazole. In addition, the significantly longer half-life of tinidazole (>12 h) offers potential cure with a single dose. This agent is currently unavailable in the United States.

Triclabendazole This narrow-spectrum benzimidazole is effective against paragonimiasis and all stages of *Fasciola hepatica*, a trematode with inherent resistance to praziquantel. Triclabendazole was originally introduced into veterinary practice in 1983 for the treatment of fascioliasis and was first used in humans in Iran in 1989 during an epidemic of fascioliasis near the Caspian Sea. In 1990, the WHO Division of Control of Tropical Diseases and the pharmaceutical company Ciba-Geigy (now Novartis) agreed to conduct additional clinical trials of triclabendazole for the treatment of fascioliasis and paragonimiasis. In light of the remarkable success of these trials, the WHO Expert Committee on the Use of Essential Drugs recommended in 1997 that the drug be put on the essential drug list. The manufacturer has initiated the process of registering triclabendazole for human use in countries where fascioliasis is endemic. The FDA has not yet approved triclabendazole for use in humans.

While most benzimidazoles have broad-spectrum antihelminthic activity, they exhibit minimal or no activity against *F. hepatica*. In

contrast, the antihelminthic activity of triclabendazole is highly specific for *Fasciola* spp. and *Paragonimus* spp., with little activity against nematodes, cestodes, and other trematodes. Triclabendazole is effective against all stages of *Fasciola* spp. The active sulfoxide metabolite of triclabendazole binds to fluke tubulin by assuming a unique nonplanar configuration and disrupts microtubule-based processes. Resistance to triclabendazole in veterinary use has been reported in Australia and Europe; however, no resistance has been documented in humans.

Triclabendazole is rapidly absorbed after oral ingestion and undergoes extensive first-pass metabolism in the liver. Its administration with food enhances its absorption and shortens the elimination half-life of the active metabolite. Both the sulfoxide and sulfone metabolites are highly protein-bound (>99%). Treatment with triclabendazole is typically given in one or two doses. No clinical data are available regarding dose adjustment in renal or hepatic insufficiency; however, given the short course of therapy and extensive hepatic metabolism of triclabendazole, dose adjustment is unlikely to be necessary. No information exists on drug interactions. Triclabendazole is currently unavailable in the United States.

Trimethoprim-Sulfamethoxazole See Table 193-1 and Chap. 118.

Section 18 Protozoal Infections

194 AMEBIASIS AND INFECTION WITH FREE-LIVING AMEBAS

Sharon L. Reed

AMEBIASIS

DEFINITION Amebiasis is an infection with the intestinal protozoan *Entamoeba histolytica*. About 90% of infections are asymptomatic, and the remaining 10% produce a spectrum of clinical syndromes ranging from dysentery to abscesses of the liver or other organs.

LIFE CYCLE AND TRANSMISSION *E. histolytica* is acquired by ingestion of viable cysts from fecally contaminated water, food, or hands. Foodborne exposure is most prevalent and is particularly likely when food handlers are shedding cysts or food is being grown with feces-contaminated soil, fertilizer, or water. Less common means of transmission include contaminated water, oral and anal sexual practices, and—in rare instances—direct rectal inoculation through colonic irrigation devices. Motile trophozoites are released from cysts in the small intestine and, in most patients, remain as harmless commensals in the large bowel. After encystation, infectious cysts are shed in the stool and can survive for several weeks in a moist environment. In some patients, the trophozoites invade either the bowel mucosa, causing symptomatic colitis, or the bloodstream, causing distant abscesses of the liver, lungs, or brain. The trophozoites may not encyst in patients with active dysentery, and motile hematophagous trophozoites are frequently present in fresh stools. Trophozoites are rapidly killed by exposure to air or stomach acid, however, and therefore cannot cause infection.

EPIDEMIOLOGY About 10% of the world's population is infected with *Entamoeba*, the majority with noninvasive *Entamoeba dispar*. Amebiasis results from infection with *E. histolytica* and is the third most common cause of death from parasitic disease (after schistosomiasis and malaria). Areas of highest incidence (due to inadequate sanitation and crowding) include most developing countries in the tropics, particularly Mexico, India, and nations of Central and South America, tropical Asia, and Africa. The main groups at risk in developed countries are travelers, recent immigrants, homosexual men, and inmates of institutions.

The wide spectrum of clinical disease is caused in part by infection with the two different species of *Entamoeba*. Isolates of *E. histolytica* from patients with invasive amebiasis have unique isoenzymes, surface antigens, DNA markers, and virulence properties and now are recognized as a distinct species from the noninvasive *E. dispar* (Table 194-1).

TABLE 194-1 *E. histolytica* and *E. dispar*, Compared and Contrasted

SIMILARITIES
1. Both species are spread through ingestion of infectious cysts.
2. Cysts of the two species are morphologically identical.
3. Both species colonize the large intestine.
DIFFERENCES
1. Only *E. histolytica* causes invasive disease.
2. Only *E. histolytica* infections elicit a positive amebic serology.
3. The two species have distinct rRNA sequences.
4. The two species have distinct surface antigens and isoenzyme markers.
5. Gal/GalNAc lectin can be used to differentiate the two species in stool ELISA.

Note: ELISA, enzyme-linked immunosorbent assay; Gal/GalNAc, galactose *N*-acetylgalactosamine. See text.

Most asymptomatic carriers, including homosexual men and AIDS patients, harbor *E. dispar* and have self-limited infections. These observations suggest that *E. dispar* is incapable of causing invasive disease, since *Cryptosporidium* and *Isospora belli*, which also cause only self-limited illnesses in immunocompetent people, cause devastating diarrhea in patients with AIDS. However, host factors play a role as well. In one study, 10% of asymptomatic patients who were colonized with *E. histolytica* went on to develop amebic colitis, while the rest remained asymptomatic and cleared the infection within 1 year.

PATHOGENESIS AND PATHOLOGY Both trophozoites (Fig. 194-1) and cysts (Fig. 194-2) are found in the intestinal lumen, but only trophozoites of *E. histolytica* invade tissue. The trophozoite is 20 to 60 μm in diameter and contains vacuoles and a nucleus with a characteristic central nucleolus. In animals, depletion of intestinal mucus, diffuse inflammation, and disruption of the epithelial barrier occur before trophozoites actually come into contact with the colonic mucosa. Trophozoites attach to colonic mucus and epithelial cells by galactose *N*-acetylgalactosamine (Gal/GalNAc) lectin. The earliest intestinal lesions are microulcerations of the mucosa of the cecum, sigmoid colon, or rectum that release erythrocytes, inflammatory cells, and epithelial cells. Proctoscopy reveals small ulcers with heaped up margins and normal intervening mucosa. Submucosal extension of ulcerations under viable-appearing surface mucosa causes the classic "flask-shaped"

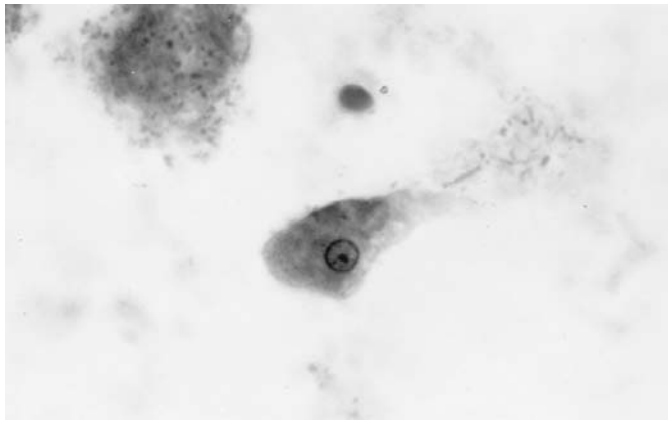

FIGURE 194-1 Trophozoite of *E. histolytica* demonstrating a single nucleus with a central, dotlike nucleolus (trichrome stain).

ulcer containing trophozoites at the margins of dead and viable tissues. Although neutrophilic infiltrates may accompany the early lesions in animals, human intestinal infection is marked by a paucity of inflammatory cells, probably in part because of the killing of neutrophils by trophozoites. Treated ulcers characteristically heal with little or no scarring. Occasionally, however, full-thickness necrosis and perforation occur.

Rarely, intestinal infection results in the formation of a mass lesion, or *ameboma*, in the bowel lumen. The overlying mucosa is usually thin and ulcerated, while other layers of the wall are thickened, edematous, and hemorrhagic; this condition results in exuberant formation of granulation tissue with little fibrous-tissue response.

A number of virulence factors have been linked to the ability of *E. histolytica* to invade through the interglandular epithelium. One consists of the extracellular cysteine proteinases that degrade collagen, elastin, IgA, IgG, and the anaphylatoxins C3a and C5a. Other enzymes may disrupt glycoprotein bonds between mucosal epithelial cells in the gut. Amebas can lyse neutrophils, monocytes, lymphocytes, and cells of colonic and hepatic cell lines. The cytolytic effect of amebas appears to require direct contact with target cells and may be linked to the release of phospholipase A and pore-forming peptides.

Liver abscesses are always preceded by intestinal colonization, which may be asymptomatic. Blood vessels may be compromised early by lysis of the wall and thrombus formation. Trophozoites invade veins to reach the liver through the portal venous system. *E. histolytica* is resistant to complement-mediated lysis, a property critical to survival in the bloodstream. In contrast, *E. dispar* is rapidly lysed by complement and is thus restricted to the bowel lumen. Inoculation of amebas into the portal system of hamsters results in an acute cellular infiltrate consisting predominantly of neutrophils. Later, the neutrophils are lysed by contact with amebas, and the release of neutrophil toxins may contribute to necrosis of hepatocytes. The liver parenchyma is replaced by necrotic material that is surrounded by a thin rim of congested liver tissue. The necrotic contents of a liver abscess are classically described as "anchovy paste," although the fluid is variable in color and is composed of bacteriologically sterile granular debris with few or no cells. Amebas, if seen, tend to be found near the capsule of the abscess.

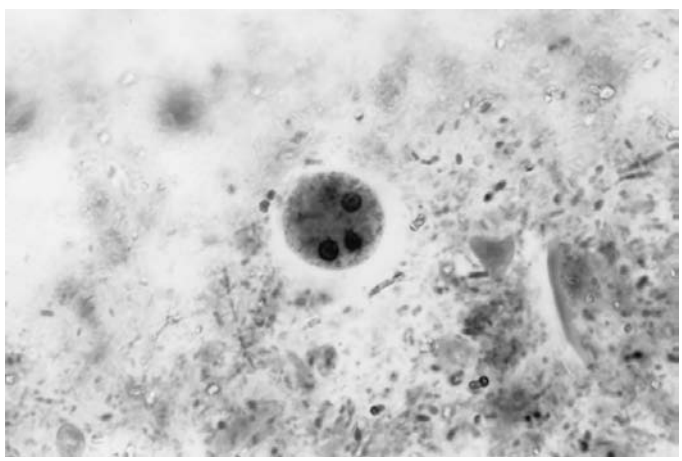

FIGURE 194-2 Cyst of *E. histolytica* showing three of the four nuclei (trichrome stain).

A recent study in Bangladeshi schoolchildren revealed that an intestinal IgA response to the Gal/GalNAc lectin reduced the risk of new *E. histolytica* infection by 64%. Serum IgG antibody is not protective; titers correlate with the length of illness rather than with the severity of disease. Indeed, Bangladeshi children with a serum IgG response were more likely than those without such a response to develop new *E. histolytica* infection. Studies of animals suggest that cell-mediated immunity may be important for protection, although patients with AIDS appear not to be predisposed to more severe disease.

CLINICAL SYNDROMES ■ Intestinal Amebiasis The most common type of amebic infection is asymptomatic cyst passage. Even in highly endemic areas, most patients harbor *E. dispar*.

Symptomatic amebic colitis develops 2 to 6 weeks after the ingestion of infectious cysts. Lower abdominal pain and mild diarrhea develop gradually and are followed by malaise, weight loss, and diffuse lower abdominal or back pain. Cecal involvement may mimic acute appendicitis. Patients with full-blown dysentery may pass 10 to 12 stools per day. The stools contain little fecal material and consist mainly of blood and mucus. In contrast to those with bacterial diarrhea, fewer than 40% of patients with amebic dysentery are febrile. Virtually all patients have heme-positive stools.

More fulminant intestinal infection, with severe abdominal pain, high fever, and profuse diarrhea, is rare and occurs predominantly in children. Patients may develop toxic megacolon, in which there is severe bowel dilation with intramural air. Patients receiving glucocorticoids are at risk for severe amebiasis. Uncommonly, patients develop a chronic form of amebic colitis, which can be confused with inflammatory bowel disease. The association between severe amebiasis complications and glucocorticoid therapy emphasizes the importance of excluding amebiasis when inflammatory bowel disease is suspected. An occasional patient presents with only an asymptomatic or tender abdominal mass caused by an ameboma, which is easily confused with cancer on barium studies. A positive serologic test or biopsy can prevent unnecessary surgery in this setting. The syndrome of postamebic colitis—persistent diarrhea following documented cure of amebic colitis—is controversial; no evidence of recurrent amebic infection can be found, and re-treatment usually has no effect.

Amebic Liver Abscess Extraintestinal infection by *E. histolytica* most often involves the liver. Of travelers who develop an amebic liver abscess after leaving an endemic area, 95% do so within 5 months. Young patients with an amebic liver abscess are more likely than older patients to present in the acute phase with prominent symptoms of <10 days' duration. Most patients are febrile and have right-upper-quadrant pain, which may be dull or pleuritic in nature and radiate to the shoulder. Point tenderness over the liver and right-sided pleural effusion are common. Jaundice is rare. Although the initial site of infection is the colon, fewer than one-third of patients with an amebic abscess have active diarrhea. Older patients from endemic areas are more likely to have a subacute course lasting 6 months, with weight loss and hepatomegaly. About one-third of patients with chronic presentations are febrile. Thus, the clinical diagnosis of an amebic liver abscess may be difficult to establish because the symptoms and signs are often nonspecific. Since 10 to 15% of patients present only with fever, amebic liver abscess must be considered in the differential diagnosis of fever of unknown origin (Chap. 18).

Complications of Amebic Liver Abscess Pleuropulmonary involvement, which is reported in 20 to 30% of patients, is the most frequent com-

plication of amebic liver abscess. Manifestations include sterile effusions, contiguous spread from the liver, and rupture into the pleural space. Sterile effusions and contiguous spread usually resolve with medical therapy, but frank rupture into the pleural space requires drainage. A hepatobronchial fistula may cause cough productive of large amounts of necrotic material that may contain amebas. This dramatic complication carries a good prognosis. Abscesses that rupture into the peritoneum may present as an indolent leak or an acute abdomen and require both percutaneous catheter drainage and medical therapy. Rupture into the pericardium, usually from abscesses of the left lobe of the liver, carries the gravest prognosis; it can occur during medical therapy and requires surgical drainage.

Other Extraintestinal Sites The genitourinary tract may become involved by direct extension of amebiasis from the colon or by hematogenous spread of the infection. Painful genital ulcers, characterized by a punched-out appearance and profuse discharge, may develop secondary to extension from either the intestine or the liver. Both these conditions respond well to medical therapy. Cerebral involvement has been reported in fewer than 0.1% of patients in large clinical series. Symptoms and prognosis depend on the size and location of the lesion.

DIAGNOSTIC TESTS ■ Laboratory Diagnosis Stool examinations, serologic tests, and noninvasive imaging of the liver are the most important procedures in the diagnosis of amebiasis. Fecal findings suggestive of amebic colitis include a positive test for heme, a paucity of neutrophils, and amebic cysts or trophozoites. The definitive diagnosis of amebic colitis is made by the demonstration of hematophagous trophozoites of *E. histolytica* (Fig. 194-1). Because trophozoites are killed rapidly by water, drying, or barium, it is important to examine at least three fresh stool specimens. Examination of a combination of wet mounts, iodine-stained concentrates, and trichrome-stained preparations of fresh stool and concentrates for cysts (Fig. 194-2) or trophozoites (Fig. 194-1) confirms the diagnosis in 75 to 95% of cases. Cultures of amebas are more sensitive but are not routinely available. If stool examinations are negative, sigmoidoscopy with biopsy of the edge of ulcers may increase the yield, but this procedure is dangerous during fulminant colitis because of the risk of perforation. Trophozoites in a biopsy specimen from a colonic mass confirm the diagnosis of ameboma, but trophozoites are rare in liver aspirates because they are found in the abscess capsule and not in the readily aspirated necrotic center. Accurate diagnosis requires experience, since the trophozoites may be confused with neutrophils and the cysts must be differentiated morphologically from *Entamoeba hartmanni*, *Entamoeba coli*, and *Endolimax nana*, which do not cause clinical disease and do not warrant therapy. Unfortunately, the cysts of *E. histolytica* cannot be distinguished microscopically from those of *E. dispar*. Therefore, the microscopic diagnosis of *E. histolytica* can be made only by the detection of *Entamoeba* trophozoites that have ingested erythrocytes (Fig. 194-1). In terms of sensitivity, stool diagnostic tests based on the detection of the Gal/GalNAc lectin of *E. histolytica* compare favorably with the polymerase chain reaction and with isolation in culture followed by isoenzyme analysis.

Serology is an important addition to the methods used for the parasitologic diagnosis of invasive amebiasis. Enzyme-linked immunosorbent assays (ELISAs) and agar gel diffusion assays are positive in more than 90% of patients with colitis, amebomas, or liver abscess. Positive results in conjunction with the appropriate clinical syndrome suggest active disease because serologic findings usually revert to negative within 6 to 12 months. Even in highly endemic areas such as South Africa, fewer than 10% of asymptomatic individuals have a positive amebic serology. The interpretation of the indirect hemagglutination test is more difficult because titers may remain positive for as long as 10 years.

Up to 10% of patients with acute amebic liver abscess may have negative serologic findings; in suspected cases with an initially negative result, testing should be repeated in a week. In contrast to carriers of *E. dispar*, most asymptomatic carriers of *E. histolytica* develop antibodies. Thus, serologic tests are helpful in assessing the risk of invasive amebiasis in asymptomatic, cyst-passing individuals in nonendemic areas. Serologic tests also should be performed in patients with ulcerative colitis before the institution of glucocorticoid therapy to prevent the development of severe colitis or toxic megacolon owing to unsuspected amebiasis.

Routine hematology and chemistry tests usually are not very helpful in the diagnosis of invasive amebiasis. About three-fourths of patients with an amebic liver abscess have leukocytosis (>10,000 cells/μL); this condition is particularly likely if symptoms are acute or complications have developed. Invasive amebiasis does not elicit eosinophilia. Anemia, if present, is usually multifactorial. Even with large liver abscesses, liver enzyme levels are normal or minimally elevated. The alkaline phosphatase level is most often elevated and may remain so for months. Aminotransferase elevations suggest acute disease or a complication.

Radiographic Studies Radiographic barium studies are potentially dangerous in acute amebic colitis. Amebomas are usually identified first by a barium enema, but biopsy is necessary for differentiation from carcinoma.

Radiographic techniques such as ultrasonography, computed tomography (CT) (Fig. 194-3), and magnetic resonance imaging are all useful for detection of the round or oval hypoechoic cyst. More than 80% of patients who have had symptoms for >10 days have a single abscess of the right lobe of the liver. Approximately 50% of patients who have had symptoms for <10 days have multiple abscesses. Findings associated with complications include large abscesses (>10 cm) in the superior part of the right lobe, which may rupture into the pleural space; multiple lesions, which must be differentiated from pyogenic abscesses; and lesions of the left lobe, which may rupture into the pericardium. Because abscesses resolve slowly and may increase in size in patients who are responding clinically to therapy, frequent follow-up ultrasonography may prove confusing. Complete resolution of a liver abscess within 6 months can be anticipated in two-thirds of patients, but 10% may have persistent abnormalities for a year.

DIFFERENTIAL DIAGNOSIS The differential diagnosis of intestinal amebiasis includes bacterial diarrheas caused by *Campylobacter*; enteroinvasive *Escherichia coli*; and *Shigella*, *Salmonella*, and *Vibrio* species. Although the typical patient with amebic colitis has less prominent fever than in these other conditions as well as heme-positive stools with few neutrophils, correct diagnosis requires bacterial cultures, microscopic examination of stools, and amebic serologic testing. As has already been mentioned, amebiasis must be ruled out in any patient thought to have inflammatory bowel disease.

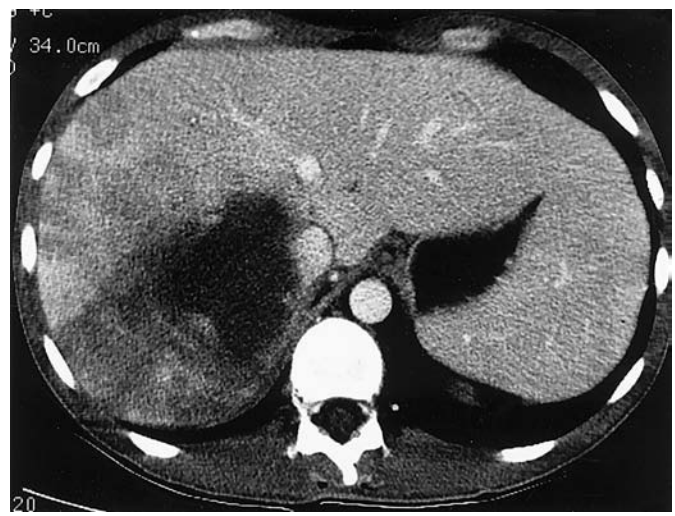

FIGURE 194-3 Abdominal computed tomography scan of a large amebic abscess of the right lobe of the liver. *(Courtesy of the Department of Radiology, UCSD Medical Center, San Diego.)*

Because of the variety of presenting signs and symptoms, amebic liver abscess can easily be confused with pulmonary or gallbladder disease or with any febrile illness with few localizing signs, such as malaria or typhoid fever. The diagnosis should be considered in members of high-risk groups who have recently traveled outside the United States and in inmates of institutions. Once radiographic studies have identified an abscess in the liver, the most important differential diagnosis is between amebic and pyogenic abscess. Patients with pyogenic abscess typically are older and have a history of underlying bowel disease or recent surgery. Amebic serology is helpful, but aspiration of the abscess, with Gram's staining and culture of the material, may be required for differentiation of the two diseases.

TREATMENT

Intestinal Disease The drugs used to treat amebiasis can be classified according to their primary site of action. Luminal amebicides are poorly absorbed and reach high concentrations in the bowel, but their activity is limited to cysts and trophozoites close to the mucosa. Only two luminal drugs are available in the United States: iodoquinol and paromomycin (Table 194-2). Indications for the use of luminal agents include eradication of cysts in patients with colitis or a liver abscess and treatment of asymptomatic carriers. The majority of asymptomatic individuals who pass cysts are colonized with *E. dispar*, which does not warrant specific therapy. However, it is prudent to treat asymptomatic individuals who pass cysts unless *E. dispar* colonization can be definitively demonstrated by specific antigen-detection tests.

Tissue amebicides reach high concentrations in the blood and tissue after oral or parenteral administration. The development of nitroimidazole compounds, especially metronidazole, was a major advance in the treatment of invasive amebiasis. Patients with amebic colitis should be treated with intravenous or oral metronidazole (750 mg three times daily for 5 to 10 days). Side effects include nausea, vomiting, abdominal discomfort, and a disulfiram-like reaction. Other imidazole compounds, such as tinidazole and ornidazole, are as effective but are not available in the United States. All patients should also receive a full course of therapy with a luminal agent, since metronidazole does not eradicate cysts. Resistance to metronidazole has not been identified. Relapses are not uncommon and probably represent reinfection or failure to eradicate amebas from the bowel because of an inadequate dosage or duration of therapy.

Amebic Liver Abscess Metronidazole is the drug of choice for amebic liver abscess. Longer-acting nitroimidazoles (tinidazole and ornidazole) have been shown to be effective as single-dose therapy in developing countries. With early diagnosis and therapy, mortality from uncomplicated amebic liver abscess is <1%. The second-line therapeutic agents emetine and chloroquine should be avoided if possible because of the potential cardiovascular and gastrointestinal side effects of the former and the higher relapse rates with the latter. There is no evidence that combined therapy with two drugs is more effective than the single-drug regimen. Studies of South Africans with liver abscesses demonstrated that 72% of patients without intestinal symptoms had bowel infection with *E. histolytica*; thus, all treatment regimens should include a luminal agent to eradicate cysts and prevent further transmission. Amebic liver abscess recurs rarely.

TABLE 194-2 *Drug Therapy for Amebiasis*

Drug	Dosage
ASYMPTOMATIC CARRIER (LUMINAL AGENTS)	
Iodoquinol (650-mg tablets)	650 mg tid for 20 days
Paromomycin (250-mg tablets)	500 mg tid for 10 days
ACUTE COLITIS	
Metronidazole (250- or 500-mg tablets) *plus*	750 mg PO or IV tid for 5 to 10 days
Luminal agent as above	
AMEBIC LIVER ABSCESS	
Metronidazole	750 mg PO or IV tid for 5 to 10 days
Tinidazole[a]	2 g PO
Ornidazole[a] *plus*	2 g PO
Luminal agent as above	

[a] Not available in the United States.

Aspiration of Liver Abscesses More than 90% of patients respond dramatically to metronidazole therapy with decreases in both pain and fever within 72 h. Indications for aspiration of liver abscesses are (1) the need to rule out a pyogenic abscess, particularly in patients with multiple lesions; (2) the failure to respond clinically in 3 to 5 days; (3) the threat of imminent rupture; and (4) the prevention of rupture of left-lobe abscesses into the pericardium. There is no evidence that aspiration, even of large abscesses (up to 10 cm), accelerates healing. Percutaneous drainage may be successful even if the liver abscess has already ruptured. Surgery should be reserved for instances of bowel perforation and rupture into the pericardium.

PREVENTION Amebic infection is spread by ingestion of food or water contaminated with cysts. Since an asymptomatic carrier may excrete up to 15 million cysts per day, prevention of infection requires adequate sanitation and eradication of cyst carriage. In high-risk areas, infection can be minimized by the avoidance of unpeeled fruits and vegetables and the use of bottled water. Because cysts are resistant to readily attainable levels of chlorine, disinfection by iodination (tetraglycine hydroperiodide) is recommended. There is no effective prophylaxis.

INFECTION WITH FREE-LIVING AMEBAS

EPIDEMIOLOGY Free-living amebas of the genera *Acanthamoeba*, *Naegleria*, and *Balamuthia* are distributed throughout the world and have been isolated from a wide variety of fresh and brackish water, including that from lakes, taps, hot springs, swimming pools, and heating and air-conditioning units, and even from the nasal passages of healthy children. Encystation may protect the protozoa from desiccation and food deprivation. The persistence of *Legionella pneumophila* in water supplies may be attributable in part to chronic infection of free-living amebas, particularly *Naegleria*.

***NAEGLERIA* INFECTIONS** Primary amebic meningoencephalitis caused by *Naegleria fowleri* follows the aspiration of water contaminated with trophozoites or cysts or the inhalation of contaminated dust, leading to invasion of the olfactory neuroepithelium. After an incubation period of 2 to 15 days, severe headache, high fever, nausea, vomiting, and meningismus develop. Photophobia and palsies of the third, fourth, and sixth cranial nerves are common. Rapid progression to seizures and coma may follow, and most patients die within a week. Infection is most common in otherwise-healthy children or young adults, who often report recent swimming in lakes or heated swimming pools.

Diagnosis depends on the detection of motile trophozoites in wet mounts of fresh spinal fluid. Other laboratory findings resemble those for fulminant bacterial meningitis, with elevated intracranial pressure, high white blood cell counts (up to 20,000 cells/μL), and elevated protein concentrations and low glucose levels in cerebrospinal fluid. The diagnosis should be considered in any patient who has purulent meningitis without evidence of bacteria on Gram's staining, antigen detection assay, and culture. The prognosis is uniformly poor. Only a few survivors, treated with high-dose amphotericin B and rifampin, have been reported. Antibodies to *Naegleria* spp. have been detected in normal adults; serologic testing is not useful in the diagnosis of acute infection.

***ACANTHAMOEBA* INFECTIONS ■ Granulomatous Amebic Encephalitis** Infection with *Acanthamoeba* species follows a more indolent course and occurs typically in chronically ill or debilitated patients. Risk factors include lymphoproliferative disorders, chemotherapy, glucocorticoid

therapy, lupus erythematosus, and AIDS. Infection usually reaches the central nervous system hematogenously from a primary focus in the sinuses, skin, or lungs. In the central nervous system, the onset is insidious, and the syndrome often mimics a space-occupying lesion. Altered mental status, headache, and stiff neck may be accompanied by focal findings such as cranial nerve palsies, ataxia, and hemiparesis. Cutaneous ulcers or hard nodules containing amebas are frequently detected in AIDS patients with disseminated *Acanthamoeba* infection.

Examination of the cerebrospinal fluid for trophozoites may be diagnostically helpful, but lumbar puncture may be contraindicated because of increased intracerebral pressure. CT frequently reveals cortical and subcortical lesions of decreased density consistent with embolic infarcts. In other patients, multiple enhancing lesions with edema may mimic the computed tomographic appearance of toxoplasmosis. Demonstration of the trophozoites and cysts of *Acanthamoeba* on wet mounts or in biopsy specimens establishes the diagnosis. Culture on nonnutrient agar plates seeded with *Escherichia coli* may also be helpful. Fluorescein-labeled antiserum is available from the Centers for Disease Control and Prevention (CDC) for the detection of protozoa in biopsy specimens. Granulomatous amebic encephalitis in patients with AIDS may have an accelerated course (with survival for only 3 to 40 days) because of the difficulty these individuals have in forming granulomas. Although studies in animals suggest that rifampin may be useful, the infection is almost uniformly fatal.

Keratitis The incidence of keratitis caused by *Acanthamoeba* has increased in the past 20 years, in part as a result of improved diagnosis. The first of these infections to be recognized were associated with trauma to the eye and exposure to contaminated water. At present, most infections are linked to extended-wear contact lenses. Risk factors include the use of homemade saline, the wearing of lenses while swimming, and inadequate disinfection. Since contact lenses presumably cause microscopic trauma, the early corneal findings may be nonspecific. The first symptoms usually include tearing and the painful sensation of a foreign body. Once infection is established, progression is rapid; the characteristic clinical sign is an annular, paracentral corneal ring representing a corneal abscess. Deeper corneal invasion and loss of vision may follow.

The differential diagnosis includes bacterial, mycobacterial, and herpetic infection. The irregular polygonal cysts of *Acanthamoeba* (Fig. 194-4) may be identified in corneal scrapings or biopsy material, and trophozoites can be grown on special media. Cysts are resistant to available drugs, and the results of medical therapy have been disappointing. Some reports have suggested partial responses to propamidine isethionate eyedrops. Severe infections usually require keratoplasty.

***BALAMUTHIA* INFECTIONS** *Balamuthia mandrillaris*, a free-living ameba previously referred to as a leptomyxid ameba, is an important etiologic agent of amebic meningoencephalitis in immunocompetent hosts. The course is typically subacute, with focal neurologic signs, fever, seizures, and headaches leading to death within 1 week to several months after onset. Examination of cerebrospinal fluid reveals mononuclear pleocytosis, elevated protein levels, and normal to low glucose concentrations. Multiple hypodense lesions are usually detected with imaging studies. The diagnosis is almost always made post-mortem, and specific identification may require immunofluorescence with antibodies from the CDC to differentiate the trophozoites from *Acanthamoeba*.

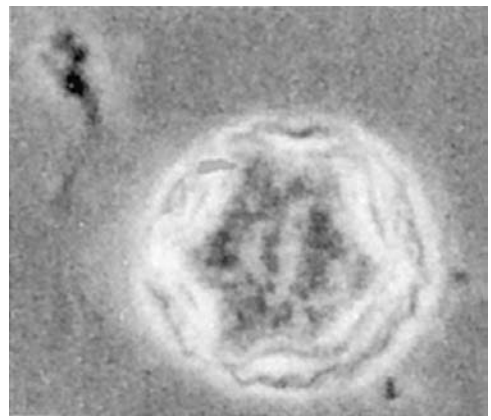

FIGURE 194-4 Double-walled cyst of *Acanthamoeba castellani*, as seen by phase-contrast microscopy. *[From DJ Krogstad et al, in A Balows et al (eds): Manual of Clinical Microbiology, 5th ed. Washington, DC, American Society for Microbiology, 1991.]*

195 MALARIA AND BABESIOSIS: DISEASES CAUSED BY RED BLOOD CELL PARASITES

Nicholas J. White, Joel G. Breman

"Humanity has but three great enemies: Fever, famine and war; of these by far the greatest, by far the most terrible, is fever."

William Osler

MALARIA

Malaria is a protozoan disease transmitted by the bite of infected *Anopheles* mosquitoes. It is the most important of the parasitic diseases of humans, with transmission in 103 countries affecting >1 billion people and causing between 1 and 3 million deaths each year. Malaria has now been eliminated from North America, Europe, and Russia but, despite enormous control efforts, has resurged in many parts of the tropics. Added to this resurgence are the increasing problems of drug resistance of the parasite and insecticide resistance of the vectors. Occasional local transmission following importation of malaria has occurred recently in several southern and eastern areas of the United States and in Europe, indicating the continual danger to nonmalarious countries. Malaria remains today, as it has been for centuries, a heavy burden on tropical communities, a threat to nonendemic countries, and a danger to travelers.

ETIOLOGY AND PATHOGENESIS Four species of the genus *Plasmodium* cause nearly all malarial infections in humans (although rare infections involve species normally affecting other primates). These are *P. falciparum*, *P. vivax*, *P. ovale*, and *P. malariae* (Table 195-1). Almost all deaths are caused by falciparum malaria. Human infection begins when a female anopheline mosquito inoculates plasmodial *sporozoites* from its salivary gland during a blood meal (Fig. 195-1). These microscopic motile forms of the malarial parasite are carried rapidly via the bloodstream to the liver, where they invade hepatic parenchymal cells and begin a period of asexual reproduction. By this amplification process (known as intrahepatic or preerythrocytic *schizogony* or *merogony*), a single sporozoite eventually may produce 10,000 to >30,000 daughter merozoites. The swollen liver cell eventually bursts, discharging motile *merozoites* into the bloodstream. These then invade the red blood cells (RBCs) and multiply 6- to 20-fold every 48 to 72 h. When the parasites reach densities of ~50/μL of blood, the symptomatic stage of the infection begins. In *P. vivax* and *P. ovale* infections, a proportion of the intrahepatic forms do not divide immediately but remain dormant for a period ranging from 3 weeks to a year or longer before reproduction begins. These dormant forms, or *hypnozoites*, are the cause of the relapses that characterize infection with these two species.

TABLE 195-1 *Characteristics of Plasmodium Species Infecting Humans*[a]

Characteristic	Finding for Indicated Species			
	P. falciparum	*P. vivax*	*P. ovale*	*P. malariae*
Duration of intrahepatic phase (days)	5.5	8	9	15
Number of merozoites released per infected hepatocyte	30,000	10,000	15,000	15,000
Duration of erythrocytic cycle (hours)	48	48	50	72
Red cell preference	Younger cells (but can invade cells of all ages)	Red cells up to 14 days old	Reticulocytes	Older cells
Morphology	Usually only ring forms; banana-shaped gametocytes	Irregularly shaped large rings and trophozoites; enlarged erythrocytes; Schüffner's dots	Infected erythrocytes, enlarged and oval with tufted ends; Schüffner's dots	Band or rectangular forms of trophozoites common
Pigment color	Black	Yellow-brown	Dark brown	Brown-black
Ability to cause relapses	No	Yes	Yes	No

[a] Parasitemias of >2% are suggestive of *P. falciparum* infection.

After entry into the bloodstream, merozoites rapidly invade erythrocytes and become *trophozoites*. Attachment is mediated via a specific erythrocyte surface receptor. In the case of *P. vivax*, this receptor is related to the Duffy blood-group antigen Fy^a or Fy^b. Most West Africans and people with origins in that region carry the Duffy-negative FyFy phenotype and are therefore resistant to *P. vivax* malaria. During the early stage of intraerythrocytic development, the small "ring forms" of the four parasitic species appear similar under light microscopy. As the trophozoites enlarge, species-specific characteristics become evident, pigment becomes visible, and the parasite assumes an irregular or ameboid shape. By the end of the 48-h intraerythrocytic life cycle (72 h for *P. malariae*), the parasite has consumed nearly all the hemoglobin and grown to occupy most of the RBC. It is now called a *schizont*. Multiple nuclear divisions have taken place (*shizogony* or *merogony*), and the RBC ruptures to release 6 to 30 daughter merozoites, each potentially capable of invading a new RBC and repeating the cycle. The disease in human beings is caused by the direct effects of RBC invasion and destruction by the asexual parasite and the host's reaction. After a series of asexual cycles (*P. falciparum*) or immediately after release from the liver (*P. vivax*, *P. ovale*, *P. malariae*), some of the parasites develop into morphologically distinct, long-lived sexual forms (*gametocytes*) that can transmit malaria.

After being ingested in the blood meal of a biting female anopheline mosquito, the male and female gametocytes form a zygote in the insect's midgut. This zygote matures into an ookinete, which penetrates and encysts in the mosquito's gut wall. The resulting oocyst expands by asexual division until it bursts to liberate myriad motile sporozoites, which then migrate in the hemolymph to the salivary gland of the mosquito to await inoculation into another human at the next feeding.

EPIDEMIOLOGY Malaria occurs throughout most of the tropical regions of the world (Fig. 195-2). *P. falciparum* predominates in Africa, New Guinea, and Haiti; *P. vivax* is more common in Central America and the Indian subcontinent. The prevalence of these two species is approximately equal in South America, eastern Asia, and Oceania. *P. malariae* is found in most endemic areas, especially throughout sub-Saharan Africa, but is much less common. *P. ovale* is relatively unusual outside of Africa and, where it is found, comprises <1% of isolates.

The epidemiology of malaria is complex and may vary considerably even within relatively small geographic areas. Endemicity tradi-

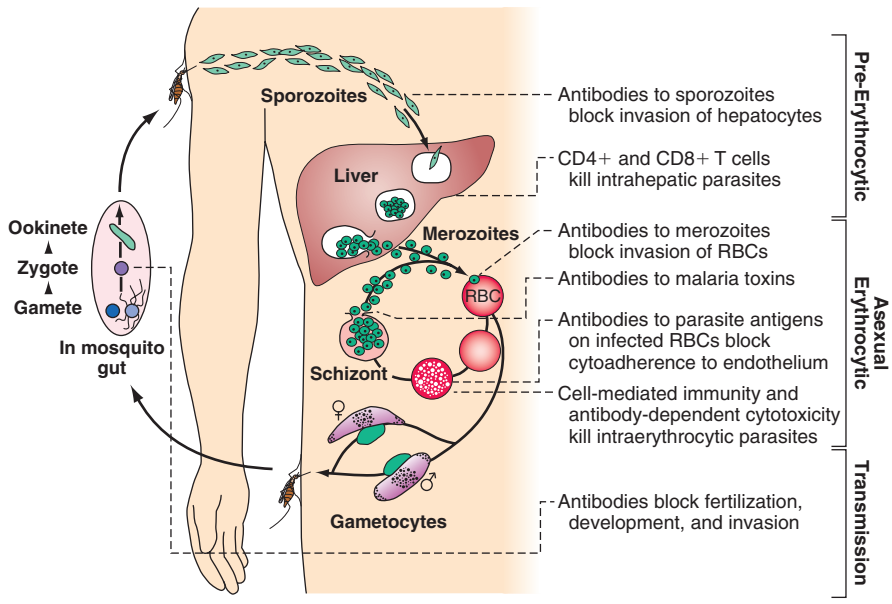

FIGURE 195-1 The malaria transmission cycle from mosquito to human. RBC, red blood cell.

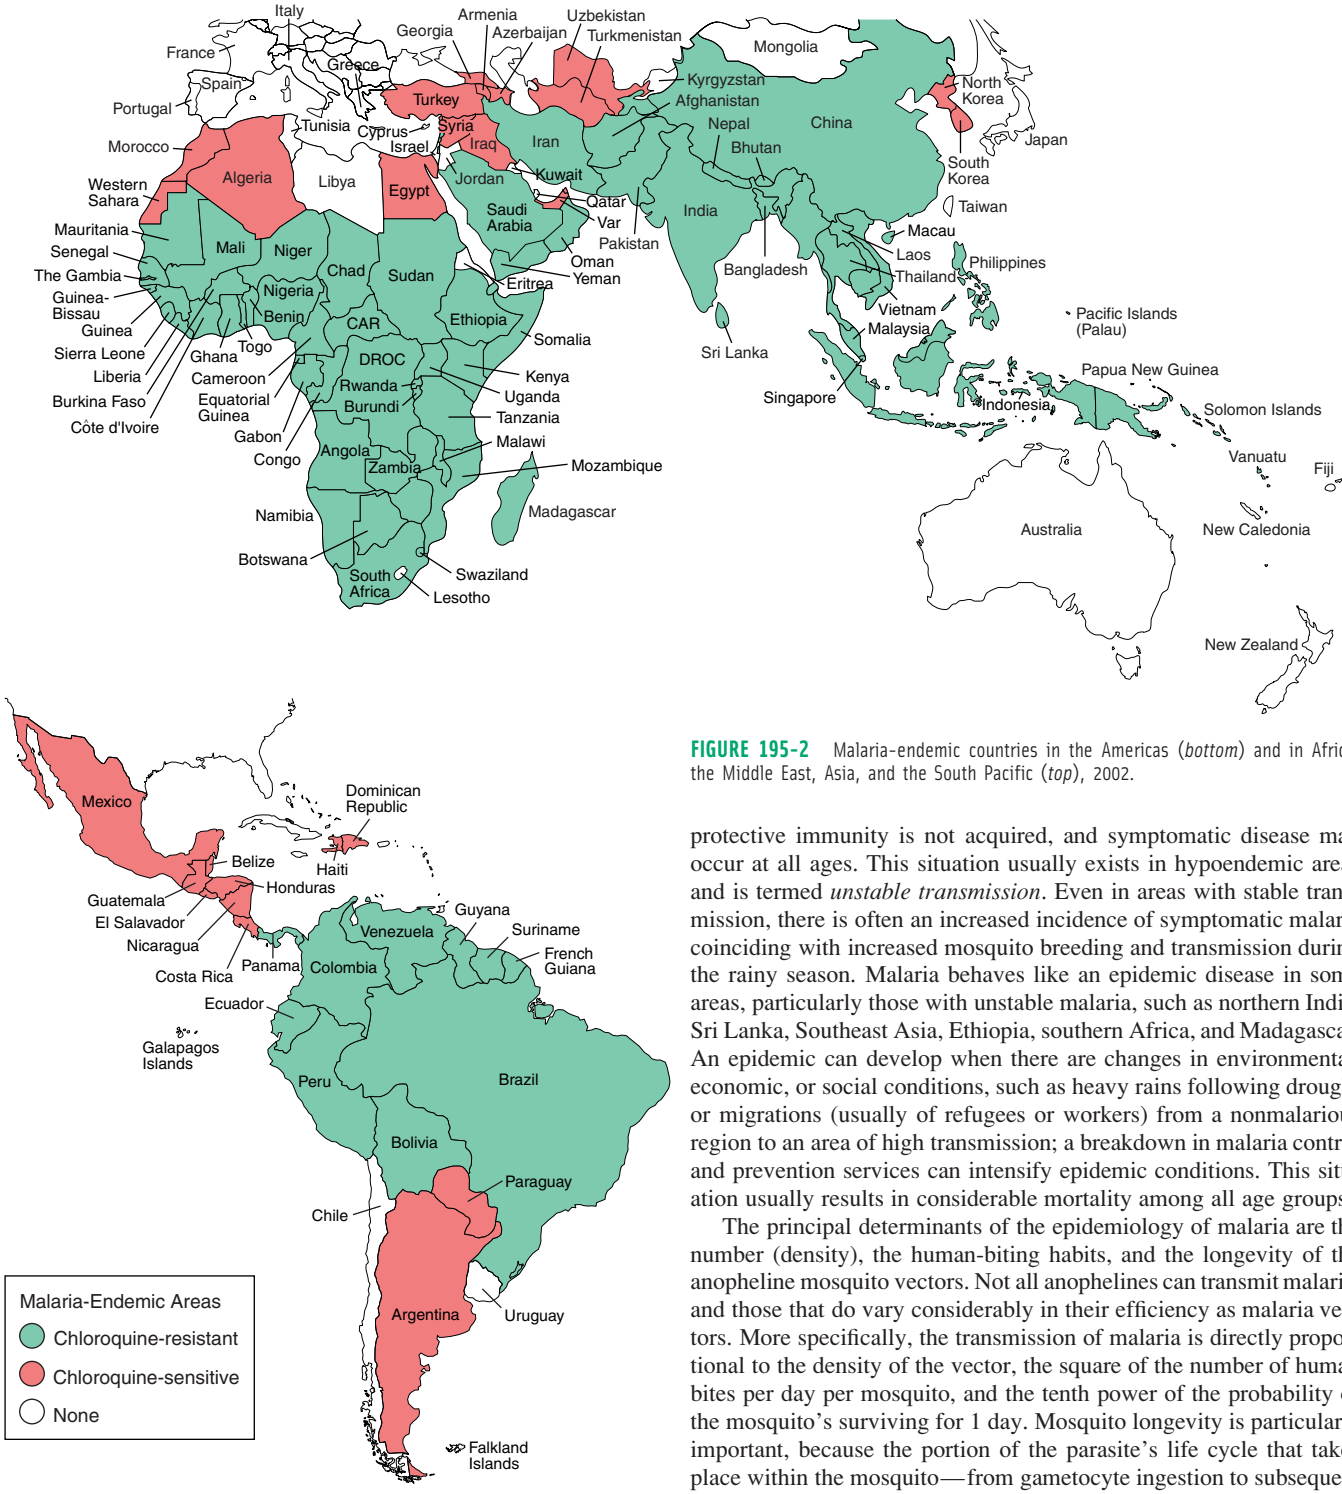

FIGURE 195-2 Malaria-endemic countries in the Americas (*bottom*) and in Africa, the Middle East, Asia, and the South Pacific (*top*), 2002.

tionally has been defined in terms of parasitemia rates or palpable-spleen rates in children 2 to 9 years of age as hypoendemic (<10%), mesoendemic (11 to 50%), hyperendemic (51 to 75%), and holoendemic (>75%). In holo- and hyperendemic areas—e.g., certain regions of tropical Africa or coastal New Guinea, where there is intense *P. falciparum* transmission and people can sustain more than one infectious mosquito bite per day—people are infected repeatedly throughout their lives. Here, morbidity and mortality due to malaria are considerable during childhood. Immunity against disease is hard won in these areas, and the young-childhood burden of disease is high; by adulthood, however, most malarial infections are asymptomatic. This situation, with frequent year-round infection, is termed *stable transmission*. In areas where transmission is low, erratic, or focal, full protective immunity is not acquired, and symptomatic disease may occur at all ages. This situation usually exists in hypoendemic areas and is termed *unstable transmission*. Even in areas with stable transmission, there is often an increased incidence of symptomatic malaria coinciding with increased mosquito breeding and transmission during the rainy season. Malaria behaves like an epidemic disease in some areas, particularly those with unstable malaria, such as northern India, Sri Lanka, Southeast Asia, Ethiopia, southern Africa, and Madagascar. An epidemic can develop when there are changes in environmental, economic, or social conditions, such as heavy rains following drought or migrations (usually of refugees or workers) from a nonmalarious region to an area of high transmission; a breakdown in malaria control and prevention services can intensify epidemic conditions. This situation usually results in considerable mortality among all age groups.

The principal determinants of the epidemiology of malaria are the number (density), the human-biting habits, and the longevity of the anopheline mosquito vectors. Not all anophelines can transmit malaria, and those that do vary considerably in their efficiency as malaria vectors. More specifically, the transmission of malaria is directly proportional to the density of the vector, the square of the number of human bites per day per mosquito, and the tenth power of the probability of the mosquito's surviving for 1 day. Mosquito longevity is particularly important, because the portion of the parasite's life cycle that takes place within the mosquito—from gametocyte ingestion to subsequent inoculation (sporogony)—lasts for 8 to 30 days, depending on ambient temperature; thus, to transmit malaria, the mosquito must survive for >7 days. In general, at temperatures <16° to 18°C, sporogony is not completed and transmission does not occur. Therefore, the most effective mosquito vectors of malaria are those such as *A. gambiae*, which are long-lived, occur in high densities in tropical climates, breed readily, and bite humans in preference to other animals. The entomologic inoculation rate—the number of sporozoite-positive mosquito bites per person per year—is the most common measure of malarial transmission and varies from <1 in some parts of Latin America and Southeast Asia to >300 in parts of tropical Africa.

ERYTHROCYTE CHANGES IN MALARIA After invading an erythrocyte, the growing malarial parasite progressively consumes and degrades intracellular proteins, principally hemoglobin. The potentially toxic heme

is polymerized to biologically inert hemozoin, or malaria pigment. The parasite also alters the RBC membrane by changing its transport properties, exposing cryptic surface antigens, and inserting new parasite-derived proteins. The RBC becomes more irregular in shape, more antigenic, and less deformable.

In *P. falciparum* infections, membrane protuberances appear on the erythrocyte's surface toward the end of the first 24 h of the asexual cycle. These "knobs" extrude a high-molecular-weight, antigenically variant, strain-specific, adhesive protein (PfEMP1) that mediates attachment to receptors on venular and capillary endothelium—an event termed *cytoadherence*. Several vascular receptors have been identified, of which intercellular adhesion molecule 1 is probably the most important in the brain, chondroitin sulfate B in the placenta, and CD36 in most other organs. Thus the infected erythrocytes stick inside the small blood vessels. At the same stage, these *P. falciparum*–infected RBCs may also adhere to uninfected RBCs to form rosettes and to other parasitized erythrocytes (agglutination). The processes of cytoadherence, rosetting, and agglutination are central to the pathogenesis of falciparum malaria. They result in the sequestration of RBCs containing mature forms of the parasite in vital organs (particularly the brain), where they interfere with microcirculatory flow and metabolism. Sequestered parasites continue to develop out of reach of the principal host defense mechanism: splenic processing and filtration. As a consequence, only the younger ring forms of the asexual parasites are seen circulating in the peripheral blood in falciparum malaria, and the level of peripheral parasitemia underestimates the true number of parasites within the body. Severe malaria is also associated with reduced deformability of the uninfected erythrocytes, which compromises their passage through the partially obstructed capillaries and venules and shortens RBC survival.

In the other three ("benign") malarias, sequestration does not occur, and all stages of the parasite's development are evident on peripheral blood smears. Whereas *P. vivax*, *P. ovale*, and *P. malariae* show a marked predilection for either young RBCs (*P. vivax*, *P. ovale*) or old cells (*P. malariae*) and produce a level of parasitemia seldom >2%, *P. falciparum* can invade erythrocytes of all ages and may be associated with very high levels of parasitemia.

HOST RESPONSE Initially, the host responds to plasmodial infection by activating nonspecific defense mechanisms. Splenic immunologic and filtrative clearance functions are augmented in malaria, and the removal of both parasitized and uninfected erythrocytes is accelerated. The parasitized cells escaping splenic removal are destroyed when the schizont ruptures. The material released induces the activation of macrophages and the release of proinflammatory mononuclear cell–derived cytokines, which cause fever and exert other pathologic effects. Temperatures of ≥40°C damage mature parasites; in untreated infections, the effect of such temperatures is to further synchronize the parasitic cycle, with eventual production of the regular fever spikes and rigors that originally served to characterize the different malarias. These regular fever patterns (tertian, every 2 days; quartan, every 3 days) are seldom seen today in patients who receive prompt and effective antimalarial treatment.

The geographic distributions of sickle cell disease, thalassemia, and glucose-6-phosphate dehydrogenase (G6PD) deficiency closely resemble that of malaria before the introduction of control measures. This observation suggests that these genetic disorders confer protection against death from falciparum malaria. For example, HbA/S heterozygotes (sickle cell trait) have a sixfold reduction in the risk of dying from severe falciparum malaria. This decrease in risk appears to be related to impaired parasite growth at low oxygen tensions. Parasite multiplication in HbA/E heterozygotes is reduced at high parasite densities. In Melanesia, children with α-thalassemia appear to have more frequent malaria (both vivax and falciparum) in the early years of life, and this pattern of infection appears to protect against severe disease. In Melanesian ovalocytosis, rigid erythrocytes resist merozoite invasion, and the intraerythrocytic milieu is hostile.

The specific immune response to malaria eventually controls the infection and, with exposure to sufficient strains, confers protection from high-level parasitemia and disease but not from infection. As a result of this state of infection without illness (*premunition*), asymptomatic parasitemia is common among adults and older children living in regions with stable and intense transmission (i.e., holo- or hyperendemic areas). Immunity is mainly specific for both the species and the strain of infecting malarial parasite. Both humoral immunity and cellular immunity are necessary for protection, but the mechanisms of each are incompletely understood (Fig. 195-1). Immune individuals have a polyclonal increase in serum levels of IgM, IgG, and IgA, although much of this antibody is unrelated to protection. Antibodies to a variety of parasitic antigens presumably act in concert to limit in vivo replication of the parasite. In the case of falciparum malaria, the most important of these antigens is the variant protein PfEMP1 mentioned above. Passively transferred IgG from immune adults has been shown to reduce levels of parasitemia in children, and passive transfer of maternal antibody contributes to the relative protection of infants from severe malaria in the first months of life. This complex immunity to disease declines when a person lives outside an endemic area for several months or longer.

Several factors retard the development of cellular immunity to malaria. These factors include the absence of major histocompatibility antigens on the surface of infected RBCs, which precludes direct T cell recognition; malaria antigen–specific immune unresponsiveness; and the enormous strain diversity of malarial parasites along with the ability of the parasites to express variant immunodominant antigens on the erythrocyte surface that change during the period of infection. Strain diversity also has an impact on the heterogeneity of the humoral antibody response. Immunity to all strains is never achieved. Parasites may persist in the blood for months (or, in the case of *P. malariae*, for many years) if treatment is not given. The complexity of the immune response in malaria, the sophistication of the parasites' evasion mechanisms, and the lack of a good in vitro correlate with clinical immunity have all slowed progress toward an effective vaccine.

CLINICAL FEATURES Malaria is a very common cause of fever in tropical countries. The first symptoms of malaria are nonspecific; the lack of a sense of well-being, headache, fatigue, abdominal discomfort, and muscle aches followed by fever are all similar to the symptoms of a minor viral illness. In some instances, a prominence of headache, chest pain, abdominal pain, arthralgia, myalgia, or diarrhea may suggest another diagnosis. Although headache may be severe in malaria, there is no neck stiffness or photophobia resembling that in meningitis. While myalgia may be prominent, it is not usually as severe as in dengue fever, and the muscles are not tender as in leptospirosis or typhus. Nausea, vomiting, and orthostatic hypotension are common. The classic malarial paroxysms, in which fever spikes, chills, and rigors occur at regular intervals, are relatively unusual and suggest infection with *P. vivax* or *P. ovale*. The fever is irregular at first (that of falciparum malaria may never become regular); the temperature of nonimmune individuals and children often rises above 40°C in conjunction with tachycardia and sometimes delirium. Although childhood febrile convulsions may occur with any of the malarias, generalized seizures are specifically associated with falciparum malaria and may herald the development of cerebral disease. Many clinical abnormalities have been described in acute malaria, but most patients with uncomplicated infections have few abnormal physical findings other than fever, malaise, mild anemia, and (in some cases) a palpable spleen. Anemia is quite common among young children living in areas with stable transmission, particularly where there is parasite resistance to chloroquine or other drugs. Splenic enlargement is very common among otherwise-healthy individuals in malaria-endemic areas and reflects repeated infections; however, in nonimmune individuals with malaria, the spleen takes several days to become palpable. Slight enlargement of the liver is also common, particularly among young children. Mild jaundice is common among adults; it may develop in pa-

tients with otherwise-uncomplicated falciparum malaria and usually resolves over 1 to 3 weeks. Malaria is not associated with a rash like those seen in meningococcal septicemia, typhus, enteric fever, viral exanthems, and drug reactions. Petechial hemorrhages in the skin or mucous membranes—features of viral hemorrhagic fevers and leptospirosis—develop only rarely in severe falciparum malaria.

Severe Falciparum Malaria Appropriately treated, uncomplicated falciparum malaria carries a mortality rate of ~0.1%. However, once vital-organ dysfunction occurs or the proportion of erythrocytes infected increases to >3%, mortality rises steeply. The major manifestations of severe falciparum malaria are shown in Table 195-2, and features indicating a poor prognosis are listed in Table 195-3.

CEREBRAL MALARIA Coma is a characteristic and ominous feature of falciparum malaria and, despite treatment, is associated with death rates of ~20% among adults and 15% among children. Lesser degrees of obtundation, delirium, and abnormal behavior should also be taken very seriously. The onset may be gradual or sudden following a convulsion.

Cerebral malaria manifests as diffuse symmetric encephalopathy; focal neurologic signs are unusual. Although some passive resistance to head flexion may be detected, signs of meningeal irritation are lacking. The eyes may be divergent and a pout reflex is common, but other primitive reflexes are usually absent. The corneal reflexes are preserved except in deep coma. Muscle tone may be either increased or decreased. The tendon reflexes are variable, and the plantar reflexes may be flexor or extensor; the abdominal and cremasteric reflexes are absent. Flexor or extensor posturing may be documented. Approximately 15% of patients have retinal hemorrhages; with pupillary dilatation and indirect ophthalmoscopy, this figure increases to 30 to 40%. Other funduscopic abnormalities include discrete spots of retinal opacification (30 to 60%), papilledema (8% among children, rare among adults), cotton wool spots (<5%), and decolorization of a retinal vessel or segment of vessel (occasional cases). Convulsions, usually generalized and often repeated, occur in up to 50% of children with cerebral malaria. More covert seizure activity is also common, particularly among children, and may manifest as repetitive tonic-clonic eye movements. Whereas adults rarely (i.e., in <3% of cases) suffer neurologic sequelae, ~15% of children surviving cerebral malaria—especially those with hypoglycemia, severe anemia, repeated seizures, and deep coma—have some residual neurologic deficit when they regain consciousness; hemiplegia, cerebral palsy, cortical blindness, deafness, and impaired cognition and learning—all of varying duration—have been reported.

HYPOGLYCEMIA An important and common complication of severe malaria, hypoglycemia is associated with a poor prognosis and is particularly problematic in children and pregnant women. Hypoglycemia in malaria results from a failure of hepatic gluconeogenesis and an increase in the consumption of glucose by both host and—to a lesser extent—the malaria parasites. To compound the situation, quinine and quinidine—drugs commonly used for the treatment of severe chloroquine-resistant malaria—are powerful stimulants of pancreatic insulin secretion. Hyperinsulinemic hypoglycemia is especially troublesome in pregnant women receiving quinine treatment. In severe

TABLE 195-2 Manifestations of Severe Falciparum Malaria

Signs	Manifestations
Major	
Unarousable coma/ cerebral malaria	Failure to localize or respond appropriately to noxious stimuli; coma persisting for >30 min after generalized convulsion
Acidemia/acidosis	Arterial pH <7.25 or plasma bicarbonate level of <15 mmol/L; venous lactate level of >5 mmol/L manifests as labored deep breathing, often termed "respiratory distress"
Severe normochromic, normocytic anemia	Hematocrit of <15% or hemoglobin level of <50 g/L (<5 g/dL) with parasitemia of >100,000/μL
Renal failure	Urine output (24 h) of <400 mL in adults or <12 mL/kg in children; no improvement with rehydration; serum creatinine level of >265 μmol/L (>3.0 mg/dL)
Pulmonary edema/ adult respiratory distress syndrome	Noncardiogenic pulmonary edema, often aggravated by overhydration
Hypoglycemia	Plasma glucose level of <2.2 mmol/L (<40 mg/dL)
Hypotension/shock	Systolic blood pressure of <50 mmHg in children 1–5 years or <80 mmHg in adults; core/skin temperature difference of >10°C
Bleeding/ disseminated intravascular coagulation	Significant bleeding and hemorrhage from the gums, nose, and gastrointestinal tract and/or evidence of disseminated intravascular coagulation
Convulsions	More than two generalized seizures in 24 h
Hemoglobinuria[a]	Macroscopic black, brown, or red urine; not associated with effects of oxidant drugs and red blood cell enzyme defects (such as G6PD deficiency)
Other	
Impaired consciousness	Obtunded but arousable
Extreme weakness	Prostration; inability to sit unaided[b]
Hyperparasitemia	Parasitemia level of >5% in nonimmune patients (>20% in any patient)
Jaundice	Serum bilirubin level of >50 mmol/L (>3.0 mg/dL) if combined with other evidence of vital-organ dysfunction

[a] Hemoglobinuria may occur in uncomplicated malaria.
[b] In a child who is normally able to sit.
Note: G6PD, glucose-6-phosphate dehydrogenase.

TABLE 195-3 Features Indicating a Poor Prognosis in Severe Falciparum Malaria

Clinical
- Marked agitation
- Hyperventilation (respiratory distress)
- Hypothermia (<36.5°C)
- Bleeding
- Deep coma
- Repeated convulsions
- Anuria
- Shock

Laboratory
- Biochemistry
  - Hypoglycemia (<2.2 mmol/L)
  - Hyperlactatemia (>5 mmol/L)
  - Acidosis (arterial pH <7.3, serum HCO_3 <15 mmol/L)
  - Elevated serum creatinine (>265 μmol/L)
  - Elevated total bilirubin (>50 μmol/L)
  - Elevated liver enzymes (AST/ALT 3 times upper limit of normal, 5-nucleotidase ↑)
  - Elevated muscle enzymes (CPK ↑, myoglobin ↑)
  - Elevated urate (>600 μmol/L)
- Hematology
  - Leukocytosis (>12,000/μL)
  - Severe anemia (PCV <15%)
  - Coagulopathy
    - Decreased platelet count (<50,000/μL)
    - Prolonged prothrombin time (>3 s)
    - Prolonged partial thromboplastin time
    - Decreased fibrinogen (<200 mg/dL)
- Parasitology
  - Hyperparasitemia
    - Increased mortality at >100,000/μL
    - High mortality at >500,000/μL
    - >20% of parasites identified as pigment-containing trophozoites and schizonts
    - >5% of neutrophils with visible pigment

Note: ALT, alanine aminotransferase; AST, aspartate aminotransferase; CPK, creatine phosphokinase; PCV, packed cell volume.

disease, the clinical diagnosis of hypoglycemia is difficult: the usual physical signs (sweating, gooseflesh, tachycardia) are absent, and the neurologic impairment caused by hypoglycemia cannot be distinguished from that caused by malaria.

LACTIC ACIDOSIS Lactic acidosis commonly coexists with hypoglycemia and is an important contributor to death from severe malaria. In adults, coexisting renal impairment often compounds the acidosis; in children, ketoacidosis may also contribute. Acidotic breathing, sometimes called respiratory distress, is a sign of poor prognosis. It is often followed by circulatory failure refractory to volume expansion or inotropic drugs or by respiratory arrest. The plasma concentrations of bicarbonate or lactate are the best biochemical prognosticators in severe malaria. Lactic acidosis is caused by the combination of anaerobic glycolysis in tissues where sequestered parasites interfere with microcirculatory flow, hypovolemia, lactate production by the parasites, and a failure of hepatic and renal lactate clearance. The prognosis of severe lactic acidosis is poor.

NONCARDIOGENIC PULMONARY EDEMA Adults with severe falciparum malaria may develop noncardiogenic pulmonary edema even after several days of antimalarial therapy. The pathogenesis of this variant of the adult respiratory distress syndrome is unclear. The mortality rate is >80%. This condition can be aggravated by overly vigorous administration of intravenous fluid. Noncardiogenic pulmonary edema can also develop in otherwise-uncomplicated vivax malaria, where recovery is usual.

RENAL IMPAIRMENT Renal impairment is common among adults with severe falciparum malaria but rare among children. The pathogenesis of renal failure is unclear but may be related to erythrocyte sequestration interfering with renal microcirculatory flow and metabolism. Clinically and pathologically, this syndrome manifests as acute tubular necrosis, although renal cortical necrosis never develops. Acute renal failure may occur simultaneously with other vital-organ dysfunction (in which case mortality is high) or may progress as other disease manifestations resolve. In survivors, urine flow resumes in a median of 4 days, and serum creatinine levels return to normal in a mean of 17 days (Chap. 260). Early dialysis or hemofiltration considerably enhances the likelihood of a patient's survival, particularly in acute hypercatabolic renal failure.

HEMATOLOGIC ABNORMALITIES Anemia results from accelerated RBC destruction and removal by the spleen in conjunction with ineffective erythropoiesis. In severe malaria, both infected and uninfected RBCs show reduced deformability, which correlates with prognosis and development of anemia. Splenic clearance of RBCs is increased. In nonimmune individuals and in areas with unstable transmission, anemia can develop rapidly and transfusion is often required. As a consequence of repeated malarial infections, children in many areas of Africa may develop severe anemia resulting from both shortened RBC survival and masked dyserythropoiesis. Anemia is a common consequence of antimalarial drug resistance, which results in repeated or continued infection.

Slight coagulation abnormalities are common in falciparum malaria, and mild thrombocytopenia is usual. As mentioned above, <5% of patients with severe malaria have significant bleeding with evidence of disseminated intravascular coagulation. Hematemesis from stress ulceration or acute gastric erosions may also occur.

LIVER DYSFUNCTION Mild hemolytic jaundice is common in malaria. Severe jaundice is associated with *P. falciparum* infections, is more common among adults than among children, and results from hemolysis, hepatocyte injury, and cholestasis. When accompanied by other vital-organ dysfunction (often renal impairment), liver dysfunction carries a poor prognosis. Hepatic dysfunction contributes to hypoglycemia, lactic acidosis, and impaired drug metabolism. Occasional patients with falciparum malaria may develop deep jaundice (with hemolytic, hepatitic, and cholestatic components) without evidence of other vital-organ dysfunction.

TABLE 195-4 *Relative Incidence of Severe Complications of Falciparum Malaria*

Complication	Nonpregnant Adults	Pregnant Women	Children
Anemia	+	++	+++
Convulsions	+	+	+++
Hypoglycemia	+	+++	+++
Jaundice	+++	+++	+
Renal failure	+++	+++	−
Pulmonary edema	++	+++	+

Key: −, rare; +, infrequent; ++, frequent; +++, very frequent.

OTHER COMPLICATIONS Aspiration pneumonia following convulsions is an important cause of death in cerebral malaria. Chest infections and catheter-induced urinary tract infections are common among patients who are unconscious for >3 days. Septicemia may complicate severe malaria, particularly in children; in endemic areas, *Salmonella* bacteremia has been associated specifically with *P. falciparum* infections. The frequency of complications of severe falciparum malaria is summarized in Table 195-4.

Malaria in Pregnancy In hyper- and holoendemic areas, falciparum malaria in primi- and secundigravid women is associated with low birth weight (average reduction, ~170 g) and consequently increased infant and childhood mortality. In general, infected mothers in areas of stable transmission remain asymptomatic despite intense accumulation of parasitized erythrocytes in the placental microcirculation. Maternal HIV infection predisposes pregnant women to malaria and predisposes their newborns to congenital malaria infection and low birth weight.

In areas with unstable transmission of malaria, pregnant women are prone to severe infections and are particularly vulnerable to high-level parasitemia with anemia, hypoglycemia, and acute pulmonary edema. Fetal distress, premature labor, and stillbirth or low birth weight are common results. Fetal death is usual in severe malaria. Congenital malaria occurs in <5% of newborns whose mothers are infected and is related directly to the parasite density in maternal blood and in the placenta. *P. vivax* malaria in pregnancy is also associated with a reduction in birth weight (average, 100 g), but, in contrast to the situation in falciparum malaria, this effect is more pronounced in multigravid than in primigravid women.

Malaria in Children Most of the estimated 1 to 3 million persons who die of falciparum malaria each year are young African children. Convulsions, coma, hypoglycemia, metabolic acidosis, and severe anemia are relatively common among children with severe malaria, whereas deep jaundice, acute renal failure, and acute pulmonary edema are unusual. Severely anemic children may present with labored deep breathing, which in the past has been attributed incorrectly to "anemic congestive cardiac failure" but in fact is usually caused by metabolic acidosis, often compounded by hypovolemia. In general, children tolerate antimalarial drugs well and respond rapidly to treatment.

Transfusion Malaria Malaria can be transmitted by blood transfusion, needle-stick injury, sharing of needles by infected drug addicts, or organ transplantation. The incubation period in these settings is often short because there is no preerythrocytic stage of development. The clinical features and management of these cases are the same as for naturally acquired infections. Radical chemotherapy with primaquine is unnecessary for transfusion-transmitted *P. vivax* and *P. ovale* infections.

CHRONIC COMPLICATIONS OF MALARIA ■ Tropical Splenomegaly (Hyperreactive Malarial Splenomegaly) Chronic or repeated malarial infections produce hypergammaglobulinemia; normochromic, normocytic anemia; and, in certain situations, splenomegaly. Some residents of malaria-endemic areas in tropical Africa and Asia exhibit an abnormal immunologic response to repeated infections that is characterized by massive splenomegaly, hepatomegaly, marked elevations in serum titers of IgM and malarial antibody, hepatic sinusoidal lymphocytosis, and (in Af-

rica) peripheral B cell lymphocytosis. This syndrome has been associated with the production of cytotoxic IgM antibodies to CD8+ T lymphocytes, antibodies to CD5+ T lymphocytes, and an increase in the ratio of CD4+ T cells to CD8+ T cells. These events may lead to uninhibited B cell production of IgM and the formation of cryoglobulins (IgM aggregates and immune complexes). This immunologic process stimulates reticuloendothelial hyperplasia and clearance activity and eventually produces splenomegaly. Patients with hyperreactive malarial splenomegaly (HMS) present with an abdominal mass or a dragging sensation in the abdomen and occasional sharp abdominal pains suggesting perisplenitis. Anemia and some degree of pancytopenia are usually evident, but in many cases malarial parasites cannot be found in peripheral-blood smears. Vulnerability to respiratory and skin infections is increased; many patients die of overwhelming sepsis. Persons with HMS who are living in endemic areas should receive antimalarial chemoprophylaxis: the results are usually good. In nonendemic areas, antimalarial treatment is advised. In some cases refractory to therapy, clonal lymphoproliferation may develop and then evolve into a malignant lymphoproliferative disorder.

Quartan Malarial Nephropathy Chronic or repeated infections with *P. malariae* (and possibly with other malarial species) may cause soluble immune-complex injury to the renal glomeruli, resulting in the nephrotic syndrome. Other, unidentified factors must contribute to this process since only a very small proportion of infected patients develop renal disease. The histologic appearance is that of focal or segmental glomerulonephritis with splitting of the capillary basement membrane. Subendothelial dense deposits are seen on electron microscopy, and immunofluorescence reveals deposits of complement and immunoglobulins; in samples of renal tissue from children, *P. malariae* antigens are often visible. A coarse-granular pattern of basement-membrane immunofluorescent deposits (predominantly IgG3) with selective proteinuria carries a better prognosis than a fine-granular, predominantly IgG2 pattern with nonselective proteinuria. Quartan nephropathy usually responds poorly to treatment with either antimalarial agents or glucocorticoids and cytotoxic drugs.

Burkitt's Lymphoma and Epstein-Barr Virus Infection It is possible that malaria-related immunosuppression provokes infection with lymphoma viruses. Burkitt's lymphoma is strongly associated with Epstein-Barr virus. The prevalence of this childhood tumor is high in malarious areas of Africa.

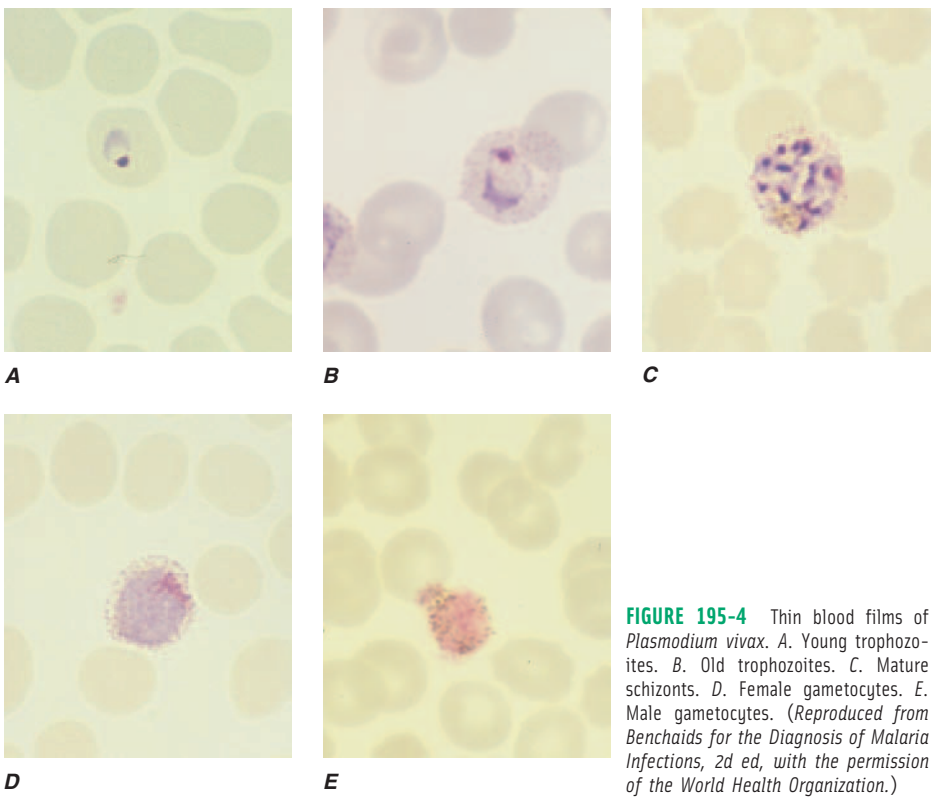

FIGURE 195-4 Thin blood films of *Plasmodium vivax*. *A*. Young trophozoites. *B*. Old trophozoites. *C*. Mature schizonts. *D*. Female gametocytes. *E*. Male gametocytes. DIAGNOSIS ■ Demonstration of the Parasite

The diagnosis of malaria rests on the demonstration of asexual forms of the parasite in stained peripheral-blood smears. After a negative blood smear, repeat smears should be made if there is a high degree of suspicion. Of the Romanowsky stains, Giemsa at pH 7.2 is preferred; Wright's, Field's, or Leishman's stain can also be used. Both thin (Fig. 195-3 through Fig. 195-6) and thick (Fig. 195-7 through Fig. 195-10) blood smears should be examined.

The thin blood smear should be rapidly

air-dried, fixed in anhydrous methanol, and stained, and the RBCs in the tail of the film should then be examined under oil immersion (×1000 magnification). The level of parasitemia is expressed as the number of parasitized erythrocytes per 1000 RBCs, or per 200 white blood cells (WBCs), and this figure is converted to the number of parasitized erythrocytes per microliter. In high-transmission areas, the presence of up to 10,000 parasites per microliter of blood may be tolerated without symptoms or signs in partially immune individuals. Rapid, simple, sensitive, and specific antibody-based diagnostic stick or card tests that detect *P. falciparum*–specific, histidine-rich protein 2 (PfHRP2) or lactate dehydrogenase antigens in finger-prick blood samples have been introduced (Table 195-5). Some of these tests carry a second antibody, which allows falciparum malaria to be distinguished from the less dangerous malarias. PfHRP2-based tests may remain positive for several weeks after acute infection. This feature is a disadvantage in high-transmission areas where infections are frequent but is of value in the diagnosis of severe malaria in patients who have taken antimalarial drugs and cleared peripheral parasitemia (but in whom the PfHRP2 test remains strongly positive) or where malaria is alleged to have been eliminated. The relationship between parasitemia and prognosis is complex; in general, patients with $>10^5$ parasites per microliter are at increased risk of dying, but nonimmune patients may die with much lower counts, and semi-immune persons may tolerate parasitemia levels many times higher with only minor symptoms. In severe malaria, a poor prognosis is indicated by a predominance of more mature *P. falciparum* parasites (i.e., >20% of parasites with visible pigment) in the peripheral blood film or by the presence of phagocytosed malarial pigment in >5% of neutrophils. In *P. falciparum* infections, gametocytemia peaks 1 week after the peak of asexual parasites. Because the mature gametocytes of *P. falciparum* are not affected by most antimalarial drugs, their persistence does not constitute evidence of drug resistance.

The thick blood film should be of uneven thickness. The smear should be dried thoroughly and stained without fixing. As many layers of erythrocytes overlie one another and are lysed during the staining procedure, the thick film has the advantage of concentrating the parasites (by 20- to 40-fold compared with a thin blood film) and thus increasing diagnostic sensitivity. Both parasites and WBCs are counted, and the number of parasites per unit volume is calculated from the total leukocyte count. Alternatively, a WBC count of 8000/μL is assumed. A minimum of 200 WBCs should be counted under oil immersion. Interpretation of blood smear films requires some experience because artifacts are common. Before a thick smear is judged to be negative, 100 to 200 fields should be examined under oil immersion. Phagocytosed malarial pigment is sometimes seen inside peripheral-blood monocytes or polymorphonuclear leukocytes and may provide a clue to recent infection if malaria parasites are not detectable. After the clearance of the parasites, this intraphagocytic malarial pigment is often evident for several days in the peripheral blood or for longer in bone marrow aspirates or smears of fluid expressed after

intradermal puncture. Staining of parasites with the fluorescent dye acridine orange allows more rapid diagnosis of malaria (but not speciation of the infection) in patients with low-level parasitemia.

Laboratory Findings Normochromic, normocytic anemia is usual. The leukocyte count is generally normal, although it may be raised in very severe infections. The erythrocyte sedimentation rate, plasma viscosity, and levels of C-reactive protein and other acute-phase proteins are high. The platelet count is usually reduced to $\sim 10^5/\mu L$. Severe infections may be accompanied by prolonged prothrombin and partial thromboplastin times and by more severe thrombocytopenia. Levels of antithrombin III are reduced even in mild infection. In uncomplicated malaria, plasma concentrations of electrolytes, blood urea nitrogen (BUN), and creatinine are usually normal. Findings in severe malaria may include metabolic acidosis, with low plasma concentrations of glucose, sodium, bicarbonate, calcium, phosphate, and albumin together with elevations in lactate, blood urea nitrogen, creatinine, urate, muscle and liver enzymes, and conjugated and unconjugated bilirubin. Hypergammaglobulinemia is usual in immune and semi-immune subjects. Urinalysis generally gives normal results. In adults and children with cerebral malaria, the mean opening pressure at lumbar puncture is ~160 mm of cerebrospinal fluid (CSF); usually the CSF is normal or has a slightly elevated total protein level [<1.0 g/L (<100 mg/dL)] and cell count (<20/μL).

TREATMENT (Table 195-6)

When a patient in or from a malarious area presents with fever, thick and thin blood smears should be prepared and examined immediately to confirm the diagnosis and identify the species of infecting parasite (Figs. 195-3 through 195-10). Repeat blood smears should be performed at least every 12 to 24 h for 2 days if the first smears are negative. Alternatively, a rapid antigen detection card or stick test should be performed. Patients with severe malaria or those unable to take oral drugs should receive parenteral antimalarial therapy. If there is any doubt about the resistance status of the infecting organism, it should be considered resistant. Antimalarial susceptibility testing can be performed but is not generally available and yields results too slowly to influence choice of treatment. Several drugs are available for oral treatment, and the choice of drug depends on the likely sensitivity of the infecting parasites. Despite recent evidence of chloroquine resistance in *P. vivax* (from parts of Indonesia, Oceania, and Central and South America), chloroquine remains the treatment of choice for the "benign" human malarias (*P. vivax*, *P. ovale*, *P. malariae*). Characteristics of various antimalarial agents are shown in Table 195-7, and drug regimens approved by the U.S. Food and Drug Administration are detailed in Table 195-6. The availability of antimalarial drugs varies considerably between countries. Many of the drugs used to treat malaria in endemic areas are not available in temperate countries such as the United States. Fake or adulterated drugs, including antimalarial agents, are being sold in many low-income countries; thus careful attention is required at purchase, especially when the patient fails to respond as expected.

Severe Malaria Because of resistance, chloroquine can no longer be relied upon in most countries for the treatment of severe malaria. The antiarrhythmic quinidine gluconate is as effective as quinine and, as it is more readily available, has replaced quinine for the treatment of malaria in the United States. The administration of quinidine must be closely monitored if dysrrhythmias and hypotension are to be avoided. Total plasma levels >8 μg/mL, a QT_c interval >0.6 s, or QRS widening beyond 25% of baseline are indications for slowing infusion rates. If arrhythmia or saline-unresponsive hypotension develops, treatment with this drug should be discontinued. Quinine is safer than quinidine; cardiovascular monitoring is not required except when the recipient has cardiac disease. Quinine is the most widely used drug for the treatment of severe malaria worldwide. In some areas, the Chinese drugs derived from artemisinin (artemether and artesunate) have become first-line treatments for severe malaria. These agents are rapidly effective against multidrug-resistant falciparum malaria and are at least as effective as and considerably safer than quinine or quinidine. Artesunate, a water-soluble derivative, can be given by intravenous or intramuscular injection or in a rectal formulation for use primarily in the rural tropics. Artemether and the closely related drug arteether are oil-based formulations given by intramuscular injection. They are not yet available in the United States.

Severe falciparum malaria constitutes a medical emergency re-

TABLE 195-5 *Methods for the Diagnosis of Malaria*[a]

Method	Procedure	Advantages	Disadvantages
Thick blood film[b]	Blood should be uneven in thickness but sufficiently thin to read watch hands through part of the spot. Stain dried, unfixed blood spot with Giemsa, Field's, or other Romanowsky stain. Count number of asexual parasites per 200 WBCs (or per 500 at low densities). Count gametocytes separately.[c]	Sensitive (0.001% parasitemia); species specific; inexpensive	Requires experience (artifacts may be misinterpreted as low-level parasitemia); underestimates true count
Thin blood film[d]	Stain fixed smear with Giemsa, Field's, or other Romanowsky stain. Count number of RBCs containing asexual parasites per 1000 RBCs. In severe malaria, assess stage of parasite development and count neutrophils containing malaria pigment.[e] Count gametocytes separately.[c]	Rapid; species specific; inexpensive; in severe malaria, provides prognostic information[e]	Insensitive (>0.05% parasitemia); uneven distribution of *P. vivax*, as enlarged infected red cells concentrate at leading edge
PfHRP2 dipstick or card test	A drop of blood is placed on the stick or card, which is then immersed in washing solutions. Monoclonal antibody captures the parasite antigen and reads out as a colored band.	Rapid; sensitivity similar to or slightly lower than that of thick films (~0.001% parasitemia)	Detects only *Plasmodium falciparum*; remains positive for weeks after infection[f]; does not quantitate *P. falciparum* parasitemia
Plasmodium LDH dipstick or card test	A drop of blood is placed on the stick or card, which is then immersed in washing solutions. Monoclonal antibodies capture the parasites and read out as colored bands. One band is genus specific (all malarias), and the other is specific for *P. falciparum*.	Rapid; sensitivity similar to or slightly lower than that of thick films for *P. falciparum* (~0.001% parasitemia); provides less sensitive diagnosis for other malarias (*P. vivax*, *P. ovale*, *P. malariae*) and does not speciate these organisms	Slightly more difficult preparation than PfHRP2 tests; may miss low-level parasitemia with *P. vivax*, *P. ovale*, and *P. malariae*; does not quantitate *P. falciparum* parasitemia
Microtube concentration methods with acridine orange staining	Blood is collected in a specialized tube containing acridine orange, anticoagulant, and a float. After centrifugation, which concentrates the parasitized cells around the float, fluorescence microscopy is performed.	Sensitivity similar or superior to that of thick films (~0.001% parasitemia); ideal for processing large numbers of samples rapidly	Does not speciate or quantitate; requires fluorescence microscopy

[a] Malaria cannot be diagnosed clinically with accuracy, but treatment should be started on clinical grounds if the laboratory confirmation is likely to be delayed. In areas of the world where malaria is endemic and transmission is high, low-level asymptomatic parasitemia is common in otherwise-healthy people. Thus malaria may not be the cause of a fever, although in this context the presence of >10,000 parasites/μL (~0.2%) *does* indicate that malaria is the cause. Antibody and polymerase chain reaction tests have no role in the diagnosis of malaria.

[b] Asexual parasites/200 WBCs × 40 = parasite count/μL (assumes a WBC count of 8000/μL). See Figs. 195-7 through 195-10.

[c] Gametocytemia may persist for days or weeks after clearance of asexual parasites. Gametocytemia without asexual parasitemia does not indicate active infection.

[d] Parasitized RBCs (%) × hematocrit × 1256 = parasite count/μL. See Figs. 195-3 through 195-6.

[e] The presence of >100,000 parasites/μL (~2%) is associated with an increased risk of severe malaria, but some patients have severe malaria with lower counts. At any level of parasitemia, the finding that >50% of parasites are tiny rings (cytoplasm width less than half of nucleus width) carries a relatively good prognosis. The presence of visible pigment in >20% of parasites or in >5% of polymorphonuclear leukocytes (indicating massive recent schizogony) carries a worse prognosis.

[f] Persistence of PfHRP2 is a disadvantage in high-transmission settings, where many asymptomatic people have positive tests, but can be used to diagnostic advantage in low-transmission settings when a sick patient has received previous unknown treatment (which, in endemic areas, often consists of antimalarial drugs). A positive PfHRP2 test indicates that the illness is falciparum malaria, even if the blood smear is negative.

Note: LDH, lactate dehydrogenase; PfHRP2, *P. falciparum* histidine-rich protein 2; RBCs, red blood cells; WBCs, white blood cells.

quiring intensive nursing care and careful management. The patient should be weighed and, if comatose, placed on his or her side or prone. Frequent evaluation of the patient's condition is essential. Ancillary drugs such as high-dose glucocorticoids, urea, heparin, dextran, desferrioxamine, antibody to tumor necrosis factor α, and high-dose phenobarbital (20 mg/kg) have proved either ineffective or harmful in clinical trials and should not be used. In acute renal failure or severe metabolic acidosis, hemofiltration or hemodialysis should be started as early as possible.

Parenteral antimalarial treatment should be started as soon as possible. An initial loading dose must be given so that therapeutic concentrations are reached as soon as possible. Both quinine and quinidine will cause dangerous hypotension if injected rapidly; when given intravenously, they must be administered carefully by rate-controlled infusion only. The optimal therapeutic range for quinine and quinidine in severe malaria is not known with certainty, but total plasma concentrations of 8 to 15 mg/mL for quinine and 3.5 to 8.0 mg/mL for quinidine are effective and do not cause serious toxicity. The systemic clearance and apparent volume of distribution of these alkaloids are markedly reduced and plasma protein binding is increased in severe malaria, so that the blood concentrations attained with a given dose are higher. If the patient remains seriously ill or in acute renal failure for >2 days, the maintenance doses of quinine or quinidine should be reduced by 30 to 50% to prevent toxic accumulation of the drugs. The initial doses should never be reduced. If one of the artemisinin derivatives or chloroquine is given, dose reductions are unnecessary, even in renal failure. Exchange transfusion should be considered for severely ill patients, although the precise indications for this procedure have not been agreed upon. It has been recommended that—if safe and feasible—exchange should be considered for patients with severe malaria and parasitemia levels of 5 to 15% and is indicated for parasitemia levels of >15%. The role of prophylactic anticonvulsants is uncertain. If respiratory support is not available, then a full loading dose of phenobarbital (20 mg/kg) to prevent convulsions should not be given as it may cause respiratory arrest.

When the patient is unconscious, the blood glucose level should be measured every 4 to 6 h, and values <2.2 mmol/L (40 mg/dL) should mandate treatment with intravenous dextrose. All patients treated with intravenous quinine or quinidine should receive a continuous infusion of 5 to 10% dextrose. The parasite count and hematocrit level should be measured every 6 to 12 h. Anemia develops rapidly; if the hematocrit falls to <20%, then whole blood (preferably fresh) or packed cells should be transfused slowly, with careful attention to circulatory status. Renal function should be checked daily. Children presenting with severe anemia and acidotic breathing are often hypovolemic; in this situation, resuscitation with crystalloids or blood is

TABLE 195-6 *Recommended Therapeutic Doses of Antimalarial Drugs*

Drug	Uncomplicated Malaria (Oral)	Severe Malaria[a] (Parenteral)
Chloroquine[b]	10 mg of base/kg followed by 10 mg/kg at 24 h and 5 mg/kg at 48 h *or* by 5 mg/kg at 12, 24, and 36 h (total dose, 25 mg/kg); for *P. vivax* or *P. ovale*, primaquine (0.25 mg of base/kg per day for 14 days[d]) added for radical cure	10 mg of base/kg by constant-rate infusion over 8 h followed by 15 mg/kg over 24 h *or* by 3.5 mg of base/kg by IM or SC injection every 6 h (total dose, 25 mg/kg)[c]
Amodiaquine[b]	15 mg of base/kg followed by 10 mg/kg per day at 24 and 48 h (total dose, 35 mg/kg)	—
Sulfadoxine/ pyrimethamine[b]	25/1.25 mg/kg, single oral dose (3 tablets for adults)	—
Mefloquine[b]	15 mg/kg followed 8–12 h later by second dose of 10 mg/kg	—
Quinine	10 mg of salt/kg q8h for 7 days combined with tetracycline[e] (4 mg/kg qid) or doxycycline (3 mg/kg once daily) or clindamycin (10 mg/kg bid) for 7 days	20 mg of salt/kg by IV infusion over 4 h[f] followed by 10 mg/kg infused over 2–8 h every 8 h
Quinidine gluconate	—	10 mg of base/kg by constant-rate infusion over 1–2 h followed by 0.02 mg/kg per min, with ECG monitoring[g]
Artesunate	In combination with 25 mg of mefloquine/kg, 12 mg/kg given in divided doses over 3–5 days (e.g., 4 mg/kg for 3 days or 4 mg/kg followed by 2 mg/kg per day for 4 days); if used alone or in combination with clindamycin or doxycycline, give for 7 days (usually 4 mg/kg initially followed by 2 mg/kg daily)	2.4 mg/kg IV or IM stat followed by 1.2 mg/kg at 12 and 24 h and then daily (or 2.4 mg/kg once daily)
Artemether	Same regimen as for artesunate	3.2 mg/kg IM stat followed by 1.6 mg/kg per day
Atovaquone-proguanil (Malarone)	For adults >40 kg, each dose comprises 4 tablets (each tablet containing atovaquone 250 mg and proguanil 100 mg) taken once daily for 3 days with food	—
Artemether-lumefantrine	For adults ≥35 kg, each dose comprises 4 tablets (each tablet containing artemether 20 mg and lumefantrine 120 mg) at 0, 8, 24, 36, 48, and 60 h, taken after food	—

[a] Oral treatment should be substituted for parenteral therapy as soon as the patient can take tablets by mouth.
[b] These drugs should be combined with either artesunate or artemether when used to treat falciparum malaria. Where there is full susceptibility to both drugs, chloroquine or amodiaquine can be combined with sulfadoxine/pyrimethamine.
[c] Chloroquine-resistant *P. falciparum* is now very widespread, so this regimen should not be used unless there is confirmed full susceptibility in the area.
[d] In Oceania and Southeast Asia, the dose should be 0.33 to 0.5 mg of base/kg. This regimen should not be used in patients with severe variants of G6PD deficiency.
[e] Neither tetracycline nor doxycycline should be given to pregnant women or to children <8 years old.
[f] Alternatively, infusion of 7 mg of salt/kg over 30 min can be followed by 10 mg of salt/kg over 4 h.
[g] Some authorities recommend a lower dose of intravenous quinidine: 6.2 mg of base/kg over 1–2 h followed by 0.0125 mg/kg per min.

Note: In severe malaria, quinine or quinidine should be used if there is any doubt about the infecting strain's sensitivity to chloroquine.

Abbreviations: IM, intramuscular; SC, subcutaneous; IV, intravenous; ECG, electrocardiogram; G6PD, glucose-6-phosphate dehydrogenase.

indicated. Accurate assessment is vital. Management of fluid balance is difficult in severe malaria, particularly in adults, because of the thin dividing line between overhydration (leading to pulmonary edema) and underhydration (contributing to renal impairment). If necessary, pulmonary artery occlusion pressures should be measured and maintained in the low-normal range. As soon as the patient can take fluids, oral therapy should be substituted for parenteral treatment.

Uncomplicated Malaria Infections due to *P. vivax*, *P. malariae*, *P. ovale*, and known sensitive strains of *P. falciparum* should be treated with oral chloroquine (total dose, 25 mg of base/kg). Chloroquine-resistant *P. falciparum* is now widespread. Chloroquine-resistant strains may be sensitive to sulfadoxine/pyrimethamine in some areas. Where there is resistance to the latter combination, either (1) quinine plus tetracycline or doxycycline (or clindamycin) or (2) mefloquine should be used; tetracycline and doxycycline cannot be given to pregnant women or to children <8 years of age. Oral quinine is extremely bitter and regularly produces cinchonism comprising tinnitus, high-tone deafness, nausea, vomiting, and dysphoria. Compliance is poor with the required 5- to 7-day regimens of this drug. Mefloquine should be given at a total dosage of 25 mg/kg (15 mg/kg followed 8 to 12 h later by 10 mg/kg) and, where available and approved for use, combined with artesunate or artemether (4 mg/kg per day for 3 days). Although significant resistance to mefloquine has been documented in Thailand, Myanmar, Vietnam, and Cambodia (Fig. 195-11), mefloquine is usually effective against multidrug-resistant strains of *P. falciparum* outside these areas. Artemether-lumefantrine and atovaquone-proguanil (Malarone) are recently introduced, well-tolerated antimalarial drugs used in 3-day regimens. They are both highly effective against multidrug-resistant falciparum malaria.

Patients should be monitored for vomiting for 1 h after the administration of any oral antimalarial drug. If there is vomiting, the dose should be repeated. Symptom-based treatment, with tepid sponging and acetaminophen administration, lowers fever and thereby reduces the patient's propensity to vomit these drugs. Minor central nervous system reactions (nausea, dizziness, sleep disturbances) are common. The incidence of serious adverse neuropsychiatric reactions to mefloquine treatment is ~1 in 1000 in Asia but may be as high as 1 in 200 among Africans and Caucasians. All the antimalarial quinolines (chloroquine, mefloquine, and quinine) exacerbate the orthostatic hypotension associated with malaria, and all are tolerated better by children than by adults. Pregnant women, young children, patients unable to tolerate oral therapy, and nonimmune subjects (e.g., travelers) with suspected malaria should be evaluated carefully and hospitalization considered. If there is any doubt as to the identity of the infecting malarial species, treatment for falciparum malaria should be given. A negative blood smear does not rule out malaria; thick blood films should be checked 1 and 2 days later to exclude the diagnosis. Nonimmune subjects receiving treatment for malaria should have daily parasite counts performed until negative thick films indicate clearance of the parasite. If the level of parasitemia does not fall below 25% of the admission value in 48 h or if parasitemia has not cleared by 7 days (and adherence is assured), drug resistance is likely and the regimen should be changed. If treatment failures occur with commonly used antimalarial agents, alternative drugs should be used (Table 195-8).

To eradicate persistent liver stages and prevent relapse (radical treatment), primaquine (0.3 mg of base/kg; 15 mg of base, adult dose) should be given daily for 14 days to patients with *P. vivax* or *P. ovale* infections after laboratory tests for G6PD deficiency have proved negative. A dose of 22.5 to 30 mg for an adult is recommended for infections acquired in Southeast Asia and Oceania. If the patient has a mild variant of G6PD deficiency, primaquine can be given in a dose of 0.6 mg of base/kg (45 mg maximum) once weekly for 8 weeks.

PREVENTING DRUG RESISTANCE In much of the tropics, drug-resistant *P. falciparum* is increasing in distribution, frequency, and intensity.

TABLE 195-7 *Properties of Antimalarial Drugs*

Drug(s)	Pharmacokinetic Properties	Antimalarial Activity	Minor Toxicity	Major Toxicity
Quinine, quinidine	Good oral and IM absorption (quinine); *Cl* and V_d reduced, but plasma protein binding (principally to ∝1 acid glycoprotein) increased (90%) in malaria; quinine $t_{1/2}$: 16 h in malaria, 11 h in healthy persons; quinidine $t_{1/2}$: 13 h in malaria, 8 h in healthy persons	Acts mainly on trophozoite blood stage; kills gametocytes of *P. vivax*, *P. ovale*, and *P. malariae* (but not *P. falciparum*); no action on liver stages	*Common:* "Cinchonism": tinnitus, high-tone hearing loss, nausea, vomiting, dysphoria, postural hypotension; ECG QT_c interval prolongation (quinine usually by <10% but quinidine by up to 25%) *Rare:* Diarrhea, visual disturbance, rashes *Note:* Very bitter taste	*Common:* Hypoglycemia *Rare:* Hypotension, blindness, deafness, cardiac arrhythmias, thrombocytopenia, hemolysis, hemolytic-uremic syndrome, vasculitis, cholestatic hepatitis, neuromuscular paralysis *Note:* Quinidine more cardiotoxic
Chloroquine	Good oral absorption, very rapid IM and SC absorption; complex pharmacokinetics; enormous *Cl* and V_d (unaffected by malaria); blood concentration profile determined by distribution processes in malaria; $t_{1/2}$: 1–2 months	As for quinine but acts slightly earlier in asexual cycle	*Common:* Nausea, dysphoria, pruritus in dark-skinned patients, postural hypotension *Rare:* Accommodation difficulties, keratopathy, rash *Note:* Bitter taste, well tolerated	*Acute:* Hypotensive shock (parenteral), cardiac arrhythmias, neuropsychiatric reactions *Chronic:* Retinopathy (cumulative dose, >100 g), skeletal and cardiac myopathy
Amodiaquine	Good oral absorption; largely converted to active metabolite desethylamodiaquine	As for chloroquine	Nausea (tastes better than chloroquine)	Agranulocytosis; hepatitis, mainly with prophylactic use
Mefloquine	Adequate oral absorption; no parenteral preparation; $t_{1/2}$: 14–20 days (shorter in malaria)	As for quinine	Nausea, giddiness, dysphoria, fuzzy thinking, sleeplessness, nightmares, sense of dissociation	Neuropsychiatric reactions, convulsions, encephalopathy
Tetracycline, doxycycline[a]	Excellent absorption; $t_{1/2}$: 8 h for tetracycline, 18 h for doxycycline	Weak antimalarial activity; should not be used alone for treatment	Gastrointestinal intolerance, deposition in growing bones and teeth, photosensitivity, moniliasis, benign intracranial hypertension	Renal failure in patients with impaired renal function (tetracycline)
Halofantrine[b]	Highly variable absorption related to fat intake; $t_{1/2}$: 1–3 days (active desbutyl metabolite $t_{1/2}$: 3–7 days)	As for quinine	Diarrhea	Cardiac conduction disturbances; atrioventricular block; ECG QT_c interval prolongation; potentially lethal ventricular tachyarrhythmias
Artemisinin and derivatives (artemether, artesunate)	Good oral absorption, slow and variable absorption of IM artemether; artesunate and artemether biotransformed to active metabolite dihydroartemisinin; all drugs eliminated very rapidly; $t_{1/2}$: <1 h	Broader stage specificity and more rapid than other drugs; no action on liver stages; kills all but fully mature gametocytes of *P. falciparum*	Reduction in reticulocyte count (but not anemia)	Anaphylaxis, urticaria, fever
Pyrimethamine	Good oral absorption, variable IM absorption; $t_{1/2}$: 4 days	For blood stages, acts mainly on mature forms; causal prophylactic	Well tolerated	Megaloblastic anemia, pancytopenia, pulmonary infiltration
Proguanil (chloroguanide)	Good oral absorption; biotransformed to active metabolite cycloguanil; $t_{1/2}$: 16 h; biotransformation reduced by oral contraceptive use and in pregnancy	Causal prophylactic; not used alone for treatment	Well tolerated; mouth ulcers and rare alopecia	Megaloblastic anemia in renal failure
Primaquine	Complete oral absorption; active compound not known; $t_{1/2}$: 7 h	Radical cure; eradicates hepatic forms of *P. vivax* and *P. ovale*; kills all stages of gametocyte development of *P. falciparum*	Nausea, vomiting, diarrhea, abdominal pain, hemolysis, methemoglobinemia	Massive hemolysis in subjects with severe G6PD deficiency
Atovaquone	Highly variable absorption related to fat intake; $t_{1/2}$: 30–70 h	Acts mainly on trophozoite blood stage	None identified	None identified
Lumefantrine	Highly variable absorption related to fat intake; $t_{1/2}$: 3–4 days	As for quinine	None identified	None identified

[a] Tetracycline and doxycycline should not be given to pregnant women or to children <8 years of age.

[b] Halofantrine should not be used by patients with long ECG QT_c intervals or known conduction disturbances or by those taking drugs that may affect ventricular repolarization, e.g., quinidine, quinine, mefloquine, chloroquine, neuroleptics, antiarrhythmics, tricyclic antidepressants, terfenadine, or astemizole.

Abbreviations: *Cl*, systemic clearance; V_d, total apparent volume of distribution; IM, intramuscular; SC, subcutaneous; ECG, electrocardiogram; G6PD, glucose-6-phosphate dehydrogenase.

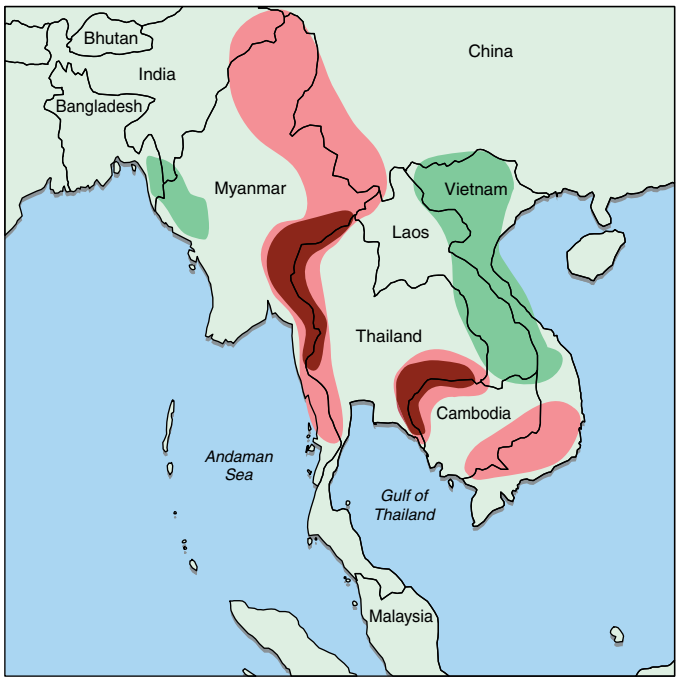

FIGURE 195-11 Mefloquine resistance in *Plasmodium falciparum* in Southeast Asia: high-level mefloquine resistance (*brown*), low-level mefloquine resistance (*red*), and mefloquine sensitivity (failure rate, <20%; *green*). There is insufficient information for the other areas.

There is a growing belief among malariologists that, to prevent resistance, falciparum malaria should be treated with drug combinations and should no longer be treated with single drugs in endemic areas; the same rationale has been applied successfully in the treatment of tuberculosis and HIV/AIDS. This combination strategy is based upon simultaneous use of two or more drugs with different modes of action: one, usually an artemisinin derivative (artesunate, artemether, or dihydroartemisinin), given for 3 days; and the other, a slower-acting antimalarial to which *P. falciparum* is sensitive. Where the malaria parasites are fully sensitive, either amodiaquine or sulfadoxine/pyrimethamine can be used in combination with the artemisinin derivative, or amodiaquine can be combined with sulfadoxine/pyrimethamine. Where there is also resistance to sulfadoxine/pyrimethamine or amodiaquine, a combination of artesunate plus mefloquine, artemether plus lumefantrine, or quinine plus tetracycline or clindamycin can be considered (although tetracycline cannot be given to pregnant women or to children <8 years of age). Atovaquone-proguanil, which is also effective against drug-resistant malaria, can also be combined with artesunate to prevent the emergence of resistance. While there is significant resistance to mefloquine in parts of Southeast Asia, the mefloquine/artesunate combinations are still reliably effective in these areas. The artemisinin derivatives and lumefantrine (all unlicensed in the United States) as well as atovaquone-proguanil are all very well tolerated, with no significant adverse effects.

COMPLICATIONS ■ Acute Renal Failure If the level of BUN or creatinine rises despite adequate rehydration, fluid administration should be restricted to prevent volume overload. As in other forms of hypercatabolic acute renal failure, renal replacement is best performed early (Chap. 260). Hemofiltration and hemodialysis are more effective than peritoneal dialysis and are associated with lower mortality. Some patients with renal impairment pass small volumes of urine sufficient to allow control of fluid balance; these cases can be managed conservatively if other indications for dialysis do not arise. Renal function usually improves within days, but full recovery may take weeks.

Acute Pulmonary Edema Patients should be positioned at 45° and given oxygen and intravenous diuretics. Pulmonary artery occlusion pressures may be normal, indicating increased pulmonary capillary permeability. Positive-pressure ventilation should be started early if the immediate measures fail (Chap. 217).

Hypoglycemia An initial slow injection of 50% dextrose (0.5 g/kg) should be followed by an infusion of 10% dextrose (0.10 g/kg per hour). The blood glucose level should be checked regularly thereafter, as recurrent hypoglycemia is common, particularly in patients receiving quinine or quinidine. In severely ill patients, hypoglycemia commonly occurs together with metabolic (lactic) acidosis and carries a poor prognosis.

Other Complications Patients who develop spontaneous bleeding should be given fresh blood and intravenous vitamin K. Convulsions should be treated with intravenous or rectal benzodiazepines and, if necessary, respiratory support. Aspiration pneumonia should be suspected in any unconscious patient with convulsions, particularly with persistent hyperventilation; intravenous antimicrobial agents and oxygen should be administered, and pulmonary toilet should be undertaken. Hypoglycemia or gram-negative septicemia should be suspected when the condition of any patient suddenly deteriorates for no obvious reason during antimalarial treatment. Systemic *Salmonella* infections are common complications among African children with falciparum malaria.

PREVENTION In most of the tropics, the eradication of malaria is not yet feasible because of the widespread distribution of *Anopheles* breeding sites; the great number of infected persons; the use of ineffective antimalarial drugs; and inadequacies in resources, infrastructure, and control programs. Malaria may be contained by judicious use of insecticides to kill the mosquito vector, rapid diagnosis and appropriate patient management, and—where effective and feasible—administration of chemoprophylaxis to high-risk groups. Malaria researchers are intensifying their efforts to understand parasite-human-mosquito interactions better and to develop more effective control and prevention interventions. Despite the enormous investment in efforts to develop a malaria vaccine, no safe, effective, long-lasting vaccine is likely to be available for general use in the near future (Chap. 107). While there is promise for one or more malaria vaccines on the more distant horizon, prevention and control measures continue to rely on antivector and drug use strategies.

Personal Protection Against Malaria Simple measures to reduce the frequency of mosquito bites in malarious areas are very important. These measures include the avoidance of exposure to mosquitoes at their peak feeding times (usually dusk and dawn), but also throughout the night and the use of insect repellents containing DEET (10 to 35%), suitable clothing, and insecticide-impregnated bed nets or other materials. Widespread use of bed nets treated with residual pyrethroids reduces the incidence of malaria in areas where vectors bite indoors at night and has been shown to reduce mortality in western and eastern Africa.

Chemoprophylaxis (Table 195-9) Few areas of therapeutics are as controversial as antimalarial drug prophylaxis. Recommendations for prophylaxis depend on knowledge of local patterns of plasmodial drug sensitivity and the likelihood of acquiring malarial infection. When there is uncertainty, drugs effective against resistant *P. falciparum* should be used [mefloquine, atovaquone-proguanil (Malarone), doxy-

TABLE 195-8 *Alternative Drugs for Use When Initial Malaria Treatment Fails*

Chloroquine	→ Sulfadoxine/pyrimethamine[a]
	↘
Sulfadoxine/pyrimethamine	→ Artesunate-mefloquine[a]
Mefloquine ± artesunate	→ Quinine ± tetracycline (or doxycycline) for 7 days
	↘ Artesunate + doxycycline or clindamycin for 7 days

[a] Or artemether-lumefantrine.

cycline, or primaquine]. Chemoprophylaxis is never entirely reliable, and malaria should always be considered in the differential diagnosis of fever in patients who have traveled to endemic areas, even if they are taking prophylactic antimalarial drugs.

Pregnant women traveling to malarious areas should be warned about the potential risks. All pregnant women at risk in endemic areas should be encouraged to attend regular antenatal clinics and should receive either prophylaxis with chloroquine (300 mg of base weekly) alone or with proguanil (chloroguanide, 200 mg daily) or intermittent preventive treatment (IPT) with sulfadoxine/pyrimethamine, provided there is not high-level resistance to these drugs. The safety of other prophylactic antimalarial agents in pregnancy has not been established. In addition, antimalarial prophylaxis should be considered for children between the ages of 3 months and 4 years in areas where malaria causes high childhood mortality; such prophylaxis may not be logistically or economically feasible in many countries. Research on IPT for infants and young children shows promise for more widespread use. Children born to nonimmune mothers in endemic areas (usually expatriates moving to these areas) should receive prophylaxis from birth.

Travelers should start taking antimalarial drugs at least 1 week before departure so that any untoward reactions can be detected and therapeutic antimalarial blood concentrations will be present when needed. Antimalarial prophylaxis should continue for 4 weeks after the traveler has left the endemic area, except if atovaquone-proguanil or primaquine has been taken; these drugs have significant activities against the liver stage of the infection (causal prophylaxis) and can be discontinued 1 week after departure from the endemic area.

TABLE 195-9 *Prophylaxis and Self-Treatment for Malaria*

Drug	Usage	Adult Dosage	Child Dosage
Prophylaxis			
Mefloquine	Used in areas where chloroquine-resistant malaria has been reported	228 mg of base (250 mg of salt) orally, once/week[a]	<15 kg: 4.6 mg of base/kg (5 mg of salt/kg) 15–19 kg: ¼ tablet/week 20–30 kg: ½ tablet/week 31–45 kg: ¾ tablet/week >45 kg: 1 tablet/week
Doxycycline[b]	Used as alternative to mefloquine or atovaquone-proguanil	100 mg orally, once/day	>8 years of age: 2 mg/kg per day orally; maximum dose, 100 mg/d
Atovaquone-proguanil (Malarone)[c]	Used as alternative to mefloquine or doxycycline	250/100 mg orally once/day	11–20 kg: 62.5 mg/25 mg 21–30 kg: 125 mg/50 mg 31–40 kg: 187.5 mg/75 mg >40 kg: 250 mg/100 mg
Chloroquine	Used in areas where chloroquine-resistant malaria has *not* been reported	300 mg of base (500 mg of salt) orally, once/week	5 mg of base/kg (8.3 mg of salt/kg) orally, once/week; maximum dose, 300 mg of base
Proguanil (not available in U.S.)	Used simultaneously *with* chloroquine as alternative to mefloquine or doxycycline	200 mg orally, once/day, in combination with weekly chloroquine	<2 years: 50 mg/d 2–6 years: 100 mg/d 7–10 years: 150 mg/d >10 years: 200 mg/d
Primaquine[c]	Used for travelers only after testing for G6PD deficiency; postexposure prevention for relapsing malaria or prophylaxis	Postexposure: 15 mg of base (26.3 mg of salt) orally, once/day for 14 days Prophylaxis: 30 mg of base daily	0.3 mg of base/kg (0.5 mg of salt/kg) orally, once/day for 14 days
Self-treatment			
Atovaquone-proguanil (Malarone)[d]	In areas with chloroquine-resistant malaria, should be carried during travel to very remote areas by persons taking mefloquine or doxycycline	4 tablets (1000 mg of atovaquone and 400 mg of proguanil) orally, as a single daily dose for 3 consecutive days	11–20 kg: 1 adult tablet 21–30 kg: 2 adult tablets 31–40 kg: 3 adult tablets >40 kg: 4 adult tablets
Sulfadoxine/pyrimethamine[e]	Used as alternative to atovaquone-proguanil for self-treatment	3 tablets (75 mg of pyrimethamine and 1500 mg of sulfadoxine) orally, as a single dose	5–10 kg: ½ tablet 11–20 kg: 1 tablet 21–30 kg: 1½ tablets 31–45 kg: 2 tablets >45 kg: 3 tablets

[a] Tablets manufactured outside the United States contain 250 mg of base.
[b] Not in pregnant women or children <8 years old.
[c] Primaquine and atovaquone-proguanil have both proved safe and effective for antimalarial chemoprophylaxis in areas with chloroquine-resistant falciparum malaria, but more data are needed, particularly in children. These drugs should not be used in pregnancy.
[d] Not for patients on atovaquone-proguanil prophylaxis.
[e] Regimen is used for treatment only (*not* prophylaxis) in areas with known susceptibility.

Mefloquine (250 mg of salt weekly, adult dose) has been the antimalarial prophylactic agent of choice for much of the tropics because it is usually effective against multidrug-resistant falciparum malaria and is reasonably well tolerated. Mild nausea, dizziness, fuzzy thinking, disturbed sleep patterns, vivid dreams, and malaise are relatively common. Approximately 1 in every 10,000 recipients develops an acute reversible neuropsychiatric reaction manifested by confusion, psychosis, convulsions, or encephalopathy. The role of mefloquine prophylaxis during pregnancy remains uncertain; in studies in Africa, mefloquine prophylaxis was found to be effective and safe during pregnancy. However, in one study from Thailand, treatment of malaria with mefloquine was associated with an increased risk of stillbirth.

Atovaquone-proguanil (Malarone; 3.75/1.5 mg per kg or 250/100 mg, daily adult dose) is a fixed-combination once-daily prophylactic agent that is very well tolerated by adults and children, with fewer adverse gastrointestinal effects than chloroquine-proguanil and fewer adverse central nervous system effects than mefloquine. It is proguanil itself, rather than the antifolate metabolite cycloguanil, that acts synergistically with atovaquone. This combination is effective against all types of malaria, including multidrug-resistant falciparum malaria, and, because of its causal activity, may be discontinued 1 week after departure from the endemic area. Atovaquone-proguanil is best taken with food or a milky drink to optimize absorption. There are insufficient data on the safety of this regimen in pregnancy.

Daily administration of doxycycline (100 mg daily, adult dose) is an effective alternative to mefloquine. Doxycycline is generally well tolerated but may cause vulvovaginal thrush, diarrhea, and photosensitivity and cannot be used by children <8 years old or by pregnant women.

Chloroquine remains the drug of choice for the prevention of infection with drug-sensitive *P. falciparum* and with the other human malarial species (although chloroquine-resistant *P. vivax* has been reported from parts of eastern Asia, Oceania, and Central and South America). Unfortunately, there are now few areas of the world with chloroquine-sensitive *P. falciparum*. Chloroquine is generally well tol-

erated, although some patients are unable to take the drug because of malaise, headache, visual symptoms (from reversible keratopathy), gastrointestinal intolerance, or (in dark-skinned patients) pruritus. A concomitant filarial infection may provoke or aggravate chloroquine-induced pruritus. Chloroquine is considered safe in pregnancy. With chronic administration for >5 years, a characteristic dose-related retinopathy may develop, but this condition is rare at the doses used for antimalarial prophylaxis. Idiosyncratic or allergic reactions are also rare. Skeletal and cardiac myopathy are potential problems with protracted prophylactic use; they are more likely to occur with the high doses used in the treatment of rheumatoid arthritis. Neuropsychiatric reactions and skin rashes are unusual. When used continuously, amodiaquine, a related aminoquinoline, is associated with a high risk of agranulocytosis (~1 person in 2000) and also hepatotoxicity (~1 person in 16,000) and should not be used for prophylaxis.

Primaquine (0.5 mg of base/kg or 30 mg, daily adult dose) has proved safe and effective in the prevention of drug-resistant falciparum and vivax malaria in adults. Abdominal pain and oxidant hemolysis, the principal adverse effects, are not common as long as the drug is taken with food and is not given to G6PD-deficient persons. Primaquine should not be given to pregnant women or neonates.

In the past, the dihydrofolate reductase inhibitors pyrimethamine and proguanil (chloroguanide) have been administered widely, but the rapid selection of resistance in both *P. falciparum* and *P. vivax* has limited their use. Whereas antimalarial quinolines such as chloroquine act on the erythrocyte stage of parasitic development, the dihydrofolate reductase inhibitors also inhibit preerythrocytic growth in the liver (causal prophylaxis) and development in the mosquito (sporontocidal activity). Proguanil is safe and well tolerated, although mouth ulceration occurs in ~8% of persons using this drug; it is considered safe for antimalarial prophylaxis in pregnancy. The prophylactic use of the combination of pyrimethamine and sulfadoxine is not recommended because of an unacceptable incidence of severe toxicity, principally exfoliative dermatitis and other skin rashes, agranulocytosis, hepatitis, and pulmonary eosinophilia (incidence, 1:7000; fatal reactions, 1:18,000). The combination of pyrimethamine with dapsone (0.2/1.5 mg/kg weekly; 12.5/100 mg, adult dose) is a second-line alternative available in some countries. Dapsone may cause methemoglobinemia and allergic reactions and (at higher doses) may pose a significant risk of agranulocytosis. Proguanil and the pyrimethamine-dapsone combination are not available in the United States.

Because of the increasing spread and intensity of antimalarial drug resistance (Figs. 195-2 and 195-11), the Centers for Disease Control and Prevention (CDC; *www.cdc.gov/travel/index.htm*), which recommends a weekly dose of mefloquine for all travelers, maintains an updated 24-h travel and malaria information audiotape that can be accessed by touch-tone telephone (888-232-3228). Regional and disease-specific documents may be requested from the CDC Fax Information Service (888-232-3299). Consultation for the evaluation of prophylaxis failures or treatment of malaria can be obtained from state and local health departments and the CDC Malaria Hotline (770-488-7788).

BABESIOSIS

Babesiosis is a worldwide protozoan disease of animals that is transmitted by ticks; humans are infected incidentally and initially develop a nonspecific febrile illness that can lead to hemolytic anemia. *Babesia* organisms enter RBCs and resemble malarial parasites morphologically, thus posing a diagnostic problem.

ETIOLOGY AND NATURAL CYCLE Of the >100 species of *Babesia*, *B. microti* and *B. divergens* are the two that cause most human infections. *Babesia* species infect many mammalian hosts. The majority of species are from rodents and birds; however, almost any mammal serving as a host for *Babesia*-infected ticks can be a reservoir. Ixodid (hard-bodied) ticks, in particular *Ixodes scapularis* (*I. dammini*) and *I. ricinus*, are the vectors of the parasite. Ticks ingest *Babesia* while feeding, and the parasite multiplies within the tick's gut wall. The organisms then spread to the salivary glands; their inoculation into a vertebrate host by a tick larva, nymph, or adult completes the cycle of transmission. Asexual reproduction of *Babesia* within RBCs produces two or four parasites.

EPIDEMIOLOGY While *Babesia* infections in wild and domestic animals are distributed globally, almost all of the >300 *B. microti* infections in the United States have occurred along the northeastern coast, including Nantucket Island, Martha's Vineyard, and Cape Cod in Massachusetts; Block Island in Rhode Island; Long Island, Shelter Island, and Fire Island in New York; and the nearby mainland, including eastern Connecticut and areas of Westchester County in New York. In Nantucket, 60% of deer mice are infected with *B. microti*. Cases have also been reported from Wisconsin, Minnesota, Virginia, Maryland, Georgia, and Mexico. *Babesia* isolates from patients in Washington (WA-1) and California (CA-1) are structurally similar but genetically and antigenically distinct from *B. microti*. A strain isolated in Japan and another in Missouri (MO-1) differ from these isolates, suggesting that babesiosis may be an "emerging infection." The vast majority of *Babesia* infections are not clinically apparent. The deer tick, *I. scapularis*, is the vector associated with *B. microti*. In Europe, *B. divergens* has been responsible for the majority of the 30 reported cases of babesiosis; Yugoslavia, Russia, France, the United Kingdom, and Ireland have accounted for most of these infections.

Transfusions are another source of babesiosis. In the >20 transfusion-associated cases reported, parasites were uncommonly detected in blood donors, but serologic testing of their blood for *Babesia* gave positive results.

Infections with *B. divergens* have occurred sporadically in previously splenectomized patients in several countries in Europe. *I. ricinus* is probably the vector in these cases, as it is for the transmission of this organism among cattle. The infected persons were predisposed to illness by their asplenic status.

I. scapularis feeds on rodents as a larva and a nymph and on deer as an adult; nymphs are abundant during the spring and summer and feed on humans readily. In some endemic areas, the seroprevalence in the human population may be >2%; residents of Shelter Island and Nantucket have had a 4 to 7% seroconversion rate. These figures indicate that asymptomatic infection is more frequent than is generally thought and that *Babesia* can be a peril for persons being transfused.

CLINICAL PRESENTATION The incubation period for *B. microti* infection is ~1 to 4 weeks. Immunosuppressed patients, splenectomized individuals, and the elderly have the most severe illness. The clinical presentation varies widely and resembles malaria or rickettsiosis; symptoms and signs include a gradual onset of irregular fever, chills, sweating, muscle pain, and fatigue. Mild hepatosplenomegaly and mild hemolytic anemia may develop, but a rash is not present. The level of parasitemia may range from 1 to 50%. The illness may continue for weeks or months, particularly in patients with HIV infection or AIDS.

Patients infected with *B. divergens* have usually been splenectomized and have a more severe illness, with a rapid onset of chills,

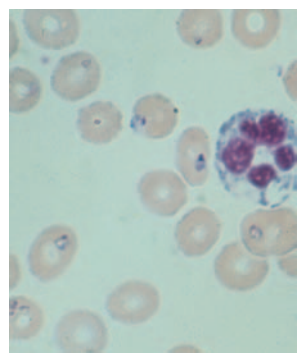

FIGURE 195-12 Thin blood film showing trophozoites of *Babesia*. (*Reproduced from Benchaids for the Diagnosis of Malaria Infections, 2d ed, with the permission of the World Health Organization.*)

fever, nausea, vomiting, and hemolytic anemia progressing to jaundice, hemoglobinemia, and renal failure. *B. divergens* infections are often fatal.

DIAGNOSIS Whether or not they have a history of exposure to ticks or tick bites, febrile persons living in endemic areas should have Giemsa-stained thick and thin blood films (Fig. 195-12) examined for small intraerythrocytic parasites. *B. microti* appears as a small ring form resembling *P. falciparum*. Unlike infection with *Plasmodium*, however, that with *Babesia* does not cause the production of pigment in parasites, nor are schizonts or gametocytes formed. Dividing within RBCs, *B. microti* can form four daughter parasites attached by strands of cytoplasm; these "tetrad" forms are seen infrequently in human blood films but are a distinguishing feature. A sensitive and specific indirect immunofluorescence antibody test is useful for the diagnosis of infection with *B. microti* and exists for *B. divergens* and WA-1 but does not replace the blood smear. The serum antibody titer rises 2 to 4 weeks after the onset of illness and then wanes over 6 to 12 months; cross-reactions can occur with other species of *Babesia* and with *Plasmodium*. A species-specific polymerase chain reaction test using the RNA gene has been used to show parasite persistence when the blood smear is negative.

About 50% of patients infected with *B. microti* have antibody to *Borrelia burgdorferi*, the agent of Lyme disease (Chap. 157); this figure varies with the geographic area. The occurrence of mixed infections is not surprising since both organisms are transmitted by *I. scapularis*. This tick species is also a potential vector of human granulocytotropic ehrlichiosis; the same tick may carry more than one tick-borne disease. Intraperitoneal inoculation of blood from patients with babesiosis into hamsters or gerbils results in detectable parasitemia within 2 to 4 weeks.

TABLE 195-10 *Treatment of Babesiosis*

Organism	Adults	Children
Babesia microti	Atovaquone 750 mg bid PO *plus* azithromycin 600 mg/d PO *or*	Atovaquone 40 mg/kg/d PO *plus* azithromycin 12 mg/kg/d PO *or*
	Quinine 650 mg tid PO *plus* clindamycin 1200 mg bid IV (or 600 mg tid PO)	Quinine 25 mg/kg tid PO *plus* clindamycin 20–40 mg/kg tid PO
Babesia divergens and other *Babesia* species, including MO-1, WA-1, and CA-1	Quinine 650 mg tid PO *plus* clindamycin 1200 mg bid IV (or 600 mg tid PO) *plus* atovaquone 750 mg bid PO[a]	Quinine 25 mg/kg tid PO *plus* clindamycin 20–40 mg/kg tid PO *plus* atovaquone 40 mg/kg per day PO[a]

[a] Consider exchange transfusion or apheresis.

TREATMENT (See Table 195-10)

B. microti infections in patients with intact spleens are often self-limiting without treatment, although symptoms may persist for months with or without treatment. Because silent parasitemia may have prolonged symptoms and signs, treatment is advised for all patients infected with *Babesia*. Patients infected with *B. divergens* or other *Babesia* species (including MO-1, WA-1, and CA-1) should receive quinine, clindamycin, and atovaquone; in addition, exchange transfusion or apheresis should be strongly considered. Treatment with the combination of quinine sulfate (650 mg of salt orally three times daily) plus clindamycin (600 mg orally three times daily or 1.2 g parenterally twice daily) for 7 to 10 days is usually effective but may not always eliminate parasites. Especially severe infections with high-level *B. microti* parasitemia in asplenic patients have been successfully treated with exchange transfusions in addition to quinine and clindamycin. The current view is that the combination of atovaquone (750 mg twice daily for adults) and azithromycin (600 mg/d for adults) for 7 to 10 days offers optimal therapy.

196 LEISHMANIASIS

Barbara L. Herwaldt

OVERVIEW

DEFINITION The term *leishmaniasis* refers collectively to various clinical syndromes caused by obligate intracellular protozoa of the genus *Leishmania* (order Kinetoplastida). Leishmaniasis is endemic in diverse ecologic settings in the tropics, the subtropics, and southern Europe that range from deserts to rain forests and from rural to periurban areas. It is typically a vector-borne zoonosis, with rodents and canids as common reservoir hosts and humans as incidental hosts. In humans, visceral, cutaneous, and mucosal leishmaniasis result from infection of macrophages throughout the reticuloendothelial system, in the skin, and in the naso-oropharyngeal mucosa, respectively. Current challenges include the emergence of leishmaniasis in new geographic areas and host populations (e.g., visceral leishmaniasis in persons infected with HIV) as well as the need for field-applicable, rapid diagnostic tests and for effective, safe, and affordable oral therapies, control measures, and vaccines.

ETIOLOGY The organisms that cause the various forms of leishmaniasis in humans (Table 196-1) are in the subgenus *Leishmania* or the subgenus *Viannia*. Visceral leishmaniasis is typically but not exclusively caused by organisms of the *Leishmania donovani* complex; Old World cutaneous leishmaniasis by *L. tropica*, *L. major*, and *L. aethiopica*; and New World (or American) cutaneous leishmaniasis by organisms of the *L. mexicana* complex and the *Viannia* subgenus. Mucosal leishmaniasis is caused primarily by some organisms in the *Viannia* subgenus and also by *L. amazonensis*.

LIFE CYCLE *Leishmania* parasites are transmitted by the bite of female phlebotomine sandflies [genus *Phlebotomus* (Old World) or *Lutzomyia* (New World)]. As the flies attempt to feed, they regurgitate the para-

TABLE 196-1 *Major* Leishmania *Species That Cause Disease in Humans*

Species[a]	Clinical Syndrome[b]	Geographic Distribution
SUBGENUS *LEISHMANIA*		
L. donovani complex		
L. donovani sensu stricto	VL (PKDL, OWCL)	China, Indian subcontinent, southwestern Asia, Ethiopia,[c] Kenya, Sudan, Uganda; possibly sporadic in sub-Saharan Africa
L. infantum sensu stricto[d]	VL (OWCL)	China, central and southwestern Asia, Middle East, southern Europe, North Africa, Ethiopia,[c] Sudan; sporadic in sub-Saharan Africa
L. chagasi[d]	VL (NWCL)	Central and South America
L. mexicana complex		
L. mexicana	NWCL (DCL)	Texas, Mexico, Central and South America
L. amazonensis	NWCL (ML, DCL, VL)	Panama and South America
L. tropica	OWCL (VL)[e]	Central Asia, India, Pakistan, southwestern Asia, Middle East, Turkey, Greece, North Africa, Ethiopia,[c] Kenya, Namibia
L. major	OWCL[f]	Central Asia, India, Pakistan, southwestern Asia, Middle East, Turkey, North Africa, Sahel region of north-central Africa, Ethiopia,[c] Sudan, Kenya
L. aethiopica	OWCL (DCL, ML)	Ethiopia,[c] Kenya, Uganda
SUBGENUS *VIANNIA*		
L. (V.) braziliensis	NWCL (ML)	Central and South America
L. (V.) guyanensis	NWCL (ML)	South America
L. (V.) panamensis	NWCL (ML)	Central America, Venezuela, Colombia, Ecuador, Peru
L. (V.) peruviana	NWCL[g]	Peru (western slopes of Andes)

[a] Species other than those listed here have been reported to infect humans.
[b] ***Abbreviations***: VL, visceral leishmaniasis; PKDL, post–kala-azar dermal leishmaniasis; OWCL, Old World cutaneous leishmaniasis; NWCL, New World (American) cutaneous leishmaniasis; DCL, diffuse cutaneous leishmaniasis; ML, mucosal leishmaniasis. Clinical syndromes less frequently associated with the various species are shown in parentheses.
[c] Cutaneous and visceral leishmaniasis also are endemic in parts of Eritrea, but the causative species have not been well established.
[d] "*L. infantum*" and "*L. chagasi*" are synonymous.
[e] *L. tropica* also causes leishmaniasis recidivans and viscerotropic leishmaniasis.
[f] *L. major*–like organisms also cause New World cutaneous leishmaniasis.
[g] The cutaneous leishmaniasis syndrome caused by this species is called *uta*.

site's flagellated promastigote stage into the skin of mammalian hosts. Components of sandfly saliva can affect the host's response to the parasite. Promastigotes attach to receptors on macrophages, are phagocytized, and transform within phagolysosomes into the nonflagellated amastigote stage, which multiplies by binary fission. After rupture of infected macrophages, amastigotes are phagocytized by other macrophages. If ingested by feeding sandflies, amastigotes transform back into promastigotes, which require at least 7 days to become infective.

IMMUNOLOGY Advances in the understanding of the immunology of leishmaniasis have made this parasitic disease the paradigm for studies of the T cell subsets and cytokines that govern resistance and susceptibility to intracellular pathogens. The paradigm is best demonstrated in murine *L. major* infection. In inbred mice, production of interferon γ (IFN-γ) by T_H1 and natural killer cells confers resistance. Interleukin (IL)12 induces naive T cells to differentiate into T_H1 cells and induces T cells and natural killer cells to produce IFN-γ. In contrast, expansion of IL-4-producing T_H2 cells and IL-10 mediate susceptibility.

Not all aspects of leishmaniasis in mice, whose susceptibility to leishmanial infection is genetically determined, apply to human infection, for which the genetic determinants are being investigated. However, a consistent principle is that healing and resistance to reinfection are associated with an intact T_H1 cell response, production of IFN-γ, and activation of macrophages to kill intracellular amastigotes. In human visceral leishmaniasis, IL-10, which deactivates the T_H1 cell response, appears particularly important in the progression of disease.

GENERAL DIAGNOSTIC PRINCIPLES Definitive diagnosis of leishmaniasis requires demonstration of the parasite. To identify amastigotes by light-microscopic examination, the specimen obtained from an infected site (e.g., thin smear, histologic section) should be stained with Giemsa or another Romanovsky stain and presumptive amastigotes (2 to 4 μm in diameter) examined under oil immersion for the presence of a nucleus and a rod-shaped kinetoplast (Fig. 196-1); the latter is aspecialized mitochondrial structure that contains extranuclear DNA. Other means of parasitologic confirmation include in vitro culture (e.g., on Novy-MacNeal-Nicolle medium), animal inoculation, and use of investigational molecular techniques [e.g., polymerase chain reaction (PCR)].

The *Leishmania* species that infect humans are morphologically similar. They can be distinguished by isoenzyme analysis of cultured promastigotes, determination of monoclonal antibody specificity, or various molecular methods.

Indirect immunologic methods for diagnosis include serologic assays and tests for *Leishmania*-specific cell-mediated immunity (e.g., skin testing for delayed-type hypersensitivity reactions). The usefulness of such methods depends in part on the clinical syndrome (see below). Traditional serologic assays (e.g., indirect fluorescent antibody testing) do not reliably distinguish past from current infection, and no leishmanin skin-test preparation has been approved for use in the United States. Advances in molecular methods (e.g., production of recombinant/synthetic antigens) are leading to the development of better diagnostic techniques.

GENERAL THERAPEUTIC PRINCIPLES For a given case of leishmaniasis, it is important to consider whether the patient's illness could result in substantial morbidity or in death and therefore requires expeditious treatment with a regimen that generally is highly effective. For more than half a century, the pentavalent antimonial (Sb^V) compounds sodium stibogluconate and meglumine antimonate have been the mainstays of antileishmanial therapy (Table 196-2). Toxicity (such as myalgia, arthralgia, fatigue,

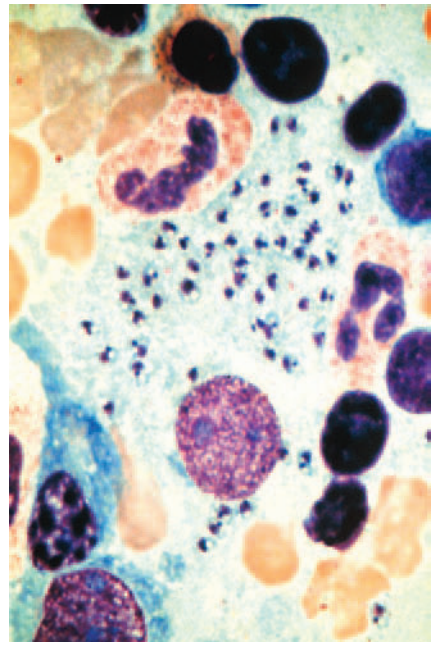

FIGURE 196-1 Amastigotes (the tissue form of the *Leishmania* parasite) in a bone marrow specimen from a patient with visceral leishmaniasis. Each amastigote has a nucleus and kinetoplast. Visualization of the kinetoplast is essential in differentiating leishmaniasis from diseases such as histoplasmosis. The extracellular amastigotes probably were released from mononuclear phagocytes during specimen collection and processing. *(Photograph courtesy of Dr. R. Hamill.)*

TABLE 196-2 *Parenteral and Oral Drug Regimens for Treatment of Leishmaniasis*[a]

Clinical Syndrome, Drug	Route of Administration	Regimen
VISCERAL LEISHMANIASIS		
First-line therapy		
Pentavalent antimony[b]	IV, IM	20 mg Sb^V/kg qd for 28 days
Amphotericin B, lipid formulation[c]	IV	2–5 mg/kg qd (total: usually ~15–21 mg/kg)
Alternatives		
Amphotericin B (deoxycholate)	IV	0.5–1 mg/kg qod or qd (total: usually ~15–20 mg/kg)
Paromomycin sulfate[d]	IV, IM	15–20 mg/kg qd for ~21 days
Pentamidine isethionate	IV, IM	4 mg/kg qod or thrice weekly for ~15–30 doses
Miltefosine	PO	See text
CUTANEOUS LEISHMANIASIS		
First-line therapy		
Pentavalent antimony[b]	IV, IM	20 mg Sb^V/kg qd for 10–20 days (standard recommendation is 20 days)
Parenteral alternatives		
Pentamidine isethionate	IV, IM	3 mg/kg qod for 4 doses or 2 mg/kg qod for 7 doses
Amphotericin B (deoxycholate)	IV	0.5–1 mg/kg qod or qd (total: up to ~20 mg/kg)[e]
Oral alternatives		
Fluconazole	PO	200 mg qd or bid for 6 weeks[f]
Ketoconazole	PO	600 mg/d for 28 days[f]
Itraconazole	PO	200 mg bid for 28 days[f]
Dapsone	PO	100 mg bid for 6 weeks[f]
MUCOSAL LEISHMANIASIS		
First-line therapy		
Pentavalent antimony[b]	IV, IM	20 mg Sb^V/kg qd for 28 days
Amphotericin B (deoxycholate)	IV	1 mg/kg qod or qd (total: usually ~20–40 mg/kg)
Alternative		
Pentamidine isethionate	IV, IM	2–4 mg/kg qod or thrice weekly for ≥15 doses

[a] See text for additional details. Some of the listed drugs are effective only against certain *Leishmania* species and only in certain areas of the world. To maximize effectiveness and minimize toxicity, the listed regimens should be individualized according to the particularities of the case and in consultation with an expert. Children may need different dosage regimens. Except for liposomal amphotericin B (see footnote[c]), none of the drugs listed are licensed by the U.S. Food and Drug Administration (FDA) for the treatment of leishmaniasis per se.

[b] The Centers for Disease Control and Prevention (CDC) provides the pentavalent antimonial (Sb^V) compound sodium stibogluconate (Pentostam; GlaxoSmithKline Export Limited, Middlesex, United Kingdom; 100 mg Sb^V/mL) to U.S.-licensed physicians through the CDC Drug Service (404-639-3670) under an IND mechanism with the FDA. The other widely used pentavalent antimonial compound, meglumine antimonate (Glucantime; Aventis Pharma Venezuela, Caracas; 85 mg Sb^V/mL), is available primarily in Spanish- and French-speaking areas of the world. Locally made Sb^V preparations may have different Sb^V concentrations and may vary in quality and safety.

[c] The lipid formulations of amphotericin B include liposomal amphotericin B and amphotericin B lipid complex. The FDA has approved the following regimen of liposomal amphotericin B for immunocompetent patients: 3 mg/kg qd on days 1–5, 14, and 21, for a total of 21 mg/kg. For immunosuppressed patients, the approved regimen is 4 mg/kg qd on days 1–5, 10, 17, 24, 31, and 38, for a total of 40 mg/kg. Alternative regimens that have been proposed for immunocompetent patients include treatment on days 1–5 and 10 with 3–4 mg/kg qd for cases from Europe or Brazil, with 3 mg/kg qd for cases from Africa, and with 2–3 mg/kg qd for cases from India.

[d] Not commercially available as of this writing.

[e] No dosage regimen has been established for use of this drug to treat cutaneous leishmaniasis.

[f] Adult dosage.

elevated aminotransferase levels, chemical pancreatitis, and electrocardiographic abnormalities) becomes increasingly common as the course of treatment progresses but usually does not limit therapy and is reversible.

The traditional parenteral alternatives to Sb^V—amphotericin B and pentamidine isethionate—are generally considered more apt to induce serious or irreversible toxicity (e.g., nephrotoxicity or diabetes). However, these agents, especially amphotericin B, are being advocated for use in some situations (see below; Table 196-2), in part because of the benefits of new formulations (e.g., lipid formulations of amphotericin B) and the decreasing effectiveness of Sb^V in some settings. Many other agents have been touted as alternatives or adjuncts to Sb^V, often on the basis of suboptimal data. Some of these agents may be useful in certain situations, with the caveat that even the results of well-conducted clinical trials are not always generalizable to the treatment of patients infected with other leishmanial species acquired in other settings. With the apparent exception of miltefosine, the other oral agents evaluated to date typically have at best modest activity against some of the *Leishmania* species.

PREVENTION AND CONTROL The transmission of *Leishmania* species typically is focal, in part because of the limited flight range of sandflies; these insects usually remain within a few hundred meters of their breeding site. They rest in dark, moist places in habitats ranging from deserts to rain forests; peridomestic sandflies rest in debris or rubble near buildings. Vector control may be useful in some settings.

Personal protective measures include avoiding outdoor activities when sandflies are most active (dusk to dawn); using mechanical barriers such as screens and bed-nets that keep out sandflies, which typically are about one-third the size of mosquitoes; wearing protective clothing; and applying insect repellent to exposed skin. Impregnating clothing, bed-nets, and screens with permethrin may also be useful, as may spraying dwellings with residual-action insecticide, if transmission of infection is intra- or peridomiciliary. If dogs are important reservoir hosts, use of insecticide-impregnated dog collars might be helpful. Vaccine strategies are being investigated. Treating human cases is an effective control measure only where humans are the primary reservoir hosts of infection (e.g., of *L. donovani* infection in India).

VISCERAL LEISHMANIASIS

More than 90% of the world's cases of visceral leishmaniasis occur in Bangladesh, northeastern India (particularly Bihar State), Nepal, Sudan, and northeastern Brazil. The causative species typically are those of the *L. donovani* complex (Table 196-1). The organisms can be transmitted not only by sandflies but also congenitally and parenterally (e.g., through blood transfusions or needle sharing). Infection begins in macrophages at the inoculation site (e.g., in dermal macrophages at the site of a sandfly bite) and disseminates throughout the reticuloendothelial system.

CLINICAL MANIFESTATIONS Visceral infection often remains subclinical but can become symptomatic, with an acute, subacute, or chronic course. In some settings, inapparent infections far outnumber clinically apparent ones; malnutrition is among the risk factors for the development of disease. The incubation period usually ranges from weeks to months but can be as long as years. Whereas the general term *visceral leishmaniasis* covers a broad spectrum of severity and manifestations, the term *kala-azar* (Hindi for "black fever," indicating that the skin of some patients turns gray) generally conjures up the classic image of profoundly cachectic, febrile patients who are heavily infected with parasites and have life-threatening disease. Splenomegaly (with the spleen most often soft and nontender) typically is more impressive than hepatomegaly, and the spleen can be massive. Peripheral lymphadenopathy is common in some settings, including Sudan.

The abnormal laboratory findings associated with advanced disease include pancytopenia—anemia, leukopenia (neutropenia, marked eosinopenia, relative lymphocytosis and monocytosis), and thrombocytopenia—as well as hypergammaglobulinemia (chiefly involving IgG, from polyclonal B cell activation) and hypoalbuminemia. Causes of anemia can include bone-marrow infiltration, hypersplenism, autoimmune hemolysis, and bleeding.

Some patients develop post-kala-azar dermal leishmaniasis. This

syndrome is manifested by skin lesions (including macules, papules, nodules, and patches) that typically are most prominent on the face. These lesions can develop during therapy or within a few months thereafter (e.g., in East Africa) or can develop years later (e.g., in India); relapse of visceral infection can occur. Persons in India (i.e., in areas where humans are the primary reservoir hosts of infection) who have persistent skin lesions can serve as reservoir hosts who maintain transmission of infection.

Viscerotropic leishmaniasis caused by *L. tropica*, which is thought typically to be dermotropic, was parasitologically confirmed in 12 U.S. soldiers who participated in Operation Desert Storm in the Persian Gulf in the early 1990s. The affected persons had light parasite burdens and nonspecific manifestations of visceral infection (e.g., fatigue, fever, and gastrointestinal symptoms).

DIAGNOSIS Although molecular techniques are under investigation, parasitologic diagnosis of visceral leishmaniasis has traditionally been accomplished by demonstration of the parasite on stained slides (Fig. 196-1) or in cultures of a tissue aspirate or a biopsy specimen (e.g., of spleen, liver, bone marrow, or lymph node). The diagnostic yield is highest for splenic aspiration (specifically, as high as 98% vs. <90% for other specimens), but this procedure can cause hemorrhage.

Patients with florid kala-azar commonly have relatively heavy parasite burdens, develop high titers of antibody to *Leishmania* (diagnostically useful but not protective), and have undetectable *Leishmania*-specific cell-mediated immunity. (Leishmanin skin-test reactivity as well as lymphocyte proliferation and IFN-γ responses to leishmanial antigens develop after recovery.) Promising noninvasive serologic methods for diagnosing kala-azar use recombinant leishmanial antigens or synthetic peptides (e.g., K39); these techniques are being field-tested.

DIFFERENTIAL DIAGNOSIS The differential diagnosis of visceral leishmaniasis includes other tropical and infectious diseases that cause fever or organomegaly (e.g., typhoid fever, miliary tuberculosis, brucellosis, histoplasmosis, malaria, tropical splenomegaly syndrome, and schistosomiasis) as well as diseases such as leukemia and lymphoma. Post-kala-azar dermal leishmaniasis should be differentiated from syphilis, yaws, and leprosy.

℞ TREATMENT (Table 196-2)

Because persons who have kala-azar generally die if not appropriately treated, highly effective therapy is essential, as is close monitoring for bleeding and intercurrent infectious conditions such as pneumonia and diarrhea. Outside of India, treatment with a pentavalent antimonial compound still is usually effective. The use of an alternative parenteral agent should be considered even for first-line therapy if unresponsiveness to Sb^V therapy is prevalent, as it is in India, or if nonantimonial therapy would be advantageous for other reasons (e.g., toxicity profile or duration of therapy).

A major advance has been the advent of lipid formulations of amphotericin B, in which various lipids have replaced deoxycholate. These formulations, which passively target amphotericin to macrophage-rich organs, are much more costly than conventional amphotericin B (cost-prohibitive in poor countries) but are associated with less nephrotoxicity and can be given in considerably shorter courses. Other parenteral alternatives that have merit in some settings include the aminoglycoside paromomycin (identical to aminosidine; not commercially available at present), which has been used as monotherapy (in India) or as an adjunct to Sb^V, and pentamidine. As judged by clinical trials in India, miltefosine (not currently available in the United States) is the first highly effective oral agent for this infection. In the phase 3 trial, the dosage regimen for adults was 50 or 100 mg (~2.5 mg/kg) daily for 28 days. Sitamaquine, another oral agent, is also being field-tested.

VISCERAL LEISHMANIASIS IN PERSONS INFECTED WITH HIV Visceral leishmaniasis is an important opportunistic infection among persons infected with HIV-1 in geographic areas in which both infections are endemic. Although most dual infections have been reported from southern Europe, where *L. infantum* (of the *L. donovani* complex) is endemic, co-infection is becoming increasingly common elsewhere. Most (95%) of the co-infected cases reported to the World Health Organization have been cases of visceral leishmaniasis. (The remaining 5% have been cases of cutaneous disease.) In patients infected with HIV, even relatively avirulent *Leishmania* strains can disseminate to the viscera. Clinical leishmaniasis in co-infected patients can represent newly acquired or reactivated infection; most co-infected patients with clinically evident leishmaniasis have fewer than 200 CD4+ T lymphocytes per microliter. The use of highly active antiretroviral therapy (HAART) decreases the incidence of clinical leishmaniasis. The diagnosis of visceral leishmaniasis should be considered for HIV-infected patients who have ever been in leishmaniasis-endemic areas and who have manifestations such as unexplained fever, organomegaly, anemia, or pancytopenia. Co-infected patients can develop unusual manifestations of visceral leishmaniasis, in part because of atypical localization of the parasite (e.g., in the gastrointestinal tract).

The diagnostic sensitivity of classic serologic methods is lower in co-infected than in immunocompetent patients (~50% vs. >90%), especially if the HIV infection preceded the leishmanial infection. However, parasitologic diagnosis by noninvasive means is easier in co-infected patients. Parasites are more commonly found in the circulating blood monocytes of these patients; the sensitivities are ~50% for a Giemsa-stained peripheral-blood smear and ~70% for culture of a buffy-coat preparation. Invasive methods of parasitologic diagnosis (e.g., microscopic examination or culture of a bone marrow aspirate) typically are highly sensitive, especially for previously untreated patients, who commonly have heavy parasite burdens.

Co-infected patients may initially respond well to standard antileishmanial therapy, albeit with more drug toxicity than is experienced by most immunocompetent persons. However, relapses are common and can occur despite the use of HAART. No standard approach to secondary prophylaxis has been established. Various drug regimens are being evaluated.

CUTANEOUS LEISHMANIASIS

Cutaneous leishmaniasis has traditionally been classified as New World (American) or Old World disease. More than 90% of the world's cases of cutaneous leishmaniasis occur in Afghanistan (Fig. 196-2), Algeria, Iran, Iraq, Saudi Arabia, Syria, Brazil, and Peru. In the Americas, the leishmaniasis-endemic area extends from southern Texas to northern Argentina; the etiologic agents typically are those of the *L. mexicana* complex and the *Viannia* subgenus (Table 196-1) but also include *L. major*–like organisms and *L. chagasi* (which is synonymous with *L. infantum*). Old World cutaneous leishmaniasis is caused by *L. tropica*, *L. major*, and *L. aethiopica* as well as by *L. infantum* and *L. donovani*.

CLINICAL MANIFESTATIONS The incubation period for clinically evident disease typically ranges from weeks to months. The first manifestation is usually a papule at the site of the sandfly bite but can be regional lymphadenopathy (sometimes bubonic) in *L. (V.) braziliensis* infection. Most skin lesions evolve from papular to nodular to ulcerative, with a central depression (which can be several centimeters in diameter) surrounded by a raised indurated border (Fig. 196-2). Some lesions persist as nodules or plaques. The skin lesions can cause considerable morbidity (Fig. 196-3). Multiple primary lesions, satellite lesions, regional adenopathy, sporotrichoid subcutaneous nodules, lesion pain or pruritus, and secondary bacterial infection are variably present. The infecting species, the location of the lesion, and the host's immune response are among the determinants of the clinical manifestations and chronicity of untreated lesions. For example, in the New World, lesions caused by *L. mexicana* tend to be smaller and less chronic than those caused by *L. (V.) braziliensis*; in the Old World, *L. major* tends to cause "wet" exudative lesions that are less chronic than

FIGURE 196-2 Ulcerative skin lesions with raised outer borders on the arm of a patient with New World (American) cutaneous leishmaniasis acquired in Costa Rica. *(Photograph courtesy of Dr. A. Wright.)*

the "dry" lesions with central crusting caused by *L. tropica*. The spontaneous resolution of lesions does not preclude reactivation or reinfection.

The polyparasitic and oligoparasitic ends of the spectrum of cutaneous leishmaniasis are respectively represented by the rare syndromes of diffuse cutaneous leishmaniasis (DCL) and leishmaniasis recidivans, both of which are notoriously difficult to treat. DCL, caused by *L. aethiopica* (Old World) or by the *L. mexicana* complex (New World), develops in the context of *Leishmania*-specific anergy and is manifested by chronic, disseminated, nonulcerative skin lesions; on histopathologic examination of specimens from these lesions, abundant parasites but few lymphocytes are noted. Leishmaniasis recidivans, a hyperergic variant with scarce parasites, is usually caused by *L. tropica* and manifested by a chronic solitary lesion on the cheek that expands slowly despite central healing.

DIAGNOSIS Although examination of histologic sections of biopsy specimens with special stains can help exclude other diagnoses (see below), amastigotes appear larger and are more easily recognizable on Giemsa-stained thin smears (e.g., smears of dermal scrapings, touch preparations of biopsy specimens). Aspirates of skin lesions and lymph nodes are useful for in vitro culture, and biopsy specimens are useful for histologic examination, culture, and PCR. As lesions age, amastigotes become scarcer, and parasitologic confirmation becomes more difficult. Species identification (see above) can be important in guiding therapy.

Serologic testing currently is an insensitive means for diagnosing cutaneous leishmaniasis; antibody titers usually are at most minimally elevated except in patients who have DCL. In contrast, leishmanin skin-test reactivity usually develops during active infection in persons who have simple cutaneous leishmaniasis or leishmaniasis recidivans but not in those who have DCL.

DIFFERENTIAL DIAGNOSIS Cutaneous leishmaniasis is frequently confused with tropical, traumatic, and venous-stasis ulcers; foreign-body reactions; superinfected insect bites; myiasis; impetigo; fungal infections (e.g., sporotrichosis); mycobacterial infections; and other diseases (e.g., sarcoidosis, neoplasms). DCL and leishmaniasis recidivans should be differentiated from lepromatous leprosy and lupus vulgaris, respectively.

℞ TREATMENT (Table 196-2)

Decisions about whether and how to treat cutaneous leishmaniasis should take into account the species, if known, and therefore whether mucosal dissemination is possible (as it is to variable degrees in the Americas with some organisms in the *Viannia* subgenus; Table 196-1) as well as the likelihood of rapid self-healing and the location (e.g., on the face), number, size, evolution, and chronicity of the cutaneous lesions. When optimal effectiveness is important, intravenous or intramuscular Sb^V therapy is generally recommended. In studies in Colombia (predominantly with the *Viannia* subgenus), relatively short courses of treatment with pentamidine were effective (cure rate, 96%) and quite well tolerated. However, preliminary data from a clinical trial in Peru with *L. (V.) braziliensis* are not looking as promising. No controlled clinical trials have been conducted for cutaneous leishmaniasis with conventional or lipid formulations of amphotericin B. Some data suggest that conventional amphotericin B is likely to be effective. The data for the lipid formulations are too few and too conflicting for this therapy to be recommended at this time. In general, the clinical response to antileishmanial therapy begins with lessening induration; the process of healing often continues after the end of therapy. Relapse typically is manifested by clinical reactivation at the margin of the lesion.

Although many oral agents have been touted for treatment of leishmaniasis, even those that are the most effective typically are moderately active at best and are effective only against some *Leishmania* species or strains. The oral agent miltefosine is being evaluated. In the New World, ketoconazole has some activity against *L. mexicana* and *L. (V.) panamensis* and may be more active than itraconazole (at least against the *Viannia* subgenus), which is better tolerated. Fluconazole led to more rapid healing of *L. major* infection in a clinical trial in Saudi Arabia. Dapsone has looked promising in India but not in Colombia. Adjunctive immunotherapy remains highly investigational. Local or topical therapy can be considered for some cases of infection without risk for mucosal dissemination (e.g., for relatively benign lesions caused by *L. mexicana* or *L. major*). Examples of local approaches include the application of an ointment containing paromomycin and methylbenzethonium chloride (not licensed in the United States), the intralesional administration of Sb^V, heat therapy, and cryotherapy.

FIGURE 196-3 People in Kabul, Afghanistan, infected with *Leishmania tropica*, standing in line for hours on a bitterly cold day in February 1997 at a treatment center for cutaneous leishmaniasis. *[Photograph courtesy of Dr. R. Ashford and reprinted with permission from Elsevier Science (Lancet 354:1193, 1999).]*

MUCOSAL LEISHMANIASIS

Clinically evident leishmanial infection of the naso-oropharyngeal mucosa is a relatively rare but potentially disfiguring metastatic complication of cutaneous leishmaniasis. Mucosal disease develops despite antileishmanial cell-mediated immunity; most commonly is caused by organisms of the *Viannia* subgenus, typically *L. (V.) braziliensis* but also *L. (V.) panamensis* and occasionally *L. (V.) guyanensis*; and is more common in South America than in Central America. Although mucosal disease usually becomes clinically evident within several years after the healing of the original cutaneous lesions, cutaneous and mucosal lesions can coexist or appear decades apart; the potential for long delay is one of the reasons that the risk for mucosal leishmaniasis in particular settings is so difficult to determine. Typically, the original cutaneous lesions of patients who develop mucosal disease were not treated or were suboptimally treated.

Mucosal involvement generally is manifested first by persistent unusual nasal symptoms (e.g., epistaxis), with erythema and edema of the nasal mucosa, and then by progressive, ulcerative, naso-oropharyngeal destruction. Supportive laboratory data (e.g., a positive serologic or PCR result) are useful, but the scarcity of amastigotes makes parasitologic confirmation difficult. The differential diagnosis includes sarcoidosis, neoplasms, midline granuloma, rhinoscleroma, paracoccidioidomycosis, histoplasmosis, leprosy, syphilis, and tertiary yaws.

Rx TREATMENT (Table 196-2)

Treatment with a pentavalent antimonial compound is moderately effective for mild mucosal disease, whereas advanced disease may not respond to such treatment or may relapse repeatedly. Amphotericin B (deoxycholate) can also be considered first-line therapy. Conflicting and limited data have been obtained for lipid formulations of amphotericin B, which therefore are not generally recommended at this time. Patients who develop respiratory compromise after initiation of therapy (e.g., because of an inflammatory reaction) may benefit from the concomitant administration of glucocorticoids.

197 TRYPANOSOMIASIS

Louis V. Kirchhoff

The genus *Trypanosoma* contains many species of protozoans. *Trypanosoma cruzi*, the cause of Chagas' disease in the Americas, and the two trypanosome subspecies that cause human African trypanosomiasis, *Trypanosoma brucei gambiense* and *T. brucei rhodesiense*, are the only members of the genus that cause disease in humans.

CHAGAS' DISEASE

DEFINITION Chagas' disease, or American trypanosomiasis, is a zoonosis caused by the protozoan parasite *T. cruzi*. Acute Chagas' disease is usually a mild febrile illness that results from initial infection with the organism. After spontaneous resolution of the acute illness, most infected persons remain for life in the indeterminate phase of chronic Chagas' disease, which is characterized by subpatent parasitemia, easily detectable antibodies to *T. cruzi*, and an absence of symptoms. In a minority of chronically infected patients, cardiac and gastrointestinal lesions develop that can result in serious morbidity and even death.

LIFE CYCLE AND TRANSMISSION *T. cruzi* is transmitted among its mammalian hosts by hematophagous triatomine insects, often called *reduviid bugs*. The insects become infected by sucking blood from animals or humans who have circulating parasites. Ingested organisms multiply in the gut of the triatomines, and infective forms are discharged with the feces at the time of subsequent blood meals. Transmission to a second vertebrate host occurs when breaks in the skin, mucous membranes, or conjunctivae become contaminated with bug feces that contain infective parasites. *T. cruzi* can also be transmitted by the transfusion of blood donated by infected persons, by organ transplantation, from mother to fetus, and in laboratory accidents.

PATHOLOGY An indurated inflammatory lesion called a *chagoma* often appears at the parasites' portal of entry. Local histologic changes include the presence of parasites within leukocytes and cells of subcutaneous tissues and the development of interstitial edema, lymphocytic infiltration, and reactive hyperplasia of adjacent lymph nodes. After dissemination of the organisms through the lymphatics and the bloodstream, muscles (including the myocardium) may become heavily parasitized. The characteristic pseudocysts present in sections of infected tissues are intracellular aggregates of multiplying parasites.

In the minority of persons with chronic *T. cruzi* infections who develop related clinical manifestations, the heart is the organ most commonly affected. Changes include thinning of the ventricular walls, biventricular enlargement, apical aneurysms, and mural thrombi. Widespread lymphocytic infiltration, diffuse interstitial fibrosis, and atrophy of myocardial cells are often apparent, but parasites are difficult to find in myocardial tissue. Conduction-system involvement often affects the right branch and the left anterior branch of the bundle of His. In chronic Chagas' disease of the gastrointestinal tract (megadisease), the esophagus and colon may exhibit varying degrees of dilatation. On microscopic examination, focal inflammatory lesions with lymphocytic infiltration are seen, and the number of neurons in the myenteric plexus may be markedly reduced. Accumulating experimental evidence implicates the persistence of parasites and the accompanying chronic inflammation—rather than autoimmune mechanisms—as the basis for the pathology in patients with chronic *T. cruzi* infection.

EPIDEMIOLOGY *T. cruzi* is found only in the Americas. Wild and domestic mammals harboring *T. cruzi* and infected triatomines are found in spotty distributions from the southern United States to southern Argentina. Humans become involved in the cycle of transmission when infected vectors take up residence in the primitive wood, adobe, and stone houses common in much of Latin America. Thus human *T. cruzi* infection is a health problem primarily among the poor in rural areas of Mexico and Central and South America. Most new *T. cruzi* infections in rural settings occur in children, but the incidence is unknown because most cases go undiagnosed. Historically, transfusion-associated transmission of *T. cruzi* has been a serious public health problem in many endemic countries. However, with some notable ex-

ceptions, transmission by this route has been markedly reduced as effective programs for the screening of donated blood have been implemented. Several dozen patients with HIV and chronic *T. cruzi* infections who underwent acute recrudescence of the latter have been described. These patients generally presented with *T. cruzi* brain abscesses, a manifestation of the illness that does not occur in immunocompetent persons. Currently, it is estimated that 16 to 18 million people are chronically infected with *T. cruzi* and that 45,000 deaths due to the illness occur each year. Of chronically infected persons, 10 to 30% eventually develop symptomatic cardiac lesions or gastrointestinal disease. The resulting morbidity and mortality make Chagas' disease the most important parasitic disease burden in Latin America.

In recent years, the rate of *T. cruzi* transmission has decreased markedly in several endemic countries as a result of successful programs involving vector control, blood-bank screening, and education of at-risk populations. A major program begun in 1991 in the "southern cone" nations of South America (Uruguay, Paraguay, Bolivia, Brazil, Chile, and Argentina) has provided the framework for much of this progress. Uruguay and Chile were certified transmission-free in the late 1990s, and Argentina and Brazil are expected to follow suit shortly. Similar control programs have been initiated in the countries of northern South America and in the Central American nations.

Acute Chagas' disease is rare in the United States. Five cases of autochthonous transmission and six instances of transmission by blood transfusion have been reported. *T. cruzi* was recently transmitted to three recipients of organs from a single *T. cruzi*–infected donor from Central America. In the past 30 years, more than a dozen instances of laboratory-acquired infection and imported cases of acute Chagas' disease were reported to the Centers for Disease Control and Prevention (CDC). Acute Chagas' disease has not been reported in tourists returning to the United States from Latin America. In contrast, the prevalence of chronic *T. cruzi* infections in the United States has increased considerably in recent years. Data from the 2000 census indicate that >12 million immigrants from Chagas'-endemic countries currently live in the United States, ~8 million of whom are Mexicans. The prevalence of *T. cruzi* infection in Mexico is 0.5 to 1.0%, and most of the 4 million immigrants from Chagas'-endemic nations who are not Mexicans come from countries in which the prevalence of *T. cruzi* infection is greater than it is in Mexico. The total number of *T. cruzi*–infected persons living in the United States can be estimated reasonably to be 80,000 to 120,000. The number of instances of transfusion-associated transmission in this country is likely to be considerably greater than the number reported.

CLINICAL COURSE The first signs of acute Chagas' disease develop at least 1 week after invasion by the parasites. When the organisms enter through a break in the skin, an indurated area of erythema and swelling (the chagoma), accompanied by local lymphadenopathy, may appear. *Romaña's sign*—the classic finding in acute Chagas' disease, which consists of unilateral painless edema of the palpebrae and periocular tissues—can result when the conjunctiva is the portal of entry (Fig. 197-1). These initial local signs may be followed by malaise, fever, anorexia, and edema of the face and lower extremities. A morbilliform rash may also appear. Generalized lymphadenopathy and hepatosplenomegaly may develop. Severe myocarditis develops rarely; most deaths in acute Chagas' disease are due to heart failure. Neurologic signs are not common, but meningoencephalitis occurs occasionally. The acute symptoms resolve spontaneously in virtually all patients, who then enter the asymptomatic or indeterminate phase of chronic *T. cruzi* infection.

Symptomatic chronic Chagas' disease becomes apparent years or even decades after the initial infection. The heart is commonly involved, and symptoms are caused by rhythm disturbances, dilated cardiomyopathy, and thromboembolism. Right bundle-branch block is a common electrocardiographic abnormality, but other types of atrioventricular block, premature ventricular contractions, and tachy- and bradyarrhythmias occur frequently. Cardiomyopathy often results in right-sided or biventricular heart failure. Embolization of mural thrombi to the brain or other areas may take place. Patients with megaesophagus suffer from dysphagia, odynophagia, chest pain, and regurgitation. Aspiration can occur (especially during sleep) in patients with severe esophageal dysfunction, and repeated episodes of aspiration pneumonitis are common. Weight loss, cachexia, and pulmonary infection can result in death. Patients with megacolon are plagued by abdominal pain and chronic constipation, and advanced megacolon can cause obstruction, volvulus, septicemia, and death.

FIGURE 197-1 Romaña's sign in an Argentinean patient with acute *T. cruzi* infection. (*Courtesy of Dr. Humberto Lugones, Centro de Chagas, Santiago del Estero, Argentina.*)

DIAGNOSIS The diagnosis of acute Chagas' disease requires the detection of parasites. Microscopic examination of fresh anticoagulated blood or of the buffy coat is the simplest way to see the motile organisms. Parasites also can be seen in Giemsa-stained thin and thick blood smears. Microhematocrit tubes containing acridine orange as a stain can be used for the same purpose. When repeated attempts to visualize the organisms are unsuccessful, polymerase chain reaction (PCR) or hemoculture in specialized media can be performed. When used by experienced personnel, all of these methods yield positive results in a high proportion of patients with acute Chagas' disease. Hemoculture has the disadvantage of taking several weeks to give positive results. Serologic testing plays no role in diagnosing acute Chagas' disease.

Chronic Chagas' disease is diagnosed by the detection of specific antibodies that bind to *T. cruzi* antigens. Demonstration of the parasite is not of primary importance. In Latin America, ~20 assays are commercially available, including several based on recombinant antigens. Unfortunately, these tests have varying levels of sensitivity and specificity, and false-positive reactions are a particular problem—typically with samples from patients who have other infectious and parasitic diseases or autoimmune disorders. In addition, confirmatory testing has presented a persistent challenge. For these reasons, it is generally recommended that specimens be tested in at least two assays and that well-characterized positive and negative comparison samples be included in each run. A highly sensitive and specific confirmatory method for detecting antibodies to *T. cruzi* [approved under the Clinical Laboratory Improvement Amendment (CLIA) and available in the author's laboratory] employs immunoprecipitation of radiolabeled *T. cruzi* antigens and electrophoresis. The use of PCR assays to detect *T. cruzi* DNA in chronically infected persons has been studied extensively.The sensitivity of this approach has not been shown to be reli-

ably greater than that of serology, and no PCR assays are commercially available.

TREATMENT

Therapy for Chagas' disease is unsatisfactory. For many years, only two drugs—nifurtimox and benznidazole—have been available for this purpose. Unfortunately, both drugs lack efficacy and often cause severe side effects.

In acute Chagas' disease, nifurtimox markedly reduces the duration of symptoms and parasitemia and decreases the mortality rate. Nevertheless, limited studies have shown that only ~70% of acute infections are cured parasitologically by a full course of treatment. Despite its limitations, treatment with nifurtimox should be initiated as early as possible in acute Chagas' disease. Moreover, when laboratory accidents occur in which it appears likely that *T. cruzi* infection could become established, nifurtimox therapy should be initiated without waiting for clinical or parasitologic indications of infection.

Common adverse effects of nifurtimox include abdominal pain, anorexia, nausea, vomiting, and weight loss. Neurologic reactions to the drug may include restlessness, disorientation, insomnia, twitching, paresthesia, polyneuritis, and seizures. These symptoms usually disappear when the dosage is reduced or treatment is discontinued. The recommended daily dosage is 8 to 10 mg/kg for adults, 12.5 to 15 mg/kg for adolescents, and 15 to 20 mg/kg for children 1 to 10 years of age. The drug should be given orally in four divided doses each day, and therapy should be continued for 90 to 120 days. Nifurtimox is available from the Drug Service of the CDC in Atlanta (telephone number, 770-639-3670).

The efficacy of benznidazole is similar to that of nifurtimox; a cure rate of 90% among congenitally infected infants treated before their first birthday has been reported. Adverse effects include peripheral neuropathy, rash, and granulocytopenia. The recommended oral dosage is 5 mg/kg per day for 60 days. Benznidazole is generally considered the drug of choice in Latin America.

The question of whether patients in the indeterminate or chronic symptomatic phase of Chagas' disease should be treated with nifurtimox or benznidazole has been debated for years. The fact that parasitologic cure rates in chronically infected persons are <20% is central to this controversy. Limited studies of *T. cruzi*–infected laboratory animals and humans suggest that elimination of the parasites reduces the appearance or progression of cardiac pathology. In view of these findings, an international panel of experts recommended that all patients infected with *T. cruzi* be treated with one drug or the other, regardless of their clinical status or the duration of infection. Considerable debate has followed this recommendation, and the issue remains unresolved.

The usefulness of allopurinol, fluconazole, and itraconazole for the treatment of acute Chagas' disease has been studied in laboratory animals and to a lesser extent in humans. None of these drugs has exhibited a level of anti–*T. cruzi* activity that warrants its use in patients. Several newer antifungal azoles have shown promise in animal studies but have not yet been tested in humans. Studies in mice have shown that recombinant interferon γ decreases the duration and severity of acute *T. cruzi* infection; however, its usefulness in persons with acute Chagas' disease has not been evaluated systematically.

Patients who develop cardiac and/or gastrointestinal disease in association with *T. cruzi* infection should be referred to appropriate subspecialists for further evaluation and treatment. Cardiac transplantation is an option for patients with end-stage chagasic cardiopathies, and >100 such transplantations have been done in Brazil and the United States. The survival rate among Chagas' disease cardiac transplant recipients is higher than that among persons receiving cardiac transplants for other reasons. This better outcome may be due to the fact that lesions are limited to the heart in most patients with symptomatic chronic Chagas' disease.

PREVENTION Since drug therapy is unsatisfactory and vaccines are not available, the control of *T. cruzi* transmission in endemic countries must depend on reduction of domiciliary vector populations by spraying of insecticides, improvements in housing, and education of at-risk persons. As noted above, these measures, coupled with serologic screening of blood donors, have markedly reduced transmission of the parasite in many endemic countries. Tourists would be wise to avoid sleeping in dilapidated houses in rural areas in endemic countries. Mosquito nets and insect repellent provide additional protection.

The question of whether blood donated in the United States should be screened for antibodies to *T. cruzi* has been considered by both public and private blood banking authorities for more than a decade. Since no assay for this purpose has been cleared by the U.S. Food and Drug Administration (FDA), serologic testing is not yet an option. Some blood-donor centers currently use a questionnaire to identify and defer donors at high risk for *T. cruzi* infection. The efficacy of this approach has not been assessed specifically, and it is important to bear in mind that approaches based solely on questionnaires have not been entirely successful at eliminating transfusion-associated transmission of other infectious agents.

In view of the possibly serious consequences of chronic *T. cruzi* infection, it would be prudent for all immigrants from endemic regions living in the United States to be tested for evidence of infection. Identification of persons harboring the parasite would permit periodic electrocardiographic monitoring, which can be important because pacemakers benefit some patients who develop ominous rhythm disturbances. The possibility of congenital transmission is yet another justification for screening.

Laboratory personnel should wear gloves and eye protection when working with *T. cruzi* and infected vectors.

SLEEPING SICKNESS

DEFINITION Sleeping sickness, or human African trypanosomiasis (HAT), is caused by flagellated protozoan parasites that belong to the *T. brucei* complex and are transmitted to humans by tsetse flies. In untreated patients, the trypanosomes first cause a febrile illness that is followed months or years later by progressive neurologic impairment and death.

THE PARASITES AND THEIR TRANSMISSION The East African (*rhodesiense*) and the West African (*gambiense*) forms of sleeping sickness are caused, respectively, by two trypanosome subspecies: *T. brucei rhodesiense* and *T. brucei gambiense*. These subspecies are morphologically indistinguishable but cause illnesses that are epidemiologically and clinically distinct (Table 197-1). The parasites are transmitted by blood-sucking tsetse flies of the genus *Glossina*. The insects acquire the infection when they ingest blood from infected mammalian hosts. After many cycles of multiplication in the midgut of the vector, the

TABLE 197-1 Comparison of West African and East African Trypanosomiases

Point of Comparison	West African (Gambiense)	East African (Rhodesiense)
Organism	*T. b. gambiense*	*T. b. rhodesiense*
Vectors	Tsetse flies (palpalis group)	Tsetse flies (morsitans group)
Primary reservoir	Humans	Antelope and cattle
Human illness	Chronic (late CNS disease)	Acute (early CNS disease)
Duration of illness	Months to years	<9 months
Lymphadenopathy	Prominent	Minimal
Parasitemia	Low	High
Diagnosis by rodent inoculation	No	Yes
Epidemiology	Rural populations	Workers in wild areas, rural populations, tourists in game parks

Abbreviation: CNS, central nervous system.

parasites migrate to the salivary glands. Their transmission takes place when they are inoculated into a mammalian host during a subsequent blood meal. The injected trypanosomes multiply in the blood and other extracellular spaces and evade immune destruction for long periods by undergoing antigenic variation, a process whereby the antigenic structure of their surface coat of glycoproteins changes periodically.

PATHOGENESIS AND PATHOLOGY A self-limited inflammatory lesion (trypanosomal chancre) may appear a week or so after the bite of an infected tsetse fly. A systemic febrile illness then evolves as the parasites are disseminated through the lymphatics and bloodstream. Systemic HAT without central nervous system (CNS) involvement is generally referred to as *stage I disease*. In this stage, widespread lymphadenopathy and splenomegaly reflect marked lymphocytic and histiocytic proliferation and invasion of morular cells, which are plasmacytes that may be involved in the production of IgM. Endarteritis, with perivascular infiltration of both parasites and lymphocytes, may develop in lymph nodes and spleen. Myocarditis develops frequently in patients with stage I disease and is especially common in *T. b. rhodesiense* infections.

Hematologic manifestations that accompany stage I HAT include moderate leukocytosis, thrombocytopenia, and anemia. High levels of immunoglobulins, consisting primarily of polyclonal IgM, are a constant feature, and heterophile antibodies, antibodies to DNA, and rheumatoid factor are often detected. High levels of antigen-antibody complexes may play a role in the tissue damage and increased vascular permeability that facilitate dissemination of the parasites.

Stage II disease involves invasion of the CNS. The presence of trypanosomes in perivascular areas is accompanied by intense infiltration of mononuclear cells. Abnormalities in cerebrospinal fluid (CSF) include increased pressure, elevated total protein concentration, and pleocytosis. In addition, trypanosomes are frequently found in CSF.

EPIDEMIOLOGY The trypanosomes that cause sleeping sickness are found only in Africa. Approximately 50 million persons are at risk of acquiring HAT, and tens of thousands of new cases occur every year. Precise data are not available because health statistics are often incomplete in the developing countries where HAT is endemic. Sleeping sickness has undergone a resurgence in recent years, with major epidemics in the Sudan, Ivory Coast, Chad, the Central African Republic, and several other endemic countries.

Humans are the only reservoir of *T. b. gambiense*, which occurs in widely distributed foci in tropical rain forests of Central and West Africa. *Gambiense* trypanosomiasis is primarily a problem in rural populations; tourists rarely become infected. Trypanotolerant antelope species in savanna and woodland areas of Central and East Africa are the principal reservoir of *T. b. rhodesiense*. Cattle can also be infected with *T. b. rhodesiense* and other trypanosome species but generally succumb to the infection. Since risk results for the most part from contact with tsetse flies that feed on wild animals, humans acquire *T. b. rhodesiense* infection only incidentally, usually while visiting or working in areas where infected game and vectors are present. Roughly one or two patients with HAT acquired in East African game parks (and typically caused by *T. b. rhodesiense*) are reported to the CDC each year.

CLINICAL COURSE A painful trypanosomal chancre appears in some patients at the site of inoculation of the parasite. Hematogenous and lymphatic dissemination (stage I disease) is marked by the onset of fever. Typically, bouts of high temperatures lasting several days are separated by afebrile periods. Lymphadenopathy is prominent in *T. b. gambiense* trypanosomiasis. The nodes are discrete, movable, rubbery, and nontender. Cervical nodes are often visible, and enlargement of the nodes of the posterior cervical triangle, or *Winterbottom's sign*, is a classic finding. Pruritus and maculopapular rashes are common. Inconstant findings include malaise, headache, arthralgias, weight loss, edema, hepatosplenomegaly, and tachycardia. The differential diagnosis of stage I HAT includes many diseases that are common in the tropics and are associated with fevers. HIV infection, malaria, and typhoid fever are common in populations at risk for HAT and need to be considered.

CNS invasion (stage II disease) is characterized by the insidious development of protean neurologic manifestations that are accompanied by progressive abnormalities in the CSF. A picture of progressive indifference and daytime somnolence develops (hence the designation "sleeping sickness"), sometimes alternating with restlessness and insomnia at night. A listless gaze accompanies a loss of spontaneity, and speech may become halting and indistinct. Extrapyramidal signs may include choreiform movements, tremors, and fasciculations. Ataxia is frequent, and the patient may appear to have Parkinson's disease, with a shuffling gait, hypertonia, and tremors. In the final phase, progressive neurologic impairment ends in coma and death.

The most striking difference between the West African and East African trypanosomiases is that the latter illness tends to follow a more acute course. Typically, in tourists with *T. b. rhodesiense* disease, systemic signs of infection, such as fever, malaise, and headache, appear before the end of the trip or shortly after the return home. Persistent tachycardia unrelated to fever is common early in the course of *T. b. rhodesiense* trypanosomiasis, and death may result from arrhythmias and congestive heart failure before CNS disease develops. In general, untreated *T. b. rhodesiense* trypanosomiasis leads to death in a matter of weeks to months, often without a clear distinction between the hemolymphatic and CNS stages. In contrast, *T. b. gambiense* disease can smolder for many months or even for years.

DIAGNOSIS A definitive diagnosis of HAT requires detection of the parasite. If a chancre is present, fluid should be expressed and examined directly by light microscopy for the highly motile trypanosomes. The fluid also should be fixed and stained with Giemsa. Material obtained by needle aspiration of lymph nodes early in the illness should be examined similarly. Examination of wet preparations and Giemsa-stained thin and thick films of serial blood samples is also useful. If parasites are not seen initially in blood, efforts should be made to concentrate the organisms; the simplest method involves the use of microhematocrit tubes containing acridine orange. In these tubes the parasites are separated from blood cells by centrifugation and are easily seen under light microscopy because of the stain. Alternatively, the buffy coat from 10 to 15 mL of anticoagulated blood can be examined directly under a microscope. The likelihood of finding parasites in blood is higher in stage I than in stage II disease and in patients infected with *T. b. rhodesiense* rather than *T. b. gambiense*. Trypanosomes may also be seen in material aspirated from the bone marrow; the aspirate can be inoculated into liquid culture medium, as can blood, buffy coat, lymph node aspirates, and CSF. Finally, *T. b. rhodesiense* infection can be detected by inoculation of these specimens into mice or rats, which—when positive—results in patent parasitemias in a week or two. Although this method is highly sensitive for the detection of *T. b. rhodesiense*, it does not detect *T. b. gambiense* because of host specificity.

It is essential to examine CSF from all patients in whom HAT is suspected. Abnormalities in the CSF that may be associated with stage II disease include an increase in the CSF mononuclear cell count as well as increases in opening pressure and in levels of total protein and IgM. Trypanosomes may be seen in the sediment of centrifuged CSF. Any CSF abnormality in a patient in whom trypanosomes have been found at other sites must be viewed as pathognomonic for CNS involvement and thus must prompt specific treatment for CNS disease. In patients with CSF pleocytosis in whom parasites are not found, tuberculous meningitis and HIV-associated CNS infections such as cryptococcosis should be considered in the differential diagnosis.

A number of serologic assays are available to aid in the diagnosis of HAT, but their variable sensitivity and specificity mandate that decisions about treatment be based on demonstration of the parasite. These tests are of value for epidemiologic surveys. PCR assays for detecting African trypanosomes in humans have been developed, but none is commercially available.

TREATMENT

The drugs traditionally used for treatment of HAT are suramin, pentamidine, and organic arsenicals. An addition to this list is eflornithine (difluoromethylornithine), which was approved by the FDA in November 1990 for the treatment of West African trypanosomiasis. In the United States these drugs can be obtained from the CDC. Therapy for HAT must be individualized on the basis of the infecting subspecies, the presence or absence of CNS disease, adverse reactions, and occasionally drug resistance. The choices of drugs for the treatment of HAT are summarized in Table 197-2.

Suramin is highly effective against stage I disease. However, it can cause serious adverse effects and must be administered under the close supervision of a physician. A 100- to 200-mg intravenous test dose should be administered to detect hypersensitivity. The dosage for adults is 1 g on days 1, 3, 7, 14, and 21. The regimen for children is 20 mg/kg (maximum, 1 g) on days 1, 3, 7, 14, and 21. The drug is given by slow intravenous infusion of a freshly prepared 10% aqueous solution. Approximately 1 patient in 20,000 has an immediate, severe, and potentially fatal reaction to the drug, developing nausea, vomiting, shock, and seizures. Less severe reactions include fever, photophobia, pruritus, arthralgias, and skin eruptions. Renal damage is the most common important adverse effect of suramin. Transient proteinuria often appears during treatment. A urinalysis should be done before each dose, and treatment should be discontinued if proteinuria increases or if casts and red cells appear in the sediment. Suramin should not be given to patients with renal insufficiency.

Eflornithine is highly effective for treatment of both stages of West African trypanosomiasis. In the trials on which the FDA based its approval, this agent cured >90% of 600 patients with stage II disease. The recommended treatment schedule is 400 mg/kg per day, given intravenously in four divided doses, for 2 weeks. Adverse reactions include diarrhea, anemia, thrombocytopenia, seizures, and hearing loss. The high dosage and duration of therapy required are disadvantages that make widespread use of eflornithine difficult.

Pentamidine is the alternative drug for patients with stage I HAT, although some *T. b. rhodesiense* infections are unresponsive to this agent. The dose for both adults and children is 4 mg/kg per day, given intramuscularly or intravenously, for 10 days. Frequent, immediate adverse reactions include nausea, vomiting, tachycardia, and hypotension. These reactions are usually transient and do not warrant cessation of therapy. Other adverse reactions include nephrotoxicity, abnormal liver function tests, neutropenia, rashes, hypoglycemia, and sterile abscesses.

The arsenical melarsoprol is the drug of choice for the treatment of East African trypanosomiasis with CNS involvement. Melarsoprol cures both stages of the disease and therefore is also indicated for the treatment of stage I disease in patients who fail to respond to or cannot tolerate suramin and/or pentamidine. However, because of its relatively high toxicity, melarsoprol is never the first choice for the treatment of stage I disease. The drug should be given to adults in three courses of 3 days each. The dosage is 2 to 3.6 mg/kg per day, given intravenously in three divided doses for 3 days, followed 1 week later by 3.6 mg/kg per day, also in three divided doses and for 3 days. The latter course is repeated 10 to 21 days later. In debilitated patients, suramin is administered for 2 to 4 days before therapy with melarsoprol is initiated; an 18-mg initial dose of the latter drug, followed by progressive increases to the standard dose, has been recommended. For children, a total of 18 to 25 mg/kg should be given over 1 month. An intravenous starting dose of 0.36 mg/kg should be increased gradually to a maximum of 3.6 mg/kg at 1- to 5-day intervals, for a total of 9 or 10 doses.

Melarsoprol is highly toxic and should be administered with great care. The incidence of reactive encephalopathy has been reported to be as high as 18% in some series. Clinical manifestations of reactive encephalopathy include high fever, headache, tremor, impaired speech, seizures, and even coma and death. Treatment with melarsoprol should be discontinued at the first sign of encephalopathy but may be restarted cautiously at lower doses a few days after signs have resolved. Extravasation of the drug results in intense local reactions. Vomiting, abdominal pain, nephrotoxicity, and myocardial damage can occur.

The treatment of patients with stage II East African disease who cannot tolerate melarsoprol is problematic. The combination of the arsenical tryparsamide and suramin is one possible approach, but its efficacy is limited because suramin does not penetrate the CNS well and tryparsamide is much less effective against *T. b. rhodesiense* than it is against *T. b. gambiense*. The schedule for tryparsamide therapy is 30 mg/kg (maximum, 2 g) in a single intravenous dose every 5 days for a total of 12 doses; that for suramin treatment is 10 mg/kg intravenously every 5 days, also for a total of 12 injections. Tryparsamide can cause encephalopathy, fever, vomiting, abdominal pain, rash, tinnitus, and a variety of ocular symptoms. Alternatively, eflornithine can be administered as outlined above to patients who cannot tolerate melarsoprol; however, the effectiveness of eflornithine against *T. b. rhodesiense* is variable.

TABLE 197-2 *Treatment of Human African Trypanosomiases*[a]

Causative Organism	Clinical Stage	
	I (Normal CSF)	II (Abnormal CSF)
T. brucei gambiense (West African)	Suramin or eflornithine Alternative: Pentamidine	Eflornithine Alternative: Tryparsamide plus suramin
T. brucei rhodesiense (East African)	Suramin Alternative: Pentamidine	Melarsoprol

Note: CSF, cerebrospinal fluid.

PREVENTION HAT poses complex public-health and epizootic problems in Africa. Considerable progress has been made in some areas through control programs that focus on eradication of vectors and drug treatment of infected humans; however, there is no consensus on the best approach to solving the overall problem, and major epidemics continue to occur. Individuals can reduce their risk of acquiring trypanosomiasis by avoiding areas known to harbor infected insects, by wearing protective clothing, and by using insect repellent. Chemoprophylaxis is not recommended, and no vaccine is available to prevent transmission of the parasites.

198 *TOXOPLASMA* INFECTION

Lloyd H. Kasper

DEFINITION Toxoplasmosis is the disease caused by infection with the obligate intracellular parasite *Toxoplasma gondii*. Acute infection acquired after birth may be asymptomatic but frequently results in the chronic persistence of cysts within the tissues of the host. Both acute and chronic toxoplasmosis are conditions in which the parasite is responsible for the development of clinically evident disease, including lymphadenopathy, encephalitis, myocarditis, and pneumonitis. Congenital toxoplasmosis is an infection of newborns that results from the transplacental passage of parasites from an infected mother to the fetus. These infants usually are asymptomatic at birth but later manifest a wide range of signs and symptoms, including chorioretinitis, strabismus, epilepsy, and psychomotor retardation.

ETIOLOGY *T. gondii* is an intracellular coccidian that infects both birds and mammals. There are two distinct stages in the life cycle of *T. gondii*: the nonfeline and feline stages (Fig. 198-1). In the nonfeline stage, tissue cysts that contain bradyzoites or sporulated oocysts are ingested by an intermediate host (e.g., a human, mouse, sheep, or pig). The cyst is rapidly digested by the acidic-pH gastric secretions. Bradyzoites or sporozoites are released, enter the small-intestinal epithelium, and transform into rapidly dividing tachyzoites. The tachyzoites can infect and replicate in all mammalian cells except red blood cells. Once attached to the host cell, the parasite penetrates the cell and forms a parasitophorous vacuole within which it divides. Parasite replication continues until the number of parasites within the cell approaches a critical mass and the cell ruptures, releasing parasites that infect adjoining cells.

As a result of this process, an infected organ soon shows evidence of cytopathology. Most tachyzoites are eliminated by means of the host's humoral and cell-mediated immune responses. Tissue cysts containing many bradyzoites develop 7 to 10 days after the systemic tachyzoite infection. These tissue cysts occur in a variety of host organs but persist principally within the central nervous system (CNS) and muscle. The development of this chronic stage completes the nonfeline portion of the life cycle. Active infection in the immunocompromised host is most likely due to the spontaneous release of encysted parasites that undergo rapid transformation into tachyzoites within the CNS.

The principal stage in the life cycle of the parasite takes place in the cat (the definitive host) and its prey. The parasite's sexual phase is defined by the formation of oocysts within the feline host. This enteroepithelial cycle begins with the ingestion of the bradyzoite tissue cysts and culminates after several intermediate stages in the production of gametes. Gamete fusion produces a zygote, which envelops itself in a rigid wall and is secreted in the feces as an unsporulated oocyst. After 2 to 3 days of exposure to air at ambient temperature, the noninfectious oocyst sporulates to produce eight sporozoite progeny. The sporulated oocyst can be ingested by an intermediate host, such as a person emptying a cat's litter box, a pig rummaging in a barnyard, or perhaps a mouse. It is in the intermediate host that the parasite completes its life cycle.

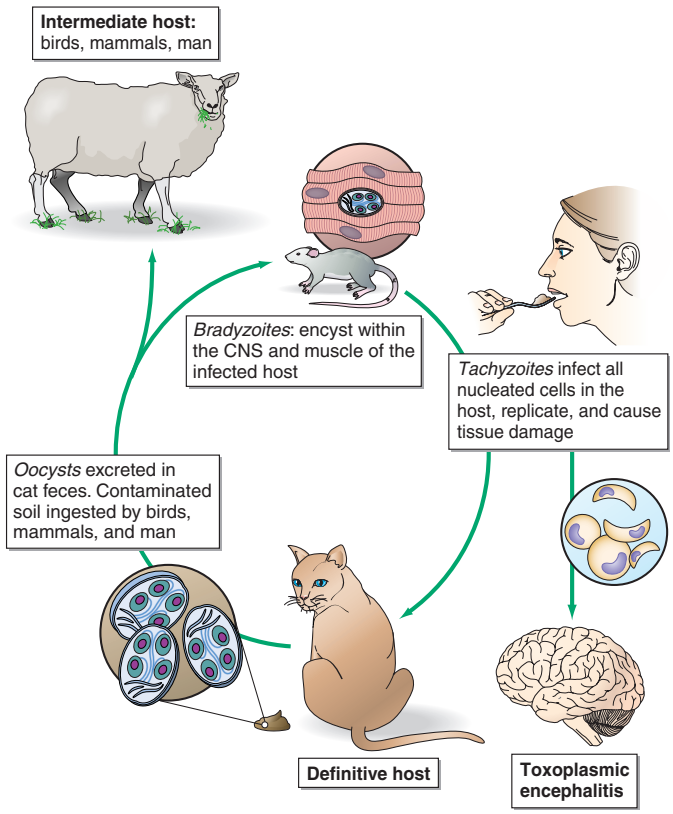

FIGURE 198-1 Life cycle of *Toxoplasma gondii*. The cat is the definitive host in which the sexual phase of the cycle is completed. Oocysts shed in cat feces can infect a wide range of animals, including birds, rodents, grazing domestic animals, and humans. The bradyzoites found in the muscle of food animals may infect humans who eat insufficiently cooked meat products, particularly lamb and pork. Although human disease can take many forms, congenital infection and encephalitis from reactivation of latent infection in the brains of immunosuppressed persons are the most important manifestations. CNS, central nervous system. (*Courtesy of Dominique Buzoni-Gatel, Institut Pasteur, Paris.*)

EPIDEMIOLOGY *T. gondii* infects a wide range of mammals and birds. Its seroprevalence depends on the locale and the age of the population. Generally, hot arid climatic conditions are associated with a low prevalence of infection. In the United States and most European countries, the prevalence of seroconversion increases with age and exposure. For example, in the United States, 5 to 30% of individuals 10 to 19 years old and 10 to 67% of those over the age of 50 years show serologic evidence of exposure; seroprevalence increases by ~1% per year. In Central America, France, Turkey, and Brazil, the seroprevalence is higher. There may be as many as 2100 cases of toxoplasmic encephalitis each year in the United States.

TRANSMISSION ■ Oral Transmission The principal source of human *Toxoplasma* infection remains uncertain. Transmission usually takes place by the oral route and can be attributable to ingestion of either sporulated oocysts from contaminated soil or bradyzoites from undercooked meat. During acute feline infection, a cat may excrete as many as 100 million parasites per day. These very stable sporozoite-containing oocysts are highly infectious and may remain viable for many years in the soil. Humans infected during a well-documented outbreak of oocyst-transmitted infection develop stage-specific antibodies to the oocyst/sporozoite.

Children and adults also can acquire infection from tissue cysts containing bradyzoites. The ingestion of a single cyst is all that is required for human infection. Undercooking or insufficient freezing of meat is an important source of infection in the developed world. In the United States, 10 to 20% of lamb products and 25 to 35% of pork products show evidence of cysts that contain bradyzoites. The incidence in beef is much lower—perhaps as low as 1%. Direct ingestion of bradyzoite cysts in these various meat products leads to acute infection.

Transmission via Blood or Organs In addition to oral transmission, direct transmission of the parasite by blood or organ products during transplantation takes place at a low rate. Viable parasites can be cultured from refrigerated anticoagulated blood, which may be a source of infection in individuals receiving blood transfusions. *T. gondii* infection also has been reported in kidney and heart transplant recipients who were uninfected before transplantation.

Transplacental Transmission About one-third of all women who acquire infection with *T. gondii* during pregnancy transmit the parasite to the

fetus; the remainder give birth to normal, uninfected babies. Of the various factors that influence fetal outcome, gestational age at the time of infection is the most critical (see below). Few data support a role for recrudescent maternal infection as the source of congenital disease. Thus, women who are seropositive before pregnancy usually are protected against acute infection and do not give birth to congenitally infected neonates.

The following general guidelines can be used to evaluate congenital infection. There is essentially no risk if the mother becomes infected ≥6 months before conception. If infection is acquired <6 months before conception, the likelihood of transplacental infection increases as the interval between infection and conception decreases. In pregnancy, if the mother becomes infected during the first trimester, the incidence of transplacental infection is lowest (~15%), but the disease in the neonate is most severe. If maternal infection occurs during the third trimester, the incidence of transplacental infection is greatest (65%), but the infant is usually asymptomatic at birth. Infected infants who are normal at birth may have a higher incidence of learning disabilities and chronic neurologic sequelae than uninfected children. Only a small proportion (20%) of women infected with *T. gondii* develop clinical signs of infection. Often the diagnosis is first appreciated when routine postconception serologic tests show evidence of specific antibody.

PATHOGENESIS Upon the host's ingestion of either tissue cysts containing bradyzoites or oocysts containing sporozoites, the parasites are released from the cysts by a digestive process. Bradyzoites are resistant to the effect of pepsin and invade the host's gastrointestinal tract. Within enterocytes (or other gut-associated cells), the parasites undergo morphologic transformation, giving rise to invasive tachyzoites. These tachyzoites induce a parasite-specific secretory IgA response. From the gastrointestinal tract, parasites are disseminated to a variety of organs, particularly lymphatic tissue, skeletal muscle, myocardium, retina, placenta, and the CNS. At these sites, the parasite infects host cells, replicates, and invades the adjoining cells. In this fashion, the hallmarks of the infection develop: cell death and focal necrosis surrounded by an acute inflammatory response.

In the normal immune host, both the humoral and the cellular immune responses control infection; parasite virulence and tissue tropism may be strain specific. Tachyzoites are sequestered by a variety of immune mechanisms, including induction of parasiticidal antibody, activation of macrophages with radical intermediates, production of interferon γ (IFN-γ), and stimulation of cytotoxic T lymphocytes of the CD8+ phenotype. These antigen-specific lymphocytes are capable of killing both extracellular parasites and target cells infected with parasites. As tachyzoites are cleared from the acutely infected host, tissue cysts containing bradyzoites begin to appear, usually within the CNS and the retina. In the immunocompromised or fetal host, the immune factors necessary to control the spread of tachyzoite infection are lacking. This altered immune state allows the persistence of tachyzoites and gives rise to the progressive focal destruction that results in organ failure (i.e., necrotizing encephalitis, pneumonia, and myocarditis).

Persistence of infection with cysts containing bradyzoites is common in the immunocompetent host. This lifelong infection usually remains subclinical. Although bradyzoites are in a slow metabolic phase, cysts do degenerate and rupture within the CNS. This degenerative process, with the development of new bradyzoite-containing cysts, is the most probable source of recrudescent infection in immunocompromised individuals and the most likely stimulus for the persistence of antibody titers in the immunocompetent host.

PATHOLOGY Cell death and focal necrosis due to replicating tachyzoites induce an intense mononuclear inflammatory response in any tissue or cell type infected. Tachyzoites rarely can be visualized by routine histopathologic staining of these inflammatory lesions. However, immunofluorescence staining with parasitic antigen-specific antibodies can reveal either the organism itself or evidence of antigen. In contrast to this inflammatory process caused by tachyzoites, bradyzoite-containing cysts cause inflammation only at the early stages of development, and even this inflammation may be a response to the presence of tachyzoite antigens. Once the cysts reach maturity, the inflammatory process can no longer be detected, and the cysts remain immunologically quiescent within the brain matrix until they rupture.

Lymph Nodes During acute infection, lymph node biopsy demonstrates characteristic findings, including follicular hyperplasia and irregular clusters of tissue macrophages with eosinophilic cytoplasm. Granulomas rarely are evident in these specimens. Although tachyzoites are not usually visible, they can be sought either by subinoculation of infected tissue into mice, with resultant disease, or by polymerase chain reaction (PCR). PCR amplification of DNA fragments representing either p30 (SAG-1) or p22 (SAG-2) surface antigen or B1 antigen is an effective and sensitive assay for establishing infection of lymph node tissue by tachyzoites.

Eyes In the eye, infiltrates of monocytes, lymphocytes, and plasma cells may produce uni- or multifocal lesions. Granulomatous lesions and chorioretinitis can be observed in the posterior chamber following acute necrotizing retinitis. Other ocular complications of infection include iridocyclitis, cataracts, and glaucoma.

Central Nervous System During CNS involvement, both focal and diffuse meningoencephalitis can be documented, with evidence of necrosis and microglial nodules. Necrotizing encephalitis in patients without AIDS is characterized by small diffuse lesions with perivascular cuffing in contiguous areas. In the AIDS population, polymorphonuclear leukocytes may be present in addition to monocytes, lymphocytes, and plasma cells. Cysts containing bradyzoites frequently are found contiguous with the necrotic tissue border. It is estimated that there are as many as 2100 cases of *Toxoplasma* encephalitis (TE) in the United States each year.

Lungs Among patients with AIDS who die of toxoplasmosis, 40 to 70% have involvement of the heart and lung. Interstitial pneumonitis can develop in the neonate and the immunocompromised patient. Thickened and edematous alveolar septa infiltrated with mononuclear and plasma cells are apparent. This inflammation may extend to the endothelial walls. Tachyzoites and bradyzoite-containing cysts have been observed within the alveolar membrane. Superimposed bronchopneumonia can be caused by other microbial agents.

Heart Cysts and aggregates of parasites in cardiac muscle tissue are evident in patients with AIDS who die of toxoplasmosis. Focal necrosis surrounded by inflammatory cells is associated with hyaline necrosis and disrupted myocardial cells. Pericarditis is associated with toxoplasmosis in some patients.

Gastrointestinal Tract Acute infection in certain strains of inbred mice (B6) results in the development of lethal ileitis within 7 to 9 days. This inflammatory bowel disease has been recognized in several mammalian species, including pigs and nonhuman primates. The association between human inflammatory bowel disease and either acute or recurrent *Toxoplasma* infection has not been established.

Other Sites Pathologic changes during disseminated infection are similar to those described for the lymph nodes, eyes, and CNS. In patients with AIDS, the skeletal muscle, pancreas, stomach, and kidneys can be involved, with necrosis, invasion by inflammatory cells, and (rarely) the presence of tachyzoites detectable by routine staining. Large necrotic lesions may cause direct tissue destruction. In addition, secondary effects from acute infection of these various organs, including pancreatitis, myositis, and glomerulonephritis, have been reported.

HOST IMMUNE RESPONSE Acute *Toxoplasma* infection evokes a cascade of protective immune responses in the normal host. *Toxoplasma* enters the host at the gut mucosal level and evokes a mucosal immune response that includes the production of antigen-specific secretory IgA. Titers of serum IgA antibody directed at p30 (SAG-1) have been

shown to be a useful marker of congenital and acute toxoplasmosis. Milk-whey IgA from acutely infected mothers contains a high titer of antibody to *T. gondii* and can block infection of enterocytes in vitro. In mice, IgA intestinal secretions directed at the parasite are abundant and are associated with the induction of mucosal T cells.

Within the host, *T. gondii* rapidly induces detectable levels of both IgM and IgG serum antibodies. Monoclonal gammopathy of the IgG class can occur in congenitally infected infants. IgM levels may be increased in newborns with congenital infection. The polyclonal IgG antibodies evoked by infection are parasiticidal in vitro in the presence of serum complement and are the basis for the Sabin-Feldman dye test. However, cell-mediated immunity is the major protective response evoked by the parasite during host infection. Macrophages are activated following phagocytosis of antibody-opsonized parasites. This activation can lead to death of the parasite by either an oxygen-dependent or an oxygen-independent process. If the parasite is not phagocytosed and enters the macrophage by active penetration, it continues to replicate, and this replication may represent the mechanism for transport and dissemination to distant organs. *Toxoplasma* stimulates a robust interleukin (IL) 12 response by human dendritic cells. The requirement for costimulation via CD40/154 has been established. The CD4+ and CD8+ T cell responses are antigen-specific and further stimulate the production of a variety of important lymphokines that expand the T cell and natural killer cell repertoire. *T. gondii* is a potent inducer of a T_H1 phenotype, with IL-12 and IFN-γ playing an essential role in the control of the parasites' growth in the host. Regulation of the inflammatory response is at least partially under the control of a T_H2 response that includes the production of IL-4 and IL-10 in seropositive individuals. Both asymptomatic patients and those with active infection may show a depression in the ratio of CD4+ to CD8+ lymphocytes. This shift may be correlated with a disease syndrome but is not necessarily correlated with disease outcome. Human T cell clones of both the CD4+ and the CD8+ phenotypes are cytolytic against parasite-infected macrophages. These T cell clones produce cytokines that are "microbistatic." IL-18, IL-7, and IL-15 upregulate the production of IFN-γ and may be important during acute and chronic infection. The effect of IFN-γ may be paradoxical, with stimulation of a host downregulatory response as well.

Although in patients with AIDS *T. gondii* infection is believed to be recrudescent, determination of antibody titers is not helpful in establishing reactivation. Because of the severe depletion in CD4+ T cells, quite frequently there is no observed increase in antibody titer during exacerbation of infection. T cells from AIDS patients with reactivation of toxoplasmosis fail to secrete both IFN-γ and IL-2. This alteration in the production of these critical immune cytokines contributes to the persistence of infection. *Toxoplasma* infection frequently develops late in the course of AIDS, when the loss of T cell–dependent protective mechanisms, particularly CD8+ T cells, becomes most pronounced.

CLINICAL MANIFESTATIONS In persons whose immune systems are intact, acute toxoplasmosis is usually asymptomatic and self-limited. This condition can go unrecognized in 80 to 90% of adults and children with acquired infection. The asymptomatic nature of this infection makes diagnosis difficult in mothers infected during pregnancy. In contrast, the wide range of clinical manifestations in congenitally infected children includes severe neurologic complications such as hydrocephalus, microcephaly, mental retardation, and chorioretinitis. If prenatal infection is severe, multiorgan failure and subsequent intrauterine fetal death can occur. In children and adults, chronic infection can persist throughout life, with little consequence to the immunocompetent host.

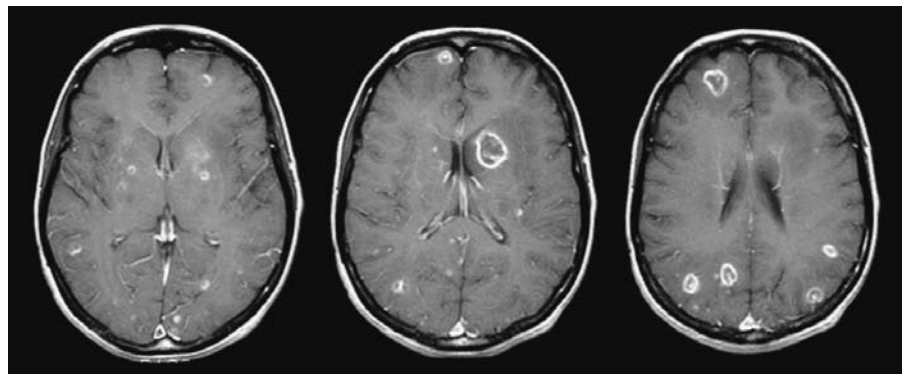

FIGURE 198-2 Toxoplasmic encephalitis in a 36-year-old patient with AIDS. The multiple lesions are demonstrated by magnetic resonance scanning (T1 weighted with gadolinium enhancement). (*Courtesy of Clifford Eskey, Dartmouth Hitchcock Medical Center, Hanover, NH.*)

Toxoplasmosis in Immunocompetent Patients The most common manifestation of acute toxoplasmosis is cervical lymphadenopathy. The nodes may be single or multiple, are usually nontender, are discrete, and vary in firmness. Lymphadenopathy also may be found in suboccipital, supraclavicular, inguinal, and mediastinal areas. Generalized lymphadenopathy occurs in 20 to 30% of symptomatic patients. Between 20 and 40% of patients with lymphadenopathy also have headache, malaise, fatigue, and fever [usually with a temperature of $<40°C$ ($<104°F$)]. A smaller proportion of symptomatic individuals have myalgia, sore throat, abdominal pain, maculopapular rash, meningoencephalitis, and confusion. Rare complications associated with infection in the normal immune host include pneumonia, myocarditis, encephalopathy, pericarditis, and polymyositis. Symptoms associated with acute infection usually resolve within several weeks, although the lymphadenopathy may persist for some months. In one epidemic, toxoplasmosis was diagnosed correctly in only 3 of the 25 patients who consulted physicians. If toxoplasmosis is considered in the differential diagnosis, routine laboratory and serologic screening should be performed before node biopsy.

The results of routine laboratory studies are usually unremarkable except for minimal lymphocytosis, an elevated sedimentation rate, and a nominal increase in liver aminotransferases. Evaluation of cerebrospinal fluid (CSF) in cases with evidence of encephalopathy or meningoencephalitis shows an elevation of intracranial pressure, mononuclear pleocytosis (10 to 50 cells/mL), a slight increase in protein concentration, and (occasionally) an increase in the gamma globulin level. PCR amplification of the *Toxoplasma* DNA target sequence in the CSF may be beneficial. The CSF of chronically infected individuals is normal.

Infection of Immunocompromised Patients Patients with AIDS and those receiving immunosuppressive therapy for lymphoproliferative disorders are at greatest risk for developing acute toxoplasmosis. This predilection may be due either to reactivation of latent infection or to acquisition of parasites from exogenous sources such as blood or transplanted organs. In individuals with AIDS, more than 95% of cases of TE are believed to be due to recrudescent infection. In most of these cases, encephalitis develops when the CD4+ cell count falls below $100/\mu L$. In the immunocompromised individual, the disease may be rapidly fatal if untreated. Thus accurate diagnosis and initiation of appropriate therapy are necessary to prevent fulminant infection.

Toxoplasmosis is a principal opportunistic infection of the CNS in persons with AIDS. Although geographic origin may be related to frequency of infection, it has no correlation with the severity of disease in the immunocompromised host. Individuals with AIDS who are seropositive for *T. gondii* are at a very high risk for developing encephalitis. In the United States, about one-third of the 15 to 40% of adult patients with AIDS who are latently infected with the parasite develop TE.

The signs and symptoms of acute toxoplasmosis in the immunocompromised patient principally involve the CNS (Fig. 198-2). More

than 50% of patients with clinical manifestations have intracerebral involvement. Clinical findings at the time of presentation range from nonfocal to focal dysfunction. CNS findings include encephalopathy, meningoencephalitis, and mass lesions. Patients may present with altered mental status (75%), fever (10 to 72%), seizures (33%), headaches (56%), and focal neurologic findings (60%), including motor deficits, cranial nerve palsies, movement disorders, dysmetria, visual-field loss, and aphasia. Patients who present with evidence of diffuse cortical dysfunction develop evidence of focal neurologic disease as the infection progresses. This altered condition is due not only to the necrotizing encephalitis caused by direct invasion of the parasite but also to secondary effects, including vasculitis, edema, and hemorrhage. The onset of infection can range from an insidious process over several weeks to an acute confusional state with fulminant focal deficits, including hemiparesis, hemiplegia, visual-field defects, localized headache, and focal seizures.

Although lesions can occur anywhere within the CNS, the areas most involved appear to be the brainstem, basal ganglia, pituitary gland, and corticomedullary junction. Brainstem involvement gives rise to a variety of neurologic dysfunctions, including cranial nerve palsy, dysmetria, and ataxia. With basal ganglionic infection, patients may develop hydrocephalus, choreiform movements, and choreoathetosis. Because *Toxoplasma* usually causes encephalitis, meningeal involvement is uncommon, and thus CSF findings may be unremarkable or may include a modest increase in cell count and in protein—but not glucose—concentration.

Cerebral toxoplasmosis needs to be differentiated from other opportunistic infections or tumors within the CNS of those afflicted with AIDS. The differential diagnosis includes herpes simplex encephalitis, cryptococcal meningitis, progressive multifocal leukoencephalopathy, and primary CNS lymphoma. Involvement of the pituitary gland can give rise to panhypopituitarism and hyponatremia from inappropriate secretion of vasopressin (antidiuretic hormone). AIDS-dementia complex may present as cognitive impairment, attention loss, and altered memory. Brain biopsy in those patients who have been treated for TE but who continue to exhibit neurologic dysfunction often fails to identify organisms.

Autopsies of patients infected with *Toxoplasma* have demonstrated the involvement of multiple organs, including the lungs, gastrointestinal tract, pancreas, skin, eyes, heart, and liver. *Toxoplasma* pneumonia can occur and can be confused with *Pneumocystis carinii* infection. Respiratory involvement usually presents as dyspnea, fever, and a nonproductive cough and may rapidly progress to acute respiratory failure with hemoptysis, metabolic acidosis, hypotension, and (occasionally) disseminated intravascular coagulation. Histopathologic studies demonstrate necrosis and a mixed cellular infiltrate. The presence of organisms is a helpful diagnostic indicator, but organisms can also be found in healthy tissue. Infection of the heart is usually asymptomatic but can be associated with cardiac tamponade or biventricular failure. Infections of the gastrointestinal tract and the liver have been documented.

Congenital Toxoplasmosis Between 400 and 4000 infants born each year in the United States are affected by congenital toxoplasmosis. Infection of the placenta leads to hematogenous infection of the fetus. As has already been stated, the proportion of fetuses that become infected increases but the clinical severity of the infection declines as gestation proceeds. Persistence of the parasite can ultimately result in reactivation and further damage decades later. Factors associated with relatively severe disabilities include delayed diagnosis and initiation of therapy, neonatal hypoxia and hypoglycemia, profound visual impairment (see "Ocular Infection," below), uncorrected hydrocephalus, and increased intracranial pressure. If treated appropriately, upwards of 70% of children have normal developmental, neurologic, and ophthalmologic findings at follow-up evaluations. Treatment for 1 year with pyrimethamine and a sulfonamide is tolerated with minimal toxicity (see "Treatment," below).

Ocular Infection Infection with *T. gondii* is estimated to cause 35% of all cases of chorioretinitis in the United States and Europe. Most ocular involvement is believed to be due to congenital infection, with a very low incidence following acquired infection. Between 1 and 3% of all patients with AIDS develop debilitating chorioretinitis due to *T. gondii*. A variety of ocular manifestations are documented, including blurred vision, scotoma, photophobia, and eye pain. Macular involvement occurs with loss of central vision, and nystagmus is secondary to poor fixation. Involvement of the extraocular muscles may lead to disorders of convergence and to strabismus. Ophthalmologic examination should be undertaken in newborns with suspected congenital infection. As the inflammation resolves, vision improves, but episodic flare-ups of chorioretinitis, which progressively destroy retinal tissue and lead to glaucoma, are common.

The ophthalmologic examination reveals yellow-white, cotton-like patches with indistinct margins of hyperemia. As the lesions age, white plaques with distinct borders and black spots within the retinal pigment become more apparent. Lesions usually are located near the posterior pole of the retina; they may be single but are more commonly multiple. Congenital lesions may be unilateral or bilateral and show evidence of massive chorioretinal degeneration with extensive fibrosis. Surrounding these areas of involvement are a normal retina and vasculature. In patients with AIDS, retinal lesions are often large, with diffuse retinal necrosis, and include both free tachyzoites and cysts containing bradyzoites. Toxoplasmic chorioretinitis may be a prodrome to the development of encephalitis.

DIAGNOSIS ■ Tissue and Body Fluids The differential diagnosis of acute toxoplasmosis can be made by appropriate culture, serologic testing, and PCR (Table 198-1). Although difficult, the isolation of *T. gondii* from blood or other body fluids can be accomplished after subinoculation of the sample into the peritoneal cavity of mice. Mice should be tested for organisms in the peritoneal fluid 6 to 10 days after inoculation. If no parasites are found in the mouse's peritoneal fluid, its anti-*Toxoplasma* serum titer can be evaluated 4 to 6 weeks after inoculation. Isolation of *T. gondii* from the patient's body fluids reflects acute infection, whereas isolation from biopsied tissue is an indication only of the presence of tissue cysts and should not be misinterpreted as evidence of acute toxoplasmosis. Persistent parasitemia in patients with latent, asymptomatic infection is rare. Histologic examination of lymph nodes may suggest the characteristic changes described above.

TABLE 198-1 *Differential Laboratory Diagnosis of Toxoplasmosis*

Clinical Setting	*Alternative Diagnosis*	*Distinguishing Characteristics*
Mononucleosis syndrome	Epstein-Barr virus	Serologic test
	Cytomegalovirus	Serologic test
	HIV	Serologic test
Congenital infection	Cytomegalovirus	Viral culture
	Herpes simplex virus	Viral culture
	Rubella virus	Viral culture/serologic test
	Syphilis	Serologic test
	Listeriosis	Bacterial culture
Retinochoroiditis in immunocompetent individual	Tuberculosis	Bacterial culture
	Syphilis	Serologic test
	Histoplasmosis	Serologic test/culture
Retinochoroiditis in AIDS	Cytomegalovirus	Viral culture/PCR
	Syphilis	Serologic test
	Herpes simplex virus	Viral culture/PCR
	Varicella-zoster virus	Viral culture/PCR
	Fungal infection	Culture
CNS lesions in AIDS	Lymphoma or metastatic tumor	Tissue biopsy
	Brain abscess	Bacterial culture
	Progressive multifocal leukoencephalopathy	PCR
	Fungal/mycobacterial infection	Biopsy and culture

Source: Adapted from Schwartzman JD: Toxoplasmosis, in *Principles and Practice of Clinical Parasitology*. Hoboken, Wiley, 2001.

Demonstration of tachyzoites in lymph nodes establishes the diagnosis of acute toxoplasmosis. Like subinoculation into mice, histologic demonstration of cysts containing bradyzoites confirms prior infection with *T. gondii* but is nondiagnostic for acute infection.

Serology The procedures just described have great diagnostic value but are limited by difficulties encountered either in the growth of parasites in vivo or in the identification of tachyzoites by histochemical methods. Serologic testing has become the routine method of diagnosis. A wide range of serologic tests that can be used to measure antibody to *T. gondii* are available commercially.

Diagnosis of acute infection with *T. gondii* can be established by detection of the simultaneous presence of IgG and IgM antibody to *Toxoplasma* in serum. The presence of circulating IgA favors the diagnosis of an acute infection. The Sabin-Feldman dye test, the indirect fluorescent antibody test, and the enzyme-linked immunosorbent assay (ELISA) all satisfactorily measure circulating IgG antibody to *Toxoplasma*. Positive IgG titers (>1:10) can be detected as early as 2 to 3 weeks after infection. These titers usually peak at 6 to 8 weeks and decline slowly to a new baseline level that persists for life. It is necessary to measure the serum IgM titer in concert with the IgG titer to better establish the time of infection. The methods currently available for this determination are the double-sandwich IgM-ELISA and the IgM-immunosorbent assay (IgM-ISAGA). Both of these assays are specific and sensitive, and their use precludes the false-positive results associated with tests for rheumatoid factor and antinuclear antibody. The double-sandwich IgA-ELISA is more sensitive than the IgM-ELISA for detecting congenital infection in the fetus and newborn.

Recently, the results obtained with PCR have suggested high sensitivity, specificity, and clinical utility in the diagnosis of TE in a resource-poor setting.

The Immunocompetent Adult or Child For the patient who presents with lymphadenopathy only, a positive IgM titer is an indication of acute infection—and an indication for therapy, if that is clinically warranted (see "Treatment," below). The serum IgM titer should be determined again in 3 weeks. An elevation in the IgG titer without an increase in the IgM titer suggests that infection is present but that it is not acute. If there is a borderline increase in either IgG or IgM, the titers should be assessed again in 3 to 4 weeks.

The Immunocompromised Host A presumptive clinical diagnosis of TE in patients with AIDS is based on clinical presentation, history of exposure as evidenced by positive serology, and radiologic evaluation. To detect latent infection with *T. gondii*, HIV-infected persons should be tested for IgG antibody to *Toxoplasma* soon after the diagnosis of HIV infection. When these criteria are used, the predictive value is as high as 80%. More than 97% of patients with AIDS and toxoplasmosis have IgG antibody to the parasite in their sera. IgM serum antibody is usually not demonstrable. Attempts to evaluate rising IgG titers or to determine whether IgM is present are not productive. Serologic evidence of infection virtually always precedes the development of TE. It is therefore important to determine the *Toxoplasma* antibody status of all patients infected with HIV. Antibody titers may range from negative to 1:1024 in patients with AIDS and TE. Fewer than 3% of patients have no demonstrable antibody to *Toxoplasma* at the time of diagnosis. Intrathecal antibody to *T. gondii* may be present; determination of the intrathecal antibody titer may be useful in identifying prior infection.

Patients with TE have focal or multifocal abnormalities demonstrable by computed tomography (CT) or magnetic resonance imaging (MRI). Neuroradiologic evaluation should include double-dose contrast CT of the head. By this test, single and frequently multiple contrast-enhancing lesions (<2 cm) may be identified. MRI usually demonstrates multiple lesions located in both hemispheres, with the basal ganglia and corticomedullary junction most commonly involved; MRI provides a more sensitive evaluation of the efficacy of therapy than does CT (Fig. 198-2). These findings are not pathognomonic of *Toxoplasma* infection since 40% of CNS lymphomas are multifocal and 50% are ring-enhancing. For both MRI and CT scans, the rate of false-negative results is ~10%. The finding of a single lesion on an MRI scan increases the suspicion of primary CNS lymphoma (in which solitary lesions are four times more likely than in TE) and strengthens the argument for the performance of a brain biopsy. A therapeutic trial of anti-*Toxoplasma* medications is frequently used to assess the diagnosis. Treatment of presumptive TE with pyrimethamine clindamycin results in quantifiable clinical improvement in more than 50% of patients by day 3. By day 7, more than 90% of treated patients show evidence of improvement. In contrast, if patients fail to respond or have lymphoma, clinical signs and symptoms worsen by day 7. Patients in this category require brain biopsy with or without a change in therapy. This procedure can now be performed by a stereotactic CT-guided method that reduces the potential for complications. Brain biopsy for *T. gondii* identifies organisms in 50 to 75% of cases. PCR amplification of genetic material of the parasite found in the CSF may prove diagnostically beneficial in the future.

Now used in some centers, single-photon emission CT (SPECT) has been touted as a definitive means of detecting or ruling out *Toxoplasma* infection when a CNS lesion is suspected. In the future, SPECT may well be widely used for this purpose.

As in other conditions, the radiologic response may lag behind the clinical response. Resolution of lesions may take from 3 weeks to 6 months. Some patients show clinical improvement despite worsening radiographic findings.

Congenital Infection The issue of concern when a pregnant woman has evidence of recent *T. gondii* infection is obviously whether the fetus is infected. PCR of the amniotic fluid to detect the B1 gene of the parasite has replaced fetal blood sampling. Serologic diagnosis is based on the persistence of IgG antibody or a positive IgM titer after the first week of life (a time frame that excludes placental leak). The IgG determination should be repeated every 2 months. An increase in IgM beyond the first week of life is indicative of acute infection. However, up to 25% of infected newborns may be seronegative and have normal routine physical examinations. Thus assessment of the eye and the brain, with ophthalmologic testing, CSF evaluation, and radiologic studies, is important in establishing the diagnosis.

Ocular Toxoplasmosis Because of the congenital nature of ocular toxoplasmosis, the serum antibody titer may not correlate with the presence of active lesions in the fundus. In general, a positive IgG titer (measured in undiluted serum if necessary) in conjunction with typical lesions establishes the diagnosis. If lesions are atypical and the titer is in the low-positive range, the diagnosis is presumptive. The parasitic antigen-specific polyclonal IgG assay as well as the parasitic antigen-specific PCR may facilitate the diagnosis.

Rx TREATMENT

Congenital Infection Congenitally infected neonates are treated with daily oral pyrimethamine (0.5 to 1 mg/kg) and sulfadiazine (100 mg/kg) for 1 year. In addition, therapy with spiramycin (100 mg/kg per day) plus prednisone (1 mg/kg per day) has been shown to be efficacious for congenital infection.

Infection in Immunocompetent Patients Immunologically competent adults and older children who have only lymphadenopathy do not require specific therapy unless they have persistent, severe symptoms. Patients with ocular toxoplasmosis should be treated for 1 month with pyrimethamine plus either sulfadiazine or clindamycin. Prenatal antibiotic therapy can reduce the number of infants severely affected by *Toxoplasma* infection.

Infection in Immunocompromised Patients ■ *PRIMARY PROPHYLAXIS* Patients with AIDS should be treated for acute toxoplasmosis; in the immunocompromised patient, toxoplasmosis is rapidly fatal if untreated. AIDS patients who are seropositive for *T. gondii* and have a CD4+ T lymphocyte count of <100/μL should receive prophylaxis against TE. The daily dose of trimethoprim-sulfamethoxazole (TMP-SMX) rec-

ommended as the preferred regimen for *P. carinii* pneumonia (PCP) prophylaxis (one double-strength tablet) is effective against TE. If patients cannot tolerate TMP-SMX, the recommended alternative is dapsone-pyrimethamine, which is also effective against PCP. Atovaquone with or without pyrimethamine also can be considered. Prophylactic monotherapy with dapsone, pyrimethamine, azithromycin, clarithromycin, or aerosolized pentamidine is probably insufficient. AIDS patients who are seronegative for *Toxoplasma* and are not receiving prophylactic medication for PCP should be retested for IgG antibody to *Toxoplasma* if their CD4+ T cell count drops to $<100/\mu L$. If seroconversion has taken place, then the patient should be given prophylactic medication as described above.

DISCONTINUING PRIMARY PROPHYLAXIS Some current studies indicate that prophylaxis against TE can be discontinued in patients who have responded to highly active antiretroviral therapy (HAART) and whose CD4+ T lymphocyte count has been $>200/\mu L$ for 3 months. Although patients with CD4+ T lymphocyte counts of $<100/\mu L$ are at greatest risk for developing TE, the risk that this condition will develop when the CD4+ T lymphocyte count has increased to $100–200/\mu L$ has not been established. Thus, prophylaxis should be discontinued only when the CD4+ T cell count has increased to $>200/\mu L$. Continued prophylaxis when the CD4+ count is $>200/\mu L$ has only a limited preventive effect against TE. Discontinuation of therapy reduces pill burden, potential for drug toxicity, drug interaction, selection of drug-resistant pathogens, and cost. Prophylaxis should be reintroduced if the CD4+ T lymphocyte count decreases to $<100–200/\mu L$.

Individuals who have completed initial therapy for TE should continue treatment indefinitely unless immune reconstitution, with a CD4+ T cell count of $>200/\mu L$, occurs as a consequence of HAART. Combination therapy with pyrimethamine plus sulfadiazine plus leucovorin is effective for this purpose. An alternative to sulfadiazine in this regimen is clindamycin. Unfortunately, only the combination of pyrimethamine plus sulfadiazine provides protection against PCP as well.

DISCONTINUING SECONDARY PROPHYLAXIS (CHRONIC MAINTENANCE THERAPY) Patients receiving secondary prophylaxis for TE are at low risk for recurrence when they have completed initial therapy for TE, remain asymptomatic, and have a CD4+ T lymphocyte count of $>200/\mu L$ for at least 6 months after HAART. This recommendation is based on limited patient assessment and is consistent with more extensive data indicating the safety of discontinuing secondary prophylaxis for other opportunistic infections during advanced HIV disease. Discontinuation of chronic maintenance therapy among these patients appears reasonable. A repeat MRI scan of the brain is recommended to determine whether discontinuing therapy is appropriate. Secondary prophylaxis should be reintroduced if the CD4+ T lymphocyte count decreases to $<200/\mu L$.

PREVENTION All HIV-infected persons, including those who lack IgG antibody to *Toxoplasma*, should be counseled regarding sources of *Toxoplasma* infection. The chances of primary infection with *Toxoplasma* can be reduced by not eating undercooked meat and by avoiding oocyst-contaminated material (i.e., a cat's litter box). Specifically, lamb, beef, and pork should be cooked to an internal temperature of 165° to 170°F; from a more practical perspective, meat cooked until it is no longer pink inside usually satisfies this requirement. Hands should be washed thoroughly after work in the garden, and all fruits and vegetables should be washed. If the patient owns a cat, the litter box should be cleaned or changed daily, preferably by an HIV-negative, nonpregnant person; alternatively, patients should wash their hands thoroughly after changing the litter box. Patients should be encouraged to keep their cats inside and not to adopt or handle stray cats. Cats should be fed only canned or dried commercial food or well-cooked table food, not raw or undercooked meats. Patients need not be advised to part with their cats or to have their cats tested for toxoplasmosis. Blood intended for transfusion into *Toxoplasma*-seronegative immunocompromised individuals should be screened for antibody to *T. gondii*. Although such serologic screening is not routinely performed, seronegative women should be screened for evidence of infection several times during pregnancy if they are exposed to environmental conditions that put them at risk for infection with *T. gondii*. HIV-positive individuals should adhere closely to these preventive measures.

199 PROTOZOAL INTESTINAL INFECTIONS AND TRICHOMONIASIS

Peter F. Weller

PROTOZOAL INFECTIONS

GIARDIASIS *Giardia lamblia* (also known as *G. intestinalis*) is a cosmopolitan protozoal parasite that inhabits the small intestines of humans and other mammals. Giardiasis is one of the most common parasitic diseases worldwide and causes both endemic and epidemic intestinal disease and diarrhea.

Life Cycle and Epidemiology (Fig. 199-1) Infection follows the ingestion of the environmentally hardy cysts, which excyst in the small intestine, releasing flagellated trophozoites (Fig. 199-2) that multiply by binary fission. *Giardia* remains a pathogen of the proximal small bowel and does not disseminate hematogenously. Trophozoites remain free in the lumen or attach to the mucosal epithelium by means of a ventral sucking disk. As a trophozoite encounters altered conditions, it forms a morphologically distinct cyst, which is the stage of the parasite usually found in the feces. Trophozoites may be present and even predominate in loose or watery stools, but it is the resistant cyst that survives outside the body and is responsible for transmission. Cysts do not tolerate heating, desiccation, or continued exposure to feces but do remain viable for months in cold fresh water. The number of cysts excreted varies widely but can approach 10^7 per gram of stool.

Giardia infections are common in both developed and developing countries. Ingestion of as few as 10 cysts is sufficient to cause infection in humans. Because cysts are infectious when excreted or shortly thereafter, person-to-person transmission occurs where fecal hygiene is poor. Giardiasis, as a symptomatic or an asymptomatic infection, is especially prevalent in day-care centers; person-to-person spread also takes place in other institutional settings with poor fecal hygiene and during anal-oral contact. If food is contaminated with *Giardia* cysts after cooking or preparation, food-borne transmission can occur. Wa-

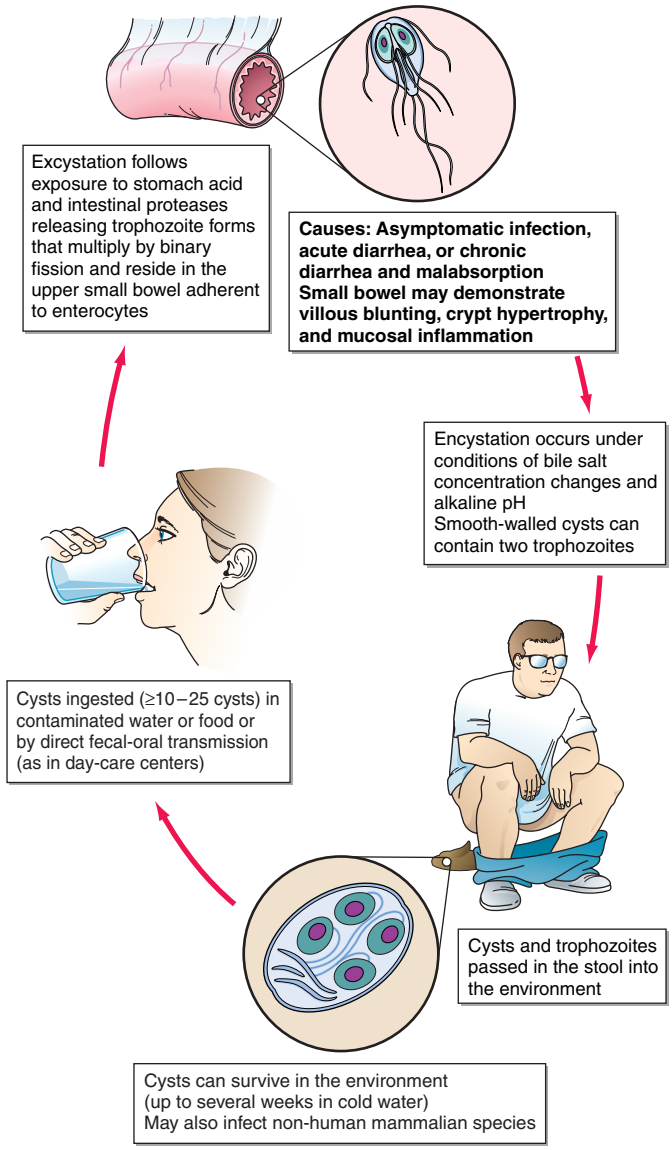

FIGURE 199-1 Life cycle of *Giardia*. (*Reprinted from RL Guerrant et al: Essentials of Tropical Infectious Diseases, 2001, p 330, with permission from Elsevier Science.*)

terborne transmission accounts for episodic infections (e.g., in campers and other travelers) and for massive epidemics in metropolitan areas. Surface water, ranging from mountain streams to large municipal reservoirs, can become contaminated with fecally derived *Giardia* cysts; outmoded water systems are subject to cross-contamination from leaking sewer lines. The efficacy of water as a means of transmission is enhanced by the small infectious inoculum of *Giardia*, the prolonged survival of cysts in cold water, and the resistance of cysts to killing by routine chlorination methods that are adequate for controlling bacteria. Viable cysts can be eradicated from water by either boiling or filtration. In the United States, *Giardia* is a common agent identified in waterborne epidemics of gastroenteritis; it is also common in developing countries.

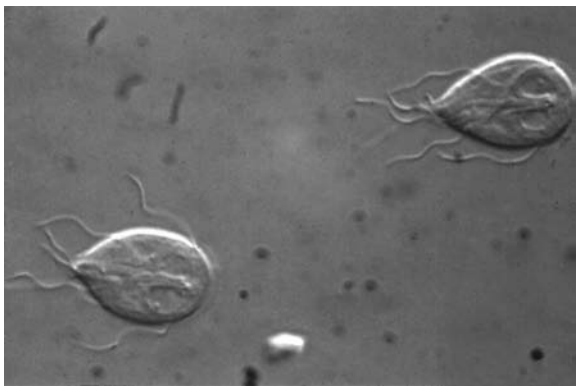

FIGURE 199-2 Flagellated, binucleate *Giardia* trophozoite.

The importance of animal reservoirs as sources of infection for humans is unclear. *Giardia* parasites morphologically similar to those in humans are found in a large number of mammals, including beavers from reservoirs implicated in epidemics, dogs, cats, and ruminants.

Giardiasis, like cryptosporidiosis (see below), creates a significant economic burden because of the costs incurred in the installation of water filtration systems required to prevent waterborne epidemics, in the management of epidemics that involve large communities, and in the evaluation and treatment of endemic infections.

Pathophysiology The reasons that some, but not all, infected patients develop clinical manifestations and the mechanisms by which *Giardia* causes alterations in small-bowel function are largely unknown. Although trophozoites adhere to the epithelium, they do not cause invasive or locally destructive alterations. The lactose intolerance and significant malabsorption that develop in a minority of infected adults and children are clinical signs of the loss of brush border enzyme activities. In most infections the morphology of the bowel is unaltered, but in a few cases—usually in chronically infected, symptomatic patients—the histopathologic findings (including flattened villi) and the clinical manifestations resemble those of tropical sprue and gluten-sensitive enteropathy. The pathogenesis of diarrhea in giardiasis is not known.

The natural history of *Giardia* infection varies markedly. Infections may be aborted, transient, recurrent, or chronic. Parasite as well as host factors may be important in determining the course of infection and disease. Both cellular and humoral responses develop in human infections, but their precise roles in the control of infection and/or disease are unknown. Because patients with hypogammaglobulinemia commonly suffer from prolonged, severe infections that are poorly responsive to treatment, humoral immune responses appear to be important. The greater susceptibility of the young than of the old and of newly exposed persons than of chronically exposed populations also suggests that at least partial protective immunity may develop. Although no strains of the parasite that are clearly nonpathogenic have been identified, *Giardia* isolates vary genotypically, biochemically, and biologically. The marked biochemical differences among some isolates may help account for the different courses of infection in experimentally infected humans and animals.

Clinical Manifestations Disease manifestations of giardiasis range from asymptomatic carriage to fulminant diarrhea and malabsorption. Most infected persons are asymptomatic, but in epidemics the proportion of symptomatic cases may be higher. Symptoms may develop suddenly or gradually. In persons with acute giardiasis, symptoms develop after an incubation period that lasts at least 5 to 6 days and usually 1 to 3 weeks. Prominent early symptoms include diarrhea, abdominal pain, bloating, belching, flatus, nausea, and vomiting. Although diarrhea is common, upper intestinal manifestations such as nausea, vomiting, bloating, and abdominal pain may predominate. The duration of acute giardiasis is usually >1 week, although diarrhea often subsides. Individuals with chronic giardiasis may present with or without having experienced an antecedent acute symptomatic episode. Diarrhea is not necessarily prominent, but increased flatus, loose stools, sulfurous burping, and (in some instances) weight loss occur. Symptoms may be continual or episodic and can persist for years. Some persons who have relatively mild symptoms for long periods recognize the extent of their discomfort only in retrospect. Fever, the presence of blood and/or mucus in the stools, and other signs and symptoms of colitis are uncommon and suggest a different diagnosis or a concomitant illness. Symptoms tend to be intermittent yet recurring and gradually

debilitating, in contrast with the acute disabling symptoms associated with many enteric bacterial infections. Because of the less severe illness and the propensity for chronic infections, patients may seek medical advice late in the course of the illness; however, disease can be severe, resulting in malabsorption, weight loss, growth retardation, dehydration, and (in rare cases) death. A number of extraintestinal manifestations have been described, such as urticaria, anterior uveitis, and arthritis; whether these are caused by giardiasis or concomitant processes is unclear.

Giardiasis can be life-threatening in patients with hypogammaglobulinemia and is typically difficult to treat and eradicate. *Giardia* infections can complicate other preexisting intestinal diseases, such as cystic fibrosis. Although *Giardia* can cause enteric illness in patients with AIDS, neither the course of infection nor the response to treatment differs for patients with and without AIDS.

Diagnosis Giardiasis is diagnosed by the detection of parasite antigen in the feces or by the identification of cysts in the feces or of trophozoites in the feces or small intestines. Cysts are oval, measure 8 to 12 μm $\times$ 7 to 10 μm, and characteristically contain four nuclei. Trophozoites are pear-shaped, dorsally convex, flattened parasites with two nuclei and four pairs of flagella. The diagnosis is sometimes difficult to establish. Direct examination of fresh or properly preserved stools as well as concentration methods should be used. Because cyst excretion is variable and may be undetectable at times, repeated examination of stool, sampling of duodenal fluid, and biopsy of the small intestine may be required to detect the parasite. Tests for parasitic antigen in stool are at least as sensitive and specific as good microscopic examinations and are easier to perform. All of these methods occasionally yield false-negative results.

Rx TREATMENT

Cure rates with metronidazole (250 mg thrice daily for 5 days) are usually >90%. Alternatively, quinacrine (100 mg thrice daily for 5 days) is effective but is available from only a limited number of compounding pharmacies. Tinidazole, which is not available in the United States, is more effective than metronidazole or quinacrine. Furazolidone (6 mg/kg daily in four doses for 7 to 10 days) is used principally for children because it is available as a palatable elixir that is not bitter. Nitazoxanide, currently available in the United States as an oral suspension, is approved by the U.S. Food and Drug Administration (FDA) for the treatment of giardiasis in children. Paromomycin, an oral aminoglycoside that is not well absorbed, can be given to symptomatic pregnant patients, although information is limited on how effectively this agent eradicates infection.

Patients in whom initial treatment fails can be re-treated with a longer course. Almost all patients respond to therapy and are cured, although some with chronic giardiasis experience delayed resolution of symptoms after eradication of *Giardia*. Those who remain infected after repeated treatments should be evaluated for reinfection through family members, close personal contacts, and environmental sources as well as for hypogammaglobulinemia. In cases refractory to multiple treatment courses, prolonged therapy with metronidazole (750 mg thrice daily for 21 days), alone or in combination with quinacrine, has been successful. When children attending day-care centers infect an entire family, treatment of all infected family members, including asymptomatic carriers, may be required to prevent reinfection.

Prevention Although *Giardia* is extremely infectious, disease can be prevented by the exclusive consumption of noncontaminated food and water. Cooking food adequately and boiling or filtering potentially contaminated water prevent infection.

CRYPTOSPORIDIOSIS The coccidian parasite *Cryptosporidium* causes diarrheal disease that is self-limited in immunocompetent human hosts but can be severe in persons with AIDS or other forms of immunodeficiency. Two distinct genotypes of *Cryptosporidium parvum* cause most human infections, although other *Cryptosporidium* species have been identified in immunocompromised patients.

Life Cycle and Epidemiology Cryptosporidiosis is acquired by the consumption of oocysts (50% infectious dose: ~132 oocysts in nonimmune individuals), which excyst to liberate sporozoites that in turn enter and infect intestinal epithelial cells. The parasite's further development involves both asexual and sexual cycles, which produce forms capable of infecting other epithelial cells and of generating oocysts that are passed in the feces. *Cryptosporidium* species infect a number of animals and can spread from infected animals to humans. Since oocysts are immediately infectious when passed in feces, person-to-person transmission takes place in child day-care centers and among household contacts and medical providers. Waterborne transmission accounts for infections in travelers and for common-source epidemics. Oocysts are quite hardy and resist killing by routine chlorination. Both drinking water and recreational water (e.g., pools, waterslides) have been increasingly recognized as sources of infection.

Pathophysiology Although intestinal epithelial cells harbor the parasite in an intracellular vacuole, the means by which secretory diarrhea is elicited remain uncertain. No characteristic pathologic changes are found by biopsy. The distribution of infection can be spotty within the principal site of infection, the small bowel. Cryptosporidia are found in some patients in the pharynx, stomach, and large bowel and at times in the respiratory tract. Especially in patients with AIDS, involvement of the biliary tract can cause papillary stenosis, sclerosing cholangitis, or cholecystitis.

Clinical Manifestations Asymptomatic infections can occur in both immunocompetent and immunocompromised hosts. In immunocompetent persons, symptoms develop after an incubation period of about a week and consist principally of watery nonbloody diarrhea, sometimes in conjunction with abdominal pain, nausea, anorexia, fever, and/or weight loss. In these hosts, the illness usually subsides after 1 to 2 weeks, whereas in immunocompromised hosts, especially those with AIDS and CD4+ cell counts <100/μL, diarrhea can be chronic, persistent, and remarkably profuse, causing clinically significant fluid and electrolyte depletion. Stool volumes may range from 1 to 25 L/d. Weight loss, wasting, and abdominal pain may be severe. Biliary tract involvement can manifest as midepigastric or right upper quadrant pain.

Diagnosis Evaluation usually starts with fecal examination for small oocysts, which are 4 to 5 μm in diameter and are smaller than the fecal stages of most other parasites. Because conventional stool examination for ova and parasites will not detect *Cryptosporidium*, specific testing must be requested. Detection is enhanced by evaluation of stools (obtained on multiple days) by several techniques, including modified acid-fast and direct immunofluorescent stains and enzyme immunoassays. Cryptosporidia also can be identified by light and electron microscopy at the apical surfaces of intestinal epithelium from biopsy specimens of the small bowel and, less frequently, the large bowel.

Rx TREATMENT

Until recently, no chemotherapeutic agents effective against *Cryptosporidium* had been identified, although paromomycin (500 to 750 mg four times daily) was thought to be partially effective for some patients infected with HIV. Nitazoxanide, currently available in the United States as an oral suspension, is FDA-approved for the treatment of cryptosporidiosis in children. In addition, improvement in immune status with antiretroviral therapy often leads to amelioration of cryptosporidiosis. Otherwise, treatment includes supportive care with replacement of fluids and electrolytes and administration of antidiarrheal agents. Biliary tract obstruction may require papillotomy or T-tube placement. Prevention requires minimizing exposure to infectious oocysts in human or animal feces. Use of submicron water filters may minimize acquisition of infection from drinking water.

ISOSPORIASIS The coccidian parasite *Isospora belli* causes human intestinal disease. Infection is acquired by the consumption of oocysts, after which the parasite invades intestinal epithelial cells and undergoes both sexual and asexual cycles of development. Oocysts excreted in stool are not immediately infectious but must undergo further maturation. Although *I. belli* infects many animals, little is known about the epidemiology or prevalence of this parasite in humans. It appears to be most common in tropical and subtropical countries. Acute infections can begin abruptly with fever, abdominal pain, and watery nonbloody diarrhea and can last for weeks or months. In patients who have AIDS or are immunocompromised for other reasons, infections often are not self-limited but rather resemble cryptosporidiosis, with chronic, profuse watery diarrhea. Eosinophilia, which is not found in other enteric protozoan infections, may be detectable. The diagnosis is usually made by detection of the large (~25-μm) oocysts in stool by modified acid-fast staining. Oocyst excretion may be low-level and intermittent; if repeated stool examinations are unrevealing, sampling of duodenal contents by aspiration or small-bowel biopsy (often with electron-microscopic examination) may be necessary.

Rx TREATMENT

In contrast to cryptosporidiosis, isosporiasis responds to chemotherapy. Trimethoprim-sulfamethoxazole (160/800 mg four times daily for 10 days and then three times daily for 3 weeks) has been effective; for patients intolerant of sulfonamides, pyrimethamine (50 to 75 mg/d) or ciprofloxacin (500 mg twice daily for 7 days) can be used. Relapses can occur in persons with AIDS and necessitate maintenance therapy with trimethoprim-sulfamethoxazole (160/800 mg three times a week) or combined sulfadoxine (500 mg) and pyrimethamine (25 mg) once weekly.

CYCLOSPORIASIS Coccidian parasites of the genus *Cyclospora* have been identified as the causative organisms in diarrheal illness formerly ascribed to blue-green algae or *Cyanobacteria*-like forms. This parasite is globally distributed: illness due to *Cyclospora cayetanensis* has been reported in the United States, Asia, Africa, Latin America, and Europe. The epidemiology of this parasite has not yet been fully defined, but waterborne transmission and food-borne transmission by basil and imported raspberries have been recognized. The full spectrum of illness attributable to *Cyclospora* has not been delineated. Some patients may harbor the infection without symptoms, but many with cyclosporiasis have diarrhea, flulike symptoms, and flatulence and burping. The illness can be self-limited, can wax and wane, or (in many cases) can involve prolonged diarrhea, anorexia, and upper gastrointestinal symptoms, with sustained fatigue and weight loss in some instances. Diarrheal illness may persist for longer than a month. *Cyclospora* can cause enteric illness in patients infected with HIV, albeit at an unknown frequency.

The parasite is detectable in epithelial cells of small-bowel biopsy samples and elicits secretory diarrhea by an unknown means. The absence of fecal blood and leukocytes indicates that disease due to *Cyclospora* is not caused by destruction of the small-bowel mucosa. The diagnosis can be made by detection of spherical 8- to 10-μm oocysts in the stool, although routine stool O and P examinations are not sufficient. Specific fecal examinations must be requested to detect the oocysts, which are variably acid-fast and are fluorescent when viewed with ultraviolet light microscopy. Cyclosporiasis should be considered in the differential diagnosis of prolonged diarrhea, with or without a history of travel by the patient to other countries.

Rx TREATMENT

Cyclosporiasis is effectively treated with trimethoprim-sulfamethoxazole (160/800 mg twice daily for 7 days). For patients intolerant of sulfonamides, ciprofloxacin (500 mg twice daily for 7 days) may be used. Patients infected with HIV, however, may experience relapses after such treatment and thus may require longer-term suppressive maintenance therapy.

MICROSPORIDIOSIS Microsporidia are obligate intracellular spore-forming protozoa that infect many animals and cause disease in humans, especially as opportunistic pathogens in AIDS. Microsporidia are members of a distinct phylum, Microspora, which contains dozens of genera and hundreds of species. The various microsporidia are differentiated by their developmental life cycles, by ultrastructural features, and by molecular taxonomy based on ribosomal RNA. The complex life cycles of the organisms result in the production of infectious spores. Currently, seven genera of microsporidia—*Encephalitozoon*, *Pleistophora*, *Nosema*, *Vittaforma*, *Trachipleistophora*, *Brachiola*, and *Enterocytozoon*—are recognized as causes of human disease; an eighth genus—*Microsporidium*, which includes organisms of uncertain taxonomic status—also causes disease in humans. Although some microsporidia are probably prevalent causes of self-limited or asymptomatic infections in immunocompetent patients, little is known of how microsporidiosis is acquired.

Microsporidiosis is most common among patients with AIDS, less common among patients with other types of immunocompromise, and rare among immunocompetent hosts. In patients with AIDS, intestinal infections with *Enterocytozoon bieneusi* and *Encephalitozoon* (formerly *Septata*) *intestinalis* are increasingly recognized to contribute to chronic diarrhea and wasting; these infections are found in 10 to 40% of patients with chronic diarrhea. Both organisms have been found in the biliary tracts of patients with cholecystitis. *E. intestinalis* may also disseminate to cause fever, diarrhea, sinusitis, cholangitis, and bronchiolitis. In patients with AIDS, *Encephalitozoon hellem* has caused superficial keratoconjunctivitis as well as sinusitis, respiratory tract disease, and disseminated infection. Myositis due to *Pleistophora* has been documented. *Nosema*, *Vittaforma*, and *Microsporidium* have caused stromal keratitis associated with trauma in immunocompetent patients.

Microsporidia are small gram-positive organisms with mature spores measuring 0.5 to 2 μm $\times$ 1 to 4 μm. Diagnosis of microsporidial infections in tissue often requires electron microscopy, although intracellular spores can be visualized by light microscopy with hematoxylin and eosin, Giemsa, or tissue Gram's stains. For the diagnosis of intestinal microsporidiosis, modified trichrome or chromotrope 2R-based staining and Uvitex 2B or calcofluor fluorescent staining reveal spores in smears of feces or duodenal aspirates. Definitive therapies for microsporidial infections remain to be established. For superficial keratoconjunctivitis due to *E. hellem*, topical therapy with fumagillin suspension has shown promise (Chap. 193). For enteric infections with *E. bieneusi* and *E. intestinalis* in HIV-infected patients, therapy with albendazole may be efficacious (Chap. 193).

OTHER INTESTINAL PROTOZOA ■ Balantidiasis *Balantidium coli* is a large ciliated protozoal parasite that can produce a spectrum of large-intestinal disease analogous to amebiasis. The parasite is widely distributed in the world. Since it infects pigs, cases in humans are more common where pigs are raised; in Muslim countries, rodents may be important carriers. Infective cysts can be transmitted from person to person and through water, but many cases are due to the ingestion of cysts derived from porcine feces in association with slaughtering, with use of pig feces for fertilizer, or with contamination of water supplies by pig feces.

Ingested cysts liberate trophozoites, which reside and replicate in the large bowel. Many patients remain asymptomatic, but some have persisting intermittent diarrhea, and a few develop more fulminant dysentery. In symptomatic individuals, the pathology in the bowel—both gross and microscopic—is similar to that seen in amebiasis, with varying degrees of mucosal invasion, focal necrosis, and ulceration. Balantidiasis, unlike amebiasis, does not spread hematogenously to other organs. The diagnosis is usually made by detection of the trophozoite stage in stool or sampled colonic tissue. Tetracycline (500 mg four times daily for 10 days) is an effective therapeutic agent.

***Blastocystis hominis* Infection** *B. hominis*, long considered a nonpathogenic yeast, is believed by some to be a protozoan capable of causing

intestinal disease, although its taxonomy and inherent pathogenicity remain uncertain. Some patients who pass *B. hominis* in their stools are asymptomatic, whereas others have diarrhea and associated intestinal symptoms. Diligent evaluation reveals other potential bacterial, viral, or protozoal causes of diarrhea in some but not all patients with symptoms. Because the pathogenicity of *B. hominis* is uncertain and because therapy for *Blastocystis* infection is neither specific nor uniformly effective, patients with prominent intestinal symptoms should be fully evaluated for other infectious causes of diarrhea. If diarrheal symptoms associated with *Blastocystis* are prominent, either metronidazole (750 mg thrice daily for 10 days) or iodoquinol (650 mg thrice daily for 20 days) can be used.

***Dientamoeba fragilis* Infection** *D. fragilis* is unique among intestinal protozoa in that it has a trophozoite stage but not a cyst stage. How trophozoites survive to transmit infection is not known, but the unusually high prevalence of *D. fragilis* infection among persons with pinworm infection raises the possibility that eggs or larvae of *Enterobius* facilitate the transmission of *D. fragilis*. When symptoms develop in patients with *D. fragilis* infection, they are generally mild and include intermittent diarrhea, abdominal pain, and anorexia. The diagnosis is made by the detection of trophozoites in stool; the lability of these forms accounts for the greater yield when fecal samples are preserved immediately after collection. Since fecal excretion rates vary, examination of several samples obtained on alternate days increases the rate of detection. Iodoquinol (650 mg three times daily for 20 days), paromomycin (25 to 30 mg/kg per day in three doses for 7 days), metronidazole (500 to 750 mg three times daily for 10 days), or tetracycline (500 mg four times daily for 10 days) is appropriate for treatment.

Sarcosporidiosis Various *Sarcocystis* species of coccidian parasites are widely distributed agents of infection in numerous animals. These parasites have an obligatory cycle of development involving two hosts. Sexual reproduction occurs in the intestine, with sporocysts passed in the feces; asexual multiplication leads to the development of muscle cysts. Humans can develop intestinal infections—although they apparently do so infrequently—by ingesting muscle-stage cysts in undercooked pork or beef. While the full spectrum of the intestinal disease is not defined, a diarrheal illness can ensue, and sporocysts are found in the stool. Alternatively, ingestion of fecally derived sporocysts can lead to the development of cysts in striated or cardiac muscle. Some patients experience muscle pain and swelling, but the frequency and nature of symptoms elicited by muscle involvement are not clear, and these cysts, measuring 100 to 325 μm, also have been found incidentally in muscle specimens. Muscle-stage infections are not followed by further spread in humans. No specific therapy exists for either intestinal or muscle-stage *Sarcocystis* infections in humans.

TRICHOMONIASIS

Various species of trichomonads can be found in the mouth (in association with periodontitis) and occasionally in the gastrointestinal tract. *Trichomonas vaginalis*—one of the most prevalent protozoal parasites in the United States—is a pathogen of the genitourinary tract and a major cause of symptomatic vaginitis.

Life Cycle and Epidemiology *T. vaginalis* is a pear-shaped, actively motile organism that measures about 10 by 7 μm, replicates by binary fission, and inhabits the lower genital tract of females and the urethra and prostate of males. In the United States, it accounts for ~3 million infections per year in women. While the organism can survive for a few hours in moist environments and could be acquired by direct contact, person-to-person venereal transmission accounts for virtually all cases of trichomoniasis. Its prevalence is greatest among persons with multiple sexual partners and among those with other sexually transmitted diseases (Chap. 115).

Clinical Manifestations Most men infected with *T. vaginalis* are asymptomatic, although some develop urethritis and a few have epididymitis or prostatitis. In contrast, infection in women, which has an incubation period of 5 to 28 days, is usually symptomatic and manifests with malodorous vaginal discharge (often yellow), vulvar erythema and itching, dysuria or urinary frequency (in 30 to 50% of patients), and dyspareunia. These manifestations, however, do not clearly distinguish trichomoniasis from other types of infectious vaginitis.

Diagnosis Detection of motile trichomonads by microscopy of wet mounts of vaginal or prostatic secretions has been the conventional means of diagnosis. Although such microscopy provides an immediate diagnosis, its sensitivity for the detection of *T. vaginalis* is only ~50 to 60% in routine evaluations of vaginal secretions. Direct immunofluorescent antibody staining is more sensitive (70 to 90%) than wet-mount examinations. *T. vaginalis* can be recovered from the urethra of both males and females and is detectable in males after prostatic massage. Culture of the parasite is the most sensitive means of detection; however, the facilities for culture are not generally available, and detection of the organism takes 3 to 7 days.

℞ TREATMENT

Metronidazole is the mainstay of treatment and may be given either as a single 2-g dose or as 500 mg twice daily for 7 days. Tinidazole (a single 2-g dose or 500 mg twice daily) is also effective but is not available in the United States. All sexual partners must be treated concurrently to prevent reinfection, especially from asymptomatic males. In males with persistent symptomatic urethritis after therapy for nongonococcal urethritis, metronidazole therapy should be considered for possible trichomoniasis. Alternatives to metronidazole for treatment during pregnancy are not readily available, although use of 100-mg clotrimazole vaginal suppositories nightly for 2 weeks may cure some infections in pregnant women. Reinfection often accounts for apparent treatment failures, but strains of *T. vaginalis* exhibiting high-level resistance to metronidazole have been encountered. Treatment of these resistant infections with higher oral doses, parenteral doses, or concurrent oral and vaginal doses of metronidazole has been successful.

200 *TRICHINELLA* AND OTHER TISSUE NEMATODES

Peter F. Weller

Nematodes are elongated, symmetric roundworms. Parasitic nematodes of medical significance may be broadly classified as either predominantly intestinal or tissue nematodes. This chapter covers trichinellosis, visceral and ocular larva migrans, cutaneous larva migrans, cerebral angiostrongyliasis, and gnathostomiasis. All are zoonotic infections caused by incidental exposure to infectious nematodes. The clinical symptoms of these infections are due largely to invasive larval stages that (except in the case of *Trichinella*) do not reach maturity in humans.

TRICHINELLOSIS Trichinellosis develops after the ingestion of meat containing cysts of *Trichinella*—for example, pork or other meat from a carnivore. Although most infections are mild and asymptomatic, heavy infections can cause severe enteritis, periorbital edema, myositis, and (infrequently) death.

Life Cycle and Epidemiology Seven species of *Trichinella* are now recognized as causes of infection in humans. Two species are distributed worldwide: *T. spiralis*, which is found in a great variety of carnivorous and omnivorous animals, and *T. pseudospiralis*, which is found in mammals and birds. *T. nativa* is present in Arctic regions and infects bears; *T. nelsoni* is found in equatorial Africa, where it is common among felid predators and scavengers such as hyenas and bush pigs; and *T. britovi* is found in temperate areas of Europe and western Asia among carnivores but not among domestic swine. *T. murrelli* is present in North American game animals, and *T. papuae* is found in pigs and game animals in Papua New Guinea.

After the consumption of trichinous meat by the host, encysted larvae are liberated by digestive acid and pepsin (Fig. 200-1). The larvae invade the small-bowel mucosa and mature rapidly into adult worms. After ~1 week, female worms release newborn larvae that migrate via the circulation to striated muscle. The larvae of all species except *T. pseudospiralis* and *T. papuae* then encyst by inducing a radical transformation in the muscle cell architecture. Although host immune responses may help to expel adult worms, they have little effect on muscle-dwelling larvae.

Human trichinellosis is most often caused by the ingestion of infected pork products and thus can occur in almost any location where the meat of domestic or wild swine is eaten. Human trichinellosis also may be acquired from the meat of other animals, including dogs (in parts of Asia and Africa), horses (in Italy and France), and bears and walruses (in northern regions). Although cattle (being herbivores) are not natural hosts of *Trichinella*, beef has been implicated in outbreaks when contaminated or adulterated with trichinous pork. Laws that prohibit the feeding of uncooked garbage to pigs have greatly reduced the transmission of trichinellosis in the United States. About 40 cases of trichinellosis are reported annually in this country, but most mild cases probably remain undiagnosed. Recent U.S. outbreaks have been attributable to undercooked ethnic pork dishes, homemade and commercial sausage, wild boar meat, and walrus meat.

Pathogenesis and Clinical Features Clinical symptoms of trichinellosis arise from the successive phases of parasite enteric invasion, larval migration, and muscle encystment (Fig. 200-1). Most light infections (those with <10 larvae per gram of muscle) are asymptomatic, whereas heavy infections (which can involve >50 larvae per gram of muscle) can be life-threatening. Invasion of the gut by large numbers of parasites occasionally provokes diarrhea during the first week after infection. Abdominal pain, constipation, nausea, or vomiting also may be prominent.

Symptoms due to larval migration and muscle invasion begin to appear in the second week after infection. The migrating *Trichinella* larvae provoke a marked local and systemic hypersensitivity reaction, with fever and hypereosinophilia. Periorbital and facial edema is common, as are hemorrhages in the subconjunctivae, retina, and nail beds ("splinter" hemorrhages). A maculopapular rash, headache, cough, dyspnea, or dysphagia sometimes develops. Myocarditis with tachyarrhythmias or heart failure—and, less commonly, encephalitis or pneumonitis—may develop and accounts for most deaths of patients with trichinellosis.

Upon onset of larval encystment in muscle 2 to 3 weeks after in-

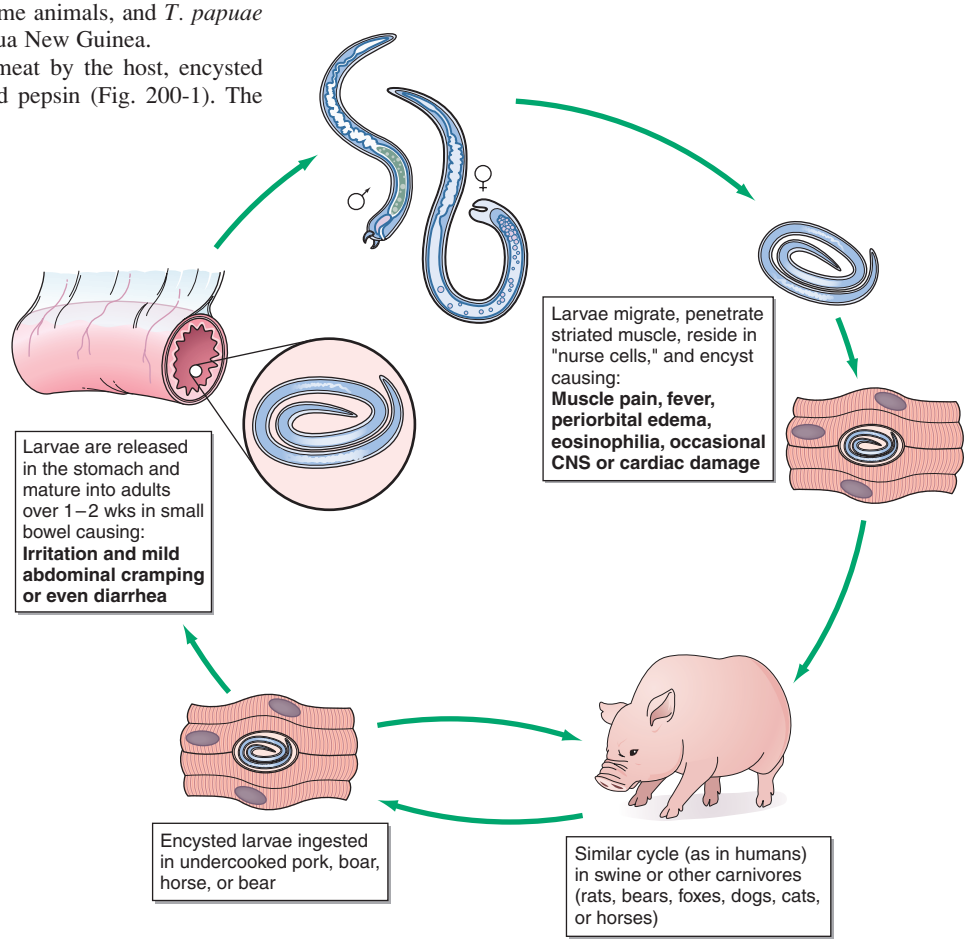

FIGURE 200-1 Life cycle of *Trichinella spiralis* (cosmopolitan); *nelsoni* (Africa); *britovi* (S. Europe); *nativa* (Arctic); and *pseudospiralis* (New Zealand). *(Reprinted from Guerrant RL et al: Essentials of Tropical Infectious Diseases, p 434. © 2001, with permission from Elsevier Science.)*

fection, symptoms of myositis with myalgias, muscle edema, and weakness develop, usually overlapping with the inflammatory reactions to migrating larvae. The most commonly involved muscle groups include the extraocular muscles; the biceps; and the muscles of the jaw, neck, lower back, and diaphragm. Peaking ~3 weeks after infection, symptoms subside only gradually during a prolonged convalescence.

Laboratory Findings and Diagnosis Blood eosinophilia develops in >90% of patients with symptomatic trichinellosis and may peak at a level of >50% between 2 and 4 weeks after infection. Serum levels of IgE and muscle enzymes, including creatine phosphokinase, are elevated in most symptomatic patients. Patients should be questioned thoroughly about their consumption of pork or wild-animal meat and about illness in other individuals who ate the same meat. A presumptive clinical diagnosis can be based on fevers, eosinophilia, periorbital edema, and myalgias after a suspect meal. A rise in the titer of parasite-specific antibody, which usually does not occur until after the third week of infection, confirms the diagnosis. Alternatively, a definitive diagnosis requires surgical biopsy of at least 1 g of involved muscle; the yields are highest near tendon insertions. The fresh muscle tissue should be compressed between glass slides and examined microscopically, because larvae may be overlooked by examination of routine histopathologic sections alone.

℞ TREATMENT

Current anthelmintic drugs are ineffective against *Trichinella* larvae in muscle. Fortunately, most lightly infected patients recover uneventfully with bed rest, antipyretics, and analgesics. Glucocorticoids like prednisone (1 mg/kg daily for 5 days) are beneficial for severe myositis and myocarditis. Mebendazole and albendazole, like thiabendazole, appear to be active against enteric stages of the parasite, but their efficacy against encysted larvae has not been conclusively demonstrated.

Prevention Larvae may be killed by cooking pork until it is no longer pink or by freezing it at −15°C for 3 weeks. However, Arctic *T. nativa* larvae in walrus or bear meat are relatively resistant and may remain viable despite freezing.

VISCERAL AND OCULAR LARVA MIGRANS Visceral larva migrans is a syndrome caused by nematodes that are normally parasitic for nonhuman host species. In humans, the nematode larvae do not typically develop into adult worms but instead migrate through host tissues and elicit eosinophilic inflammation. The most common form of visceral larva migrans is toxocariasis due to larvae of the canine ascarid *Toxocara canis* or, less commonly, the feline ascarid *T. cati*. Rare cases with eosinophilic meningoencephalitis have been caused by the raccoon ascarid *Baylisascaris procyonis*.

Life Cycle and Epidemiology The canine roundworm *T. canis* is distributed among dogs worldwide. Ingestion of infective eggs by dogs is followed by liberation of *Toxocara* larvae, which penetrate the gut wall and migrate intravascularly into canine tissues, where most remain in a developmentally arrested state. During pregnancy, some larvae resume migration in bitches and infect puppies prenatally (through transplacental transmission) or after birth (through suckling). Thus, in lactating bitches and puppies, larvae return to the intestinal tract and develop into adult worms, which produce eggs that are released in the feces. Humans acquire toxocariasis mainly by eating soil contaminated by puppy feces that contains infective *T. canis* eggs. Visceral larva migrans is most common among children who habitually eat dirt, but most toxocaral infections are subclinical.

Pathogenesis and Clinical Features Clinical disease most commonly afflicts preschool children. After humans ingest *Toxocara* eggs, the larvae hatch and penetrate the intestinal mucosa, from which they are carried by the circulation to a wide variety of organs and tissues. The larvae invade the liver, lungs, central nervous system, and other sites, releasing toxic products and provoking intense local eosinophilic granulomatous responses. The degree of clinical illness depends on larval number and tissue distribution, reinfection, and host immune responses. Most light infections are asymptomatic and may be manifest only by blood eosinophilia. Characteristic symptoms of visceral larva migrans include fever, malaise, anorexia and weight loss, cough, wheezing, and rashes. Hepatosplenomegaly is common. These features are often accompanied by extraordinary peripheral eosinophilia, which may approach 90%. Uncommonly, seizures or behavioral disorders develop. Rare deaths are due to severe neurologic, pneumonic, or myocardial involvement.

The ocular form of the larva migrans syndrome occurs when *Toxocara* larvae invade the eye. An eosinophilic granulomatous mass, most commonly in the posterior pole of the retina, develops around the entrapped larva. The retinal lesion can mimic retinoblastoma in appearance, and mistaken diagnosis of the latter condition can lead to unnecessary enucleation. The spectrum of eye involvement also includes endophthalmitis, uveitis, and chorioretinitis. Unilateral visual disturbances, strabismus, and eye pain are the most common presenting symptoms. In contrast to visceral larva migrans, ocular toxocariasis usually develops in older children or young adults with no history of pica; these patients seldom have eosinophilia or visceral manifestations.

Diagnosis In addition to eosinophilia, leukocytosis and hypergammaglobulinemia may be evident. Transient pulmonary infiltrates are apparent on chest x-rays of about half of patients with symptoms of pneumonitis. The clinical diagnosis can be confirmed by an enzyme-linked immunosorbent assay for toxocaral antibodies. Stool examination for parasite eggs, while important in the evaluation of unexplained eosinophilia, is worthless for toxocariasis, since the larvae do not develop into egg-producing adults in humans.

℞ TREATMENT

The vast majority of *Toxocara* infections are self-limited and resolve without specific therapy. In patients with severe myocardial, central nervous system, or pulmonary involvement, glucocorticoids may be employed to reduce inflammatory complications. Available anthelmintic drugs, including mebendazole, and albendazole, have not been shown conclusively to alter the course of larva migrans. Control measures include prohibiting dog excreta in public parks and playgrounds, deworming dogs, and preventing pica in children. Treatment of ocular disease is not fully defined, but the administration of albendazole (800 mg twice daily for adults; 400 mg twice daily for children) for 5 to 20 days in conjunction with glucocorticoids has been effective.

CUTANEOUS LARVA MIGRANS Cutaneous larva migrans ("creeping eruption") is a serpiginous skin eruption caused by burrowing larvae of animal hookworms, usually the dog and cat hookworm *Ancylostoma braziliense*. The larvae hatch from eggs passed in dog and cat feces and mature in the soil. Humans become infected after skin contact with soil in areas frequented by dogs and cats, such as areas underneath house porches or scrub vegetation. Cutaneous larva migrans is especially prevalent among children and in regions with warm humid climates, including the southeastern United States.

After larvae penetrate the skin, erythematous lesions form along the tortuous tracks of their migration through the dermal-epidermal junction; the larvae advance several centimeters in a day. The intensely pruritic lesions may occur anywhere on the body and can be numerous if the patient has lain on the ground. Vesicles and bullae may form later. The animal hookworm larvae do not mature in humans and, without treatment, will die out after several weeks, with resolution of skin lesions. The diagnosis is made readily on clinical grounds, and a skin biopsy only rarely yields diagnostic parasite material. Symptoms can be alleviated by ivermectin (a single dose of 200 μg/kg) or albendazole (200 mg twice daily for 3 days).

ANGIOSTRONGYLUS CANTONENSIS INFECTION

A. cantonensis, the rat lungworm, is the most common cause of human eosinophilic meningitis (Fig. 200-2).

Life Cycle and Epidemiology This infection occurs principally in Southeast Asia and the Pacific Basin but has spread to other areas of the world. *A. cantonensis* larvae produced by adult worms in the rat lung migrate to the gastrointestinal tract and are expelled with the feces. They develop into infective larvae in land snails and slugs. Humans acquire the infection by ingesting raw infected mollusks; vegetables contaminated by mollusk slime; or crabs, freshwater shrimp, and certain marine fish that have themselves eaten infected mollusks. The larvae then migrate to the brain.

Pathogenesis and Clinical Features The parasites eventually die in the central nervous system, but not before initiating pathologic consequences that, in heavy infections, can result in permanent neurologic sequelae or death. Migrating larvae cause proteolytic damage and marked local eosinophilic inflammation and hemorrhage, with subsequent necrosis and granuloma formation around dying worms. Clinical symptoms develop between 2 and 35 days after the ingestion of larvae. Patients usually present with an insidious or abrupt excruciating frontal, occipital, or bitemporal headache. Neck stiffness, nausea and vomiting, and paresthesias are also common. Fever, cranial and extraocular nerve palsies, seizures, paralysis, and lethargy are uncommon.

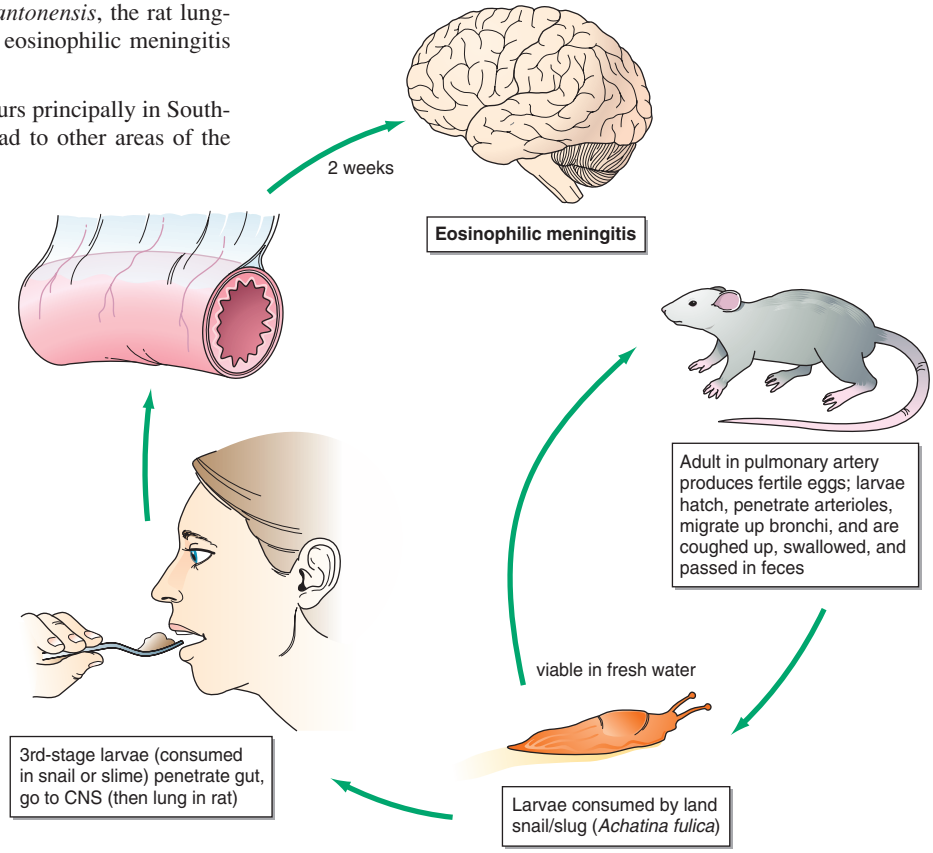

FIGURE 200-2 Life cycle of *Angiostrongylus cantonensis* (rat lung worm). Also found in Southeast Asia, Pacific Islands, and in U.S. ports, Cuba, Australia, Japan, China, and Mauritius. *(Reprinted from Guerrant RL et al: Essentials of Tropical Infectious Diseases, p 439. © 2001, with permission from Elsevier Science.)*

Laboratory Findings Examination of the cerebrospinal fluid is mandatory in suspected cases and usually reveals an elevated opening pressure, a white blood cell count of 150 to 2000/μL, and an eosinophilic pleocytosis of >20%. The protein concentration is usually elevated and the glucose level normal. The motile larvae of *A. cantonensis* are only rarely seen in the cerebrospinal fluid. Peripheral-blood eosinophilia may be mild. The diagnosis is generally based on the clinical presentation of eosinophilic meningitis together with a compatible epidemiologic history.

TREATMENT

Specific chemotherapy is not of benefit in angiostrongyliasis; larvicidal agents may actually exacerbate inflammatory brain lesions. Management consists of supportive measures, including the administration of analgesics, sedatives, and—in severe cases—glucocorticoids. In most patients, cerebral angiostrongyliasis has a self-limited course, and recovery is complete. The infection may be prevented by adequately cooking snails, crabs, and prawns and inspecting vegetables for mollusk infestation. Other parasitic or fungal causes of eosinophilic meningitis in endemic areas may include gnathostomiasis, paragonimiasis, schistosomiasis, neurocysticercosis, and coccidioidomycosis.

GNATHOSTOMIASIS

Infection of human tissues with larvae of *Gnathostoma spinigerum* can cause eosinophilic meningoencephalitis, migratory cutaneous swellings, or invasive masses of the eye and visceral organs.

Life Cycle and Epidemiology Human gnathostomiasis occurs in many countries and is notably endemic in Southeast Asia and parts of China and Japan. In nature, the mature adult worms parasitize the gastrointestinal tract of dogs and cats. First-stage larvae hatch from eggs passed into water and are ingested by *Cyclops* species (water fleas). Infective third-stage larvae develop in the flesh of many animal species (including fish, frogs, eels, snakes, chickens, and ducks) that have eaten either infected *Cyclops* or another infected second intermediate host. Humans typically acquire the infection by eating raw or undercooked fish or poultry. Raw fish dishes, such as *somfak* in Thailand and *sashimi* in Japan, account for many cases of human gnathostomiasis. Some cases in Thailand result from the local practice of applying frog or snake flesh as a poultice.

Pathogenesis and Clinical Features Clinical symptoms are due to the aberrant migration of a single larva into cutaneous, visceral, neural, or ocular tissues. After invasion, larval migration may cause local inflammation, with pain, cough, or hematuria accompanied by fever and eosinophilia. Painful, itchy, migratory swellings may develop in the skin, particularly in the distal extremities or periorbital area. Cutaneous swellings usually last about a week but often recur intermittently over many years. Larval invasion of the eye can provoke a sight-threatening inflammatory response. Finally, invasion of the central nervous system results in eosinophilic meningitis with myeloencephalitis, a serious complication due to ascending larval migration along a large nerve track. Patients characteristically present with agonizing radicular pain and paresthesias in the trunk or a limb, which are followed shortly by paraplegia. Cerebral involvement, with focal hemorrhages and tissue destruction, is often fatal.

Diagnosis and Treatment Cutaneous migratory swellings with marked peripheral eosinophilia, supported by an appropriate geographic and dietary history, generally constitute an adequate basis for a clinical diagnosis of gnathostomiasis. However, patients may present with ocular or cerebrospinal involvement without antecedent cutaneous swellings. In the latter case, eosinophilic pleocytosis is demonstrable (usually along with hemorrhagic or xanthochromic cerebrospinal fluid), but worms are almost never recovered from the cerebrospinal fluid. Surgical removal of the parasite from subcutaneous or ocular tissue, though rarely feasible, is both diagnostic and therapeutic. Albendazole (400 mg twice daily for 21 days) or ivermectin (200 μg/kg daily for

2 days) may be helpful. At present, cerebrospinal involvement is managed with supportive measures and generally with a course of glucocorticoids. Gnathostomiasis can be prevented by adequate cooking of fish and poultry in endemic areas.

ACKNOWLEDGMENT

The contributions of Leo X. Liu, M.D., to earlier editions of this chapter are gratefully acknowledged.

201 INTESTINAL NEMATODES

Peter F. Weller, Thomas B. Nutman

More than a billion people worldwide are infected with one or more species of intestinal nematodes. Table 201-1 summarizes biologic and clinical features of infections due to the major intestinal parasitic nematodes. These parasites are most common in regions with poor fecal sanitation, particularly in developing countries in the tropics and subtropics but also in the United States. Although nematode infections are not usually fatal, they contribute to malnutrition and diminished work capacity. An interesting point is that these same infections may protect some individuals from allergic disease. Humans may on occasion be infected with nematode parasites that ordinarily infect animals; these zoonotic infections include trichostrongyliasis, anisakiasis, capillariasis, and abdominal angiostrongyliasis.

Intestinal nematodes are roundworms; they range in length from 1 mm to many centimeters when mature (Table 201-1). Their life cycles are complex and highly varied; some species, including *Strongyloides stercoralis* and *Enterobius vermicularis*, can be transmitted directly from person to person, while others, such as *Ascaris lumbricoides*, *Necator americanus*, and *Ancylostoma duodenale*, require a soil phase for development. Because most helminth parasites do not self-replicate, the acquisition of a heavy burden of adult worms requires repeated exposure to the parasite in its infectious stage, whether larva or egg. Hence, clinical disease, as opposed to asymptomatic infection, generally develops only with prolonged residence in an endemic area. In persons with marginal nutrition, intestinal helminth infections may impair growth and development. Eosinophilia and elevated serum IgE levels are features of many helminthic infections and, when unexplained, should always prompt a search for occult helminthiasis. Significant protective immunity to intestinal nematodes appears not to develop in humans, although mechanisms of parasite immune evasion and host immune responses to these infections have not been elucidated in detail.

[a] Time from infection to egg production by mature female worm.

ASCARIASIS *A. lumbricoides* is the largest intestinal nematode parasite of humans, reaching up to 40 cm in length. Most infected individuals have low worm burdens and are asymptomatic. Clinical disease arises from larval migration in the lungs or effects of the adult worms in the intestines.

Life Cycle Adult worms live in the lumen of the small intestine. Mature female *Ascaris* worms are extraordinarily fecund, each producing up to 240,000 eggs a day, which pass with the feces. Ascarid eggs, which are remarkably resistant to environmental stresses, become infective after several weeks of maturation in the soil and can remain infective for years. After infective eggs are swallowed, larvae hatched in the intestine invade the mucosa, migrate through the circulation to the lungs, break into the alveoli, ascend the bronchial tree, and return via swallowing to the small intestine, where they develop into adult worms. Between 2 and 3 months elapse between initial infection and egg production. The adult worms live for 1 to 2 years.

Epidemiology *Ascaris* is widely distributed in tropical and subtropical regions as well as in other humid areas, including the rural southeastern United States. Transmission typically occurs through fecally contaminated soil and is due either to a lack of sanitary facilities or to the use of human manure ("night soil") as fertilizer. With their propensity for hand-to-mouth fecal carriage, younger children in impoverished rural areas are most affected. Infection outside endemic areas, though uncommon, can occur from eggs borne on transported vegetables.

Clinical Features During the lung phase of larval migration, about 9 to 12 days after egg ingestion, patients may develop an irritating nonproductive cough and burning substernal discomfort that is aggravated by coughing or deep inspiration. Dyspnea and blood-tinged sputum are less common. Fever is usually reported, with temperatures sometimes exceeding 38.5°C (101.3°F). Eosinophilia develops during this symptomatic phase and subsides slowly over weeks. Chest x-rays may reveal evidence of eosinophilic pneumonitis (Löffler's syndrome), with round or oval infiltrates a few millimeters to several centimeters in size. These infiltrates may be transient and intermittent, clearing after several weeks. Where there is seasonal transmission of the parasite, seasonal pneumonitis with eosinophilia may develop in previously infected and sensitized hosts.

In established infections, adult worms in the small intestine usually cause no symptoms. In heavy infections, particularly in children, a large bolus of entangled worms can cause pain and small-bowel obstruction, sometimes complicated by perforation, intussusception, or volvulus. Single worms may cause disease when they migrate into aberrant sites. A large worm can enter and occlude the biliary tree, causing biliary colic, cholecystitis, cholangitis, pancreatitis, or (rarely) intrahepatic abscesses. Migration of an adult worm up the esophagus can provoke coughing and oral expulsion of the worm. In highly endemic areas, intestinal and biliary ascariasis can rival acute appendicitis and gallstones as causes of surgical acute abdomen.

Laboratory Findings Most cases of ascariasis can be diagnosed by the microscopic detection of characteristic mamillated *Ascaris* eggs (65 by 45 μm) in fecal samples. Occasionally, patients present after passing an adult worm—identifiable by its large size and smooth cream-colored surface—in the stool or through the mouth or nose. During the early transpulmonary migratory phase, when eosinophilic pneumonitis occurs, larvae can be found in sputum or gastric aspirates before diagnostic eggs appear in the stool. The eosinophilia that is prominent during this early stage usually decreases to minimal levels in established infection. The large adult worms may be visualized, occasionally serendipitously, on contrast studies of the gastrointestinal tract. A plain abdominal film may reveal masses of worms in gas-filled loops of bowel in patients with intestinal obstruction. Pancreaticobiliary worms can be detected by ultrasound and endoscopic retrograde cholangiopancreatography; the latter method also has been used to extract biliary *Ascaris* worms.

TREATMENT

Ascariasis should always be treated to prevent potentially serious complications. Albendazole (400 mg once), which is considered an investigational drug by the Food and Drug Administration for this indication, or mebendazole (500 mg once) is effective. These benzimidazoles are contraindicated in pregnancy, however. Pyrantel pamoate (11 mg/kg once; maximum, 1 g) is safe in pregnancy. Mild diarrhea and abdominal pain are uncommon side effects of these agents. Partial intestinal obstruction should be managed with nasogastric suction, intravenous fluid administration, and instillation of piperazine through the nasogastric tube, but complete obstruction and its severe complications require immediate surgical intervention.

HOOKWORM One-fourth of the world's population is infected with one of the two hookworm species (*A. duodenale* and *N. americanus*). Most infected individuals are asymptomatic. Hookworm disease develops from a combination of factors—a heavy worm burden, a prolonged duration of infection, and an inadequate iron intake—and results in iron-deficiency anemia and, on occasion, hypoproteinemia.

Life Cycle Adult hookworms, which are ~1 cm long, use buccal teeth (*Ancylostoma*) or cutting plates (*Necator*) to attach to the small-bowel mucosa and suck blood (0.2 mL/d per *Ancylostoma* adult) and interstitial fluid. The adult hookworms produce thousands of eggs daily. The eggs are deposited with feces in soil, where rhabditiform larvae hatch and develop over a 1-week period into infectious filariform larvae. Infective larvae penetrate the skin and reach the lungs by way of the bloodstream. There they invade alveoli and ascend the airways before being swallowed and reaching the small intestine. The prepatent period from skin invasion to appearance of eggs in the feces is about 6 to 8 weeks, but it may be longer with *A. duodenale*. Larvae of *A. duodenale*, if swallowed, can survive and develop directly in the intestinal mucosa. Adult hookworms may survive over a decade but usually live about 6 to 8 years for *A. duodenale* and 2 to 5 years for *N. americanus*.

Epidemiology *A. duodenale* is prevalent in southern Europe, North Africa, and northern Asia, and *N. americanus* is the predominant species in the western hemisphere and equatorial Africa. The two species overlap in many tropical regions, particularly Southeast Asia. In most areas, older children have the greatest incidence and intensity of hookworm infection. In rural areas where fields are fertilized with night soil, older working adults also may be heavily affected.

Clinical Features Most hookworm infections are asymptomatic. Infective larvae may provoke pruritic maculopapular dermatitis ("ground itch") at the site of skin penetration as well as serpiginous tracks of subcutaneous migration (similar to cutaneous larva migrans) in previously sensitized hosts. Larvae migrating through the lungs occasionally cause mild transient pneumonitis, but this condition develops less frequently in hookworm infection than in ascariasis. In the early intestinal phase, infected persons may develop epigastric pain (often with postprandial accentuation), inflammatory diarrhea, or other abdominal symptoms accompanied by eosinophilia. The major consequence of chronic hookworm infection is iron deficiency. Symptoms are minimal if iron intake is adequate, but marginally nourished individuals develop symptoms of progressive iron-deficiency anemia and hypoproteinemia, including weakness, shortness of breath, and skin depigmentation.

Laboratory Findings The diagnosis is established by the finding of characteristic 40- by 60-μm oval hookworm eggs in the feces. Stool-concentration procedures may be required to detect light infections. Eggs of the two species are indistinguishable by light microscopy. In a stool sample that is not fresh, the eggs may have hatched to release rhabditiform larvae, which need to be differentiated from those of *S. ster-*

coralis. Hypochromic microcytic anemia, occasionally with eosinophilia or hypoalbuminemia, is characteristic of hookworm disease.

TREATMENT

Hookworm infection can be eradicated with several safe and highly effective anthelmintic drugs, including albendazole (400 mg once), mebendazole (500 mg once), and pyrantel pamoate (11 mg/kg for 3 days). Mild iron-deficiency anemia can often be treated with oral iron alone. Severe hookworm disease with protein loss and malabsorption necessitates nutritional support and oral iron replacement along with deworming.

Ancylostoma caninum* and *Ancylostoma braziliense *A. caninum*, the canine hookworm, has been identified as a cause of human eosinophilic enteritis, especially in northeastern Australia. In this zoonotic infection, adult hookworms attach to the small intestine (where they may be visualized by endoscopy) and elicit abdominal pain and intense local eosinophilia. Treatment with mebendazole (100 mg twice daily for 3 days) or albendazole (400 mg once) is effective. Both of these animal hookworm species can cause cutaneous larva migrans ("creeping eruption"; Chap. 200).

STRONGYLOIDIASIS *S. stercoralis* is distinguished by its ability—unusual among helminths—to replicate in the human host. This capacity permits ongoing cycles of autoinfection as infective larvae are internally produced. Strongyloidiasis can thus persist for decades without further exposure of the host to exogenous infective larvae. In immunocompromised hosts, large numbers of invasive *Strongyloides* larvae can disseminate widely and can be fatal.

Life Cycle In addition to a parasitic cycle of development, *Strongyloides* can undergo a free-living cycle of development in the soil. This adaptability facilitates the parasite's survival in the absence of mammalian hosts. Rhabditiform larvae passed in feces can transform into infectious filariform larvae either directly or after a free-living phase of development. Humans acquire strongyloidiasis when filariform larvae in fecally contaminated soil penetrate the skin or mucous membranes. The larvae then travel through the bloodstream to the lungs, where they break into the alveolar spaces, ascend the bronchial tree, are swallowed, and thereby reach the small intestine. There the larvae mature into adult worms that penetrate the mucosa of the proximal small bowel. The minute (2-mm-long) parasitic adult female worms reproduce by parthenogenesis; parasitic adult males do not exist. Eggs hatch locally in the intestinal mucosa, releasing rhabditiform larvae that migrate to the lumen and pass with the feces into soil. Alternatively, rhabditiform larvae in the bowel can develop directly into filariform larvae that penetrate the colonic wall or perianal skin and enter the circulation to repeat the migration that establishes ongoing internal reinfection. This autoinfection cycle allows strongyloidiasis to persist for decades after the host has left an endemic area.

Epidemiology *S. stercoralis* is spottily distributed in tropical areas and other hot, humid regions and is particularly common in Southeast Asia, sub-Saharan Africa, and Brazil. In the United States, the parasite is endemic in parts of the South and is found in institutionalized patients who practice poor hygiene and in immigrants and military veterans who have lived in endemic areas abroad.

Clinical Features In uncomplicated strongyloidiasis, many patients are asymptomatic or have mild cutaneous and/or abdominal symptoms. Recurrent urticaria, often involving the buttocks and wrists, is the most common cutaneous manifestation. Migrating larvae can elicit a pathognomonic serpiginous eruption, *larva currens* ("running larva")—a pruritic, raised, erythematous lesion that advances as rapidly as 10 cm/h along the course of larval migration. Adult parasites burrow into the duodenojejunal mucosa and can cause abdominal (usually midepigastric) pain, which resembles peptic ulcer pain except that it is aggravated by food ingestion. Nausea, diarrhea, gastrointestinal bleeding, mild chronic colitis, and weight loss can occur. Small-bowel obstruction may develop with early, heavy infection. Pulmonary symptoms are rare in uncomplicated strongyloidiasis. Eosinophilia is common, with levels fluctuating over time.

The ongoing autoinfection cycle of strongyloidiasis is normally contained by unknown factors of the host's immune system. Abrogation of host immunity, especially with glucocorticoid therapy and much less commonly with other immunosuppressive medications, leads to hyperinfection, with the generation of large numbers of filariform larvae. Colitis, enteritis, or malabsorption may develop. In disseminated strongyloidiasis, larvae may invade not only gastrointestinal tissues and the lungs but also the central nervous system, peritoneum, liver, and kidney. Moreover, bacteremia may develop because of the entry of enteric flora through disrupted mucosal barriers. Gram-negative sepsis, pneumonia, or meningitis may complicate or dominate the clinical course. Eosinophilia is often absent in severely infected patients. Disseminated strongyloidiasis, particularly in patients with unsuspected infection who are given glucocorticoids, can be fatal. Strongyloidiasis is a frequent complication of infection with human T cell lymphotropic virus type I, but disseminated strongyloidiasis is not common among patients infected with HIV.

Diagnosis In uncomplicated strongyloidiasis, the finding of rhabditiform larvae in feces is diagnostic. The eggs are almost never detectable because they hatch in the intestine. Rhabditiform larvae are 200 to 250 μm long, with a short buccal cavity that distinguishes them from hookworm rhabditiform larvae. Single stool examinations detect only about one-third of uncomplicated infections, in which few larvae are passed. Serial examinations and the use of the agar plate detection method improve the sensitivity of stool diagnosis. In uncomplicated—but not hyperinfection—strongyloidiasis, stool examinations may be repeatedly negative. If stool examinations are negative, *Strongyloides* can be assayed by sampling of the duodenojejunal contents by aspiration or biopsy. An enzyme-linked immunosorbent assay for antibodies to excretory-secretory or somatic antigens of *Strongyloides* is a sensitive method of diagnosing uncomplicated infections. In disseminated strongyloidiasis, filariform larvae (550 μm long) should be sought in stool as well as in samples obtained from sites of potential larval migration, including sputum, bronchoalveolar lavage fluid, or surgical drainage fluid.

TREATMENT

Even in the asymptomatic state, strongyloidiasis must be treated because of the potential for fatal hyperinfection. Ivermectin (200 μg/kg daily for 1 or 2 days) is more effective than albendazole (400 mg daily for 3 days, repeated at 2 weeks) and is better tolerated than thiabendazole (25 mg/kg twice daily for 2 days), whose common adverse effects include nausea, vomiting, diarrhea, dizziness, and neuropsychiatric disturbances. Because thiabendazole is not uniformly effective, stool examinations, eosinophil counts, and monitoring of clinical symptoms should be continued after treatment. For disseminated strongyloidiasis, treatment with ivermectin should be extended for at least 5 to 7 days or until the parasites are eradicated.

Strongyloides fülleborni This unusual species, which has been encountered in Africa and Papua New Guinea, is thought to be transmitted from person to person and through maternal milk. *S. fülleborni* releases membranous sacs filled with eggs into the stool. Most commonly affected are infants and young children, who present with abdominal distention, respiratory distress, vomiting, or diarrhea.

TRICHURIASIS Most infections with the whipworm *Trichuris trichiura* are asymptomatic, but heavy infections may cause gastrointestinal symptoms. Like the other soil-transmitted helminths, whipworm is distributed globally in the tropics and subtropics and is most common among poor children.

Life Cycle A broad posterior section and a thin anterior portion give *Trichuris* its characteristic whiplike shape. The adult worms reside in

the colon and cecum, the anterior portions threaded into the superficial mucosa. Thousands of eggs laid daily by adult female worms pass with the feces and mature in the soil. After ingestion, infective eggs hatch in the duodenum, releasing larvae that mature before migrating to the large bowel. The entire cycle takes about 3 months, and adult worms may live for several years.

Clinical Features Tissue reactions to whipworms are mild. Most infected individuals have no symptoms or eosinophilia. Heavy infections may result in abdominal pain, anorexia, and bloody or mucoid diarrhea resembling inflammatory bowel disease. Rectal prolapse can result from massive infections in children, who often suffer from malnourishment and other diarrheal illnesses. Moderately heavy whipworm burdens also contribute to growth retardation.

Diagnosis and Treatment The characteristic 50- by 20-μm lemon-shaped whipworm eggs are readily detected on stool examination. Adult worms, which are 3 to 5 cm long, occasionally can be seen on proctoscopy. Mebendazole (500 mg once) or albendazole (400 mg daily for 3 doses) is safe and effective for treatment.

ENTEROBIASIS (PINWORM) *E. vermicularis* is more common in temperate countries than in the tropics. In the United States, >40 million people are estimated to be infected with pinworms; schoolchildren account for a disproportionate number of cases.

Life Cycle and Epidemiology *Enterobius* adult worms are ~1 cm long and dwell in the bowel lumen. The gravid female worm migrates nocturnally out into the perianal region and releases up to 10,000 immature eggs. The eggs become infective within hours and are transmitted by hand-to-mouth passage. The larvae hatch and mature entirely within the intestine. This life cycle takes ~1 month, and adult worms survive for ~2 months. Self-infection results from perianal scratching and transport of infective eggs on the hands or under the nails to the mouth. Because of the ease of person-to-person spread, pinworm infections are common among family members and institutionalized populations.

Clinical Features Most pinworm infections are asymptomatic. Perianal pruritus is the cardinal symptom. The itching, which is often worse at night as a result of the nocturnal migration of the female worms, may lead to excoriation and bacterial superinfection. Heavy infections have been claimed to cause abdominal pain and weight loss. On rare occasions, pinworms invade the female genital tract, causing vulvovaginitis and pelvic or peritoneal granulomas. Eosinophilia or elevated levels of serum IgE are rare.

Diagnosis Since pinworm eggs are not usually released in the bowel, the diagnosis cannot be made by looking for eggs in the feces. Instead, eggs deposited in the perianal region are detected by the application of clear cellulose acetate tape to the perianal region in the morning. After the tape is transferred to a microscope slide, low-power examination will reveal the characteristic pinworm eggs, which are oval, measure 55 by 25 μm, and are flattened along one side.

℞ TREATMENT

All affected individuals should be given a dose of mebendazole (100 mg once), albendazole (400 mg once), or pyrantel pamoate (11 mg/kg base once; maximum, 1 g), with the same treatment repeated after 10 to 14 days. Treatment of household members is also advocated to eliminate asymptomatic reservoirs of potential reinfection.

TRICHOSTRONGYLIASIS *Trichostrongylus* species, which are normally parasites of herbivorous animals, occasionally infect humans, particularly in Asia and Africa. This parasite has been termed *pseudohookworm* because of similarities to the hookworms in life cycle and egg morphology. Humans acquire the infection by accidentally ingesting *Trichostrongylus* larvae on contaminated leafy vegetables. The larvae do not migrate in humans but mature directly into adult worms in the small bowel. These worms ingest far less blood than hookworms; most infected people are asymptomatic, but heavy infections may give rise to mild anemia and eosinophilia. *Trichostrongylus* eggs encountered on stool examination resemble those of hookworms but are larger (85 by 115 μm). Appropriate treatment consists of mebendazole or albendazole (Chap. 193).

ANISAKIASIS Anisakiasis is a gastrointestinal infection caused by the accidental ingestion in uncooked saltwater fish of nematode larvae belonging to the family Anisakidae. The incidence of anisakiasis in the United States has increased as a result of the growing popularity of raw fish dishes. Most cases occur in Japan, the Netherlands, and Chile, where raw fish—sushi, pickled green herring, and seviche, respectively—are national culinary staples. Anisakid nematodes parasitize large sea mammals such as whales, dolphins, and seals. As part of a complex parasitic life cycle involving marine food chains, infectious larvae migrate to the musculature of a variety of fish. Both *Anisakis simplex* and *Pseudoterranova decipiens* have been implicated in human anisakiasis, but an identical gastric syndrome may be caused by the red larvae of eustrongylid parasites of fish-eating birds.

When humans consume infected raw fish, live larvae may be coughed up within 48 h. Alternatively, larvae may immediately penetrate the mucosa of the stomach. Within hours, violent upper abdominal pain accompanied by nausea and occasionally vomiting ensues, mimicking an acute abdomen. The diagnosis can be established by direct visualization on upper endoscopy, outlining of the worm by contrast radiographic studies, or histopathologic examination of extracted tissue. In experienced hands, the first technique is preferable because extraction of the burrowing larvae by endoscopic technique is curative. In addition, larvae may pass to the small bowel, where they penetrate the mucosa and provoke a vigorous eosinophilic granulomatous response. Symptoms may appear 1 or 2 weeks after the infective meal, with intermittent abdominal pain, diarrhea, nausea, and fever resembling the manifestations of Crohn's disease. The diagnosis may be suggested by barium studies and confirmed by curative surgical resection of a granuloma in which the worm is embedded. Anisakid eggs are not found in the stool, since the larvae do not mature in humans. Anisakid larvae in saltwater fish are killed by cooking to 60°C, freezing at −20°C for 3 days, or commercial blast freezing, but not usually by salting, marinating, or cold smoking. No medical treatment is available; if possible, surgical or endoscopic removal should be undertaken.

CAPILLARIASIS Intestinal capillariasis is caused by ingestion of raw fish infected with *Capillaria philippinensis*. Subsequent autoinfection can lead to a severe wasting syndrome. The disease occurs in the Philippines and Thailand and, on occasion, elsewhere in Asia. The natural cycle of *C. philippinensis* involves fish from fresh and brackish water. When humans eat infected raw fish, the larvae mature in the intestine into adult worms, which produce invasive larvae that cause intestinal inflammation and villus loss. Capillariasis has an insidious onset with nonspecific abdominal pain and watery diarrhea. If untreated, progressive autoinfection can lead to protein-losing enteropathy and severe malabsorption and ultimately to death from cachexia, cardiac failure, or superinfection. The diagnosis is established by identification of the characteristic peanut-shaped (20- by 40-μm) eggs on stool examination. Severely ill patients require hospitalization and supportive therapy in addition to prolonged anthelmintic treatment with mebendazole or albendazole (Chap. 193).

ABDOMINAL ANGIOSTRONGYLIASIS Abdominal angiostrongyliasis is found in Latin America and Africa. The zoonotic parasite *Angiostrongylus costaricensis* causes eosinophilic ileocolitis after the ingestion of contaminated vegetation. *A. costaricensis* normally parasitizes the cotton rat and other rodents, with slugs and snails serving as intermediate hosts. Humans become infected by accidentally ingesting infective larvae in mollusk slime deposited on fruits and vegetables; children are at highest risk. The larvae penetrate the gut wall and migrate to the mesenteric artery, where they develop into adult worms. Eggs deposited in the gut wall provoke an intense eosinophilic

granulomatous reaction, and adult worms may cause mesenteric arteritis, thrombosis, or frank bowel infarction. Symptoms may mimic those of appendicitis, including abdominal pain and tenderness, fever, vomiting, and a palpable mass in the right iliac fossa. Leukocytosis and eosinophilia are prominent. A barium enema may reveal ileocecal filling defects, but a definitive diagnosis is usually made surgically with partial bowel resection. Pathologic study reveals a thickened bowel wall with eosinophilic granulomas surrounding the *Angiostrongylus* eggs. In nonsurgical cases, the diagnosis rests solely on clinical grounds because larvae and eggs cannot be detected in the stool. Medical therapy for abdominal angiostrongyliasis (thiabendazole; Chap. 193) is of uncertain efficacy. Careful observation and surgical resection for severe symptoms are the mainstays of treatment.

202 FILARIAL AND RELATED INFECTIONS

Thomas B. Nutman, Peter F. Weller

Filarial worms are nematodes that dwell in the subcutaneous tissues and the lymphatics. Eight filarial species infect humans (Table 202-1); of these, four—*Wuchereria bancrofti*, *Brugia malayi*, *Onchocerca volvulus*, and *Loa loa*—are responsible for most serious filarial infections. Filarial parasites, which infect an estimated 170 million persons worldwide, are transmitted by specific species of mosquitoes or other arthropods and have a complex life cycle including infective larval stages carried by insects and adult worms that reside in either lymphatic or subcutaneous tissues of humans. The offspring of adults are microfilariae, which, depending on their species, are 200 to 250 μm long and 5 to 7 μm wide, may or may not be enveloped in a loose sheath, and either circulate in the blood or migrate through the skin (Table 202-1). To complete the life cycle, microfilariae are ingested by the arthropod vector and develop over 1 to 2 weeks into new infective larvae. Adult worms live for many years, whereas microfilariae survive from 3 to 36 months. There has been a resurgence of interest in the rickettsia-like endosymbiont of *Wolbachia* that has been found intracellularly in all stages of *Brugia*, *Wuchereria*, *Mansonella*, and *Onchocerca*. These intracellular bacteria have recently been viewed as possible targets for antifilarial chemotherapy.

Usually, infection is established only with repeated and prolonged exposures to infective larvae. Since the clinical manifestations of filarial diseases develop relatively slowly, these infections should be considered chronic diseases with possible long-term debilitating effects. In terms of the nature, severity, and timing of clinical manifestations, patients with filarial infections who are native to endemic areas and undergo lifelong exposure may differ significantly from those who are travelers or who have recently moved to these areas. Characteristically, the disease is more acute and intense in newly exposed individuals than in natives of endemic areas.

LYMPHATIC FILARIASIS

Lymphatic filariasis is caused by *W. bancrofti*, *B. malayi*, or *B. timori*. The threadlike adult parasites reside in lymphatic channels or lymph nodes, where they may remain viable for more than two decades.

EPIDEMIOLOGY *W. bancrofti*, the most widely distributed human filarial parasite, affects an estimated 115 million people and is found throughout the tropics and subtropics, including Asia and the Pacific Islands, Africa, areas of South America, and the Caribbean basin. Humans are the only definitive host for the parasite. Generally, the subperiodic form is found only in the Pacific Islands; elsewhere, *W. bancrofti* is nocturnally periodic. (Nocturnally periodic forms of microfilariae are scarce in peripheral blood by day and increase at night, whereas sub-

periodic forms are present in peripheral blood at all times and reach maximal levels in the afternoon.) Natural vectors for *W. bancrofti* are *Culex fatigans* mosquitoes in urban settings and anopheline or aedean mosquitoes in rural areas.

Brugian filariasis due to *B. malayi* occurs primarily in China, India, Indonesia, Korea, Japan, Malaysia, and the Philippines. *B. malayi* also has two forms distinguished by the periodicity of microfilaremia. The more common nocturnal form is transmitted in areas of coastal rice fields, while the subperiodic form is found in forests. *B. malayi* naturally infects cats as well as humans. *B. timori* exists only on islands of the Indonesian archipelago.

PATHOLOGY The principal pathologic changes result from inflammatory damage to the lymphatics, which is caused by adult worms and not by microfilariae. Adult worms live in afferent lymphatics or sinuses of lymph nodes and cause lymphatic dilatation and thickening of the vessel walls. The infiltration of plasma cells, eosinophils, and macrophages in and around the infected vessels, along with endothelial and connective tissue proliferation, leads to tortuosity of the lymphatics and damaged or incompetent lymph valves. Lymphedema and chronic-stasis changes with hard or brawny edema develop in the overlying skin. These consequences of filariasis are due both to direct effects of the worms and to the inflammatory response of the host to the parasite. These inflammatory responses are believed to cause the granulomatous and proliferative processes that precede total lymphatic obstruction. It is thought that the lymphatic vessel remains patent as long as the worm remains viable and that death of the worm leads to enhanced granulomatous reaction and fibrosis. Lymphatic obstruction results, and, despite collateralization of the lymphatics, lymphatic function is compromised.

CLINICAL FEATURES The most common presentations of the lymphatic filariases are asymptomatic (or subclinical) microfilaremia, hydrocele (Fig. 202-1), acute adenolymphangitis (ADL), and chronic lymphatic disease. In areas where *W. bancrofti* or *B. malayi* is endemic, the overwhelming majority of infected individuals have few overt clinical manifestations of filarial infection despite large numbers of circulating microfilariae in the peripheral blood. Although they may be clinically asymptomatic, virtually all persons with *W. bancrofti* or *B. malayi* microfilaremia have some degree of subclinical disease that includes microscopic hematuria and/or proteinuria, dilated (and tortuous) lymphatics (visualized by imaging), and—in men—scrotal lymphangiectasia (detectable by ultrasound). In spite of these findings, the majority of individuals appear to remain clinically asymptomatic for years; relatively few progress to the acute and chronic stages of infection.

ADL is characterized by high fever, lymphatic inflammation (lymphangitis and lymphadenitis), and transient local edema. The lymphangitis is retrograde, extending peripherally from the lymph node draining the area where the adult parasites reside. Regional lymph nodes are often enlarged, and the entire lymphatic channel can become indurated and inflamed. Concomitant local thrombophlebitis can occur as well. In brugian filariasis, a single local abscess may form along the involved lymphatic tract and subsequently rupture to the surface. The lymphadenitis and lymphangitis can involve both the upper and lower extremities in both bancroftian and brugian filariasis, but involvement of the genital lymphatics occurs almost exclusively with *W. bancrofti* infection. This genital involvement can be manifested by funiculitis, epididymitis, and scrotal pain and tenderness. In endemic areas, another type of acute disease—dermatolymphangioadenitis (DLA)—is recognized as a syndrome that includes high fever, chills, myalgias, and headache. Edematous inflammatory plaques clearly demarcated from normal skin are seen. Vesicles, ulcers, and hyperpigmentation may also be noted. There is often a history of trauma, burns, radiation, insect bites, punctiform lesions, or chemical injury. Entry lesions, especially in the interdigital area, are common. DLA is often diagnosed as cellulitis.

If lymphatic damage progresses, transient lymphedema can develop into lymphatic obstruction and the permanent changes associated with elephantiasis (Fig. 202-2). Brawny edema follows early pitting edema, and thickening of the subcutaneous tissues and hyperkeratosis occur. Fissuring of the skin develops, as do hyperplastic changes. Superinfection of these poorly vascularized tissues becomes a problem. In bancroftian filariasis, in which genital involvement is common, hydroceles may develop; in advanced stages, this condition may evolve into scrotal lymphedema and scrotal elephantiasis. Furthermore, if there is obstruction of the retroperitoneal lymphatics, the increased renal lymphatic pressure leads to rupture of the renal lymphatics and the development of chyluria, which is usually intermittent and most prominent in the morning.

FIGURE 202-1 Hydrocele associated with *Wuchereria bancrofti* infection.

FIGURE 202-2 Elephantiasis of the lower extremity associated with *Wuchereria bancrofti* infection.

The clinical manifestations of filarial infections in travelers or transmigrants who have recently entered an endemic region are distinctive. Given a sufficient number of bites by infected vectors, usually over a 3- to 6-month period, recently exposed patients can develop acute lymphatic or scrotal inflammation with or without urticaria and localized angioedema. Lymphadenitis of epitrochlear, axillary, femoral, or inguinal lymph nodes is often followed by retrogradely evolving lymphangitis. Acute attacks are short-lived and, in contrast to filarial fevers in patients native to endemic areas, are usually not accompanied by fever. With prolonged exposure to infected mosquitoes, these attacks, if untreated, become more severe and lead to permanent lymphatic inflammation and obstruction.

DIAGNOSIS A definitive diagnosis can be made only by detection of the parasites and hence can be difficult. Adult worms localized in lymphatic vessels or nodes are largely inaccessible. Microfilariae can be found in blood, in hydrocele fluid, or (occasionally) in other body fluids. Such fluids can be examined microscopically, either directly or—for greater sensitivity—after concentration of the parasites by the passage of fluid through a polycarbonate cylindrical pore filter (pore size, 3 μm) or by the centrifugation of fluid fixed in 2% formalin (Knott's concentration technique). The timing of blood collection is critical and should be based on the periodicity of the microfilariae in the endemic region involved. Many infected individuals do not have microfilaremia, and definitive diagnosis in such cases can be difficult. Assays for circulating antigens of *W. bancrofti* permit the diagnosis of microfilaremic and cryptic (amicrofilaremic) infection. Two tests are commercially available: one is an enzyme-linked immunosorbent assay (ELISA) and the other a rapid-format immunochromatographic card test. Both assays have sensitivities that range from 96 to 100% and specificities that approach 100%. There are currently no tests for circulating antigens in brugian filariasis.

Polymerase chain reaction (PCR)–based assays for DNA of *W. bancrofti* and *B. malayi* in blood have been developed. A number of studies indicate that this diagnostic method is of equivalent or greater sensitivity compared with parasitologic methods, detecting patent infection in almost all infected subjects.

In cases of suspected lymphatic filariasis, examination of the scrotum or the female breast using high-frequency ultrasound in conjunction with Doppler techniques may result in the identification of motile adult worms within dilated lymphatics. Worms may be visualized in the lymphatics of the spermatic cord in up to 80% of infected men. Live adult worms have a distinctive pattern of movement within the lymphatic vessels (termed the *filaria dance sign*). Radionuclide lymphoscintigraphic imaging of the limbs reliably demonstrates widespread lymphatic abnormalities in both asymptomatic microfilaremic persons and those with clinical manifestations of lymphatic pathology. While of potential utility in the delineation of anatomic changes associated with infection, lymphoscintigraphy is unlikely to assume primacy in the diagnostic evaluation of individuals with suspected infection; it is principally a research tool, although it has been used more widely for assessment of lymphedema of all causes. Eosinophilia and elevated serum concentrations of IgE and antifilarial antibody support the diagnosis of lymphatic filariasis. There is, however, extensive cross-reactivity between filarial antigens and antigens of other helminths, including the common intestinal roundworms; thus, interpretations of serologic findings can be difficult. In addition, residents of endemic areas can become sensitized to filarial antigens through exposure to infected mosquitoes without having patent filarial infections.

In acute episodes, lymphatic filariasis must be distinguished from thrombophlebitis, infection, and trauma. Retrogradely evolving lymphangitis is a characteristic feature that helps distinguish filarial lymphangitis from typically ascending bacterial lymphangitis. Chronic filarial lymphedema must be distinguished from the lymphedema of malignancy, postoperative scarring, trauma, chronic edematous states, and congenital lymphatic system abnormalities.

TREATMENT

With newer definitions of clinical syndromes in lymphatic filariasis and new tools to assess clinical status (e.g., ultrasound, lymphoscintigraphy, circulating filarial antigen assays, PCR), approaches to treatment based on infection status can be considered. Diethylcarbamazine (DEC, 6 mg/kg daily for 12 days), which has both macro- and microfilaricidal properties, remains the treatment of choice for the individual with active lymphatic filariasis (microfilaremia, antigen positivity, or adult worms on ultrasound), although albendazole (400 mg twice daily for 21 days) has also demonstrated macrofilaricidal efficacy.

As has already been mentioned, a growing body of evidence indicates that, although they may be asymptomatic, virtually all persons with *W. bancrofti* or *B. malayi* microfilaremia have some degree of subclinical disease (hematuria, proteinuria, abnormalities on lymphoscintigraphy). Thus, early treatment of asymptomatic persons is recommended to prevent further lymphatic damage. For ADL, supportive treatment (including the administration of antipyretics and analgesics) is recommended, as is antibiotic therapy if secondary bacterial infection is likely. Similarly, because lymphatic disease is associated with the presence of adult worms, treatment with DEC is recommended for microfilaria-negative adult-worm carriers.

In persons with chronic manifestations of lymphatic filariasis, treatment regimens that emphasize hygiene, prevention of secondary bacterial infections, and physiotherapy have gained wide acceptance for morbidity control. These regimens are similar to those recommended for lymphedema of most nonfilarial causes and known by a variety of names, including *complex decongestive physiotherapy* and *complex lymphedema therapy*. Hydroceles can be drained repeatedly or managed surgically. With chronic manifestations of lymphatic filariasis, drug treatment should be reserved for individuals with evidence of active infection; therapy has been associated with clinical improvement and, in some cases, reversal of lymphedema.

The recommended course of DEC treatment (12 days; total dose, 72 mg/kg) has remained standard for many years; however, data indicate that single-dose DEC treatment with 6 mg/kg may be equally efficacious. The 12-day course provides more rapid short-term microfilarial suppression. Regimens that utilize single-dose DEC or ivermectin or combinations of single doses of albendazole and either DEC or ivermectin have all been demonstrated to have a sustained microfilaricidal effect.

Side effects of DEC treatment include fever, chills, arthralgias, headaches, nausea, and vomiting. Both the development and the severity of these reactions are directly related to the number of microfilariae circulating in the bloodstream and may represent either an acute hypersensitivity reaction to the antigens being released by dead and dying parasites or an inflammatory reaction induced by lipopolysaccharides from the intracellular *Wolbachia* endosymbionts freed from their intracellular niche. Ivermectin has a side effect profile similar to that of DEC when used in lymphatic filariasis.

PREVENTION AND CONTROL Avoidance of mosquito bites is usually not feasible for residents of endemic areas, but visitors should make use of insect repellent and mosquito nets. Impregnated bednets have been shown to have a salutary effect. DEC can kill developing forms of filarial parasites and has been shown to be useful as a prophylactic agent in humans.

Community-based intervention is the current approach to elimination of lymphatic filariasis as a public health problem. The underlying tenet of this approach is that mass annual distribution of antimicrofilarial chemotherapy—albendazole with either DEC (for all areas except those where onchocerciasis is coendemic) or ivermectin—will profoundly suppress microfilaremia. If the suppression is sustained, then transmission can be interrupted. As an added benefit, these combinations have secondary effects on gastrointestinal helminths. An alternative approach to the control of lymphatic filariasis is the use of

salt fortified with DEC. Community use of DEC-fortified salt dramatically reduces microfilarial density with no apparent adverse reactions. Community education and clinical care for persons already suffering from the chronic sequelae of lymphatic filariasis are important components of filariasis control and elimination programs.

TROPICAL PULMONARY EOSINOPHILIA

Tropical pulmonary eosinophilia (TPE) is a distinct syndrome that develops in some individuals infected with lymphatic filarial species. This syndrome affects males and females in a ratio of 4:1, often during the third decade of life. The majority of cases have been reported from India, Pakistan, Sri Lanka, Brazil, Guyana, and Southeast Asia.

CLINICAL FEATURES The main features include a history of residence in filarial-endemic regions, paroxysmal cough and wheezing that are usually nocturnal (and probably related to the nocturnal periodicity of microfilariae), weight loss, low-grade fever, adenopathy, and pronounced blood eosinophilia (>3000 eosinophils/μL). Chest x-rays may be normal but generally show increased bronchovascular markings; diffuse miliary lesions or mottled opacities may be present in the middle and lower lung fields. Tests of pulmonary function show restrictive abnormalities in most cases and obstructive defects in half. Total serum IgE levels (10,000 to 100,000 ng/mL) and antifilarial antibody titers are characteristically elevated.

PATHOLOGY In TPE there is rapid clearance of microfilariae and parasite antigens from the bloodstream by the lungs, and the clinical symptoms result from allergic and inflammatory reactions elicited by the cleared parasites. In some patients, trapping of microfilariae in other reticuloendothelial organs can cause hepatomegaly, splenomegaly, or lymphadenopathy. A prominent, eosinophil-enriched, intraalveolar infiltrate is often reported, and with it comes the release of cytotoxic proinflammatory granular proteins that may mediate some of the pathology seen in TPE. In the absence of successful treatment, interstitial fibrosis can lead to progressive pulmonary damage.

DIFFERENTIAL DIAGNOSIS TPE must be distinguished from asthma, Löffler's syndrome, allergic bronchopulmonary aspergillosis, allergic granulomatosis with angiitis (Churg-Strauss syndrome), the systemic vasculitides (most notably periarteritis nodosa and Wegener's granulomatosis), chronic eosinophilic pneumonia, and the idiopathic hypereosinophilic syndrome. In addition to a geographic history of filarial exposure, useful features for distinguishing TPE include wheezing that is solely nocturnal, very high levels of antifilarial antibodies, and a rapid initial response to treatment with DEC.

Rx TREATMENT

DEC is used at a dosage of 4 to 6 mg/kg of body weight per day for 14 days. Symptoms usually resolve within 3 to 7 days after the initiation of therapy. Relapse, which occurs in ~12 to 25% of cases (sometimes after an interval of years), requires re-treatment.

ONCHOCERCIASIS

Onchocerciasis ("river blindness") is caused by the filarial nematode *O. volvulus*, which infects an estimated 13 million individuals. The majority of individuals infected with *O. volvulus* live in the equatorial region of Africa extending from the Atlantic coast to the Red Sea. About 70,000 persons are infected in Guatemala and Mexico, with smaller foci in Venezuela, Colombia, Brazil, Ecuador, Yemen, and Saudi Arabia. Onchocerciasis is the second leading cause of infectious blindness worldwide.

ETIOLOGY AND EPIDEMIOLOGY Infection in humans begins with the deposition of infective larvae on the skin by the bite of an infected blackfly. The larvae develop into adults, which are typically found in subcutaneous nodules. About 7 months to 3 years after infection, the gravid female releases microfilariae that migrate out of the nodule and throughout the tissues, concentrating in the dermis. Infection is transmitted to other persons when a female fly ingests microfilariae from the host's skin and these microfilariae then develop into infective larvae. Adult *O. volvulus* females and males are about 40 to 60 cm and 3 to 6 cm in length, respectively. The life span of adults can be as long as 18 years, with an average of ~9 years. Because the blackfly vector breeds along free-flowing rivers and streams (particularly in rapids) and generally restricts its flight to an area within several kilometers of these breeding sites, both biting and disease transmission are most intense in these locations.

PATHOLOGY Onchocerciasis affects primarily the skin, eyes, and lymph nodes. In contrast to that in lymphatic filariasis, the damage in onchocerciasis is elicited by microfilariae and not by adult parasites. In the skin, there are mild but chronic inflammatory changes that can result in loss of elastic fibers, atrophy, and fibrosis. The subcutaneous nodules, or onchocercomata, consist primarily of fibrous tissues surrounding the adult worm, often with a peripheral ring of inflammatory cells. In the eye, neovascularization and corneal scarring lead to corneal opacities and blindness. Inflammation in the anterior and posterior chambers frequently results in anterior uveitis, chorioretinitis, and optic atrophy. Although punctate opacities are due to an inflammatory reaction surrounding dead or dying microfilariae, the pathogenesis of most manifestations of onchocerciasis is still unclear.

CLINICAL FEATURES ■ Skin Pruritus and rash are the most frequent manifestations of onchocerciasis. The pruritus can be incapacitating; the rash is typically a papular eruption (Fig. 202-3) that is generalized rather than localized to a particular region of the body. Long-term infection results in exaggerated and premature wrinkling of the skin, loss of elastic fibers, and epidermal atrophy that can lead to loose, redundant skin and hypo- or hyperpigmentation. Localized eczematoid dermatitis can cause hyperkeratosis, scaling, and pigmentary changes. Such lesions are often seen in the lower extremities but can be distributed more extensively.

Onchocercomata These subcutaneous nodules, which can be palpable and/or visible, contain the adult worm. In African patients, they are common over the coccyx and sacrum, the trochanter of the femur, the lateral anterior crest, and other bony prominences; in Latin American patients, nodules tend to develop preferentially in the upper part of the body, particularly on the head, neck, and shoulders. Nodules vary in size and characteristically are firm and not tender. It has been estimated that, for every palpable nodule, there are four deeper nonpalpable ones.

Ocular Tissue Visual impairment is the most serious complication of onchocerciasis and usually affects only those persons with moderate or heavy infections. Lesions may develop in all parts of the eye. The most common early finding is conjunctivitis with photophobia. In the

FIGURE 202-3 Papular eruption as a consequence of onchocerciasis.

cornea, punctate keratitis—consisting of acute inflammatory reactions surrounding dying microfilariae manifested as "snowflake" opacities—is frequent in younger patients and resolves without apparent complications. Sclerosing keratitis occurs in 1 to 5% of infected persons and is the leading cause of onchocercal blindness in Africa. Anterior uveitis and iridocyclitis develop in ~5% of infected persons in Africa. In Latin America, complications of the anterior uveal tract (pupillary deformity) may cause secondary glaucoma. Characteristic chorioretinal lesions develop as a result of atrophy and hyperpigmentation of the retinal pigment epithelium. Constriction of the visual field and frank optic atrophy may occur.

Lymph Nodes Mild to moderate lymphadenopathy is frequent, particularly in the inguinal and femoral areas, where the enlarged nodes may hang down in response to gravity ("hanging groin"), sometimes predisposing to inguinal and femoral hernias.

Systemic Manifestations Some heavily infected individuals develop cachexia with loss of adipose tissue and muscle mass. Among adults who become blind, there is a three- to fourfold increase in the mortality rate.

DIAGNOSIS Definitive diagnosis depends on the detection of an adult worm in an excised nodule or, more commonly, of microfilariae in a skin snip. Skin snips are obtained with a corneal-scleral punch, which collects a blood-free skin biopsy sample extending to just below the epidermis, or by lifting of the skin with the tip of a needle and excision of a small (1- to 3-mm) piece with a sterile scalpel blade. The biopsy tissue is incubated in tissue culture medium or in saline on a glass slide or flat-bottomed microtiter plate. After incubation for 2 to 4 h (or occasionally overnight in light infections), microfilariae emergent from the skin can be visualized by low-power microscopy.

Eosinophilia and elevated serum IgE levels are common but, because they occur in many parasitic infections, are not diagnostic in themselves. Assays to detect specific antibodies to *Onchocerca* and PCR to detect onchocercal DNA in skin snips are now in use in specialized laboratories and are highly sensitive and specific.

The *Mazzotti test* is a provocative technique that can be used in cases where the diagnosis of onchocerciasis is still in doubt (i.e., when skin snips and ocular examination reveal no microfilariae). A small dose of DEC (0.5 to 1.0 mg/kg) is given orally; the development or exacerbation of pruritus or dermatitis within hours is highly suggestive of onchocerciasis.

TREATMENT

The main goals of therapy are to prevent the development of irreversible lesions and to alleviate symptoms. Surgical excision is recommended when nodules are located on the head (because of the proximity of microfilaria-producing adult worms to the eye), but chemotherapy is the mainstay of management. Ivermectin, a semisynthetic macrocyclic lactone active against microfilariae, is the first-line agent for the treatment of onchocerciasis. It is given orally in a single dose of 150 μg/kg, either yearly or semiannually. Recently, more frequent ivermectin administration (every 3 months) has been suggested to ameliorate pruritus and skin disease; moreover, quadrennial administration of ivermectin has been demonstrated to have some macrofilaricidal activity. After treatment, most individuals have few or no reactions. Pruritus, cutaneous edema, and/or maculopapular rash occurs in ~1 to 10% of treated individuals. In areas of Africa coendemic for *O. volvulus* and *L. loa*, however, ivermectin is contraindicated (as it is for pregnant or breastfeeding women) because of severe posttreatment encephalopathy seen in patients, especially children, who are heavily microfilaremic for *L. loa* (2000 to 5000 microfilariae per milliliter). Although ivermectin treatment results in a marked drop in microfilarial density, its effect can be short-lived (<3 months in some cases). Thus, it is occasionally necessary to give ivermectin more frequently for persistent symptoms. A 6-week course of doxycycline has been demonstrated to be macrofilaristatic (rendering the female adult worms sterile for long periods). Because this regimen targets the *Wolbachia* endosymbiont of the filarial parasite, new options for definitive treatment may become available.

PREVENTION Vector control has been beneficial in highly endemic areas in which breeding sites are vulnerable to insecticide spraying, but most areas endemic for onchocerciasis are not suited to this type of control. Community-based administration of ivermectin every 6 to 12 months is now being used to interrupt transmission in endemic areas. This measure, in conjunction with vector control, has already helped reduce the prevalence of disease in endemic foci in Africa and Latin America. No drug has proven useful for prophylaxis of *O. volvulus* infection.

LOIASIS

ETIOLOGY AND EPIDEMIOLOGY Loiasis is caused by *L. loa* (the African eye worm), which is present in the rain forests of West and Central Africa. Adult parasites (females, 50 to 70 mm long and 0.5 mm wide; males, 25 to 35 mm long and 0.25 mm wide) live in subcutaneous tissues; microfilariae circulate in the blood with a diurnal periodicity that peaks between 12:00 noon and 2:00 P.M.

CLINICAL FEATURES Manifestations of loiasis in natives of endemic areas may differ from those in temporary residents or visitors. Among the indigenous population, loiasis is often an asymptomatic infection with microfilaremia. Infection may be recognized only after subconjunctival migration of an adult worm (Fig. 202-4) or may be manifested by episodic Calabar swellings—evanescent localized areas of angioedema and erythema developing on the extremities and less frequently at other sites. Nephropathy, encephalopathy, and cardiomyopathy are rare. In patients who are not residents of endemic areas, allergic symptoms predominate, episodes of Calabar swelling tend to be more frequent and debilitating, microfilaremia is rare, and eosinophilia and increased levels of antifilarial antibodies are characteristic.

PATHOLOGY The pathogenesis of the manifestations of loiasis is poorly understood. Calabar swellings are thought to result from a hypersensitivity reaction to the adult worm.

DIAGNOSIS Definitive diagnosis of loiasis requires the detection of microfilariae in the peripheral blood or the isolation of the adult worm from the eye or from a subcutaneous biopsy specimen from a site of swelling developing after treatment. PCR-based assays for the detection of *L. loa* DNA in blood are now available in specialized laboratories and are highly sensitive and specific. In practice, the diagnosis must often be based on a characteristic history and clinical presentation, blood eosinophilia, and elevated levels of antifilarial antibodies,

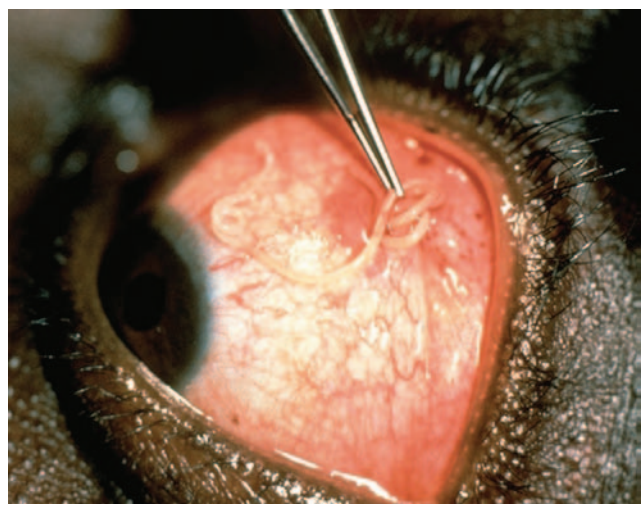

FIGURE 202-4 Adult *Loa loa* in the process of surgical removal after its subconjunctival migration.

particularly in travelers to an endemic region, who are usually amicrofilaremic. Other clinical findings in the latter individuals include hypergammaglobulinemia, elevated levels of serum IgE, and elevated leukocyte and eosinophil counts.

TREATMENT

DEC (8 to 10 mg/kg per day for 21 days) is effective against both the adult and the microfilarial forms of *L. loa*, but multiple courses are frequently necessary before the disease resolves completely. In cases of heavy microfilaremia, allergic or other inflammatory reactions can take place during treatment, including central nervous system involvement with coma and encephalitis. Heavy infections can be treated initially with apheresis to remove the microfilariae and with glucocorticoids (40 to 60 mg of prednisone per day) followed by doses of DEC (0.5 mg/kg per day). If antifilarial treatment has no adverse effects, the prednisone dose can be rapidly tapered and the dose of DEC gradually increased to 8 to 10 mg/kg per day.

Albendazole or ivermectin (although neither is approved for this use by the Food and Drug Administration) has been shown to be effective in reducing microfilarial loads. DEC (300 mg weekly) is an effective prophylactic regimen for loiasis.

STREPTOCERCIASIS

Mansonella streptocerca, found mainly in the tropical forest belt of Africa from Ghana to Zaire, is transmitted by biting midges. The major clinical manifestations involve the skin and include pruritus, papular rashes, and pigmentation changes. Many infected individuals have inguinal adenopathy, although most are asymptomatic. The diagnosis is made by detection of the characteristic microfilariae in skin snips. DEC (6 mg/kg per day in divided doses for 14 to 21 days) is effective in killing both microfilariae and adult worms. As in onchocerciasis, treatment is sometimes accompanied by urticaria, arthralgias, myalgias, headaches, and abdominal discomfort. Ivermectin at a single dose of 150 μg/kg leads to sustained suppression of microfilariae in the skin and is likely to assume primacy in the treatment of streptocerciasis.

MANSONELLA PERSTANS INFECTION

Mansonella perstans, distributed across the center of Africa and in northeastern South America, is transmitted by midges. Adult worms reside in serous cavities—pericardial, pleural, and peritoneal—as well as in the mesentery and the perirenal and retroperitoneal tissues. Microfilariae circulate in the blood without periodicity. The clinical and pathologic features of the infection are poorly defined. Most patients appear to be asymptomatic, but manifestations may include transient angioedema and pruritus of the arms, face, or other parts of the body (analogous to the Calabar swellings of loiasis); fever; headache; arthralgias; and right-upper-quadrant pain. Occasionally, pericarditis and hepatitis occur. The diagnosis is based on the demonstration of microfilariae in blood or serosal effusions. Perstans filariasis is often associated with peripheral-blood eosinophilia and antifilarial antibody elevations. Although DEC (8 to 10 mg/kg per day for 21 days) is the standard therapeutic agent, there is little evidence that it is effective. Cure is indicated by the disappearance of symptoms and eosinophilia; multiple courses of therapy are usually required. Ivermectin, used in frequent repeated doses, has been shown to be capable of reducing blood microfilarial levels. Both mebendazole (100 mg twice daily for 30 days) and albendazole (400 mg twice daily for 10 days) have been reported occasionally to be effective.

MANSONELLA OZZARDI INFECTION

The distribution of *Mansonella ozzardi* is restricted to Central and South America and certain Caribbean islands. Adult worms are rarely recovered from humans. Microfilariae circulate in the blood without periodicity. Although this organism has often been considered nonpathogenic, headache, articular pain, fever, pulmonary symptoms, adenopathy, hepatomegaly, pruritus, and eosinophilia have been ascribed to *M. ozzardi* infection. Diagnosis is made by the detection of microfilariae in peripheral blood. Ivermectin (a single dose of 6 mg) has been shown to be effective in treating this infection.

DRACUNCULIASIS (GUINEA WORM INFECTION)

ETIOLOGY AND EPIDEMIOLOGY Dracunculiasis, caused by *Dracunculus medinensis*, is a parasitic infection whose incidence has declined dramatically because of global eradication efforts. Current estimates suggest that there are 56,000 cases worldwide, the majority in Sudan. Humans acquire this infection when they ingest water containing infective larvae derived from *Cyclops*, a crustacean that is the intermediate host. Larvae penetrate the stomach or intestinal wall, mate, and mature. The adult male probably dies; the female *Dracunculus* develops over a year and migrates to subcutaneous tissues, usually in the lower extremity. As the thin female *Dracunculus*, ranging in length from 300 cm to 1 m, approaches the skin, a blister forms that, over days, breaks down and forms an ulcer. When the blister opens, large numbers of motile, rhabditiform larvae can be released into stagnant water; ingestion by *Cyclops* completes the life cycle.

CLINICAL FEATURES Few or no clinical manifestations of dracunculiasis are evident until just before the blister forms, when there is an onset of fever and generalized allergic symptoms, including periorbital edema, wheezing, and urticaria. The emergence of the worm is associated with local pain and swelling. When the blister ruptures (usually as a result of immersion in water), the adult worm releases larva-rich fluid, and this release is associated with a relief of symptoms. The shallow ulcer surrounding the emerging adult worm heals over weeks to months. Such ulcers, however, can become secondarily infected, the result being cellulitis, local inflammation, abscess formation, or (uncommonly) tetanus. Occasionally, the adult worm does not emerge but becomes encapsulated and calcified.

DIAGNOSIS The diagnosis is based on the findings developing with the emergence of the adult worm, as described above.

TREATMENT

Gradual extraction of the worm by winding of a few centimeters on a stick each day remains the common and effective practice. Worms may be excised surgically. The administration of metronidazole (250 mg three times daily for 10 days) may relieve symptoms but has no proven activity against the worm.

PREVENTION Prevention, which remains the only real control measure, depends on the provision of safe drinking water.

ZOONOTIC FILARIAL INFECTIONS

Dirofilariae that affect primarily dogs, cats, and raccoons occasionally infect humans incidentally, as do *Brugia* and *Onchocerca* parasites that affect small mammals. Because humans are an abnormal host, the parasites never develop fully. Pulmonary dirofilarial infection caused by the canine heartworm *Dirofilaria immitis* generally presents in humans as a solitary pulmonary nodule. Chest pain, hemoptysis, and cough are uncommon. Infections with *D. repens* (from dogs) or *D. tenuis* (from raccoons) can cause local subcutaneous nodules in humans. Zoonotic *Brugia* infection can produce isolated lymph node enlargement, whereas zoonotic *Onchocerca* can cause subconjunctival masses. Eosinophilia levels and antifilarial antibody titers are not commonly elevated. Excisional biopsy is both diagnostic and curative; these infections usually do not respond to chemotherapy.

203 SCHISTOSOMIASIS AND OTHER TREMATODE INFECTIONS

Adel A.F. Mahmoud

Trematodes, or flatworms, are a group of morphologically and biologically heterogeneous organisms that belong to the phylum Platyhelminthes. Human infection with trematodes occurs in many geographic areas and can cause considerable morbidity and mortality. For clinical purposes, the significant trematode infections of humans may be divided according to the tissues invaded by adult flukes: blood, biliary tree, intestines, and lungs (Table 203-1).

Trematodes share some common morphologic features, including macroscopic size (from 1 cm to several cm); dorsoventral, flattened, bilaterally symmetric bodies (adult worms); and the prominence of two suckers. Except for the schistosomes, all trematodes that parasitize humans are hermaphroditic. The life cycle of trematodes involves a definitive host (mammalian/human), in which adult worms initiate sexual reproduction, and an intermediate host (snails), in which asexual multiplication of the larval forms occurs. More than one intermediate host may be necessary for some species of trematodes. Human infection is initiated either by direct penetration of intact skin or by ingestion. Upon maturation within the human host, adult flukes initiate sexual reproduction that results in egg production. Helminth ova leave the definitive host in excreta or sputum and, upon reaching suitable environmental conditions, they hatch, releasing free-living miracidia that must find a specific snail intermediate host. After asexual reproduction, cercariae are released from infected snails; these organisms either infect humans or must find another intermediate host to allow encystment into metacercariae—the infective stage in these species.

The host-parasite relationship in trematode infections is a product of the biologic features of these organisms: they are multicellular, undergo several developmental changes within the host, and usually result in chronic infections. In general, the distribution of worm infections in human populations is *overdispersed*; i.e., it follows a negative binomial mathematical relationship in which most infected individuals harbor low worm burdens while a small percentage are heavily infected. It is the heavily infected minority who are particularly prone to disease sequelae and who constitute an epidemiologically significant reservoir of infection in endemic areas. It is also important to appreciate that worms do not multiply within the definitive host and that they have a relatively long life span, ranging from a few months to a few years. Morbidity and mortality due to trematode infections reflect a multifactorial process that results from the tipping of a delicate balance based on the intensity of infection and the host reactions that initiate and modulate pathologic outcome. Furthermore, the genetics of the parasite and the human host contribute to the outcome of infection and disease. Infections with trematodes that migrate through or reside in host tissues are associated with a moderate to high degree of peripheral blood eosinophilia; this association is of significance in protective and immunopathologic sequelae and is a useful clinical indicator of infection.

APPROACH TO THE PATIENT

The approach to individuals with suspected trematode infection begins with a question: Where have you been? Details of geographic history, exposure to freshwater bodies, and indulgence in local eating habits without ensuring safety of food and drink are all essential elements in the history. The workup plan must include a detailed physical examination and tests appropriate for the suspected infection. Diagnosis is based either on detection of the relevant stage of the parasite in excreta, sputum, or (rarely) tissue samples or on sensitive and specific serologic tests. Consultation with physicians familiar with these infections or with the U.S. Centers for Disease Control and Prevention (CDC) is helpful in guiding diagnosis and selecting therapy.

BLOOD FLUKES: SCHISTOSOMIASIS

Human schistosomiasis is caused by five species of this parasitic trematode: the intestinal species *Schistosoma mansoni*, *S. japonicum*, *S. mekongi*, and *S. intercalatum* and the urinary species *S. haematobium*. Infection may cause considerable morbidity in the intestines, liver, and urinary tract, and a proportion of affected individuals die. Other schistosome species (e.g., avian species) may invade human skin but then die in subcutaneous tissue, producing only self-limiting cutaneous manifestations.

Information on the prevalence and geographic distribution of human schistosomiasis is inexact. The five species are estimated to infect 200 to 300 million people in South America, the Caribbean, Africa, the Middle East, and Southeast Asia. The total population living under conditions favoring transmission approximates double or triple that number—a fact reflecting the public health significance of schistosomiasis.

ETIOLOGY Human infection is initiated by penetration of intact skin with infective cercariae. These organisms are released from infected snails in freshwater bodies; they measure ~2 mm in length and possess an anterior and a ventral sucker that attach to the skin surface and facilitate penetration. Once in the subcutaneous tissue, the organism transforms into the next stage: the schistosomula. This transformation involves morphologic, membrane, and immunologic changes, prominent among which is the transformation of the cercarial outer membrane from a trilaminar to a heptalaminar membrane that is then maintained throughout the life span of the worms in humans. The transformation to a heptalaminar structure is thought to be the schistosome's main adaptive mechanism for survival in humans. Schistosomulae begin their migration within 2 to 4 days via venous or lymphatic vessels, reaching the lungs and finally the liver parenchyma. Sexually mature worms descend into the venous system at specific anatomical locations: intestinal veins (*S. mansoni*, *S. japonicum*, *S. mekongi*, and *S. intercalatum*) and vesical veins (*S. haematobium*). After mating, adult gravid females travel against venous blood flow to small tributaries, where they deposit their ova intravascularly. Schistosome ova (Fig. 203-1) have specific morphologic features that can be used to differentiate species. Aided by enzymatic secretions through minipores in eggshells, ova move through the venous wall, traversing host tissues to reach the lumen of the intestinal or urinary tract, and

are voided with stools or urine. Approximately 50% of ova are retained in host tissues locally (intestines or urinary tract) or are carried by venous blood flow to the liver and other organs. Schistosome ova that reach freshwater bodies hatch, releasing free-living miracidia that seek the snail intermediate host to undergo several asexual multiplication cycles. Finally, infective cercariae are shed from snails.

Adult schistosome worms measure ~1 to 2 cm in length. The male is slightly shorter, with a flattened body; its edges curve anteriorly to form the gynecophoral canal, in which mature adult females are usually held. The females are longer, slender, and rounded in cross-section. The precise nature of biochemical and reproductive exchanges between the two sexes is unknown, as are the regulatory mechanisms for pairing. Adult schistosomes parasitize specific sites in the host venous system. What guides adult intestinal schistosomes to branches of the superior or inferior mesenteric veins or adult *S. haematobium* worms to the vesical plexus is unknown. In addition, the evasion mechanisms by which adult worms inhibit the coagulation cascade and the effector arms of the host immune responses are not fully understood. The genome of schistosomes is made of 16 chromosomes; its DNA sequence is currently being determined.

TABLE 203-1 *Major Human Trematode Infections*

Trematode	Transmission	Endemic Area(s)
BLOOD FLUKES		
Schistosoma mansoni	Skin penetration by cercariae released from snails	Africa, South America, Middle East
S. japonicum	Skin penetration by cercariae released from snails	China, Philippines, Indonesia
S. intercalatum	Skin penetration by cercariae released from snails	West Africa
S. mekongi	Skin penetration by cercariae released from snails	Southeast Asia
S. haematobium	Skin penetration by cercariae released from snails	Africa, Middle East
BILIARY (HEPATIC) FLUKES		
Clonorchis sinensis	Ingestion of metacercariae in freshwater fish	Far East
Opisthorchis viverrini	Ingestion of metacercariae in freshwater fish	Far East, Thailand
O. felineus	Ingestion of metacercariae in freshwater fish	Far East, Europe
Fasciola hepatica	Ingestion of metacercariae on aquatic plants or in water	Worldwide
F. gigantica	Ingestion of metacercariae on aquatic plants or in water	Sporadic, Africa
INTESTINAL FLUKES		
Fasciolopsis buski	Ingestion of metacercariae on aquatic plants	Southeast Asia
Heterophyes heterophyes	Ingestion of metacercariae in freshwater or brackish-water fish	Far East, North Africa
LUNG FLUKES		
Paragonimus westermani	Ingestion of metacercariae in crayfish or crabs	Global except North America and Europe

EPIDEMIOLOGY The distribution of schistosome infection and related disease syndromes in human populations (Fig. 203-2) is dependent on both parasite and host factors. In endemic areas, the rate of yearly onset of new infection, or incidence, is generally low. Prevalence, on the other hand, starts to be appreciable by the age of 3 to 4 years and builds to a maximum that varies by endemic region (up to 100%) in the 15- to 20-year age group. Prevalence then stabilizes or decreases slightly in older age groups (>40 years). Intensity of infection (as measured by fecal or urinary egg counts, which correlate with adult worm burdens in most circumstances) follows the increase in prevalence up to the age of 15 to 20 years and then declines markedly in older age groups. This decline may reflect acquisition of resistance, or it may be due to changes in water contact patterns, since older people are exposed less. Furthermore, the unique distribution of schistosomes in human populations (i.e., an overdispersed distribution) may be due to the heterogeneity of worm populations, with some more invasive than others; alternatively, it may be due to differences in the genetic susceptibility of host populations, as has recently been demonstrated.

Disease due to schistosome infection is the outcome of parasitologic, host, and additional infectious, nutritional, and environmental factors. Most of the disease syndromes relate to the presence of one or more of the parasite stages in the human host. The distribution of disease manifestations in the populations of endemic areas correlates, in general, with the intensity and duration of infection as well as with the age and genetic susceptibility of the host. Overall, disease manifestations are clinically relevant in only a small proportion of persons infected with any of the intestinal schistosomes. In contrast, urinary schistosomiasis manifests clinically in most infected individuals.

Patients with both HIV infection and schistosomiasis have been found to excrete far fewer eggs in their stools than those infected with *S. mansoni* alone; the mechanism underlying this difference is unknown. The two groups, however, respond equally to treatment with praziquantel.

PATHOGENESIS AND IMMUNITY During the invasive stage, cercaria-associated dermatitis reflects dermal and subdermal inflammatory responses—both humoral and cell-mediated. As the parasites approach sexual maturity and the commencement of oviposition, acute schistosomiasis or Katayama fever (a serum sickness–like illness; see "Clinical Features," below) may occur. The associated antigen excess results in the formation of soluble immune complexes, which may be deposited in several tissues, initiating the sequence of pathologic events. In chronic schistosomiasis, most disease manifestations are due to eggs retained in host tissues. The granulomatous response around these ova is cell-mediated and is regulated both positively and negatively by a cascade of cytokine, cellular, and humoral responses. Granuloma formation begins with recruitment of a host of inflammatory cells in response to antigens secreted by the living organism within the ova. Cells recruited initially include phagocytes, antigen-specific T cells, and eosinophils. Fibroblasts, giant cells, and B lymphocytes predominate later. Once activated, T cells produce cytokines [such as tumor necrosis factor α (TNF-α), interleukin (IL) 2, IL-4, and IL-5, which in turn activate endothelial cells] as well as specific chemokines [such as monocyte chemotactic protein 1 (MCP-1)]. The result is recruitment of the cellular elements that organize in the form of granulomas around parasite eggs. These lesions reach a size many times that of the eggs, thus inducing organomegaly and obstruction. Immunomodulation or downregulation of host responses to schistosome eggs plays a significant role in limiting the extent of the granulomatous lesions—and consequently disease—in chronically infected experimental animals or humans. The underlying mechanisms involve another cascade of regulatory cytokines (IL-10, IL-12) and idiotypic antibodies. Subsequent to the granulomatous response, fibrosis sets in, resulting in more permanent disease sequelae. Because schistosomiasis is a chronic infection, the accumulation of antigen-antibody complexes results in deposits in renal glomeruli and may cause significant kidney disease.

The better-studied pathologic sequelae in schistosomiasis are those observed in liver disease. Ova that are carried by portal blood embolize to the liver. Because of their size (~150 × 60 μm in the case of *S. mansoni*), they lodge at presinusoidal sites, where granulomas are formed. The granulomas contribute to the liver enlargement observed in infected individuals. Schistosomal hepatomegaly is also associated

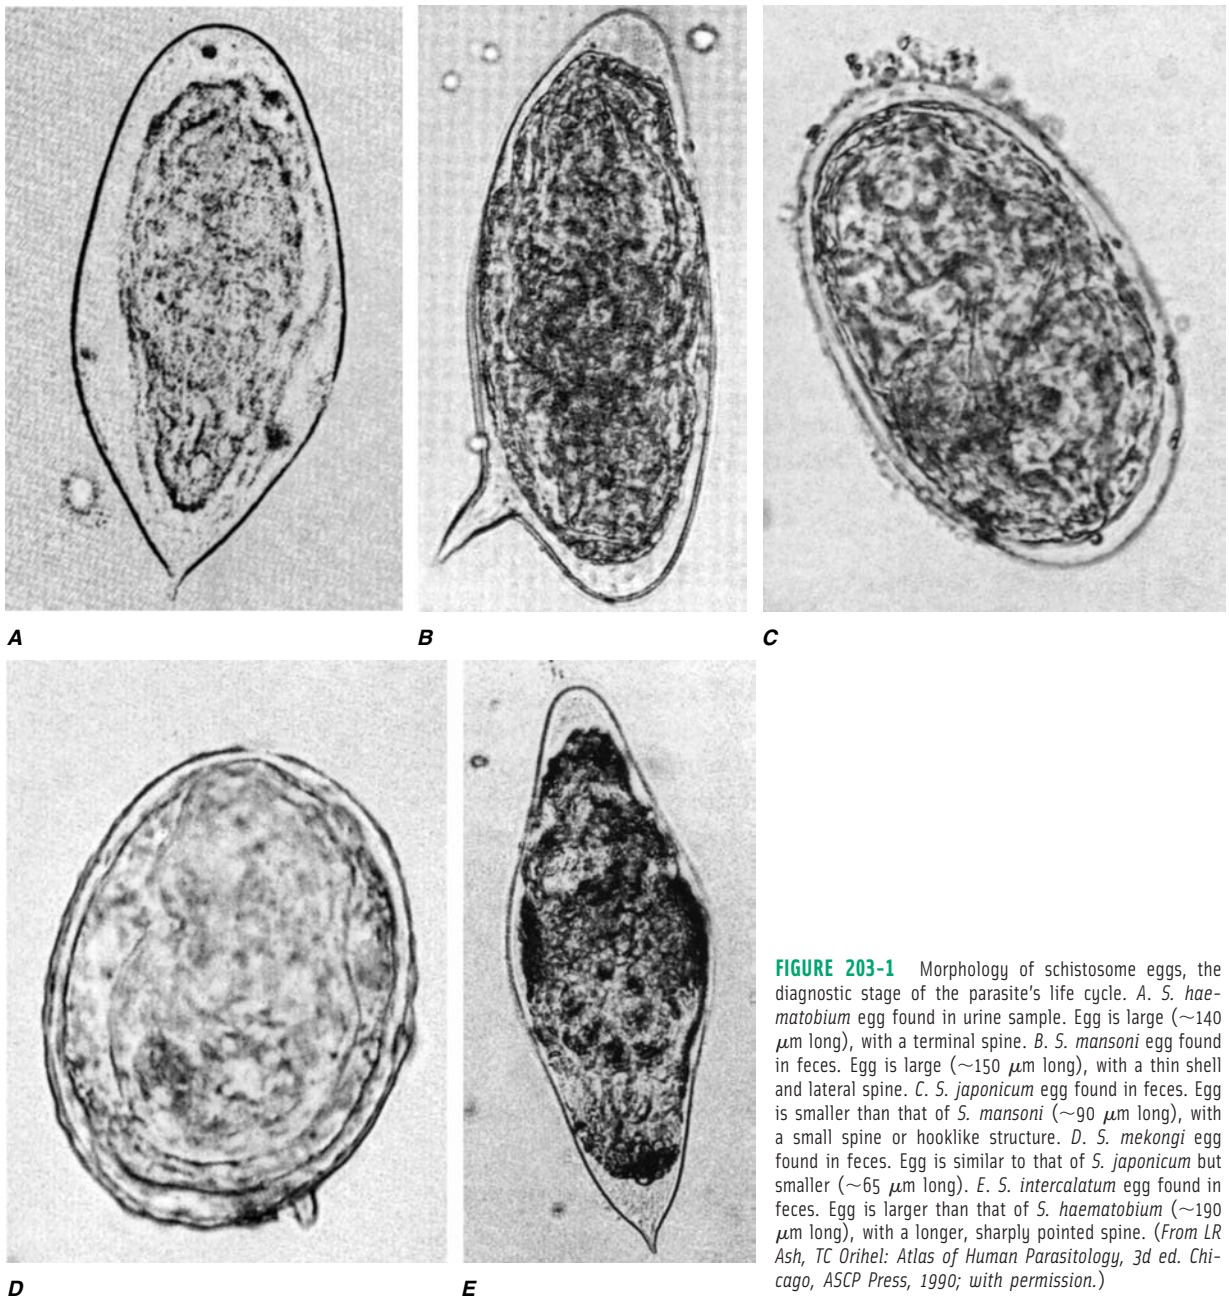

FIGURE 203-1 Morphology of schistosome eggs, the diagnostic stage of the parasite's life cycle. *A. S. haematobium* egg found in urine sample. Egg is large (~140 μm long), with a terminal spine. *B. S. mansoni* egg found in feces. Egg is large (~150 μm long), with a thin shell and lateral spine. *C. S. japonicum* egg found in feces. Egg is smaller than that of *S. mansoni* (~90 μm long), with a small spine or hooklike structure. *D. S. mekongi* egg found in feces. Egg is similar to that of *S. japonicum* but smaller (~65 μm long). *E. S. intercalatum* egg found in feces. Egg is larger than that of *S. haematobium* (~190 μm long), with a longer, sharply pointed spine. (*From LR Ash, TC Orihel: Atlas of Human Parasitology, 3d ed. Chicago, ASCP Press, 1990; with permission.*)

with certain class I and class II human leukocyte antigen (HLA) markers; its genetic basis appears to be multigenic. Presinusoidal portal blockage causes several hemodynamic changes, including portal hypertension and associated development of portosystemic collaterals at the esophagogastric junction and other sites. Esophageal varices are most likely to break and cause repeated episodes of hematemesis. Because changes in liver hemodynamics in schistosomiasis are slow, compensatory arterialization of blood flow through the liver is established. While this compensatory mechanism may be associated with certain metabolic side effects, the retention of hepatocyte perfusion permits the maintenance of normal liver function for several years.

After granuloma formation, the second most significant pathologic change in the liver relates to the onset of fibrosis. It is characteristically periportal (Symmers' clay pipe–stem fibrosis) but may be diffuse. Fibrosis, when diffuse, may be seen in areas of egg deposition and granuloma formation, but it is also seen in distant locations such as portal tracts. Schistosomiasis alone results in pure fibrotic lesions in the liver; cirrhosis occurs when other nutritional or infectious agents (e.g., hepatitis B or C virus) are involved. In recent years, it has been recognized that deposition of fibrotic tissue in the extracellular matrix results from the interaction of T lymphocytes with cells of the fibroblast series; several cytokines, such as IL-2, IL-4, IL-1, and transforming growth factor β (TGF-β), are known to stimulate fibrogenesis. The process may be dependent on the genetic constitution of the host. Furthermore, regulatory cytokines that can suppress fibrogenesis, such as interferon γ (IFN-γ) or IL-12, may play a role in modulating the response.

While the above description focuses on granuloma formation and fibrosis of the liver, similar processes occur in urinary schistosomiasis. Granuloma formation at the lower end of the ureters obstructs urinary flow, with subsequent development of hydroureter and hydronephrosis. Similar lesions in the urinary bladder cause the protrusion of papillomatous structures into its cavity; these may ulcerate and/or bleed. The chronic stage of infection is associated with scarring and deposition of calcium in the bladder wall.

Immunomodulation is an essential mechanism in shaping the clinical and pathologic outcome of schistosomiasis. While most detailed immunologic analyses have been performed in experimental animals, enough evidence exists from studies in humans to delineate the suppression of T cell responses in association with active infections and a regulatory role for IL-10.

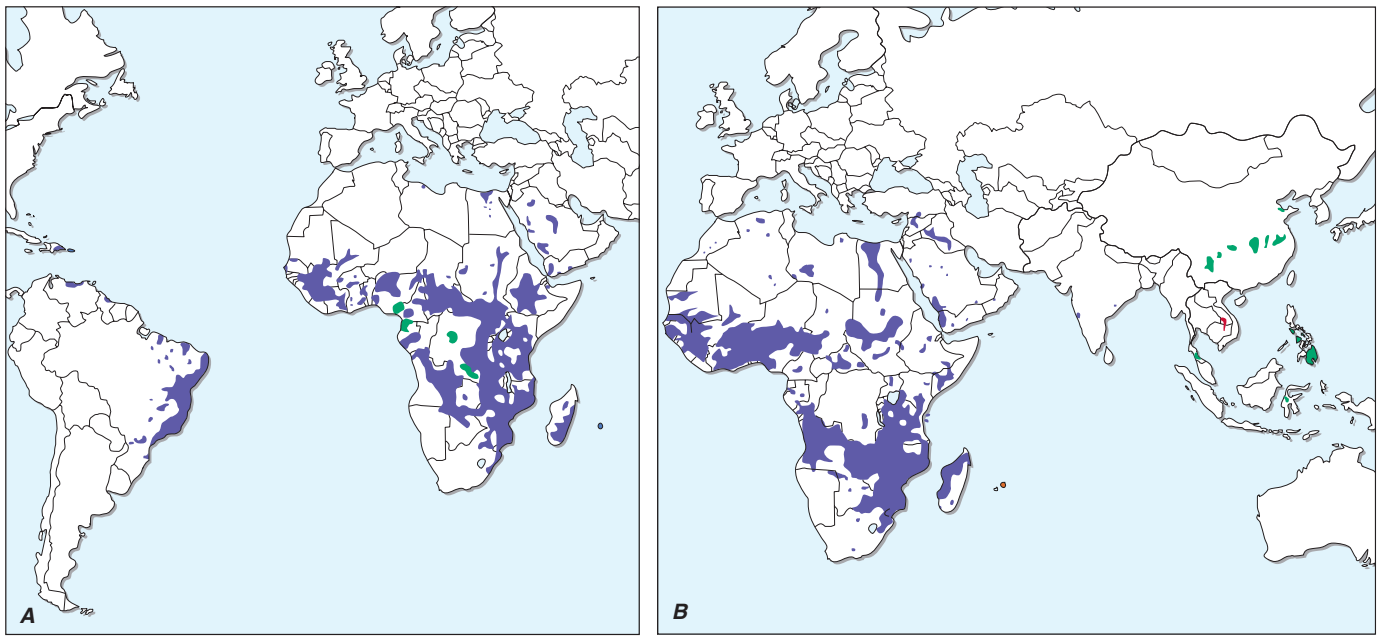

FIGURE 203-2 Global distribution of schistosomiasis. *A. S. mansoni* infection (*dark blue*) is endemic in Africa, the Middle East, South America, and a few Caribbean countries. *S. intercalatum* infection (*green*) is endemic in sporadic foci in West and Central Africa. *B. S. haematobium* infection (*purple*) is endemic in Africa and the Middle East. The major endemic countries for *S. japonicum* infection (*green*) are China, the Philippines, and Indonesia. *S. mekongi* infection (*red*) is endemic in sporadic foci in Southeast Asia.

Studies on immunity to schistosomiasis, whether innate or acquired, have expanded our knowledge of the components of these responses and the target antigens. The concept of innate immunity is illustrated by the inability of avian schistosomes, which cause swimmers' itch, to reach maturity in humans. The critical question, however, is whether humans acquire immunity to schistosomes. Epidemiologic evidence suggests the onset of acquired immunity during the course of infection in young adults. Curative treatment of infection divides populations in endemic areas into those who acquire reinfection rapidly (susceptible) and those who follow a protracted course (resistant). This difference may be explained by differences in transmission, immunologic response, or genetic susceptibility. The mechanism of acquired immunity involves antibodies, complement, and several effector cells, particularly eosinophils. Furthermore, the intensity of schistosome infection has been correlated with a region in chromosome 5. In several recent studies, a few protective schistosome antigens have been identified as vaccine candidates, but none has been evaluated in human populations to date.

CLINICAL FEATURES In general, disease manifestations of schistosomiasis occur in three stages, which vary not only by species but also by intensity of infection and other host factors, such as age and genetics. During the phase of cercarial invasion, a form of dermatitis may be observed. This so-called swimmers' itch occurs most often with *S. mansoni* and *S. japonicum* infections, manifesting 2 or 3 days after invasion as an itchy maculopapular rash on the affected areas of the skin. The condition is particularly severe when humans are exposed to avian schistosomes. This form of cercarial dermatitis is seen around the freshwater lakes in the northern United States, particularly in the spring. Cercarial dermatitis is a self-limiting clinical entity. During worm maturation and at the beginning of oviposition (i.e., 4 to 8 weeks after skin invasion), acute schistosomiasis or Katayama fever—a serum sickness–like syndrome with fever, generalized lymphadenopathy, and hepatosplenomegaly—may develop. Individuals suffering from acute schistosomiasis show a high degree of peripheral blood eosinophilia. Parasite-specific antibodies may be detected before schistosome eggs are identified in excreta. Acute schistosomiasis has become an important clinical entity worldwide because of increased travel to endemic areas. Travelers are exposed to parasites while swimming or wading in freshwater bodies and upon their return present with the acute manifestations. The course of acute schistosomiasis is generally benign, but deaths are occasionally reported in association with heavy exposure to schistosomes.

The main clinical manifestations of chronic schistosomiasis are species-dependent. Intestinal species (*S. mansoni*, *S. japonicum*, *S. mekongi*, and *S. intercalatum*) cause intestinal and hepatosplenic disease as well as several manifestations associated with portal hypertension. During the intestinal phase, which may begin a few months after infection and may last for years, symptomatic patients characteristically have colicky abdominal pain and bloody diarrhea. Patients may also report fatigue and an inability to perform daily routine functions and may show evidence of growth retardation. The severity of intestinal schistosomiasis is often related to the intensity of the worm burden. The disease runs a chronic course but rarely progresses to a functional level (e.g., malabsorption) or to anatomical lesions of the gut. The exception is colonic polyposis, which has been seen in some endemic areas, such as Egypt.

The hepatosplenic phase of disease manifests early (during the first year of infection, particularly in children) with enlargement of the liver due to parasite-induced granulomatous lesions. Hepatomegaly is seen in ~15 to 20% of infected individuals; it correlates roughly with intensity of infection, occurs more often in children, and may be related to specific HLA haplotypes. In subsequent phases of infection, presinusoidal blockage of blood flow leads to portal hypertension and splenomegaly. Moreover, portal hypertension may lead to varices at the lower end of the esophagus and at other sites. Patients with schistosomal liver disease may have right-upper-quadrant "dragging" pain during the hepatomegaly phase, and this pain may move to the left upper quadrant as splenomegaly progresses. Bleeding from esophageal varices may, however, be the first clinical manifestation of this phase. Patients may experience repeated bleeding but seem to tolerate its impact, since an adequate total hepatic blood flow permits normal liver function for a considerable period in schistosomal hepatomegaly. In late-stage disease, typical fibrotic changes occur along with liver function deterioration and the onset of ascites, hypoalbuminemia, and defects in coagulation. Intercurrent viral infections of the liver (especially hepatitis B and C) or nutritional deficiencies may well accelerate or exacerbate the deterioration of hepatic function.

The extent and severity of intestinal and hepatic disease in schistosomiasis mansoni and japonica have been well described. While it was originally thought that *S. japonicum* might induce more severe disease manifestations because the adult worms can produce ten times more eggs than *S. mansoni*, subsequent field studies have not supported this claim. Clinical observations of individuals infected with *S. mekongi* or *S. intercalatum* have been less detailed, partly because of the far more limited geographic distribution of these organisms.

The clinical manifestations of *S. haematobium* infection occur relatively early and involve a relatively high percentage of individuals. Up to 80% of children infected with *S. haematobium* have dysuria, frequency, and hematuria, which may be terminal. Urine examination reveals blood and albumin as well as an unusually high frequency of bacterial urinary tract infection and urinary sediment cellular metaplasia. These manifestations correlate with intensity of infection, the presence of urinary bladder granulomas, and subsequent ulceration. Along with the local effects of granuloma formation in the urinary bladder, obstruction of the lower end of the ureters results in hydroureter and hydronephrosis, which can be seen in 25 to 50% of infected children. As infection progresses, bladder granulomas undergo fibrosis; the result is the presence of typical sandy patches visible on cystoscopy. In many endemic areas, an association between squamous cell carcinoma of the bladder and *S. haematobium* infection has been observed. Such malignancy is detected in a younger age group than is transitional cell carcinoma. In fact, *S. haematobium* has now been classified as a human carcinogen.

Significant disease may occur in other organs during chronic schistosomiasis. Most important is disease in the lungs and central nervous system (CNS); other locations, such as the skin and the genital organs, are far less frequently affected. In pulmonary schistosomiasis, embolized eggs lodge in small arterioles, producing acute necrotizing arteriolitis and granuloma formation. During *S. mansoni* and *S. japonicum* infection, schistosome eggs reach the lungs after the development of portosystemic collateral circulation; in *S. haematobium* infection, ova may reach the lungs directly via connections between the vesical and systemic circulation. After the development of arteriolitis and granuloma formation, fibrous tissue deposition is detected and leads to endarteritis obliterans, pulmonary hypertension, and cor pulmonale. This clinical entity is an uncommon presentation during chronic schistosomiasis. The most frequent symptoms are cough, fever, and dyspnea; ascites and hemoptysis are less frequently encountered. Cor pulmonale may be diagnosed radiologically on the basis of prominent right side of the heart and dilation of the pulmonary artery. Frank evidence of right-sided heart failure may be seen in late cases.

CNS schistosomiasis is important but less common than pulmonary schistosomiasis. It characteristically occurs as cerebral disease due to *S. japonicum* infection. Migratory worms deposit eggs in the brain and induce a granulomatous response. The frequency of this manifestation among infected individuals in some endemic areas (e.g., the Philippines) is calculated at 2 to 4%. Jacksonian epilepsy due to *S. japonicum* infection is the second most common cause of epilepsy in these areas. *S. mansoni* and *S. haematobium* infections have been associated with transverse myelitis. This syndrome is thought to be due to eggs traveling to the venous plexus around the spinal cord. In schistosomiasis mansoni, transverse myelitis is usually seen in the chronic stage after the development of portal hypertension and portosystemic shunts, which allow ova to travel to the spinal cord veins. This proposed sequence of events has been challenged because of a few reports of transverse myelitis occurring early in the course of *S. mansoni* infection. More information is needed to confirm these observations. During schistosomiasis haematobia, ova may travel through communication between vesical and systemic veins, resulting in spinal cord disease that may be detected at any stage of infection. Pathologic study of lesions in schistosomal transverse myelitis may reveal eggs along with necrotic or granulomatous lesions. Patients usually present with acute or rapidly progressing lower-leg weakness accompanied by sphincter dysfunction.

DIAGNOSIS Physicians in areas not endemic for schistosomiasis face considerable diagnostic challenges. In the most common clinical presentation, a traveler returns with symptoms and signs of acute syndromes of schistosomiasis—namely, cercarial dermatitis or Katayama fever. Central to correct diagnosis is a thorough inquiry into travel history and exposure to freshwater bodies, whether slow or fast running. Differential diagnosis of fever in returned travelers includes a spectrum of infections whose etiologies are viral (e.g., Dengue fever), bacterial (e.g., enteric fever, leptospirosis), rickettsial, or protozoal (e.g., malaria). In cases of Katayama fever, prompt diagnosis is essential and is based on clinical presentation, high-level peripheral blood eosinophilia, and a positive serologic assay for schistosomal antibodies. Two tests are available at the CDC: the Falcon assay screening test/enzyme-linked immunosorbent assay (FAST-ELISA) and the confirmatory enzyme-linked immunoelectrotransfer blot (EITB). Both tests are highly sensitive and ~96% specific. In some instances, examination of stool or urine for ova may yield positive results.

Individuals with established infection are diagnosed by a combination of geographic history, characteristic clinical presentation, and presence of schistosome ova in excreta. The diagnosis may also be established with the serologic assays mentioned above or with those that detect circulating schistosome antigens. These assays can be applied either to blood or to other body fluids (e.g., cerebrospinal fluid). For stool examination, the Kato thick smear or any other concentration method generally identifies all but the most lightly infected individuals. Urine may be examined by microscopy of sediment or by filtration of a known volume through Nuclepore filters. Kato thick smear and Nuclepore filtration provide quantitative data on the intensity of infection, which is of value in assessing the degree of tissue damage and in monitoring the effect of chemotherapy. Finally, schistosome infection may be diagnosed by examination of tissue samples, typically rectal biopsies; other biopsy procedures (e.g., liver biopsy) are not needed, except in special circumstances.

Differential diagnosis of schistosomal hepatomegaly must include viral hepatitis of all etiologies, miliary tuberculosis, malaria, visceral leishmaniasis, ethanol abuse, and causes of hepatic and portal vein obstruction. Of patients with these conditions, only a few may present with organomegaly and relatively intact liver function. The differential diagnosis of hematuria in *S. haematobium* infection includes bacterial cystitis, tuberculosis, urinary stones, and malignancy.

Rx TREATMENT

Treatment of schistosomiasis depends on the stage of infection and the clinical presentation. Other than topical dermatologic applications for relief of itching, no specific treatment is indicated for cercarial dermatitis caused by avian schistosomes. Therapy for acute schistosomiasis or Katayama fever needs to be adjusted appropriately for each case. While antischistosomal chemotherapy is indicated, it does not address immediate pathologic changes. In severe acute schistosomiasis, management in an acute-care setting is necessary, with supportive measures and consideration of glucocorticoid treatment. Once the acute critical phase is over, specific chemotherapy is indicated. For all individuals with infection established by either the demonstration of schistosome eggs or positive serology, treatment to eradicate the parasite should be administered. The drug of choice is praziquantel, which—depending on the infecting species (Table 203-2)—is administered orally as 40 or 60 mg/kg in two or three doses over a single day. Praziquantel treatment results in parasitologic cure in ~85% of cases and reduces egg counts by >90%. Few side effects have been encountered, and those that do develop usually do not interfere with completion of treatment. The dependence on a single chemotherapeutic agent has raised the possibility of the development of resistance in the schistosomes; to date, such resistance does not seem to be clinically significant. Other antischistosomal chemotherapeutic agents are cur-

TABLE 203-2 *Drug Therapy for Human Trematode Infections*

Infection	Drug of Choice	Adult Dose and Duration
BLOOD FLUKES		
S. mansoni, *S. intercalatum*, *S. haematobium*	Praziquantel	20 mg/kg, 2 doses in 1 day
S. japonicum, *S. mekongi*	Praziquantel	20 mg/kg, 3 doses in 1 day
BILIARY (HEPATIC) FLUKES		
C. sinensis, *O. viverrini*, *O. felineus*	Praziquantel	25 mg/kg, 3 doses in 1 day
F. hepatica, *F. gigantica*	Triclabendazole	10 mg/kg once
INTESTINAL FLUKES		
F. buski, *H. heterophyes*	Praziquantel	25 mg/kg, 3 doses in 1 day
LUNG FLUKES		
P. westermani	Praziquantel	25 mg/kg, 3 doses per day for 2 days

rently considered only as alternatives when praziquantel is unavailable. The effect of antischistosomal treatment on disease manifestations varies by stage. Early hepatomegaly and bladder lesions are known to resolve following chemotherapy, but the late established manifestations, such as fibrosis, do not change. Additional management modalities are needed for individuals with other manifestations, such as hepatocellular failure or recurrent hematemesis. The use of these interventions is guided by general medical and surgical principles.

PREVENTION AND CONTROL Since transmission of schistosomiasis is dependent on human behavior, it is theoretically possible to devise an effective preventive strategy. The geographic distribution of infections in endemic regions of the world is not clearly demarcated. It is therefore prudent for travelers to avoid contact with all freshwater bodies, irrespective of the speed of water flow or unsubstantiated claims of safety. Some topical agents, when applied to the skin, may conceivably inhibit cercarial penetration, but none of these agents is currently available. If exposure occurs, a follow-up visit with a health care provider is strongly recommended. Prevention of infection in inhabitants of endemic areas is a significant challenge. People of these regions use freshwater bodies for sanitary, domestic, recreational, and agricultural purposes. Several control measures have been used, including application of molluscicides, provision of sanitary water and means for sewage disposal, chemotherapy, and health education. Current recommendations to countries endemic for schistosomiasis emphasize the use of multiple approaches. Particularly with the advent of an oral, safe, and effective antischistosomal agent, chemotherapy has been most successful in reducing the intensity of infection and reversing disease. The duration of this positive impact depends on transmission dynamics of the parasite in any specific endemic region. The ultimate goal of research on prevention and control is the development of a vaccine. Although there are a few promising leads, this goal is probably not within reach during the next decade or so.

LIVER (BILIARY) FLUKES

Several species of biliary fluke infecting humans are particularly common in Southeast Asia and Russia. Other species are transmitted in Europe, Africa, and the Americas. On the basis of their migratory pathway in humans, these infections may be divided into the *Clonorchis* and *Fasciola* groups (Table 203-1).

CLONORCHIASIS AND OPISTHORCHIASIS Infection with *Clonorchis sinensis*, the Chinese or oriental fluke, is endemic among fish-eating mammals in Southeast Asia. Humans are an incidental host; the prevalence of human infection is highest in China, Vietnam, and Korea. Infection with *Opisthorchis viverrini* and *O. felineus* is zoonotic in cats and dogs. Transmission to humans occurs occasionally, particularly in Thailand (*O. viverrini*) and in Southeast Asia and eastern Europe (*O. felineus*). Data on the exact geographic distribution of these infectious agents in human populations are rudimentary.

Infection with any of these three species is established by ingestion of raw or inadequately cooked freshwater fish harboring metacercariae. These organisms excyst in the duodenum, releasing larvae that travel through the ampulla of Vater and mature into adult worms in the bile canaliculi. Mature flukes are flat and elongated, measuring 1 to 2 cm in length. The hermaphroditic worms reproduce by releasing small operculated eggs, which pass with bile into the intestines and are voided with stools. The life cycle is completed in the environment in specific freshwater snails (the first intermediate host) and encystment of metacercariae in freshwater fish.

Except for late sequelae, the exact clinical syndromes caused by clonorchiasis and opisthorchiasis are not well defined. Since most infected individuals harbor a low worm burden, many are asymptomatic. Moderate to heavy infection may be associated with vague right-upper-quadrant pain. In contrast, chronic or repeated infection is associated with manifestations such as cholangitis, cholangiohepatitis, and biliary obstruction. Cholangiocarcinoma is epidemiologically related to *C. sinensis* infection in China and to *O. viverrini* infection in northeastern Thailand. This association has resulted in the classification of these infectious agents as human carcinogens.

FASCIOLIASIS Infections with *Fasciola hepatica* and *F. gigantica* are worldwide zoonoses that are particularly endemic in sheep-raising countries. Human cases have been reported in South America, Europe, Africa, Australia, and the Far East. Recent estimates indicate a worldwide prevalence of 17 million cases. High endemicity has been reported in certain areas of Peru and Bolivia. In most endemic areas the predominant species is *F. hepatica*, but in Asia and Africa a varying degree of overlap with *F. gigantica* has been observed.

Humans acquire fascioliasis by ingestion of metacercariae attached to certain aquatic plants, such as watercress. Infection may also be acquired by consumption of contaminated water or ingestion of food items washed with such water. Acquisition of human infection through consumption of freshly prepared raw liver containing immature flukes has been reported. Infection is initiated when metacercariae excyst, penetrate the gut wall, and travel through the peritoneal cavity to invade the liver capsule. Adult worms finally reach the bile ducts, where they produce large operculated eggs, which are voided in the bile and through the gastrointestinal tract to the outside environment. The flukes' life cycle is completed in specific snails (the first intermediate host) and encystment on aquatic plants.

The clinical features of fascioliasis relate to the stage and intensity of infection. Acute disease develops during the parasites' migration (1 to 2 weeks after infection) and includes fever, right-upper-quadrant pain, hepatomegaly, and eosinophilia. Computed tomography of the liver may show migratory tracks. Symptoms and signs usually subside as the parasites reach their final habitat. In individuals with chronic infection, bile duct obstruction and biliary cirrhosis are infrequently demonstrated. No relation to hepatic malignancy has been ascribed to fascioliasis.

DIAGNOSIS The diagnosis of infection with any of the biliary flukes depends on a high degree of suspicion, the elicitation of an appropriate geographic history, and stool examination for the characteristically shaped parasite ova. Additional evidence may be obtained by documenting peripheral blood eosinophilia or imaging the liver. Serologic testing is helpful, particularly in lightly infected individuals.

℞ TREATMENT

Drug therapy (praziquantel or triclabendazole) is summarized in Table 203-2. Patients with anatomical lesions in the biliary tract or malignancy are managed according to general medical guidelines.

INTESTINAL FLUKES

Two species of intestinal flukes cause human infection in defined geographic areas worldwide (Table 203-1). The large *Fasciolopsis buski* (adults measure 2 by 7 cm) is endemic in Southeast Asia, while the smaller *Heterophyes heterophyes* is found in the Nile Delta of Egypt and in the Far East. Infection is initiated by ingestion of metacercariae attached to aquatic plants (*F. buski*) or encysted in freshwater or brackish-water fish (*H. heterophyes*). Flukes mature in human intestines, and eggs are passed with stools. Most individuals infected with intestinal flukes are asymptomatic. In heavy *F. buski* infection, diarrhea, abdominal pain, and malabsorption may be encountered. Heavy infection with *H. heterophyes* may be associated with abdominal pain and mucous diarrhea. The diagnosis is established by detection of the characteristically shaped ova in stool samples. The drug of choice for treatment is praziquantel (Table 203-2).

LUNG FLUKES

Infection with the lung fluke *Paragonimus westermani* (Table 203-1) and related species (e.g., *P. africanus*) is endemic in many parts of the world, excluding North America and Europe. Endemicity is particularly noticeable in West Africa, Central and South America, and Asia. In nature, the reservoir hosts of *P. westermani* are wild and domestic felines. In Africa, *P. africanus* has been found in other species, such as dogs. Adult lung flukes, which are 7 to 12 mm in length, are found encapsulated in the lungs of infected persons. In rare circumstances, flukes are found encysted in the CNS (cerebral paragonimiasis) or abdominal cavity. Humans acquire lung fluke infection by ingesting infective metacercariae encysted in the muscles and viscera of crayfish and freshwater crabs. In endemic areas, these crustaceans are consumed either raw or pickled. Once the organisms reach the duodenum, they excyst, penetrate the gut wall, and travel through the peritoneal cavity, diaphragm, and pleural space to reach the lungs. Mature flukes are found in the bronchioles surrounded by cystic lesions. Parasite eggs are either expectorated with sputum or swallowed and passed to the outside environment with feces. The life cycle is completed in snails and freshwater crustacea.

When maturing flukes lodge in lung tissues, they cause hemorrhage and necrosis, resulting in cyst formation. The adjacent lung parenchyma shows evidence of inflammatory infiltration, predominantly by eosinophils. Cysts usually measure 1 to 2 cm in diameter and may contain 1 or 2 worms each. With the onset of oviposition, cysts usually rupture in adjacent bronchioles—an event allowing ova to exit from the human host. Older cysts develop thickened walls, which may undergo calcification. During the active phase of paragonimiasis, lung tissues surrounding parasite cysts may contain evidence of pneumonia, bronchitis, bronchiectasis, and fibrosis.

Pulmonary paragonimiasis is particularly symptomatic in persons with moderate to heavy infection. Productive cough with brownish sputum or frank hemoptysis associated with peripheral blood eosinophilia is usually the presenting feature. Chest examination may reveal signs of pleurisy. In chronic cases, bronchitis or bronchiectasis may predominate, but these conditions rarely proceed to lung abscess. Imaging of the lungs demonstrates characteristic features, including patchy densities, cavities, pleural effusion, and ring shadows. Cerebral paragonimiasis presents as either space-occupying lesions or epilepsy.

DIAGNOSIS Pulmonary paragonimiasis is diagnosed by the detection of parasite ova in sputum and/or stools. Serology is of considerable help in egg-negative cases and in cerebral paragonimiasis.

TREATMENT

The drug of choice for treatment is praziquantel (Table 203-2). Other medical or surgical management may be needed for pulmonary or cerebral lesions.

CONTROL AND PREVENTION OF TISSUE FLUKES

For residents of nonendemic areas who are visiting an endemic region, the only effective preventive measure is to avoid ingestion of local plants, fish, or crustaceans; if their ingestion is necessary, these items should be washed or cooked thoroughly. Instruction on water and food preparation and consumption should be included in physicians' advice to travelers (Chap. 108). Interruption of transmission among residents of endemic areas depends on avoiding ingestion of the infective stage of the helminths and appropriate disposal of feces and sputum to prevent the hatching of eggs in the environment. These two approaches rely greatly on socioeconomic development and health education. In countries where economic progress has resulted in financial and social improvements, transmission has decreased. The third approach to control in endemic communities entails selective use of chemotherapy for individuals posing the highest risk of transmission—i.e., those with heavy infections. The availability of praziquantel—a broad-spectrum, safe, and effective anthelmintic agent—provides a means for reducing the reservoirs of infection in human populations. However, the existence of most of these helminths as zoonoses in several animal species complicates control efforts.

204 CESTODES

A. Clinton White, Jr., Peter F. Weller

Cestodes, or tapeworms, are segmented worms. The adults reside in the gastrointestinal tract, but the larvae can be found in almost any organ. Human tapeworm infections can be divided into two major clinical groups. In one group, humans are the definitive hosts, with the adult tapeworms living in the gastrointestinal tract (*Taenia saginata*, *Diphyllobothrium*, *Hymenolepis*, and *Dipylidium caninum*). In the other, humans are intermediate hosts, with larval-stage parasites present in the tissues. Diseases in this category include echinococcosis, sparganosis, and coenurosis. For *Taenia solium*, the human may be either the definitive or the intermediate host.

The ribbon-shaped tapeworm attaches to the intestinal mucosa by means of sucking cups or hooks located on the scolex. Behind the scolex is a short, narrow neck from which proglottids (segments) form. As each proglottid matures, it is displaced further back from the neck by the formation of new, less mature segments. The progressively elongating chain of attached proglottids, called the *strobila*, constitutes

the bulk of the tapeworm. The length varies among species. In some, the tapeworm may consist of more than 1000 proglottids and may be several meters long. The mature proglottids are hermaphroditic and produce eggs, which are intermittently released. Since eggs of the different *Taenia* species are morphologically identical, differences in the morphology of the scolex or proglottids provide the basis for diagnostic identification to the species level. Most human tapeworms require at least one intermediate host for complete larval development. After ingestion of the eggs or proglottids by an intermediate host, the larval oncospheres are activated, escape the egg, and penetrate the intestinal mucosa. The oncosphere migrates to tissues and develops into an encysted form known as a *cysticercus* (single scolex), a *coenurus* (multiple scolices), or a *hydatid* (cyst with daughter cysts, each containing several protoscolices). Ingestion by the definitive host of tissues containing a cyst enables a scolex to develop into a tapeworm.

TAENIASIS SAGINATA The beef tapeworm *T. saginata* occurs in all countries where raw or undercooked beef is eaten. It is most prevalent in sub-Saharan African and Middle Eastern countries. *T. saginata asiatica* is a variant of *T. saginata* that is found in Asia and for which pigs are the intermediate host.

Etiology and Pathogenesis Humans are the only definitive host for the adult stage of *T. saginata*. This tapeworm, which can reach 8 m in length, inhabits the upper jejunum and has a scolex with four prominent suckers and 1000 to 2000 proglottids. Each gravid segment has 15 to 30 uterine branches (in contrast to 8 to 12 for *T. solium*). The eggs are indistinguishable from those of *T. solium*; they measure 30 to 40 μm, contain the oncosphere, and have a thick brown striated shell. Eggs deposited on vegetation can live for months to years until they are ingested by cattle or other herbivores. The embryo released after ingestion invades the intestinal wall and is carried to striated muscle, where it transforms into a cysticercus. When ingested in raw or undercooked beef, this form can infect humans. After the cysticercus is ingested, it takes ~2 months for the mature adult worm to develop.

Clinical Manifestations Patients become aware of the infection most commonly by noting passage of proglottids in their feces. The proglottids are often motile, and patients may experience perianal discomfort when proglottids are discharged. Mild abdominal pain or discomfort, nausea, change in appetite, weakness, and weight loss can occur with *T. saginata* infection.

Diagnosis The diagnosis is made by the detection of eggs or proglottids in the stool. Eggs may also be present in the perianal area; thus, if proglottids or eggs are not found in the stool, the perianal region should be examined with use of a cellophane-tape swab (as in pinworm infection; Chap. 201). Distinguishing *T. saginata* from *T. solium* requires examination of mature proglottids or the scolex. Serologic tests are not helpful diagnostically. Eosinophilia and elevated levels of serum IgE may be detected.

℞ TREATMENT

A single dose of praziquantel (10 mg/kg) is highly effective.

Prevention The major method of preventing infection is the adequate cooking of beef; exposure to temperatures as low as 56°C for 5 min will destroy cysticerci. Refrigeration or salting for long periods or freezing at −10°C for 9 days also kills cysticerci in beef. General preventive measures include inspection of beef and proper disposal of human feces.

TAENIASIS SOLIUM AND CYSTICERCOSIS The pork tapeworm *T. solium* can cause two distinct forms of infection. The form that develops depends on whether humans are infected with adult tapeworms in the intestine or with larval forms in the tissues (cysticercosis). Humans are the only definitive hosts for *T. solium*; pigs are the usual intermediate hosts, although other animals may harbor the larval forms. *T. solium* exists worldwide but is most prevalent in Latin America, sub-Saharan Africa, China, southern and Southeast Asia, and eastern Europe. Cysticercosis occurs in industrialized nations largely as a result of the immigration of infected persons from endemic areas.

Etiology and Pathogenesis The adult tapeworm generally resides in the upper jejunum. The scolex attaches by both sucking disks and two rows of hooklets. Often only one adult worm is present, but that worm may live for years. The tapeworm, usually about 3 m in length, may have as many as 1000 proglottids, each of which produces up to 50,000 eggs. Groups of three to five proglottids are generally released and excreted into the feces, and the eggs in these proglottids are infective for both humans and animals. The eggs may survive in the environment for several months. After ingestion of eggs by the intermediate host, the larvae are activated, escape the egg, penetrate the intestinal wall, and are carried to many tissues, with a predilection for striated muscle of the neck, tongue, and trunk. Within 60 to 90 days, the encysted larval stage develops. These cysticerci can survive for months to years. Humans acquire infections that lead to intestinal tapeworms by ingesting undercooked pork containing cysticerci. Infections that cause human cysticercosis follow the ingestion of *T. solium* eggs, usually from close contact with a tapeworm carrier. Autoinfection may occur if an individual with an egg-producing tapeworm ingests eggs derived from his or her own feces.

Clinical Manifestations Intestinal infections with *T. solium* may be asymptomatic. Epigastric discomfort, nausea, a sensation of hunger, weight loss, and diarrhea are infrequent. Fecal passage of proglottids may be noted by patients.

In cysticercosis, the clinical manifestations are variable. Cysticerci can be found anywhere in the body but are most commonly detected in the brain, skeletal muscle, subcutaneous tissue, or eye. The clinical presentation of cysticercosis depends on the number and location of cysticerci as well as the extent of associated inflammatory responses or scarring. Neurologic manifestations are the most common (Fig. 204-1). Seizures are associated with inflammation surrounding cysticerci in the brain parenchyma. These seizures may be generalized, focal, or Jacksonian. Hydrocephalus results from obstruction of cerebrospinal fluid (CSF) flow by cysticerci and accompanying inflammation or by CSF outflow obstruction from arachnoiditis. Signs of increased intracranial pressure, including headache, nausea, vomiting, changes in vision, dizziness, ataxia, or confusion, are often evident. Patients with hydrocephalus may develop papilledema or display altered mental status. When cysticerci develop at the base of the brain or in the subarachnoid space, they may cause chronic meningitis or arachnoiditis, communicating hydrocephalus, or strokes.

Diagnosis The diagnosis of intestinal *T. solium* infection is made by the detection of eggs or proglottids, as described for *T. saginata*. In cysticercosis, diagnosis can be difficult. A consensus conference has proposed absolute, major, minor, and epidemiologic criteria for diagnosis (Table 204-1). Diagnostic certainty is possible only with definite demonstration of the parasite (absolute criteria). This task can be accomplished by histologic observation of the parasite in excised tissue, by funduscopic visualization of the parasite in the eye (in the anterior chamber, vitreous, or subretinal spaces), or by neuroimaging studies demonstrating cystic lesions containing a characteristic scolex. In most cases, diagnostic certainty is not possible. Instead, a clinical diagnosis is made on the basis of a combination of clinical presentation, radiographic studies, serologic tests, and exposure history.

Neuroimaging findings suggestive of neurocysticercosis constitute the primary major diagnostic criterion. These findings include cystic lesions with or without enhancement (e.g., ring enhancement), one or more nodular calcifications (which may also have associated enhancement), or focal enhancing lesions. Cysticerci in the brain parenchyma are usually 5 to 20 mm in diameter and rounded. Cystic lesions in the subarachnoid space or fissures may enlarge up to 6 cm in diameter and may be lobulated. For cysticerci within the subarachnoid space or ventricles, the walls may be very thin and the cyst fluid is often isodense

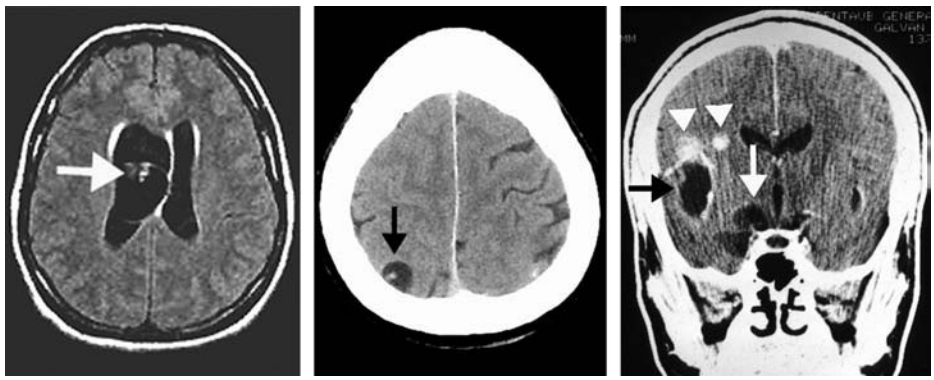

FIGURE 204-1 Neurocysticercosis is caused by *Taenia solium*. Neurologic infection can be classified on the basis of the location and viability of the parasites. When the parasites are in the ventricles, they often cause obstructive hydrocephalus. *Left*: MRI scan showing a cysticercus in the lateral ventricle, with resultant hydrocephalus. The arrow points to the scolex within the cystic parasite. *Center*: CT scan showing a parenchymal cysticercus, with enhancement of the cyst wall and an internal scolex (*arrow*). *Right*: Multiple cysticerci, including calcified lesions from prior infection (*arrowheads*), viable cysticerci in the basilar cisterns (*white arrow*), and a large degenerating cysticercus in the Sylvian fissure (*black arrow*). (*Modified with permission from JC Bandres et al: Clin Infect Dis 15:799, 1992. The University of Chicago Press.*)

with CSF. Thus, obstructive hydrocephalus or enhancement of the basilar meninges may be the only finding on computed tomography (CT) in extraparenchymal neurocysticercosis. Cysticerci in the ventricles or subarachnoid space are usually visible to an experienced neuroradiologist on magnetic resonance imaging (MRI) or on CT with intraventricular contrast injection. CT is more sensitive than MRI in identifying calcified lesions, whereas MRI is better for identifying cystic lesions and enhancement.

The second major diagnostic criterion is detection of specific antibodies to cysticerci. While most tests employing unfractionated antigen have high rates of false-positive and false-negative results, this problem can be overcome by using the more specific immunoblot assay. An immunoblot assay using lentil-lectin purified glycoproteins has >99% specificity and is highly sensitive. However, patients with single intracranial lesions or with calcifications may be seronegative. With this assay, serum samples provide greater diagnostic sensitivity than CSF. CSF may be useful when only unfractionated antigens are used. Antigen detection assays, especially those detecting antigen in the spinal fluid, may also improve diagnosis. However, these assays are not widely available, and the number of publications on their use is limited.

Studies have demonstrated that clinical criteria can aid in the diagnosis in selected cases. In patients from endemic areas who had single enhancing lesions presenting with seizures, a normal physical examination, and no evidence of systemic disease (e.g., no fever, adenopathy, or abnormal chest radiograph), the constellation of rounded CT lesions 5 to 20 mm in diameter with no midline shift was almost always caused by neurocysticercosis. Finally, spontaneous resolution or resolution after therapy with albendazole alone is consistent with neurocysticercosis.

Minor diagnostic criteria include neuroimaging findings consistent with but less characteristic of cysticercosis, clinical manifestations suggestive of neurocysticercosis (e.g., seizures, hydrocephalus, or altered mental status), evidence of cysticercosis outside the central nervous system (e.g., cigar-shaped soft tissue calcifications), or antibody in CSF detected by enzyme-linked immunosorbent assay (ELISA). Epidemiologic criteria include exposure to a tapeworm carrier or household member infected with *T. solium*, current or prior residence in an endemic area, and frequent travel to an endemic area.

Diagnosis is confirmed in patients with either one absolute criterion or a combination of two major criteria, one minor criterion, and one epidemiologic criterion (Table 204-1). A probable diagnosis is supported by the fulfillment of (1) one major criterion plus two minor criteria; (2) one major criterion plus one minor criterion and one epidemiologic criterion; or (3) three minor criteria plus one epidemiologic criterion. While the CSF is usually abnormal in neurocysticercosis, CSF abnormalities are not pathognomonic. Patients may have CSF pleocytosis with a predominance of lymphocytes, neutrophils, or eosinophils. The protein level in CSF may be elevated; the glucose concentration is usually normal but may be depressed.

TREATMENT

Intestinal *T. solium* infection is treated with a single dose of praziquantel (10 mg/kg). However, praziquantel can evoke an inflammatory response in the central nervous system if concomitant cryptic cysticercosis is present. Niclosamide (2 g) is also effective but is not widely available.

The management of neurocysticercosis focuses primarily on symptom-based treatment of seizures or hydrocephalus. Seizures can usually be controlled with antiepileptics. If parenchymal lesions resolve without development of calcifications and patients remain free of seizures, antiepileptic therapy can usually be discontinued after 2 years. Five placebo-controlled trials failed to identify any clinical advantage of antiparasitic drugs for parenchymal neurocysticercosis. However, trends toward faster resolution of neuroradiologic abnormalities were observed. Thus, some authorities favor use of antiparasitic drugs, including praziquantel (50 to 60 mg/kg daily in three divided doses for 15 days or 100 mg/kg in three doses given over a single day) or albendazole (15 mg/kg per day for 8 to 28 days). Both agents may exacerbate the inflammatory response around the dying parasite, exacerbating seizures or hydrocephalus. Thus, patients receiving these drugs should be carefully monitored. High-dose glucocorticoids can be used during treatment or if symptoms worsen. Since glucocorticoids induce first-pass metabolism of praziquantel and may decrease its antiparasitic effect, cimetidine should be coadministered to inhibit praziquantel metabolism.

For patients with hydrocephalus, the emergent reduction of intracranial pressure is the mainstay of therapy. In the case of obstructive hydrocephalus, the preferred approach is removal of the cysticercus via endoscopic surgery. However, this intervention is not always possible. An alternative approach is initially to perform a diverting procedure, such as ventriculoperitoneal shunting. Historically, shunts

TABLE 204-1 Proposed Diagnostic Criteria for Human Cysticercosis, 2001

1. Absolute criteria
   a. Demonstration of cysticerci by histologic or microscopic examination of biopsy material
   b. Visualization of the parasite in the eye by funduscopy
   c. Neuroradiologic demonstration of cystic lesions containing a characteristic scolex
2. Major criteria
   a. Neuroradiologic lesions suggestive of neurocysticercosis
   b. Demonstration of antibodies to cysticerci in serum by enzyme-linked immunoelectrotransfer blot
   c. Resolution of intracranial cystic lesions spontaneously or after therapy with albendazole or praziquantel alone
3. Minor criteria
   a. Lesions compatible with neurocysticercosis detected by neuroimaging studies
   b. Clinical manifestations suggestive of neurocysticercosis
   c. Demonstration of antibodies to cysticerci or cysticercal antigen in cerebrospinal fluid by ELISA
   d. Evidence of cysticercosis outside the central nervous system (e.g., cigar-shaped soft tissue calcifications)
4. Epidemiologic criteria
   a. Residence in a cysticercosis-endemic area
   b. Frequent travel to a cysticercosis-endemic area
   c. Household contact with an individual infected with *Taenia solium*

Note: ELISA, enzyme-linked immunosorbent assay.
Source: Modified from Del Brutto et al.

have usually failed, but low failure rates have recently been attained with treatment with antiparasitic drugs, chronic administration of glucocorticoids, or use of flow-sensitive shunts. Open craniotomy to remove the cysticerci is now required only infrequently. For patients with subarachnoid cysts or giant cysticerci, glucocorticoids are needed to reduce arachnoiditis and accompanying vasculitis. Most authorities recommend prolonged courses of antiparasitic drugs and shunting when hydrocephalus is present. In patients with cerebral edema and elevated intracranial pressure due to multiple inflamed lesions, glucocorticoids are the mainstay of therapy, and antiparasitic drugs should be avoided. For ocular and spinal medullary lesions, drug-induced inflammation may cause irreversible damage. Most patients should be managed surgically, although case reports have described cures with medical therapy.

Prevention Measures for the prevention of intestinal *T. solium* infection consist of the application to pork of precautions similar to those described above for beef with regard to *T. saginata* infection. The prevention of cysticercosis involves minimizing the opportunities for ingestion of fecally derived eggs by means of good personal hygiene, effective fecal disposal, and treatment and prevention of human intestinal infections.

ECHINOCOCCOSIS Echinococcosis is an infection caused in humans by the larval stage of *Echinococcus granulosus*, *E. multilocularis*, or *E. vogeli*. *E. granulosus*, which produces unilocular cystic lesions, is prevalent in areas where livestock is raised in association with dogs. This tapeworm species is found in Australia, Argentina, Chile, Africa, eastern Europe, the Middle East, New Zealand, and the Mediterranean region, particularly Lebanon and Greece. Molecular evidence suggests that *E. granulosus* strains may actually belong to more than one species; specifically, strains from sheep, cattle, pigs, horses, and camels probably represent separate species. *E. multilocularis*, which causes multilocular alveolar lesions that are locally invasive, is found in Alpine, sub-Arctic, or Arctic regions, including Canada, the United States, and central and northern Europe and Asia. *E. vogeli* causes polycystic hydatid disease and is found only in Central and South America. Like other cestodes, echinococcal species have both intermediate and definitive hosts. The definitive hosts are dogs that pass eggs in their feces. Cysts develop in the intermediate hosts—sheep, cattle, humans, goats, camels, and horses for *E. granulosus* and mice and other rodents for *E. multilocularis*—after the ingestion of eggs. When a dog ingests beef or lamb containing cysts, the life cycle is completed.

Etiology The small (5 mm long) adult *E. granulosus* worm, which lives for 5 to 20 months in the jejunum of dogs, has only three proglottids—one immature, one mature, and one gravid. The gravid segment splits to release eggs that are morphologically similar to *Taenia* eggs and are extremely hardy. After humans ingest the eggs, embryos escape from the eggs, penetrate the intestinal mucosa, enter the portal circulation, and are carried to various organs, most commonly the liver and lungs. Larvae develop into fluid-filled unilocular hydatid cysts that consist of an external membrane and an inner germinal layer. Daughter cysts develop from the inner aspect of the germinal layer, as do germinating cystic structures called *brood capsules*. New larvae, called *protoscolices*, develop in large numbers within the brood capsule. The cysts expand slowly over a period of years.

The life cycle of *E. multilocularis* is similar except that small rodents serve as the intermediate hosts. The larval form of *E. multilocularis*, however, is quite different in that it remains in the proliferative phase, the parasite is always multilocular, and vesicles without brood capsule or protoscolices progressively invade the host tissue by peripheral extension of processes from the germinal layer.

Clinical Manifestations Slowly enlarging echinococcal cysts generally remain asymptomatic until their expanding size or their space-occupying effect in an involved organ elicits symptoms. The liver and the lungs are the most common sites of these cysts. The liver is involved in about two-thirds of *E. granulosus* infections and in nearly all *E. multilocularis* infections. Since a period of years elapses before cysts enlarge sufficiently to cause symptoms, they may be discovered incidentally on a routine x-ray or ultrasound study.

Patients with hepatic echinococcosis who are symptomatic most often present with abdominal pain or a palpable mass in the right upper quadrant. Compression of a bile duct or leakage of cyst fluid into the biliary tree may mimic recurrent cholelithiasis, and biliary obstruction can result in jaundice. Rupture of or episodic leakage from a hydatid cyst may produce fever, pruritus, urticaria, eosinophilia, or anaphylaxis. Pulmonary hydatid cysts may rupture into the bronchial tree or peritoneal cavity and produce cough, chest pain, or hemoptysis. Rupture of hydatid cysts may lead to multifocal dissemination of protoscolices, which can form additional cysts. Rupture can occur spontaneously or at surgery. Other presentations are due to the involvement of bone (invasion of the medullary cavity with slow bone erosion producing pathologic fractures), the central nervous system (space-occupying lesions), the heart (conduction defects, pericarditis), and the pelvis (pelvic mass).

The larval forms of *E. multilocularis* characteristically present as a slowly growing hepatic tumor, with progressive destruction of the liver and extension into vital structures. Patients commonly complain of upper quadrant and epigastric pain, and obstructive jaundice may be apparent. The lesions may infiltrate adjoining organs (e.g., diaphragm, kidneys, or lungs) or may metastasize to the spleen, lungs, or brain.

Diagnosis Radiographic and related imaging studies are important in detecting and evaluating echinococcal cysts. Plain films will define pulmonary cysts of *E. granulosus*—usually as rounded masses of uniform density—but may miss cysts in other organs unless there is cyst wall calcification (as occurs in the liver). MRI, CT, and ultrasound reveal well-defined cysts with thick or thin walls. When older cysts contain a layer of hydatid sand that is rich in accumulated scolices, these imaging methods may detect this fluid layer of different density. However, the most pathognomonic finding, if demonstrable, is that of daughter cysts within the larger cyst. This finding, like eggshell or mural calcification on CT, is indicative of *E. granulosus* infection and helps to distinguish the cyst from carcinomas, bacterial or amebic liver abscesses, or hemangiomas. In contrast, ultrasound or CT of alveolar hydatid cysts reveals indistinct solid masses with central necrosis and plaquelike calcifications.

A specific diagnosis of *E. granulosus* infection can be made by the examination of aspirated fluids for protoscolices or hooklets, but diagnostic aspiration is not usually recommended because of the risk of fluid leakage resulting in either dissemination of infection or anaphylactic reactions. Serodiagnostic assays can be useful, although a negative test does not exclude the diagnosis of echinococcosis. Cysts in the liver elicit positive antibody responses in ~90% of cases, whereas up to 50% of individuals with cysts in the lungs are seronegative. Detection of antibody to specific echinococcal antigens by immunoblotting has the highest degree of specificity.

Rx TREATMENT

Therapy for cystic echinococcosis is based on considerations of the size, location, and manifestations of cysts and the overall health of the patient. Surgery has traditionally been the principal definitive method of treatment. Currently, ultrasound staging is recommended for *E. granulosus* infections (Fig. 204-2). For uncomplicated CE1 lesions and for some CE2 and CE3 lesions, PAIR (*p*ercutaneous *a*spiration, *i*nfusion of scolicidal agents, and *r*easpiration) is now recommended instead of surgery. PAIR is contraindicated for superficially located cysts (because of the risk of rupture), for cysts with multiple thick internal septal divisions (honeycombing pattern), and for cysts communicating with the biliary tree. For prophylaxis of secondary peritoneal echinococcosis due to inadvertent spillage of fluid during PAIR, the administration of albendazole (15 mg/kg daily in two divided

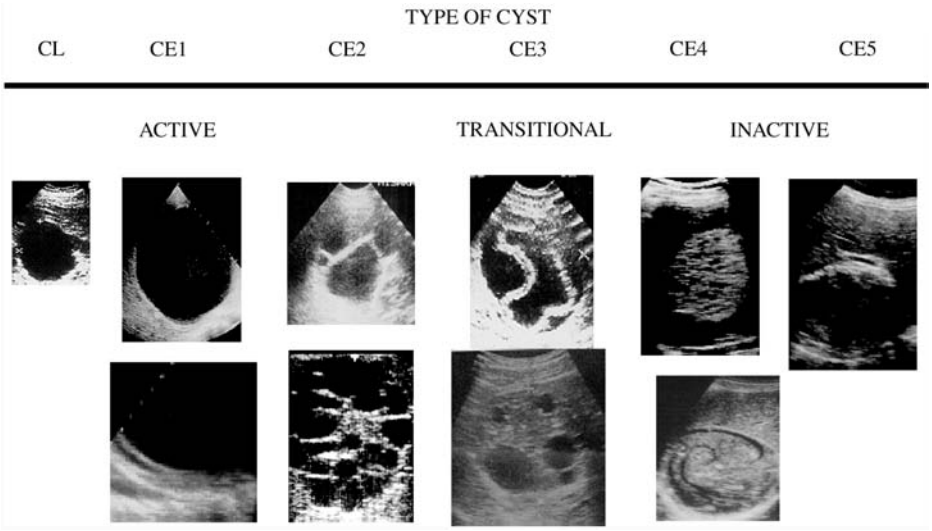

FIGURE 204-2 Management of cystic hydatid disease caused by *Echinococcus granulosus* should be based on viability of the parasite, which can be estimated from radiographic appearance. The ultrasound appearance includes lesions classified as active, transitional, and inactive. *Active* cysts include types CL (with a cystic lesion and no visible cyst wall), CE1 [with a visible cyst wall and internal echoes (snowflake sign)], and CE2 (with a visible cyst wall and internal septation). *Transitional cysts* (CE3) may have detached laminar membranes or may be partially collapsed. *Inactive cysts* include types CE4 (a nonhomogeneous mass) and CE5 (a cyst with a thick calcified wall).

doses) should be initiated at least 4 days before the procedure and continued for at least 4 weeks afterward. Ultrasound- or CT-guided aspiration allows confirmation of the diagnosis by demonstration of protoscolices in the aspirate. After aspiration, contrast material should be injected to detect occult communications with the biliary tract. Alternatively, the fluid should be checked for bile staining by dipstick. If no bile is found and no communication visualized, the contrast material is reaspirated, with subsequent infusion of scolicidal agents (usually either alcohol or hypertonic saline). Daughter cysts within the primary cyst may need to be punctured separately. In experienced hands, this approach yields rates of cure and relapse equivalent to those following surgery, with less perioperative morbidity and shorter hospitalization.

Surgery remains the treatment of choice for complicated *E. granulosus* cysts (e.g., those communicating with the biliary tract) or for areas where PAIR is not possible. For *E. granulosus*, the preferred surgical approach is pericystectomy, in which the entire cyst and the surrounding fibrous tissue are removed. The risks posed by leakage of fluid during surgery or PAIR include anaphylaxis and dissemination of infectious protoscolices. The latter complication has been minimized by careful attention to the prevention of spillage of the cyst and by soaking of the drapes with hypertonic saline. Infusion of scolicidal agents is no longer recommended because of problems with hypernatremia, intoxication, or sclerosing cholangitis. Albendazole, which is active against *Echinococcus*, should be administered adjunctively, beginning several days before resection and continuing for several weeks for *E. granulosus*. Praziquantel (50 mg/kg daily for 2 weeks), may hasten the death of the protoscolices. Medical therapy with albendazole alone for 12 weeks to 6 months results in cure in ~30% of cases and improvement in another 50%. In many instances of treatment failure, *E. granulosus* infections are subsequently treated successfully with PAIR or additional courses of medical therapy. Response to treatment is best assessed by serial imaging studies, with attention to cyst size and consistency.

Surgical resection remains the treatment of choice for *E. multilocularis* infection. Complete removal of the parasite continues to offer the best chance for cure. Ongoing therapy with albendazole for at least 2 years after presumptively curative surgery is recommended. Most cases are diagnosed at a stage at which complete resection is not possible; in these cases, albendazole treatment should be continued indefinitely, with careful monitoring. In some cases, liver transplantation has been used because of the size of the necessary liver resection. However, continuous immunosuppression favors the proliferation of *E. multilocularis* larvae and reinfection of the transplant. Thus, indefinite treatment with albendazole is required.

Prevention In endemic areas, echinococcosis can be prevented by administering praziquantel to infected dogs, by denying dogs access to infected animals, or by vaccinating sheep. Limitation of the number of stray dogs is helpful in reducing the prevalence of infection among humans.

HYMENOLEPIASIS NANA Infection with *Hymenolepis nana*, the dwarf tapeworm, is the most common of all the cestode infections. *H. nana* is endemic in both temperate and tropical regions of the world. Infection is spread by fecal/oral contamination and is common among institutionalized children.

Etiology and Pathogenesis *H. nana* is the only cestode of humans that does not require an intermediate host. Both the larval and adult phases take place in the human. The adult—the smallest tapeworm parasitizing humans—is ~2 cm long and dwells in the proximal ileum. Proglottids, which are quite small and are rarely seen in the stool, release spherical eggs 30 to 44 μm in diameter, each of which contains an oncosphere with six hooklets. The eggs are immediately infective and are unable to survive for >10 days in the external environment. *H. nana* can also be acquired by the ingestion of infected insects (especially larval meal-worms and larval fleas). When the egg is ingested by a new host, the oncosphere is freed and penetrates the intestinal villi, becoming a cysticercoid larva. Larvae migrate back into the intestinal lumen, attach to the mucosa, and mature into adult worms over 10 to 12 days. Eggs may also hatch before passing into the stool, causing internal autoinfection with increasing numbers of intestinal worms. Although the life span of adult *H. nana* is only ~4 to 10 weeks, the autoinfection cycle perpetuates the infection.

Clinical Manifestations *H. nana* infection, even with many intestinal worms, is usually asymptomatic. When infection is intense, anorexia, abdominal pain, and diarrhea develop.

Diagnosis Infection is diagnosed by the finding of eggs in the stool.

TREATMENT

Praziquantel (25 mg/kg once) is the treatment of choice, since it acts against both the adult worms and the cysticercoids in the intestinal villi.

Prevention Good personal hygiene and improved sanitation can eradicate the disease. Epidemics have been controlled by mass chemotherapy coupled with improved hygiene.

HYMENOLEPIASIS DIMINUTA *Hymenolepis diminuta*, a cestode of rodents, occasionally infects small children, who ingest the larvae in uncooked cereal foods contaminated by fleas and other insects in which larvae develop. Infection is usually asymptomatic and is diagnosed by the detection of eggs in the stool. Treatment with praziquantel results in cure in most cases.

DIPHYLLOBOTHRIASIS *Diphyllobothrium latum* and other *Diphyllobothrium* species are found in the lakes, rivers, and deltas of the northern hemisphere, Central Africa, and Chile.

Etiology and Pathogenesis The adult worm—the longest tapeworm (up to 25 m)—attaches to the ileal and occasionally to the jejunal mucosa by its suckers, which are located on its elongated scolex. The adult worm has 3000 to 4000 proglottids, which release ~1 million eggs

daily into the feces. If an egg reaches water, it hatches and releases a free-swimming embryo that can be eaten by small freshwater crustaceans (*Cyclops* or *Diaptomus* species). After an infected crustacean containing a developed procercoid is swallowed by a fish, the larva migrates into the fish's flesh and grows into a plerocercoid, or sparganum larva. Humans acquire the infection by ingesting infected raw fish. Within 3 to 5 weeks, the tapeworm matures into an adult in the human intestine.

Clinical Manifestations Most *D. latum* infections are asymptomatic, although manifestations may include transient abdominal discomfort, diarrhea, vomiting, weakness, and weight loss. Occasionally, infection can cause acute abdominal pain and intestinal obstruction; in rare cases, cholangitis or cholecystitis may be produced by migrating proglottids. Because the tapeworm absorbs large quantities of vitamin B_{12} and interferes with ileal B_{12} absorption, vitamin B_{12} deficiency can develop. Up to 2% of infected patients, especially the elderly, have megaloblastic anemia resembling pernicious anemia and may exhibit neurologic sequelae of B_{12} deficiency.

Diagnosis The diagnosis is made readily by the detection of the characteristic eggs in the stool. The eggs possess a single shell with an operculum at one end and a knob at the other. Mild to moderate eosinophilia may be detected.

Rx TREATMENT

Praziquantel (5 to 10 mg/kg once) is highly effective. Parenteral vitamin B_{12} should be given if B_{12} deficiency is manifest.

Prevention Infection can be prevented by heating fish to 54°C for 5 min or by freezing it at −18°C for 24 h. Placing fish in brine with a high salt concentration for long periods kills the eggs.

DIPYLIDIASIS *Dipylidium caninum*, a common tapeworm of dogs and cats, may accidentally infect humans. Dogs, cats, and occasionally humans become infected by ingesting fleas harboring cysticercoids. Children are more likely to become infected than adults. Most infections are asymptomatic, but abdominal pain, diarrhea, anal pruritus, urticaria, eosinophilia, or passage of segments in the stool may occur. The diagnosis is made by the detection of proglottids in the stool. As in *D. latum* infection, therapy consists of praziquantel. Prevention requires anthelmintic treatment and flea control for pet dogs or cats.

SPARGANOSIS Humans can be infected by the sparganum, or plerocercoid larva, of a diphyllobothrid tapeworm of the genus *Spirometra*. Infection can be acquired by the consumption of water containing infected *Cyclops*; by the ingestion of infected snakes, birds, or mammals; or by the application of infected flesh as poultices. The worm migrates slowly in tissues, and infection commonly presents as a subcutaneous swelling. Periorbital tissues can be involved, and ocular sparganosis may destroy the eye. Surgical excision is used to treat localized sparganosis.

COENUROSIS This rare infection of humans by the larval stage (coenurus) of the dog tapeworm *Taenia multiceps* or *T. serialis* results in a space-occupying cystic lesion. As in cysticercosis, involvement of the central nervous system and subcutaneous tissue is most common. Both definitive diagnosis and treatment require surgical excision of the lesion. Chemotherapeutic agents generally are not effective.

PART VII BIOTERRORISM AND CLINICAL MEDICINE

205 MICROBIAL BIOTERRORISM

H. Clifford Lane, Anthony S. Fauci

Descriptions of the use of microbial pathogens as potential weapons of war or terrorism date from ancient times. Among the most frequently cited of such episodes are the poisoning of water supplies in the sixth century B.C. with the fungus *Calviceps purpurea* (rye ergot) by the Assyrians, the hurling of the dead bodies of plague victims over the walls of the city of Kaffa by the Tartar army in 1346, and the spreading of smallpox via contaminated blankets by the British to the native American population loyal to the French in 1767. Although the use of chemical weapons in wartime took place in the not-too-distant past (Chap. 206), the tragic events of September 11, 2001, followed closely by the anthrax attacks through the U.S. Postal System, dramatically changed the mindset of the American public regarding both our vulnerability to microbial bioterrorist attacks and the seriousness and intent of the Federal government to protect its citizens against future attacks.

Although the potential impact of a bioterrorist attack can be enormous, leading to thousands of deaths and extensive morbidity, acts of bioterrorism typically have their greatest impact through the fear and terror they generate. In contrast to biowarfare, where the primary goal is destruction of the enemy through mass casualties, an important goal of bioterrorism is to destroy the morale of a society through fear and uncertainty. While the actual biologic impact of a single act may be small, the degree of disruption created by the realization that such an attack is possible may be enormous. This was readily apparent with the impact on the U.S. Postal System and the functional interruption of the activities of the legislative branch of government following the anthrax attacks noted above. Thus, the key to the defense against these attacks is a highly functioning system of public health surveillance and education so that attacks can be quickly recognized and effectively contained. This is complemented by the availability of appropriate countermeasures in the form of diagnostics, therapeutics, and vaccines, both in response to and in anticipation of bioterrorist attacks.

The Working Group for Civilian Biodefense has put together a list of key features that characterize the elements of biologic agents that make them particularly effective as weapons (Table 205-1). Included among these are the ease of spread and transmission of the agent as well as the presence of an adequate database to allow newcomers to the field to quickly apply the good science of others to bad intentions of their own. Agents of bioterrorism may be used in their naturally occurring forms or they can be deliberately modified to provide maximal impact. Among the approaches to maximizing the deleterious effects of biologic agents are the genetic modification of microbes for the purposes of antimicrobial resistance or evasion by the immune system, creation of fine-particle aerosols, chemical treatment to stabilize and prolong infectivity, and alteration of host range through changes in surface proteins. Certain of these approaches fall under the category of *weaponization*, which is a term generally used to describe the processing of microbes or toxins in a manner that would ensure a devastating effect of a release. For example, weaponization of anthrax by the Soviets comprised the production of vast amounts of spores in a form that maintained aerosolization for prolonged periods of time; the spores were of sufficient size to enter the lower respiratory tract easily and could be delivered in a massive release, such as via a bomblet.

The U.S. Centers for Disease Control and Prevention (CDC) classifies potential biologic threats into three categories: A, B, and C (Table 205-2). Category A agents are the highest-priority pathogens. They pose the greatest risk to national security because they (1) can be easily disseminated or transmitted from person to person, (2) result in high mortality rates and have the potential for major public health impact, (3) might cause public panic and social disruption, and (4) require special action for public health preparedness. Category B agents are the second highest priority pathogens and include those that are moderately easy to disseminate, result in moderate morbidity rates and low mortality rates, and require specifically enhanced diagnostic capacity. Category C agents are the third highest priority. These include emerging pathogens, to which the general population lacks immunity, that could be engineered for mass dissemination in the future because of availability, ease of production, ease of dissemination, potential for high morbidity and mortality, and major public health impact. The recent emergence of a novel human coronavirus leading to outbreaks of severe acute respiratory syndrome (SARS) is one example of such an agent. It should be pointed out, however, that these designations are empirical, and, depending on evolving circumstances such as threat assessments, the priority rating of any given microbe or toxin could change.

TABLE 205-1 Key Features of Biologic Agents Used as Bioweapons

1. High morbidity and mortality
2. Potential for person-to-person spread
3. Low infective dose and highly infectious by aerosol
4. Lack of rapid diagnostic capability
5. Lack of universally available effective vaccine
6. Potential to cause anxiety
7. Availability of pathogen and feasibility of production
8. Environmental stability
9. Database of prior research and development
10. Potential to be "weaponized"

TABLE 205-2 CDC Category A, B, and C Agents

Category A
- Anthrax (*Bacillus anthracis*)
- Botulism (*Clostridium botulinum* toxin)
- Plague (*Yersinia pestis*)
- Smallpox (*Variola major*)
- Tularemia (*Francisella tularensis*)
- Viral hemorrhagic fevers
  - Arenaviruses: Lassa, New World (Machupo, Junin, Guanarito, and Sabia)
  - Bunyaviridae: Crimean Congo, Rift Valley
  - Filoviridae: Ebola, Marburg
  - Flaviviridae: Yellow fever; Omsk fever; Kyasanur Forest

Category B
- Brucellosis (*Brucella* spp.)
- Epsilon toxin of *Clostridium perfringens*
- Food safety threats (e.g., *Salmonella* spp., *Escherichia coli* 0157:H7, *Shigella*)
- Glanders (*Burkholderia mallei*)
- Melioidosis (*B. pseudomallei*)
- Psittacosis (*Chlamydia psittaci*)
- Q fever (*Coxiella burnetii*)
- Ricin toxin from *Ricinus communis* (castor beans)
- Staphylococcal enterotoxin B
- Typhus fever (*Rickettsia prowazekii*)
- Viral encephalitis [alphaviruses (e.g., Venezuelan, eastern, and western equine encephalitis)]
- Water safety threats (e.g., *Vibrio cholerae*, *Cryptosporidium parvum*)

Category C
- Emerging infectious diseases threats such as Nipah, hantavirus, and SARS coronoavirus.

CATEGORY A AGENTS

ANTHRAX (*BACILLUS ANTHRACIS*) (See also Chap. 122) ■ **Anthrax as a Bioweapon** Anthrax may be the prototypic disease of bioterrorism. Although rarely spread from person to person, it contains the other features of an ideal bioweapon outlined in Table 205-1. U.S. and British government scientists studied anthrax as a biologic weapon beginning approximately at the time of World War II (WWII). Offensive bioweapons activity including bioweapons research on microbes and toxins in the United States ceased in 1969 as a result of two executive orders by President Richard M. Nixon. The 1972 Biological and Toxin Weapons Convention Treaty outlawed research of this type worldwide. Clearly, the Soviet Union was in direct violation of this treaty until at least the dissolution of the Soviet Union in the late 1980s. It is well documented that during this post-treaty period, the Soviets produced and stored hundreds of tons of anthrax spores for potential use as a bioweapon. At present there is suspicion that research on anthrax as an agent of bioterrorism is ongoing by several nations and extremist groups. One example of this is the release of anthrax spores by the Aum Shrinrikyo cult in Tokyo in 1993. Fortunately, there were no casualties associated with this episode because of the inadvertent use of a nonpathogenic strain of anthrax by the terrorists.

The potential impact of anthrax spores as a bioweapon was clearly demonstrated in 1979 following the accidental release of spores into the atmosphere from a Soviet Union bioweapons facility in Sverdlosk, Russia. While actual figures are not known, at least 77 cases of anthrax were diagnosed with certainty, of which 66 were fatal. These victims appeared to have been exposed in an area within 4 km downwind of the facility. Deaths due to anthrax were also noted in livestock up to 50 km away from the facility. The interval between probable exposure and development of clinical illness ranged from 2 to 43 days. The majority of cases were within the first 2 weeks. Death typically occurred within 1 to 4 days following the onset of symptoms. It is likely that the widespread use of penicillin prophylaxis limited the total number of cases. The extended period of time between exposure and disease in some individuals supports the data from nonhuman primate studies suggesting the anthrax spores can lie dormant in the respiratory tract for at least 4 to 6 weeks. This extended period of microbiologic latency following exposure poses a significant challenge for management of victims in the postexposure period.

In September 2001, the American public was exposed to anthrax spores as a bioweapon delivered through the U.S. Postal System. The CDC identified 22 confirmed or suspected cases of anthrax as a consequence of this attack. These included 11 patients with inhalational anthrax, of whom 5 died, and 11 patients with cutaneous anthrax (7 confirmed), all of whom survived (Fig. 205-1). Cases occurred in individuals who opened contaminated letters as well as in postal workers involved in the processing of mail. A minimum of five letters mailed from Trenton, NJ, served as the vehicles for these attacks. One of these letters was reported to contain 2 g of material, equivalent to 100 billion to 1 trillion weapon-grade spores. This is an inoculum with a theoretical potential under optimal conditions of infecting up to 50 million individuals when one considers an LD_{50} of 10,000 spores. The strain used in this attack was the Ames strain. Although it was noted to have an inducible β-lactamase and to constitutively express a cephalosporinase, it was susceptible to all antibiotics standard for *B. anthracis*.

Microbiology and Clinical Features Anthrax is caused by *B. anthracis*, a gram-positive, nonmotile, spore-forming rod that is found in soil and predominantly causes disease in herbivores such as cattle, goats, and sheep. The long-lived spores of this organism can also be found in soil, and their stability makes them an ideal bioweapon. Anthrax spores can remain viable for decades, and their destruction in decontamination activities can be a challenge. Naturally occurring human infection is generally the result of contact with anthrax-infected animals or animal products such as goat hair. Studies performed in the 1950s using monkeys exposed to aerosolized anthrax suggested that ~10,000 spores were required to produce lethal disease in 50% of animals exposed to this dose (the LD_{50}). However, it has also been suggested that as few as one to three spores may be adequate to cause disease in some settings. Advanced technology is likely to be necessary to generate spores of the optimal size (1 to 5 μm) to travel to the alveolar spaces as a bioweapon.

The three major clinical forms of anthrax are gastrointestinal, cutaneous, and inhalational. *Gastrointestinal anthrax* is rarely seen and is unlikely to be the result of a bioterrorism event. The lesion of *cutaneous anthrax* typically begins as a papule following the introduction of spores through an opening in the skin. This papule then evolves to a painless vesicular stage followed by the development of a coal-black, necrotic eschar. It is the Greek word for coal (*anthrax*) that gives the organism and the disease its name. Cutaneous anthrax was ~20% fatal prior to the availability of antibiotics. *Inhalational anthrax* is the form most likely to be responsible for death in the setting of a bioterrorist attack. It occurs following the inhalation of spores that become de-

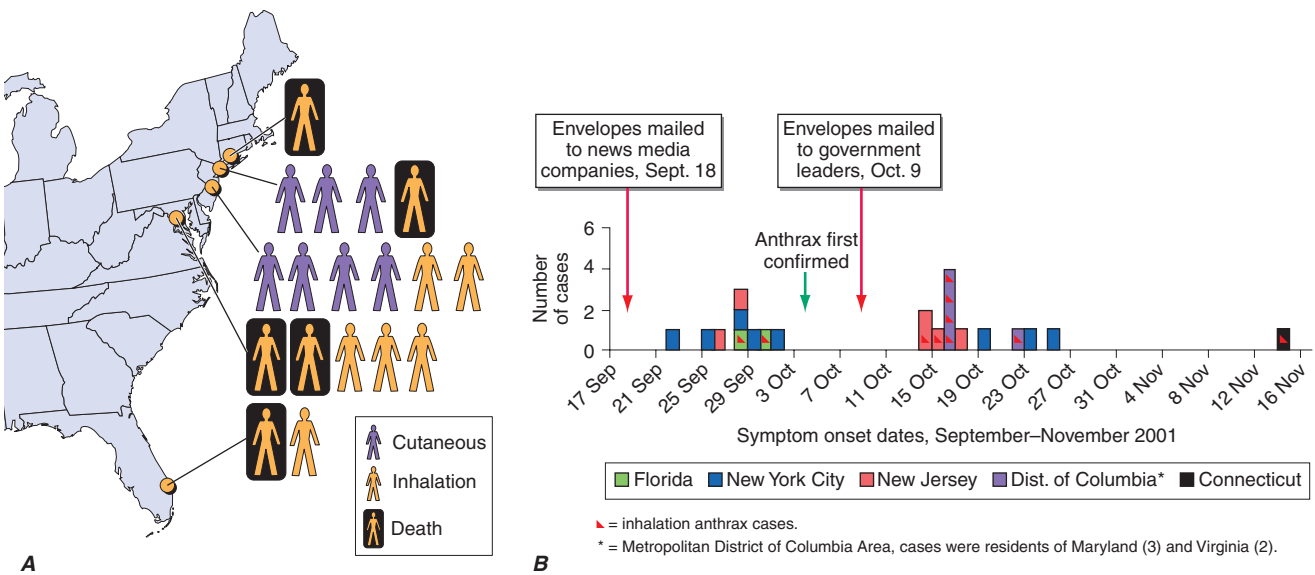

FIGURE 205-1 Confirmed anthrax cases associated with bioterrorism: United States, 2001. *A*. Geographic location, clinical manifestation, and outcome of the 11 cases of confirmed inhalational and 7 cases of confirmed cutaneous anthrax. *B*. Epidemic curve for the 18 confirmed cases of inhalational and cutaneous anthrax and additional 4 cases of suspected cutaneous anthrax. (*From DB Jernigan et al: Investigation of bioterrorism-related anthrax, US 2001: Epidemiologic findings. Emerg Infect Dis 8:1019, 2002; with permission.*)

posited in the alveolar spaces. These spores are phagocytosed by macrophages and transported to the mediastinal and peribronchial lymph nodes where they germinate, leading to active bacterial growth and elaboration of the bacterial products edema toxin and lethal toxin. Subsequent hematogenous spread of bacteria is accompanied by cardiovascular collapse and death. The earliest symptoms are typically a viral-like prodrome with fever, malaise, and abdominal and/or chest symptoms that rapidly progress to a moribund state. A characteristic finding is mediastinal widening and pleural effusions on chest x-ray (Fig. 205-2). While initially thought to be 100% fatal, the experiences at Sverdlosk in 1979 and in the United States in 2001 (see below) indicate that with prompt initiation of antibiotic therapy survival is possible. The characteristics of the 11 cases of inhalational anthrax diagnosed in the United States in 2001 following exposure to contaminated letters postmarked September 18 or October 9, 2001, are detailed in Table 205-3. These cases followed the classic pattern established for this illness, with patients presenting with a rapidly progressive course characterized by fever, fatigue or malaise, nausea or vomiting, cough, and shortness of breath. At presentation, the total white blood cell counts were ~10,000 cells/μL; transaminases tended to be elevated, and all 11 had abnormal findings on chest x-ray and computed tomography (CT). Pulmonary findings included infiltrates, mediastinal widening, and hemorrhagic pleural effusions. For cases in which the dates of exposure were known, symptoms appeared within 4 to 6 days. Death occurred within 7 days of diagnosis in the five fatal cases (overall mortality rate 55%). Rapid diagnosis and prompt initiation of antibiotic therapy were key to survival.

TREATMENT

Anthrax can be successfully treated if the disease is promptly recognized and appropriate therapy is initiated early. While penicillin, ciprofloxacin, and doxycycline are the currently licensed antibiotics for this indication, clindamycin and rifampin have in vitro activity against the organism and have been used as part of treatment regimens. Until sensitivity results are known, suspected cases are best managed with a combination of widely active agents (Table 205-4). Patients with inhalational anthrax are not contagious and do not require special isolation procedures.

Vaccination and Prevention The first successful vaccine for anthrax was developed for animals by Louis Pasteur in 1881. At present, the single vaccine licensed for human use is a product produced from the cell-free culture supernatant of an attenuated, nonencapsulated strain of *B. anthracis* (Stern strain), referred to as *anthrax vaccine adsorbed* (AVA). Clinical trials for safety in humans and efficacy in animals are currently under way to evaluate the role of recombinant protective antigen (one of the major components, along with lethal factor and edema factor, of *B. anthracis* toxins) as an alternative to AVA. Since

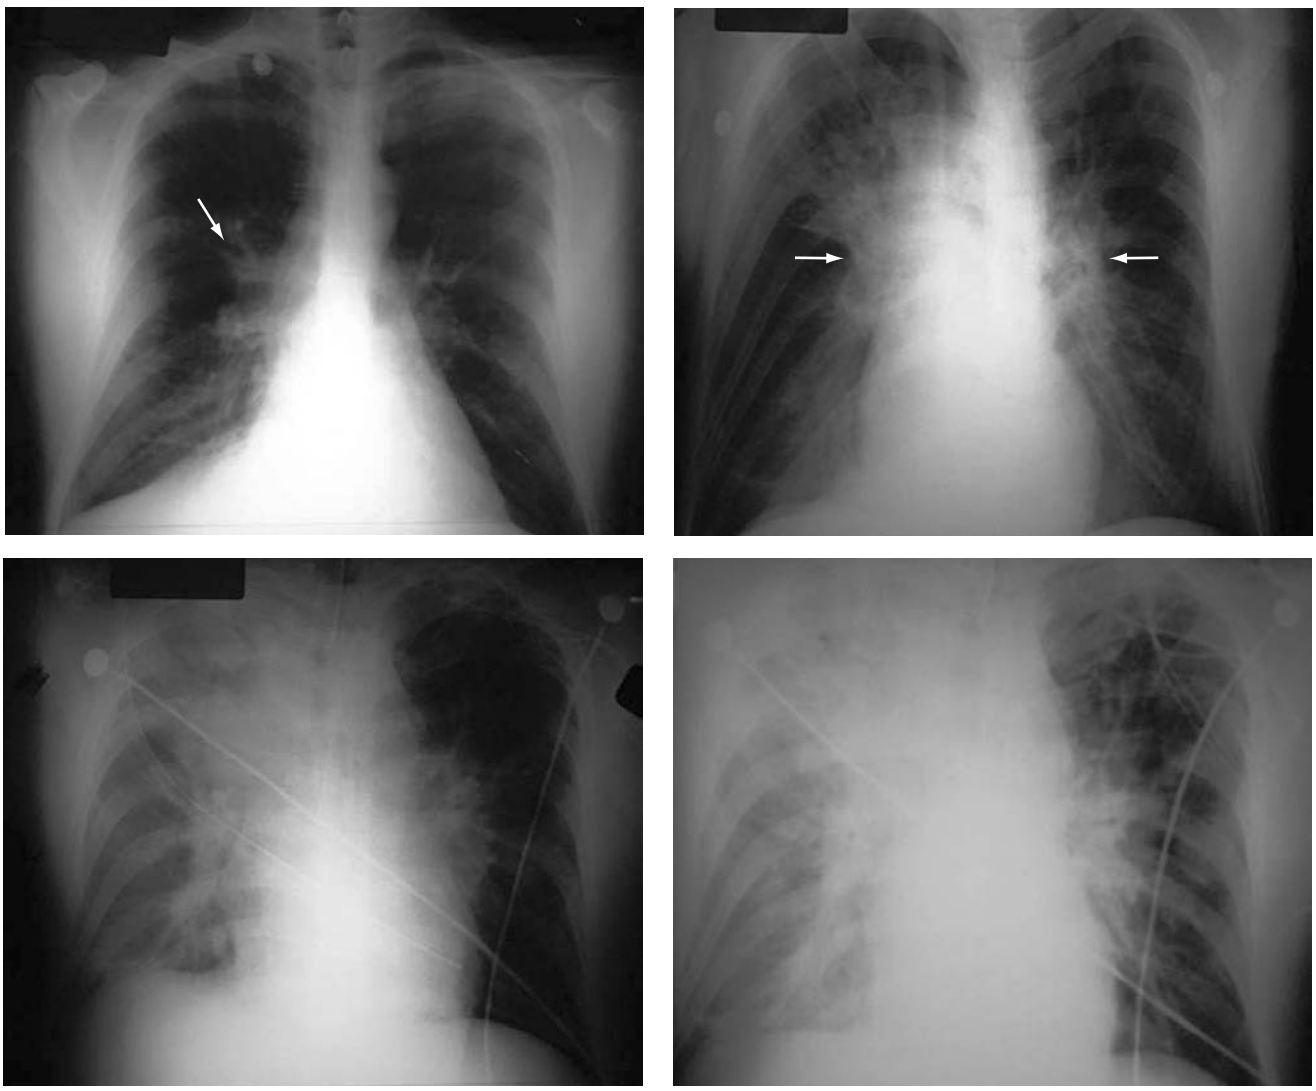

FIGURE 205-2 Progression of chest x-ray findings in a patient (Table 205-3, Patient 9) with inhalational anthrax. Findings evolved from subtle hilar prominence and right perihilar infiltrate to a progressively widened mediastinum, marked perihilar infiltrates, peribronchial cuffing, and air bronchograms. (*From L Borio et al: Death due to bioterrorism-related inhalational anthrax. JAMA 286:2554, 2001; with permission.*)

TABLE 205-3 *Characteristics of the 11 Confirmed Cases of Inhalational Anthrax Associated with Bioterrorism in the United States in 2001*

Case	Age/Sex	Location	Occupation	Initial Symptoms	Radiograph Findings CXR/CT	Initial WBC	Time Interval from 1st Symptom to Death, Days	Treatment[a]
FATAL CASES								
1	63 y/o man	FL	Photo editor, media company	Fever, malaise, fatigue, altered mental state	Widened upper mediastinum, pleural effusion	9400	8	Cefotaxime, ceftazidime, gentamicin, metronidazole, doxycycline, ampicillin, trimethoprim-sulfamethoxazole, penicillin G, levofloxacin, clindamycin
2	55 y/o man	DC	Postal worker	Fever, fatigue, myalgia, cough	Infiltrate, perihilar fullness, pleural effusion	10,300	5	Levofloxacin, diltiazem, insulin, mechanical ventilation
3	47 y/o man	DC	Postal worker	Nausea, vomiting, abdominal pain, syncope, cough	Perihilar infiltrate, mediastinal adenopathy, pleural effusion	13,300	6	Penicillin, ceftriaxone, rifampin, levofloxacin, mechanical ventilation
4	61 y/o woman	NY	Hospital worker	Malaise, myalgia, cough, chest pain, dyspnea, fatigue	Mediastinal adenopathy, pleural effusions	11,400	6	Levofloxacin, rifampin, gentamicin, nafcillin, ciprofloxacin, clindamycin, ceftazidime, mechanical ventilation, chest tubes
5	94 y/o woman	CT	Retired	Fever, fatigue, loss of appetite, cough, myalgia	Perihilar fullness, pleural effusion	8100	8	Vancomycin, ceftazidime, ampicillin, sulbactam, ciprofloxacin, clindamycin, thoracentesis, mechanical ventilation
NONFATAL CASES								
6	73 y/o man	FL	Mail handler, media company	Fever, fatigue, abdominal pain, vomiting, cough, dyspnea, conjunctivitis	Consolidation, pleural effusion	9900		Azithromycin, cefotaxime, ciprofloxacin
7	56 y/o woman	NJ	Postal worker	Fever, vomiting, diarrhea, cough, chest pain, dyspnea	Bibasilar infiltrates, mediastinal adenopathy, pleural effusion	8100		Levofloxacin, rifampin, ciprofloxacin, vancomycin, thoracentesis, chest tube
8	43 y/o woman	NJ	Postal worker	Fever, myalgia, vomiting, fatigue, cough, chest pain, dyspnea, headache	Perihilar consolidation, mediastinal adenopathy, pleural effusion	11,200		Levofloxacin, azithromycin, ciprofloxacin, clindamycin, ceftriaxone, doxycycline, thoracentesis X2
9	56 y/o man	DC	Postal worker	Fever, headache, malaise, sore throat, cough, dyspnea, nausea, vomiting	Bilateral hilar adenopathy, widened mediastinum, pleural effusion	7500		Ciprofloxacin, rifampin, clindamycin, diuretics, glucocorticoids, thoracentesis X3
10	56 y/o man	DC	Postal worker	Fever, headache, malaise, sore throat, nausea, photophobia, cough, dyspnea, chest pain	Widened mediastinum, bilateral hilar adenopathy, airspace disease, pleural effusion	9700		Ciprofloxacin, rifampin, clindamycin, glucocorticoids thoracentesis X2
11	59 y/o man	VA	Postal worker	Fever, sweats, myalgia, fatigue, headache, nausea, vomiting, abdominal pain, cough, chest pain	Mediastinal widening, mediastinal adenopathy, pleural effusion	9700		Ciprofloxacin, penicillin, rifampin, vancomycin, thoracentesis

[a] At anytime during the illness.

the efficacy of AVA in a postexposure setting in humans has not been established, the current recommendation for postexposure prophylaxis is 60 days of antibiotics. Given the potential for *B. anthracis* to be engineered to express penicillin resistance, the empirical regimen of choice in this setting is either ciprofloxacin or doxycycline.

PLAGUE (*YERSINIA PESTIS*) (See also Chap. 143) ■ **Plague as a Bioweapon** Although it lacks the environmental stability of anthrax, the highly contagious nature and high mortality of plague make it a close to ideal agent of bioterrorism, particularly if delivered in a weaponized form. Occupying a unique place in history, plague has been alleged to have been used as a biologic weapon for centuries. The catapulting of plague-infected corpses into besieged fortresses is a practice that was first noted in 1346 during the assault of the city of Kaffa by the Tartars. There are some who believe this may have played a role in the start

TABLE 205-4 *Clinical Syndromes, Prevention, and Treatment Strategies for Diseases Caused by Category A Agents*

Agent	Clinical Syndrome	Incubation Period	Diagnosis	Treatment	Prophylaxis
Bacillus anthracis (anthrax)	Cutaneous lesion: Papule to eschar Inhalational disease: Fever, malaise, chest and abdominal discomfort Pleural effusion, widened mediastinum on chest x-ray	1–12 days 1–60 days	Culture, Gram stain, PCR, Wright stain of peripheral smear	Postexposure: Ciprofloxacin, 500 mg, PO bid × 60 d *or* Doxycycline, 100 mg PO bid ×60 d Amoxicillin, 500 mg PO q8h, likely to be effective if strain penicillin sensitive *Active disease:* Ciprofloxacin, 400 mg IV q12h *or* Doxycycline, 100 mg IV q12 *plus* Clindamycin, 900 mg IV q8h and/or rifampin, 300 mg IV q12h; switch to PO when stable ×60 d total *Antitoxin strategies:* Neutralizing monoclonal antibodies are under study	Anthrax vaccine adsorbed Recombinant protective antigen vaccines are under study
Yersinia pestis (pneumonic plague)	Fever, cough, dyspnea, hemoptysis Infiltrates and consolidation on chest x-ray	1–6 days	Culture, Gram stain, direct fluorescent antibody, PCR	Gentamicin, 2.0 mg/kg IV loading then 1.7 mg/kg q8h IV *or* Streptomycin, 1.0 g q12h IM or IV Alternatives include doxycycline, 100 mg bid PO or IV; chloramphenicol 500 mg bid PO or IV	Doxycycline, 100 mg PO bid (ciprofloxacin may also be active) Formalin-fixed vaccine (FDA licensed; not available)
Variola major (smallpox)	Fever, malaise, headache, backache, emesis Maculopapular to vesicular to pustular skin lesions	7–17 days	Culture, PCR, electron microscopy	Supportive measures; consideration for cidofovir, antivaccinia immunoglobulin	Vaccinia immunization
Francisella tularensis (tularemia)	Fever, chills, malaise, myalgia, chest discomfort, dyspnea, headache, skin rash, pharyngitis, conjunctivitis Hilar adenopathy on chest x-ray	1–14 days	Gram stain, culture, immunohistochemistry, PCR	Streptomycin, 1 g IM bid *or* Gentamicin, 5 mg/kg per day div q8h IV for 14 days *or* Doxycycline, 100 mg IV bid *or* Chlorphenid, 15 mg/kg IV qid *or* Ciprofloxacin, 400 mg IV bid	Doxycycline, 100 mg PO bid × 14 days *or* Ciprofloxacin, 500 mg PO bid × 14 days
Viral hemorrhagic fevers	Fever, myalgia, rash, encephalitis, prostration	2–21 days	RT-PCR, serologic testing for antigen or antibody Viral isolation by CDC or U.S. Army Medical Institute of Infectious Diseases (USAMRIID)	Supportive measures Ribavirin 30 mg/kg up to 2 g × 1, followed by 16 mg/kg IV up to 1 g q6h for 4 days, followed by 8 mg/kg IV up to 0.5 g q8h × 6 days	No known chemoprophylaxis Consideration for ribavirin in high-risk situations Vaccine exists for yellow fever
Botulinum toxin (*Clostridium botulinum*)	Dry mouth, blurred vision, ptosis, weakness, dysarthria, dysphagia, dizziness, respiratory failure, progressive paralysis, dilated pupils	12–72 h	Mouse bioassay, toxin immunoassay	Supportive measures including ventilation 5000–9000 IU equine antitoxin	Administration of antitoxin

Note: CDC, U.S. Centers for Disease Control and Prevention; FDA, U.S. Food and Drug Administration; PCR, polymerase chain reaction; RT-PCR, reverse transcriptase PCR.

of the Black Death pandemic of the fourteenth and fifteenth centuries in Europe. Given that plague was already moving across Asia toward Europe at this time, it is unclear whether such an allegation is accurate. During WWII, the infamous Unit 731 of the Japanese army was reported to have repeatedly dropped plague-infested fleas over parts of China, including Manchuria. These drops were associated with subsequent outbreaks of plague in the targeted areas. Following WWII, the United States and the Soviet Union conducted programs of research on how to create direct aerosols containing *Y. pestis* that could be used as a direct bioweapon leading to primary pneumonic plague. As mentioned above, plague was thought to be an excellent bioweapon due to the fact that in addition to causing infection in those inhaling the aerosol, significant numbers of secondary cases of primary pneumonic plague would likely occur due to the contagious nature of the disease and person-to-person transmission via respiratory aerosol. Secondary reports of research conducted during that time suggest that organisms

remain viable for up to 1 h and can be dispersed for distances up to 10 km. While the offensive bioweapons program in the United States was terminated prior to production of sufficient quantities of plague organisms for use as a weapon, it is believed that Soviet scientists did manufacture quantities sufficient for such a purpose. It has also been reported that more than 10 Soviet Institutes and over 1000 scientists were working with plague as a biologic weapon. Of concern is the fact that in 1995 a microbiologist in Ohio was arrested for having obtained *Y. pestis* in the mail from the American Type Culture Collection, using a credit card and a false letterhead. In the wake of this incident, the U.S. Congress passed a law in 1997 requiring that anyone intending to send or receive any of 42 different agents that could potentially be used as bioweapons first register with the CDC.

Microbiology and Clinical Features Plague is caused by *Y. pestis*, a nonmotile, gram-negative bacillus that exhibits bipolar, or "safety pin," staining with Wright, Giemsa, or Wayson stains. It has had a major impact on the course of history, thus adding to the element of fear evoked by its mention. The earliest reported plague epidemic was in 224 B.C. in China. The most infamous pandemic began in Europe in the fourteenth century, during which time one-third to one-half of the entire population of Europe was killed. During a plague outbreak in India in 1994, it is estimated that 500,000 individuals fled their homes in fear of this disease.

The clinical syndromes of plague generally reflect the mode of infection. *Bubonic plague* is the consequence of an insect bite; primary *pneumonic plague* arises through the inhalation of bacteria. Most of the plague seen in the world today is bubonic plague and is the result of a bite by a plague-infected flea. Plague infection of rodents exists widely in nature, and each year thousands of cases of plague occur worldwide through contact with infected animals or fleas. Following inoculation of regurgitated bacteria into the skin by a flea bite, organisms travel through the lymphatics to regional lymph nodes, where they are phagocytized but not destroyed. Inside the cell, they multiply rapidly leading to inflammation, painful lymphadenopathy with necrosis, fever, bacteremia, septicemia, and death. The characteristic enlarged nodes, or *buboes*, give this form of plague its name. In some instances, patients may develop bacteremia without lymphadenopathy following infection, a condition referred to as *primary septicemic plague*. Extensive ecchymoses may develop due to disseminated intravascular coagulation, and gangrene of the digits and/or nose may develop in patients with advanced septicemic plague. It is thought that this appearance of some patients gave rise to the term *Black Death* in reference to the plague epidemic of the fourteenth and fifteenth centuries. Some patients may develop pneumonia (secondary pneumonic plague) as a complication of bubonic or septicemic plague. These patients may then transmit the agent to others via the respiratory route, causing cases of primary pneumonic plague. Primary pneumonic plague is the manifestation most likely to occur as the result of a bioterrorist attack, with an aerosol of bacteria spread over a wide area or a particular environment that is densely populated. In this setting patients would be expected to develop fever, cough with hemoptysis, dyspnea, and gastrointestinal symptoms 1 to 6 days following exposure. Clinical features of pneumonia would be accompanied by pulmonary infiltrates and consolidation on chest x-ray. In the absence of antibiotics, the mortality of this disease is on the order of 85%, and death usually occurs within 2 to 6 days.

TREATMENT

Streptomycin, tetracycline, and doxycycline are licensed by the U.S. Food and Drug Administration (FDA) for the treatment of plague. Multiple additional antibiotics licensed for other infections are commonly used and are likely effective. Among these are aminoglycosides such as gentamicin, cephalosporins, trimethoprim/sulfamethoxazole, chloramphenicol, and ciprofloxacin (Table 205-4). A multidrug resistant strain of *Y. pestis* was identified in 1995 from a patient with bubonic plague in Madagascar. While this organism was resistant to streptomycin, ampicillin, chloramphenicol, sulfonamides, and tetracycline, it retained its susceptibility to other aminoglycosides and cephalosporins. Given the subsequent identification of a similar organism in 1997 coupled with the fact that this resistance is plasmid-mediated, it seems likely that genetically modifying *Y. pestis* to a multidrug resistant form is possible. Unlike patients with inhalational anthrax (see above), patients with pulmonary plague should be cared for under conditions of strict respiratory isolation comparable to that used for multidrug resistant tuberculosis.

Vaccination and Prevention A formalin-fixed, whole-organism vaccine was licensed by the FDA for the prevention of plague. That vaccine is no longer being manufactured, but its potential value as a current countermeasure against bioterrorism would likely have been modest at best as it was ineffective against primary pneumonic plague in animal studies. Efforts are under way to develop a second generation of vaccines that will protect against aerosol challenge. Among the candidates being tested are recombinant forms of the F1 and V antigens of *Y. pestis*. It is likely that doxycycline or ciprofloxacin would provide coverage in a chemoprophylaxis setting. Unlike the case with anthrax, in which one has to be concerned about the presence of spores, the duration of prophylaxis against plague need only extend to 7 days following exposure.

SMALLPOX (*VARIOLA MAJOR* AND *V. MINOR*) (See also Chap. 167)

Smallpox as a Bioweapon Given that an effective vaccine exists for smallpox, it would not have been considered a good candidate as a bioweapon 30 years ago. However, with the cessation of immunization programs in the United States in 1972 and throughout the world in 1980 due to the successful global eradication of smallpox, close to 50% of the U.S. population is fully susceptible to smallpox today. Given its infectious nature and the 10 to 30% mortality in unimmunized individuals, the deliberate spread of this virus could have a devastating effect on our society and unleash a previously conquered deadly disease. It is estimated that an initial infection of 50 to 100 persons in a first-generation of cases could expand by a factor of 10 to 20 with each succeeding generation in the absence of any effective containment measures.

At the time that the World Health Organization (WHO) recommended that all immunization programs be terminated in 1980, it also recommended that remaining stocks of virus be destroyed and that samples be transferred to only two locations: one at the CDC in Atlanta, GA, in the United States and the other at the Institute of Virus Preparations in the Soviet Union. Several years later, it was recommended that these remaining two stocks be destroyed. However, these latter recommendations were reversed in the wake of increased concerns on the use of *Variola* as a biologic weapon and thus the need to maintain an active program of defensive research. Many of these concerns were based upon allegations made by former Soviet officials that extensive programs had been in place in that country for the production and weaponization of large quantities of smallpox virus. The dismantling of these programs with the fall of the Soviet Union led to fears that stocks of *V. major* may have made their way to other countries. In addition, accounts that efforts had been taken to produce recombinant strains of *Variola* that would be more virulent and more contagious than the wild-type virus have led to an increase in the need to be vigilant for the reemergence of this often fatal infectious disease.

Microbiology and Clinical Features Smallpox is caused by one of two closely related viruses, *V. major* and *V. minor*. Both are double-strand DNA viruses and members of the Orthopoxvirus genus of the Poxviridae family. Infections with *V. minor* are generally less severe, with milder constitutional symptoms and lower mortality rates; thus *V. major* is the only one considered to be a viable bioweapon. Infection with *V. major* typically occurs following contact with an infected person from the time that a maculopapular rash occurs through the appearance of scabbing of the pustular lesions. Infection is thought to occur from inhalation of saliva droplets containing virus from the oropharyngeal exanthem. Contaminated clothing or linen can also spread infection.

Several days after exposure, a primary viremia is believed to occur that results in dissemination of virus to lymphoid tissues. A secondary viremia occurs ~4 days later that leads to localization of infection in the dermis. Approximately 12 to 14 days following the initial exposure the patient develops high fever, malaise, vomiting, headache, backache, and a maculopapular rash that begins on the face and extremities and spreads to the trunk (centripetal). The lesions are initially maculopapular and evolve to vesicles that eventually become pustules and then scabs. The oral mucosa also develops maculopapular lesions that evolve to ulcers. The lesions appear over a period of 1 to 2 days and evolve at the same rate. Although virus can be isolated from the scabs on the skin, the conventional thinking is that once the scabs have formed the patient is no longer contagious. Smallpox is associated with a 10 to 30% mortality, with patients typically dying of severe systemic illness during the second week of symptoms. Historically, ~5 to 10% of naturally occurring smallpox cases take either of two highly virulent atypical forms, classified as *hemorrhagic* and *malignant*. These are difficult to recognize because of their atypical presentations. The hemorrhagic form is uniformly fatal and begins with the relatively abrupt onset of a severely prostrating illness characterized by high fevers and severe headache and back and abdominal pain. Cutaneous erythema develops accompanied by petechiae and hemorrhages into the skin and mucous membranes. Death usually occurs within 5 to 6 days. The malignant form is frequently fatal and has an onset similar to the hemorrhagic form, but with confluent lesions developing more slowly and never progressing to the pustular stage.

TREATMENT

Given the highly infectious nature of smallpox and the extreme vulnerability of contemporary society, patients who are suspected cases should be handled with strict isolation procedures. While laboratory confirmation of a suspected case by culture and electron microscopy is essential, it is equally important that appropriate precautions be employed when obtaining samples for culture and laboratory testing. All health care and laboratory workers caring for patients should have been recently immunized with vaccinia, and all samples should be transported in doubly sealed containers. Patients should be cared for in negative-pressure rooms with strict isolation precautions.

There is no licensed specific therapy for smallpox, and historic treatments have focused solely on supportive care. While several antiviral agents, including cidofovir, that are licensed for other diseases have in vitro activity against *V. major*, they have never been tested in the setting of human disease. For this reason it is difficult to predict whether or not they would be effective in cases of smallpox and, if effective, whether or not they would be of value in patients with advanced disease. Research programs studying the efficacy of new antiviral compounds against *V. major* are currently under way.

Vaccination and Prevention In 1796 Edward Jenner demonstrated that deliberate infection with cowpox could prevent subsequent infection with smallpox. Today, smallpox is a preventable disease following immunization with vaccinia. The current dilemma facing our society regarding assessment of the risk and/or benefit of smallpox vaccination is that the degree of risk that someone will deliberately and effectively release smallpox into our society is unknown. As a prudent first step in preparedness for a smallpox attack, virtually all members of the U.S. armed services have received primary or booster immunizations with vaccinia. In addition, tens of thousands of civilian health care workers who comprise smallpox-response teams at the state and local public health level have been vaccinated. The voluntary vaccination of other civilian first responders continues as part of a broader smallpox preparedness program.

Initial fears regarding the immunization of a segment of the American population with vaccinia when there are more individuals receiving immunosuppressive drugs and other immunocompromised patients than ever before have largely been dispelled as data are generated from the current military and civilian immunization campaigns. Adverse event rates for the first 450,000 immunizations are similar to and, in certain categories of adverse events, even lower than those from historic data (Table 205-5). In addition, 11 patients with early stage HIV infection have been inadvertently immunized without problem. One significant concern during the recent immunization campaign, however, has been the description of a syndrome of myopericarditis, which was not appreciated during prior immunization campaigns with vaccinia.

TULAREMIA (*FRANCISELLA TULARENSIS*) (See also Chap. 142) ■ **Tularemia as a Bioweapon** Tularemia has been studied as an agent of bioterrorism since the mid-twentieth century, and it has been suggested that the outbreak of tularemia among German and Soviet soldiers during fighting on the Eastern Front during WWII might have been the consequence of a deliberate release. Unit 731 of the Japanese Army studied the use of tularemia as a bioweapon during WWII. Large quantities of *F. tularensis* were grown by the United States and were reportedly grown by the Soviet Union in the mid-1950s. It has also been suggested that the Soviet program extended into the era of molecular biology and that some strains were engineered to be resistant to common antibiotics. *F. tularensis* is an extremely infectious organism, and human infections have occurred from merely examining an uncovered petri dish streaked with colonies. Given these facts, it is reasonable to conclude that this organism might be utilized as a bioweapon through either an aerosol or contamination of food or drinking water.

Microbiology and Clinical Features While similar in many ways to anthrax and plague, tularemia, also referred to as rabbit fever or deer fly fever, is neither as lethal nor as fulminant as either of these other two category A bacterial infections. It is, however, extremely infectious, and as few as 10 organisms can lead to establishment of infection. Despite this fact, it is not spread from person to person. Tularemia is caused by *F. tularensis*, a small, nonmotile, gram-negative coccobacillus. Although it is not a spore-forming organism, it is a hardy bacterium that can survive for weeks in the environment. Infection typically comes from insect bites or contact with organisms in the environment. Large waterborne outbreaks have been recorded.

Humans can become infected through a variety of environmental sources. Infection is most common in rural areas where a variety of small mammals may serve as reservoirs. Human infections in the summer are often the result of insect bites from ticks, flies, or mosquitoes that have bitten infected animals. In colder months infections are most likely the result of direct contact with infected mammals and are most common in hunters. In these settings infection typically presents as a systemic illness with an area of inflammation and necrosis at the site

TABLE 205-5 *Complications from 438,134 Administrations of Vaccinia During the United States Department of Defense (DoD) Smallpox Immunization Campaign Initiated in December 2002*

Complication	Number of Cases	DoD Rate per Million Vaccinees (95% Confidence Interval)	Historic Rate Per Million Vaccinees
Mild or temporary:			
Generalized vaccinia, mild	35	67 (52, 85)	45 to 212[a]
Inadvertent inoculation, self	62	119 (98, 142)	606[a]
Vaccinia transfer to contact	28	53 (40, 69)	8 to 27[a]
Moderate or serious:			
Encephalitis	1	2.2 (0.6, 7.2)	2.6 to 8.7[a]
Acute myopericarditis	69	131 (110, 155)	100[b]
Eczema vaccinatum	0	0 (0, 3.7)	2 to 35[a]
Progressive vaccinia	0	0 (0, 3.7)	1 to 7[a]
Death[c]	1	1.9 (0.2, 5.6)	1 to 2[a]

[a] Based on adolescent and adult smallpox vaccinations from 1968 studies, both primary and revaccinations.
[b] Based on case series in Finnish military recruits given the Finnish strain of smallpox vaccine.
[c] Potentially attributable to vaccination; after lupus-like illness.

of tissue entry of the infection. Drinking of contaminated water may lead to an oropharyngeal form of tularemia characterized by pharyngitis with cervical and/or retropharyngeal lymphadenopathy (Chap. 142). The most likely mode of dissemination of tularemia as a biologic weapon would be as an aerosol. Approximately 1 to 14 days following exposure by this route one would expect to see inflammation of the airways with pharyngitis, pleuritis, and bronchopneumonia. Typical symptoms would include the abrupt onset of fever, fatigue, chills, headache, and malaise (Table 205-3). Some patients might experience conjunctivitis with ulceration, pharyngitis, and/or cutaneous exanthems. A pulse-temperature dissociation might be present. Approximately 50% of patients would show a pulmonary infiltrate on chest x-ray. Hilar adenopathy might also be present, and a small percent of patients could have adenopathy without infiltrates. Diagnosis is made by immunohistochemistry or culture of infected tissues or blood. Untreated, mortality rates range from 5 to 15% for cutaneous routes of infection and 30 to 60% for infection by inhalation. Since the advent of antibiotic therapy, these rates have dropped to <2%.

TREATMENT

Both streptomycin and doxycycline are licensed for treatment of tularemia. Other agents likely to be effective include gentamicin, chloramphenicol, and ciprofloxacin (Table 205-4). Given the potential for genetic modification of this organism to yield antibiotic-resistant strains, broad-spectrum coverage should be the rule until sensitivities have been determined. As mentioned above, special isolation procedures are not required.

Vaccination and Prevention There are no vaccines currently licensed for the prevention of infection with *F. tularensis*. While a live, attenuated strain of the organism has been used in the past with some reported success, there are inadequate data to support its widespread use at this time. Development of a vaccine for this agent is an important part of the current biodefense research agenda. In the absence of an effective vaccine, chemoprophylaxis with either doxycycline or ciprofloxacin appears to be a reasonable approach in individuals who have been exposed (Table 205-4).

VIRAL HEMORRHAGIC FEVERS (See also Chaps. 180 and 181) ■ **Hemorrhagic Fever Viruses as Bioweapons** Several of the hemorrhagic fever viruses have been reported to have been weaponized by the Soviet Union and the United States. Nonhuman primate studies indicate that infection can be established with very few virions and that infectious aerosol preparations can be produced. Under the guise of wanting to aid victims of the latest Ebola outbreak, members of the Aum Shrinrikyo cult in Japan were reported to have traveled to central Africa in 1992 in an attempt to obtain Ebola virus for use in a bioterrorist attack. Thus, while there has been no evidence that these agents have ever been used in a biologic attack, there is clear interest in their potential for this purpose.

Microbiology and Clinical Features The viral hemorrhagic fevers are a group of illnesses caused by any one of a number of similar viruses (Table 205-2). These viruses are all enveloped, single-strand RNA viruses that are thought to depend upon a rodent or insect host reservoir for long-term survival. They tend to be geographically restricted according to the migration patterns of their hosts. It is felt that Ebola has been responsible for the deaths of significant numbers of apes in sub-Saharan Africa. While humans are not a reservoir for these viruses, humans can become infected with them if they come into contact with an infected host or other infected animals. Person-to-person transmission has been documented for Ebola, Marburg, Lassa, and New World arenaviruses. While the modes of transmission for naturally occurring infections are largely unknown, these viruses have been shown in animal models to be highly infectious by the aerosol route. This, coupled with mortality rates as high as 90%, makes them excellent candidate agents of bioterrorism.

The clinical features of the viral hemorrhagic fevers may vary depending upon the particular agent (Table 205-4). Initial signs and symptoms typically include fever, myalgia, prostration, and diffuse intravascular coagulation with thrombocytopenia and capillary hemorrhage. A variety of different maculopapular or erythematous rashes may be seen. Leukopenia, temperature-pulse dissociation, renal failure, and seizures may also be part of the clinical presentation. Outbreaks of most of these diseases are sporadic and unpredictable. As a consequence it has been very difficult to study the pathogenesis and epidemiology in any detail. The diagnosis should be suspected in anyone with temperature >38.3°C for <3 weeks who also exhibits at least two of the following: hemorrhagic or purpuric rash, epistaxis, hematemesis, hemoptysis, or hematochezia in the absence of any other identifiable cause. In this setting, samples of blood should be sent to the CDC or the U.S. Army Medical Research Institute of Infectious Diseases (USAMRIID) for serologic testing for antigen and antibody as well as reverse transcriptase polymerase chain reaction (RT-PCR) testing for hemorrhagic fever viruses. All samples should be handled with double-bagging. Given how little is known regarding the human-to-human transmission of these viruses, appropriate isolation measures would include full barrier precautions with negative-pressure rooms and use of N95 masks or powered air-purifying respirators (PAPRs). Unprotected skin contact with cadavers has been implicated in the transmission of certain hemorrhagic fever viruses such as Ebola, so it is recommended that autopsies be performed using the strictest measures for protection and that burial or cremation be performed promptly without embalming.

TREATMENT

There are no approved and effective antiviral therapies for this class of viruses (Table 205-4). While there are anecdotal reports of the efficacy of ribavirin, interferon α, or hyperimmune immunoglobulin, definitive data are lacking. The best data for ribavirin are in arenavirus (Lassa and New World) infections. In some animal models specific immunoglobulin has been reported to enhance disease progression, and thus these potential treatments must be approached with caution.

Vaccination and Prevention A live attenuated virus vaccine is available in limited quantities for prevention of yellow fever. There are no other licensed and effective vaccines for these agents. Studies are currently under way examining the potential role of DNA, recombinant viruses, and attenuated viruses as vaccines for several of these infections. Among the most promising at present are vaccines for Argentine, Ebola, Rift Valley, and Kayasanur Forest viruses. Vaccines for Marburg and Lassa viruses are in preclinical testing.

BOTULISM TOXIN (*CLOSTRIDIUM BOTULINUM*) (See also Chap. 126) ■ **Botulism Toxin as a Bioweapon** In a bioterrorist attack, botulinum toxin would likely be dispersed as an aerosol or as contamination of a food supply. While contamination of a water supply is possible, it is likely that any toxin would be rapidly inactivated by the chlorine used to purify drinking water. Similarly, toxin can be inactivated by heating any food to >85°C for >5 min. Without external facilitation, the environmental decay rate is estimated at 1% per minute, and thus the time interval between deposition and ingestion or inhalation needs to be rather short. The Japanese biologic warfare group, Unit 731, is reported to have conducted experiments on botulism poisoning in prisoners in the 1930s. The United States and the Soviet Union both acknowledged producing botulinum toxin, and there is some evidence that the Soviet Union attempted to create recombinant bacteria containing the gene for botulinum toxin. In records submitted to the United Nations, Iraq admitted to having produced 19,000 L of concentrated toxin—enough toxin to kill the entire population of the world three times over. By many accounts, botulinum toxin was the primary focus of the pre-1991 Iraqi bioweapons program. In addition to these examples of state-supported research into the use of botulinum toxin as a bioweapon, the Aum Shrinrikyo cult has unsuccessfully attempted on a least three

occasions to disperse botulism toxin into the civilian population of Tokyo.

Microbiology and Clinical Features Unique among the category A agents for not being a live microorganism, botulinum toxin is one of the most potent toxins ever described and is thought by some to be the most poisonous substance in existence. It is estimated that 1 g of botulinum toxin would be sufficient to kill 1 million individuals if adequately dispersed. Botulinum toxin is produced by the gram-positive, spore-forming anaerobe *C. botulinum* (Chap. 126). Its natural habitat is soil. There are seven antigenically distinct forms of botulinum toxin, designated A to G. The majority of naturally occurring human cases are of types A, B, and E. Antitoxin directed toward one of these will have little to no activity against the others. The toxin is a 150-kDa zinc-containing protease that prevents the intracellular fusion of acetylcholine vesicles with the motor neuron membrane, thus preventing the release of acetylcholine. In the absence of acetylcholine-dependent triggering of muscle fibers, a flaccid paralysis develops. Although person-to-person spread does not occur, the ease of production of botulinum toxin coupled with its high morbidity and 60 to 100% mortality make it a close to ideal bioweapon.

Botulism can result from the presence of *C. botulinum* infection in a wound or the intestine, the ingestion of contaminated food, or the inhalation of aerosolized toxin. The latter two forms are the most likely modes of transmission for bioterrorism. Once toxin is absorbed into the bloodstream it binds to the neuronal cell membrane, enters the cell, and cleaves one of the proteins required for the intracellular binding of the synaptic vesicle to the cell membrane, thus preventing release of the neurotransmitter to the membrane of the adjacent muscle cell. Patients initially develop multiple cranial nerve palsies that are followed by a flaccid paralysis. The extent of the neuromuscular compromise is dependent upon the level of toxemia. The majority of patients experience diplopia, dysphagia, dysathria, dry mouth, ptosis, dilated pupils, fatigue, and extremity weakness. There are minimal true central nervous system effects, and patients rarely show significant alterations in mental status. Severe cases can involve complete muscular collapse, loss of the gag reflex, and respiratory failure. Recovery requires the regeneration of new motor neuron synapses with the muscle cell, a process that can take weeks to months. In the absence of secondary infections, which may be common during the protracted recovery phase of this illness, patients remain afebrile. The diagnosis is suspected on clinical grounds and confirmed by a mouse bioassay or toxin immunoassay.

TREATMENT

Treatment for botulism is mainly supportive and may require intubation, mechanical ventilation, and parenteral nutrition (Table 205-4). If diagnosed early enough, administration of equine antitoxin may lead to a decrease in the level of nerve damage and severity of disease. At present antitoxins are available on a limited basis as a licensed bivalent product with activity against toxin types A and B and as an experimental product with activity against toxin type E. In the event of attack with another toxin type, an investigational antitoxin with activity against all seven toxin types is also available through the U.S. Army. A single dose of antitoxin is usually adequate to neutralize any circulating toxin. Given that these preparations are all derived from horse serum, one needs to be vigilant for hypersensitivity reactions, including serum sickness and anaphylaxis following their administration. Once the damage to the nerve axon has been done, however, there is little possible in the way of specific therapy, and vigilance for secondary complications during recovery is of the utmost importance. During the protracted recovery phase of botulism, patients may experience secondary infections. Due to their ability to worsen neuromuscular blockade, aminoglycosides and clindamycin should be avoided in the treatment of these infections.

Vaccination and Prevention A botulinum toxoid preparation has been used as a vaccine for laboratory workers at high risk of exposure and in certain military situations; however, it is not currently available in quantities that could be used for the general population. At present, early recognition of the clinical syndrome and use of appropriate equine antitoxin is the mainstay of prevention of full-blown disease in exposed individuals. The development of human monoclonal antibodies as a replacement for equine antitoxin antibodies is an area of active research interest.

CATEGORY B AND C AGENTS

The category B agents include those that are moderately easy to disseminate and result in moderate morbidity and low mortality rates. A listing of the current category B agents is provided in Table 205-2. As can be seen, it includes a wide array of microorganisms and products of microorganisms. Several of these agents have been used in bioterrorist attacks, although never with the impact of the agents described above. Among the more notorious of these was the contamination of salad bars in Oregon in 1984 with *Salmonella typhimurium* by the Indian religious cult Rajneeshee. In this outbreak, which many consider to be the first bioterrorist attack against U.S. citizens, >750 individuals were poisoned and 40 were hospitalized in an effort to influence a local election.

Category C agents are the third highest priority agents in the biodefense agenda. These agents include emerging pathogens to which little or no immunity exists in the general population, such as the SARS coronavirus, that could potentially be engineered for mass dissemination in the future because of their availability in nature. These agents are characterized as being relatively easy to produce and disseminate and as having high morbidity and mortality rates as well as a major public health impact. There is no running list of category C agents at the present time.

PREVENTION AND PREPAREDNESS

As noted above, a numerous and diverse array of agents have the potential to be used in a bioterrorist attack. In contrast to the military situation with biowarfare, where the primary objective is to inflict mass casualties on a healthy and prepared militia, the objectives of bioterrorism are to harm civilians as well as to create fear and disruption among the civilian population. While the military needs only to prepare their troops to deal with the limited number of agents that pose a legitimate threat of biowarfare, the public health system needs to prepare the entire civilian population to deal with the multitude of agents and settings that could be utilized in a bioterrorism attack. This includes anticipating issues specific to the very young and the very old, the pregnant patient, and the immunocompromised individual. The challenges in this regard are enormous and immediate. While military preparedness emphasizes vaccines toward a limited number of agents, civilian preparedness needs to rely upon rapid diagnosis and treatment of a wide array of conditions.

The medical profession must maintain a high index of suspicion that unusual clinical presentations or clustering of rare disease may not be a chance occurrence but rather the first sign of a bioterrorist event. This is particularly true when such diseases occur in traditionally healthy populations, when surprisingly large numbers of rare conditions occur, and when diseases commonly seen in rural settings appear in urban populations. Given the importance of rapid diagnosis and early treatment for many of these conditions, it is important that the medical care team report any suspected cases of bioterrorism immediately to local and state health authorities and/or to the CDC (888-246-2675). Recent enhancements have been made to the public health surveillance network to facilitate the rapid sharing of information among public health agencies.

At present a series of efforts are taking place to ensure the biomedical security of the civilian population in the United States. The Public Health Service is moving toward a larger, more highly trained, fully deployable force. A National Pharmaceutical Stockpile (NPSP) has been created by the CDC to provide rapid access to quantities of

pharmaceuticals, antidotes, vaccines, and other medical supplies that may be of value in the event of a biologic or biochemical terrorist event. The NPSP has two basic components. The first of these consists of eight 50-ton (45,360-kg) "push packages" that can be deployed anywhere in the United States within 12 h. These push packages are a preassembled set of supplies, pharmaceuticals, and medical equipment ready for immediate delivery to the field. They provide treatment for a variety of conditions given the fact that an actual threat may not have been precisely identified at the time of stockpile deployment. The contents of the push packs are constantly updated to ensure that they reflect current needs as determined by national security threat assessments; they include antibiotics for treatment of anthrax, plague, and tularemia as well as a cache of vaccine to deal with a smallpox threat. The second component of the NPSP comprises inventories managed by specific vendors and consists of the provision of additional pharmaceuticals, supplies, and/or products tailored to the specific attack.

The number of FDA-approved and -licensed drugs and vaccines for category A and B agents is currently limited and not reflective of the pharmacy of today. In an effort to speed the licensure of additional drugs and vaccines for these diseases, the FDA has proposed a new rule for the licensure of such countermeasures against agents of bioterror when adequate and well-controlled clinical efficacy studies cannot be ethically conducted in humans. Thus, for indications in which field trials of naturally occurring disease are not feasible, the FDA is proposing to rely on evidence solely from animal studies. For this rule to apply it must be shown that (1) there are reasonably well-understood pathophysiologic mechanisms for the condition and its treatment; (2) the effect of the intervention is independently substantiated in multiple animal species, including species expected to react with a response predictive for humans; (3) the animal study end point is clearly related to the desired benefit in humans; and (4) the data in animals allow selection of an effective dose in humans.

Finally, an initiative referred to as Project BioShield has been established to facilitate biodefense research within the federal government, create a stable source of funding for the purchase of countermeasures against agents of bioterrorism, and create a category of "emergency use authorization" to allow the FDA to approve the use of unlicensed treatments during times of extraordinary unmet needs as might be present in the context of a bioterrorist attack.

While the prospect of a deliberate attack on civilians with disease-producing agents may seem to be an act of incomprehensible evil, history shows us that it is something that has been done in the past and will likely be done again in the future. It is the responsibility of health care providers to be aware of this possibility, to be able to recognize early signs of a potential bioterrorist attack and alert the public health system, and to respond quickly to provide care to the individual patient. Among the web sites with current information on microbial bioterrorism are *www.bt.cdc.gov*, *www.niaid.nih.gov*, *www.hopkinsbiodefense.org*, and *www.cns.miis.edu/research/cbw/index.htm*.

206 CHEMICAL BIOTERRORISM

Charles G. Hurst, Jonathan Newmark, James A. Romano

The use of chemical warfare agents (CWAs) as weapons of terror against civilian populations is a potential reality that must be addressed by public health officials and by the medical profession. The use of sulfur mustard and nerve agents by Iraq against the Iranian military and Kurdish civilians, the sarin attacks in 1994–1995 in Japan, and the terrorist strikes of September 11, 2001, followed by the anthrax attacks in Florida, New York, and Washington, D.C., underscore this threat.

Many of the World War I (WWI) chemical agents, including chlorine, phosgene, and cyanide, are used in large amounts in industry. They are produced in chemical plants, stockpiled in large tanks, and travel up and down highways and railways in large tanker cars. The rupture of any of these by accident or purposefully could cause many injuries and deaths. Hazardous materials (HAZMATs), not used on the battlefield, can also be used as terrorist weapons. Some of these, including insecticides and ammonia, could wreak as much damage and injury as the weaponized chemical agents.

Military planners consider the WWI blistering agent, sulfur mustard, and the organophosphorus nerve agents as the most likely agents to be used on the battlefield. In a civilian or terrorist scenario, the choice widens considerably. Cyanide, a common chemical, causes symptoms within seconds and death in 5 to 10 min if not treated rapidly. Chlorine and phosgene have no specific antidotes but can require intensive care for weeks to months. Many believe these agents or one of the industrial HAZMATs will be the likely choice of terrorists.

Many mistakenly believe that chemical attacks will always be so severe that little can be done except to bury the dead. History proves the opposite. Even in WWI, when intravenous fluids, endotracheal tubes, and antibiotics were unavailable, the mortality rate in U.S. forces on the battlefield from chemical warfare agents, chiefly sulfur mustard and the pulmonary intoxicants, was only 1.9%. This was far less than the mortality rate from conventional wounds (7%). In the 1995 Tokyo subway sarin incident, of the 5500 patients who sought medical attention at hospitals, 80% of whom were not actually symptomatic, only 12 died. Thus, it is prudent to attempt to understand the pathophysiology of the syndromes that these agents cause, with a view to treating all patients who present for care expeditiously and with an expectation of saving the vast majority. As we prepare to defend our civilian population from the effects of chemical terrorism, we must also consider that the concept of terrorism can itself produce sequelae in some individuals—physiologic and/or psychological effects that may resemble the effects of nonlethal exposures to CWAs. These effects are due to a general fear of chemicals, fear of decontamination, fear of protective ensemble, or other phobic reactions.

There may be difficulty in differentiating between stress reactions and nerve agent–induced organic brain syndromes. Knowledge of the behavioral effects of CWAs and their medical countermeasures is imperative in order to ensure that military and civilian medical and mental health organizations can deal with possible incidents involving weapons of mass destruction.

The agents of chemical terrorism together with their North Atlantic Treaty Organization (NATO) codes, their unique characteristics, and initial effects are summarized in Table 206-1. An outline of the approaches to decontamination and treatment of the agents of chemical terrorism is shown in Table 206-2. This chapter will restrict its discussion to vesicants and nerve agents, which are considered as a priority based on threat assessments and prior experiences in chemical warfare. For a more comprehensive listing and discussion of agents of

TABLE 206-1 *Recognizing and Diagnosing Health Effects of Chemical Terrorism*

Agent	Agent Name	Unique Characteristics	Initial Effects
Nerve	Cyclohexyl sarin (GF) Sarin (GB) Soman (GD) Tabun (GA) VX	Miosis (pinpoint pupils) Copious secretions Muscle twitching/fasciculations	Miosis (pinpoint pupils) Blurred/dim vision Headache Nausea, vomiting, diarrhea Copious secretions/sweating Muscle twitching/fasciculations Breathing difficulty Seizures
Asphyxiant/blood	Arsine Cyanogen chloride Hydrogen cyanide	Possible cherry red skin Possible cyanosis Possible frostbite[a]	Confusion Nausea Patients may gasp for air, similar to asphyxiation but more abrupt onset Seizures prior to death
Choking/pulmonary-damaging	Chlorine Hydrogen chloride Nitrogen oxides Phosgene	Chlorine is a greenish-yellow gas with pungent odor Phosgene gas smells like newly mown hay or grass Possible frostbite[a]	Eye and skin irritation Airway irritation Dyspnea, cough Sore throat Chest tightness
Blistering/vesicant	Mustard/Sulfur mustard (HD, H) Mustard gas (H) Nitrogen mustard (HN-1, HN-2, HN-3) Lewisite (L) Phosgene oxime (CX)	Mustard (HD) has an odor like burning garlic or horseradish Lewisite (L) has an odor like penetrating geranium Phosgene oxime (CX) has a pepperish or pungent odor	Severe irritation Redness and blisters of the skin Tearing, conjunctivitis, corneal damage Mild respiratory distress to marked airway damage May cause death
Incapacitating/behavior-altering	Agent 15/BZ	May appear as mass drug intoxication with erratic behaviors, shared realistic and distinct hallucinations, disrobing and confusion Hyperthermia Mydriasis (dilated pupils)	Dry mouth and skin Initial tachycardia Altered consciousness, delusions, denial of illness, belligerence Hyperthermia Ataxia (lack of coordination) Hallucinations Mydriasis (dilated pupils)

[a] Frostbite may occur from skin contact with liquid arsine, cyanogen chloride, or phosgene.

chemical terrorism, the reader is referred to Tables 206-1 and 206-2 as well as to the Centers for Disease Control and Prevention website at http://www.bt.cdc.gov/agent/agentlistchem.asp. Also, the antidote recommendations for exposure to cyanide are given in Table 206-3.

VESICANTS

SULFUR MUSTARD, NITROGEN MUSTARD, LEWISITE Sulfur mustard has been a military threat since it first appeared on the battlefield in Belgium during WWI. In modern times it remains a threat on the battlefield as well as a potential terrorist threat because of simplicity of manufacture and extreme effectiveness. Sulfur mustard accounted for 70% of the 1.3 million chemical casualties in WWI. Only sulfur mustard will be discussed here due to space constraints and because it is the prototypical vesicant or blistering agent (Table 206-1).

Mechanism Sulfur mustard constitutes both a vapor and a liquid threat to all exposed epithelial surfaces. Mustard's effects are delayed, appearing hours after exposure. Organs most commonly affected are the skin (with erythema and vesicles), eyes (ranging from mild conjunctivitis to severe eye damage), and airways (ranging from mild upper airway irritation, to severe bronchiolar damage). Following exposure to large quantities of mustard, precursor cells of the bone marrow are damaged, leading to pancytopenia and secondary infection. The gastrointestinal mucosa may be damaged, and there are sometimes central nervous system (CNS) signs of unknown mechanism. No specific antidotes exist; management is entirely supportive.

Mustard dissolves slowly in aqueous media, such as sweat, but once dissolved, it rapidly forms extremely reactive cyclic ethylene sulfonium ions, which reacts with cell proteins, cell membranes, and especially DNA in rapidly dividing cells. Mustard's ability to react with and alkylate DNA gives rise to the effects by which it has been characterized as "radiomimetic," similar to radiation injury. Mustard has many biological actions, but their actual mechanism of action is largely unknown. Much of the biological damage from mustard results from DNA alkylation and cross-linking in rapidly dividing cells: corneal epithelium, basal keratinocytes, bronchial mucosal epithelium, gastrointestinal mucosal epithelium, and bone marrow precursor cells. This may lead to cellular death and inflammatory reactions. In the skin, proteolytic digestion of anchoring filaments at the epidermal-dermal junction may be the major mechanism of action resulting in blister formation. Mustard also possesses mild cholinergic activity, which may be responsible for effects such as early gastrointestinal and CNS symptoms.

Mustard reacts with tissue within minutes of entering the body. Its circulating half-life in unaltered form is extremely brief.

Clinical Features Topical effects of mustard occur in the skin, airways, and eyes, with the latter being most sensitive, followed by the airways. Absorbed mustard may produce effects in the bone marrow, gastrointestinal tract, and CNS. Direct injury to the gastrointestinal tract may also occur following ingestion of the compound through contamination of water or food.

Erythema is the mildest and earliest form of mustard skin injury (Table 206-1). It resembles sunburn and is associated with pruritus, burning, or stinging pain. Erythema begins to appear within 2 h to 2 days after vapor exposure. Time of onset depends on the severity of exposure, ambient temperature and humidity, and type of skin. The most sensitive sites are the warm moist locations and thin delicate skin, such as the perineum, external genitalia, axillae, antecubital fossae, and neck.

Within the erythematous areas, small vesicles can develop, which may later coalesce to form bullae. The typical bulla is large, dome-shaped, flaccid, thin-walled, translucent, and surrounded by erythema. The blister fluid, a transudate, is clear to straw-colored, which becomes yellow, tending to coagulate. The fluid does not contain mustard and is not itself a vesicant. Lesions from high-dose liquid exposure may develop a central zone of coagulation necrosis with blister formation at the periphery. These lesions take longer to heal and are more prone to secondary infection than the uncomplicated lesions seen at lower exposure levels. Severe lesions may require skin grafting.

TABLE 206-2 *Decontamination and Treatment of Chemical Terrorism*

Agent	Decontamination	First Aid	Other Patient Considerations
Nerve	Remove clothing immediately Gently wash skin with soap and water Do not abrade skin For eyes, flush with plenty of water or normal saline	Atropine before other measures Pralidoxime (2-PAM) chloride	Onset of symptoms from dermal contact with liquid forms may be delayed Repeated antidote administration may be necessary
Asphyxiant/blood	Remove clothing immediately if no frostbite* Gently wash skin with soap and water Do not abrade skin For eyes, flush with plenty of water or normal saline	Rapid treatment with oxygen For cyanide, use antidotes (sodium nitrate and then sodium thiosulfate)	Arsine and cyanogen chloride may cause delayed pulmonary edema
Choking/pulmonary-damaging	Remove clothing immediately if no frostbite* Gently wash skin with soap and water Do not abrade skin For eyes, flush with plenty of water or normal saline	Fresh air, forced rest Semi-upright position If signs of respiratory distress are present, oxygen with or without positive airway pressure may be needed Other supportive therapy, as needed	May cause delayed pulmonary edema, even following a symptom-free period that varies in duration with the amount inhaled
Blistering/vesicant	Immediate decontamination is essential to minimize damage Remove clothing immediately Gently wash skin with soap and water Do not abrade skin For eyes, flush with plenty of water or normal saline	Immediately decontaminate skin Flush eyes with water or normal saline for 10–15 minutes If breathing difficulty, give oxygen Supportive care	Mustard has an asymptomatic latent period There is no antidote or treatment for mustard Lewisite has immediate burning pain, blisters later Specific antidote British Anti-Lewisite (BAL) may decrease systemic effects of Lewisite Phosgene oxime causes immediate pain Possible pulmonary edema
Incapacitating/behavior-altering	Remove clothing immediately Gently wash skin with water or soap and water Do not abrade skin	Remove heavy clothing Evaluate mental status Use restraints as needed Monitor core temperature carefully Supportive care	Hyperthermia and self-injury are largest risks Hard to detect because it is an odorless and non-irritating substance Possible serious arrhythmias Specific antidote (physostigmine) may be available

[a] For frostbite areas, do NOT remove any adhering clothing. Wash area with plenty of warm water to release clothing.
Source: State of New York, Department of Health.

The primary airway lesion is necrosis of the mucosa with possible damage to underlying smooth muscle. The damage begins in the upper airways and descends to the lower airways in a dose-dependent manner. Usually, the terminal airways and alveoli are affected only as a terminal event. Pulmonary edema is not usually present unless the damage is very severe; in this case, it often becomes hemorrhagic.

The earliest effects from mustard, perhaps the only effects from a low concentration, involve the nose, sinuses, and pharynx. There may be irritation or burning of the nares, epistaxis, sinus pain, and pharyngeal pain. As the concentration increases, laryngitis, voice changes, and nonproductive cough develop. Damage to the trachea and upper bronchi leads to a productive cough. Lower airway involvement causes dyspnea, severe cough, and increasing quantities of sputum. Terminally, there may be necrosis of the smaller airways with hemorrhagic edema into the surrounding alveoli. Hemorrhagic pulmonary edema is rare.

Necrosis of airway mucosa causes "pseudomembrane" formation. These membranes may cause obstruction of the bronchi. During WWI, high-dose mustard exposure caused acute death via this mechanism in a small minority of cases.

The eyes are the organs most sensitive to mustard vapor injury. The latent period is shorter for eye injury than for skin injury and is also exposure concentration–dependent. After low-dose vapor exposure, irritation evidenced by reddening of the eyes may be the only effect. As the dose increases, the injury includes progressively more severe conjunctivitis, photophobia, blepharospasm, pain, and corneal damage (Fig. 206-1).

Ninety percent of eye casualties heal in 2 weeks to 2 months without sequelae. Scarring between the iris and lens may follow severe effects; this scarring may restrict pupillary movements and may predispose victims to glaucoma. The most severe damage is caused by liquid mustard. After extensive eye exposure, severe corneal damage with possible perforation of the cornea and loss of the eye can occur. In some individuals, chronic eye irritation, sometimes associated with corneal ulcerations, has been described 10 to 20 years after exposure.

The mucosa of the gastrointestinal tract is susceptible to mustard damage, either from systemic absorption or ingestion of the agent. Mustard exposure in small amounts will cause nausea and possible vomiting lasting up to 24 h. The mechanism of the nausea and vomiting is not understood, but mustard does have a cholinergic-like effect. The CNS effects of mustard, likewise, remain poorly defined. Large exposures can cause seizures in animals. Reports from WWI and Iran described the behavior of persons exposed to small amounts of mustard as sluggish, apathetic, and lethargic. These reports suggest that minor psychological problems could linger for a year or longer.

The causes of death in the majority of mustard poisoning cases are sepsis and respiratory failure. Mechanical obstruction via pseudomembrane formation and agent-induced laryngospasm is important in the first 24 h, but only in cases of severe exposure. From the third through the fifth day after exposure, a secondary bacterial pneumonia can be expected due to invasion of denuded necrotic mucosa. The third wave of death is caused by agent-induced bone marrow suppression, which peaks 7 to 21 days after exposure and causes death via sepsis.

TREATMENT

A patient severely ill from mustard poisoning requires the general supportive care provided for any severely ill patient as well as the

specific care given to a burn patient. Liberal use of systemic analgesics, maintenance of fluid and electrolyte balance and nutrition, use of appropriate antibiotics, and other supportive measures are necessary (Table 206-2).

The management of a patient exposed to mustard may range from simple, as in the provision of symptomatic care for a sunburn-like erythema, to complex, as in the provision of total management for a severely ill patient with burns, immunosuppression, and multisystem involvement. Before raw denuded areas of skin develop, especially with less severe exposures, topical cortisone creams or lotions may be of benefit. Some very basic research data point to the early use of anti-inflammatory preparations. Small blisters (<1 to 2 cm) should be left intact. Because larger bullae will eventually break, they should be carefully unroofed. Denuded areas should be irrigated three to four times daily with saline, other sterile solutions, or soapy water and then liberally covered with the topical antibiotic of choice, such as silver sulfadiazine or mafenide acetate, to a thickness of 1 to 2 mm. Some advocate sterile needle drainage of large blisters, collapsing the blister roof to form a sterile dressing. Mustard blister fluid does not contain sulfur mustard, only sterile tissue fluid. Health care staff should not fear possible contamination. If an antibiotic cream is not available, sterile petrolatum is useful. Modified Dakins solution (sodium hypochlorite 0.5%) was used both in WWI and in Iranian casualties (1984–1987) for field-expedient irrigation and antisepsis. Large areas of vesication require hospitalization, intravenous therapy, and whirlpool bath irrigation.

TABLE 206-3 *Antidote Recommendations Following Exposure to Cyanide*

Patient	Mild (Conscious)	Severe (Unconscious)	Other Treatment
Child	If patient is conscious and has no other signs or symptoms, antidotes may not be necessary.	Sodium nitrite[a]: 0.12–0.33 mL/kg, not to exceed 10 mL of 3% solution[b] slow IV over no less than 5 min, or slower if hypotension develops *and* Sodium thiosulfate: 1.65 mL/kg of 25% solution IV over 10–20 min	For sodium nitrite–induced orthostatic hypotension, normal saline infusion and supine position are recommended. If still apneic after antidote administration, consider sodium bicarbonate for severe acidosis.
Adult	If patient is conscious and has no other signs or symptoms, antidotes may not be necessary.	Sodium nitrite[a]: 10–20 mL of 3% solution[b] slow IV over no less than 5 min, or slower if hypotension develops *and* Sodium thiosulfate: 50 mL of 25% solution IV over 10–20 min	

[a] If sodium nitrite is unavailable, administer amyl nitrite by inhalation from crushable ampules.
[b] Available in Pasadena Cyanide Antidote Kit, formerly Lilly Cyanide Kit.
Note: Victims whose clothing or skin is contaminated with hydrogen cyanide liquid or solution can secondarily contaminate response personnel by direct contact or through off-gassing vapors. Avoid dermal contact with cyanide-contaminated victims or with gastric contents of victims who may have ingested cyanide-containing materials. Victims exposed only to hydrogen cyanide gas do not pose contamination risks to rescuers. *If the patient is a victim of recent smoke inhalation (may have high carboxyhemoglobin levels), administer only sodium thiosulfate.*
Source: State of New York, Department of Health.

Systemic analgesics should be used liberally, particularly before manipulation of the patient. Monitoring of fluids and electrolytes is important in any sick patient, but it must be recognized that fluid loss is usually not of the magnitude seen with thermal burns. This may be because mustard burns, in general, are more superficial than thermal burns (no definitive data exist to support this supposition). Overly rigorous hydration seems to have precipitated pulmonary edema in a few Iranian casualties sent to European hospitals.

Conjunctival irritation from a low vapor exposure will respond to any of a number of available ophthalmic solutions after the eyes are thoroughly irrigated. A topical antibiotic applied several times a day will reduce the incidence and severity of infection. Animal laboratory data have shown remarkable results with commercially available topical antibiotic/glucocorticoid ophthalmologic ointments applied early. Topical glucocorticoids alone are not of proven value, but their use during the first few hours or days may significantly reduce inflammation and subsequent damage. Further use should be relegated to an ophthalmologist, who should be consulted in any case.

Vaseline or a similar substance should be applied regularly to the edges of the lids to prevent them from sticking together. Although topical analgesics may be useful initially if blepharospasm is too severe to permit an adequate examination, they have limited value.

A productive cough and dyspnea accompanied by fever and leukocytosis occurring within 12 to 24 h is indicative of a chemical pneumonitis. The clinician must resist the urge to use prophylactic antibiotics for this process. Infection often occurs on the third to fifth day and is signaled by an increased fever, pulmonary infiltrate, and an increase in sputum production with a change in color. Initial antibiotic therapy should await evidence of infection from Gram stain of sputum; regimens can then be changed, if appropriate according to the results of sputum culture and sensitivity.

Intubation may be necessary if laryngeal spasm or edema makes it difficult or becomes life-threatening. Intubation permits better ventilation and facilitates suction of the necrotic and inflammatory debris. Early use of positive end-expiratory pressure (PEEP) or continuous positive airway pressure (CPAP) may be beneficial. Pseudomembrane formation may require fiberoptic bronchoscopy for suctioning of the necrotic debris.

Bronchodilators are of benefit for bronchospasm. If additional relief of bronchospasm is needed, glucocorticoids should be used. There is little evidence that the routine use of glucocorticoids is beneficial, except for additional relief of bronchospasm.

Leukopenia begins around day 3 with major systemic absorption. Marrow suppression peaks at 7 to 14 days. In the Iran-Iraq war, a white blood count of $\leq 200/\mu L$ usually resulted in death of the patient. Sterilization of the gut by nonabsorbable antibiotics should be considered to reduce the possibility of sepsis from enteric organisms. Cellular

FIGURE 206-1 World War I photograph of troops exposed to sulfur mustard vapor. The vast majority of these troops survived with no long-term damage to the eyes; however, they were effectively rendered blind for days to weeks.

replacement (bone marrow transplants or transfusions) may be successful. In one study, granulocyte colony-stimulating factor produced a 50% reduction in the time for the bone marrow to recover in nonhuman primates exposed to sulfur mustard and should be considered in the case of human exposure. Medication for nausea and vomiting may be necessary for gastrointestinal side effects.

Excellent assessments of the contributions of DNA alkylation, inflammation, activation of proteolytic enzymes, or lipid peroxidation to the mustard injury have been developed in the past 15 years. Examples include (1) the demonstration up to 75% reduction of inflammation and tissue damage in the mouse ear swelling test by vanilloid compounds, and (2) the demonstration of 50 to 60% protection by *N*-acetylcysteine in the generation of free radicals within guinea pig lung exposed to mustard. In many cases, the demonstration of protection is dependent on the availability of sufficient amounts of drug with adequate half-lives. Strategies to enhance bioavailability include attachment of polyethylene glycol to the antioxidant drug/enzyme or delivery of the drug/enzyme in a liposome (or both).

NERVE AGENTS

The organophosphorus nerve agents are the deadliest of the chemical warfare agents. They work by inhibition of tissue synaptic acetylcholinesterase, creating an acute cholinergic crisis. Death ensues because of respiratory depression and can occur within seconds to minutes (Table 206-1).

The "classic" nerve agents include tabun (GA), sarin (GB), soman (GD), cyclosarin (GF), and VX. VR, similar to VX, was manufactured in the former Soviet Union (Table 206-1). The two-letter codes are a NATO international convention and convey no clinical implications. All of the nerve agents are organophosphorus compounds, which are liquid at standard temperature and pressure. The "G" agents evaporate at about the rate of water, except for GF, which is oily, and thus will probably have evaporated within 24 h after deposition on the ground. Their high volatility thus makes a spill of any amount a serious vapor hazard. In the Tokyo subway attack where sarin was used (see below), 100% of the symptomatic patients inhaled sarin vapor that spilled out on the floor of the subway cars. VX, an oily liquid, is the exception. Its low vapor pressure makes it much less of a vapor hazard but potentially a greater environmental hazard because it persists in the environment far longer.

The nerve agents tabun and sarin were first used on the battlefield by Iraq against Iran during the first Persian Gulf war, 1984–1987. Estimates of casualties from these agents range from 20,000 to 100,000. In 1994 and 1995, the Japanese cult Aum Shinrikyo used sarin in two terrorist attacks in Matsumoto and Tokyo.

Mechanism Acetylcholinesterase inhibition accounts for the major life-threatening effects of nerve agent poisoning. Reversal of this inhibition by antidotal therapy is effective, proving that this is the primary toxic action of these poisons. At cholinergic synapses, acetylcholinesterase, bound to the postsynaptic membrane, functions as a turn-off switch to regulate cholinergic transmission. Inhibition of acetylcholinesterases causes the released neurotransmitter, acetylcholine, to accumulate abnormally. End-organ overstimulation, recognized by clinicians as cholinergic crisis, ensues (Fig. 206-2).

Clinical Features Clinical effects of nerve agent exposure are identical for vapor and liquid exposure routes if the dose is sufficiently large. The speed and order of symptom onset will differ (Table 206-1).

Exposure of a patient to nerve agent vapor, overwhelmingly the more likely route of exposure in both battlefield and terrorist scenarios, will cause cholinergic symptoms in the order that the toxin encounters cholinergic synapses. The most exposed synapses on the integument of the human are in the pupillary muscles. Nerve agent vapor easily crosses the cornea, interacts with these synapses, and produces miosis, described by Tokyo subway victims as "the world going black." Rarely, this can also cause eye pain and nausea. Exocrine glands located in the nose, mouth, and pharynx next become exposed to the vapor, and cholinergic overload here causes increased secretions, rhinorrhea, excess salivation, and drooling. Next, toxin interacts with exocrine glands in the upper airway, causing bronchorrhea, and with bronchial smooth muscle, causing bronchospasm, the combination of which can cause hypoxia.

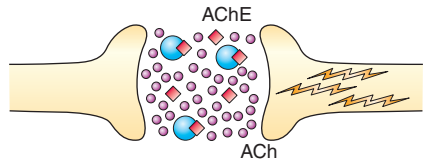

FIGURE 206-2 Schematic diagram of the pathophysiology of nerve agent exposure. Nerve agent (◆) binds to the active site of acetylcholinesterase (AChE), which is shown as floating free in space but is in reality a postsynaptic membrane-bound enzyme. As a result, acetylcholine (●), which is normally released from presynaptic membrane but not normally degraded, accumulates, and this leads (↯) to organ overstimulation and cholinergic crisis.

Once the victim has inhaled, vapor can passively cross the alveolar-capillary membrane, enter the bloodstream, and, incidentally and asymptomatically, inhibit circulating cholinesterases, particularly free butyrylcholinesterase and erythrocyte acetylcholinesterase, both of which can be assayed. Unfortunately, the assay may not be easily interpreted without a baseline, since cholinesterase levels vary enormously between persons and over time in an individual healthy patient.

Usually the first organ system to become symptomatic from bloodborne nerve agent exposure is the gastrointestinal tract, where cholinergic overload causes abdominal cramping and pain, nausea, vomiting, and diarrhea. After the gastrointestinal tract is involved, nerve agents affect the heart, distant exocrine glands, muscles, and brain. Because there are cholinergic synapses on both the vagal (parasympathetic) and sympathetic sides of the autonomic input to the heart, one cannot predict how heart rate and blood pressure will change. Remote exocrine activity will include oversecretion in the salivary, nasal, respiratory, and sweat glands—the patient will be "wet all over." Bloodborne nerve agents overstimulate neuromuscular junctions in skeletal muscles, causing fasciculations followed by frank twitching. If the process goes on long enough, ATP in muscle will eventually be depleted and flaccid paralysis will ensue, although this is never the first sign.

In the brain, since the cholinergic system is so widely distributed, bloodborne nerve agents, in sufficient doses, cause rapid loss of consciousness, seizures, and central apnea, leading to death within minutes. If respiration is supported, status epilepticus, which does not respond to usual anticonvulsants, may ensue (Chap. 349). If status persists, neuronal death and permanent brain dysfunction may occur. Even in mild nerve agent intoxication, patients may recover but experience weeks of irritability, sleep disturbance, and nonspecific neurobehavioral symptoms.

The time from exposure to development of the full-blown cholinergic crisis from nerve agent vapor inhalation can be minutes or even seconds; however, there is no depot effect. Since nerve agents have a short circulating half-life, improvement should be rapid with no subsequent deterioration if the patient is supported and, ideally, treated with antidotes.

Liquid exposure to nerve agents differs in speed and order of symptom onset. A nerve agent on intact skin will partially evaporate and partially begin to travel through the skin, causing localized sweating and then localized fasciculations when it encounters neuromuscular junctions. Once in muscle, it will cross into the circulation and cause gastrointestinal discomfort, respiratory distress, heart rate changes, generalized fasciculations and twitching, loss of consciousness, seizures, and central apnea. The time course will be much longer than with vapor inhalation; even a large, lethal droplet can take up to 30 min to have effect, and a small, sublethal dose could continue to take effect over 18 h. Clinical worsening that occurs hours after treatment has started is far more likely with liquid than with vapor exposure.

Additionally, miosis, practically unavoidable with vapor exposure, is not always present with liquid exposure and may be the last symptom to present in this situation. This is due to the relative insulation of the pupillary muscle from the systemic circulation.

Unless a nerve agent is removed by specific therapy (oximes), its binding to cholinesterase is essentially irreversible. Erythrocyte acetylcholinesterase activity recovers at about 1% per day. Plasma butyrylcholinesterase recovers more quickly and is a better guide to recovery of tissue enzyme activity.

TREATMENT

Acute nerve agent poisoning is treated by decontamination, respiratory support, and three antidotes—an anticholinergic, an oxime, and an anticonvulsant (Tables 206-2 and 206-4). In acute cases, all of these forms of therapy may be given simultaneously.

Decontamination Decontamination of a vapor is theoretically not necessary, but in the Tokyo subway attack, sarin vapor trapped in the patients' clothing caused miosis in 10% of emergency personnel. Removal of clothing would have avoided most of this. Decontamination of liquid is accomplished in the military using the M291 skin decontamination kit, containing an active carbon impregnated with ion exchange resins (Ambergard) capable of absorbing liquid off the skin. Civilian agencies now stockpile this product, which is approved by the U.S. Food and Drug Administration (FDA). At hospitals, soap and copious amounts of water should suffice. Physical removal of the agent trumps all known decontamination solutions and lotions. In any even, decontamination must be accomplished before the patient enters the hospital facility to avoid contaminating the facility and its staff. In patients with contaminated wounds, extract from the wound potentially contaminated clothing and other foreign material that may serve as a depot for liquid agent.

Respiratory Support Death from nerve agent poisoning is almost always respiratory. Ventilation will be complicated by increased resistance and secretions. Atropine should be given before ventilation or as it begins as it will make ventilation far easier.

Antidotal Therapy ■ *ATROPINE* In theory, any anticholinergic could be used to treat nerve agent poisoning, but worldwide the choice is invariably atropine because of its wide temperature stability and rapid effectiveness, either intramuscularly or intravenously, and because inadvertent administration of this drug usually causes little CNS dysfunction (Table 206-4). Atropine rapidly reverses cholinergic overload at muscarinic synapses but has little effect at nicotinic synapses. Practically, this implies that atropine can quickly treat the life-threatening respiratory effects of nerve agents but will probably not help neuromuscular and possibly sympathetic effects. In the field, military personnel are given MARK I kits (Fig. 206-3*A*), which contain 2 mg atropine in autoinjector form for use intramuscularly. Civilian agencies are now stockpiling this FDA-approved product as well. One can only give full autoinjector doses and not divide them. The field-loading dose is 2, 4, or 6 mg, with retreatment every 5 to 10 min until the patient's breathing and secretions improve. The Iranians used larger doses initially during the Iran-Iraq war, in which oximes were in short supply. When the patient reaches a level of medical care where drugs can be given intravenously, this is the preferred route; in small children, this may be the preferred initial route of administration of atropine therapy. There is no upper bound to atropine therapy in a patient either intramuscularly or intravenously; however, a total average adult dose for a severely afflicted patient would usually be 20 to 30 mg.

In a mildly afflicted patient with miosis and no other systemic symptoms, atropine or homatropine eye drops may suffice for therapy. This will produce roughly 24 h of mydriasis. Frank miosis or imperfect accommodation may persist for weeks or even months after all other signs and symptoms have resolved.

TABLE 206-4 *Antidote Recommendations Following Exposure to Nerve Agents*

	Antidotes		
Patient Age	*Mild/Moderate Effects*[a]	*Severe Effects*[b]	*Other Treatment*
Infants (0–2 yrs)	Atropine: 0.05 mg/kg IM, *or* 0.02 mg/kg IV; *and* 2-PAM chloride: 15 mg/kg IM *or* IV slowly	Atropine: 0.1 mg/kg IM, *or* 0.02 mg/kg IV; *and* 2-PAM chloride: 25 mg/kg IM, *or* 15 mg/kg IV slowly	Assisted ventilation after antidotes for severe exposure. Repeat atropine (2 mg IM, or 1 mg IM for infants) at 5- to 10-min intervals until secretions have diminished and breathing is comfortable or airway resistance has returned to near normal. Phentolamine for 2-PAM-induced hypertension: (5 mg IV for adults; 1 mg IV for children). Diazepam for convulsions: (0.2 to 0.5 mg IV for infants <5 years: 1 mg IV for children >5 years; 5 mg IV for adults).
Child (2–10 yrs)	Atropine: 1 mg IM, *or* 0.02 mg/kg IV; *and* 2-PAM chloride[c]: 15 mg/kg IM *or* IV slowly	Atropine: 2 mg IM, *or* 0.02 mg/kg IV; *and* 2-PAM chloride[c]: 25 mg/kg IM, *or* 15 mg/kg IV slowly	
Adolescent (>10 yrs)	Atropine: 2 mg IM, *or* 0.02 mg/kg IV; *and* 2-PAM chloride[c]: 15 mg/kg IM *or* IV slowly	Atropine: 4 mg IM, *or* 0.02 mg/kg IV; *and* 2-PAM chloride[c]: 25 mg/kg IM, *or* 15 mg/kg IV slowly	
Adult	Atropine: 2 to 4 mg IM *or* IV; *and* 2-PAM chloride: 600 mg IM, *or* 15 mg/kg IV slowly	Atropine: 6 mg IM; *and* 2-PAM chloride: 1800 mg IM, *or* 15 mg/kg IV slowly	
Elderly, frail	Atropine: 1 mg IM; *and* 2-PAM chloride: 10 mg/kg IM, *or* 5 to 10 mg/kg IV slowly	Atropine: 2 to 4 mg IM; *and* 2-PAM chloride: 25 mg/kg IM, *or* 5 to 10 mg/kg IV slowly	

[a] Mild/moderate effects include localized sweating, muscle fasciculations, nausea, vomiting, weakness, dyspnea.
[b] Severe effects include unconsciousness, convulsions, apnea, flaccid paralysis.
[c] If calculated dose exceeds the adult IM dose, adjust accordingly.
Note: 2-PAM chloride is pralidoxime chloride or protopam chloride.

FIGURE 206-3 Antidotes to nerve agents. *A*. MARK I autoinjector set containing one 600-mg dose of 2-pralidoxime chloride and one 2-mg dose of atropine. Such sets are carried by all U.S. military forces in a potentially chemical battlefield and are now being stockpiled by civilian first responders. *B*. Diazepam 10-mg autoinjector. These are carried by all U.S. military forces in a potential chemical battlefield and are being stockpiled by civilian first responders.

OXIME THERAPY Oximes are nucleophiles that reactivate the cholinesterase whose active site has been occupied and bound to nerve agent (Table 206-4). Therapy with oximes therefore restores normal enzyme function. Oxime therapy is limited by a second side reaction, called *aging*, in which a side chain on nerve agents falls off the complex at a characteristic rate. "Aged" complexes are negatively charged, and oximes cannot reactivate negatively charged complexes. The practical effect of this differs from one nerve agent to another since each ages at a characteristic rate. VX, for practical purposes, never ages, sarin ages in 3 to 5 h, and tabun ages over a longer period. All of these are so much longer than the patient's expected lifespan after untreated acute nerve agent toxicity that they may be ignored. Soman, on the other hand, ages in 2 min. Thus, after only a few minutes following exposure, oximes are useless in treating soman poisoning. The oxime used varies by country; the United States has approved and fielded 2-pralidoxime chloride (2-PAM Cl). MARK I kits (Fig. 206-3*A*) contain autoinjectors of 600 mg of 2-PAM Cl. Initial field loading doses are 600, 1200, or 1800 mg. Since blood pressure elevation may occur after administration of 45 mg/kg in adults, field use of 2-PAM Cl is restricted to 1800 mg, intramuscularly, per hour. During the time when more oxime cannot be given, atropine alone is recommended. In the hospital setting, 2.5 to 25 mg/kg of 2-PAM Cl intravenously has been found to reactive 50% of inhibited cholinesterase. The usual recommendation is 1000 mg through slow intravenous drip over 20 to 30 min, with no more than 2500 mg over a period of 1 to 1.5 h.

ANTICONVULSANT Nerve agent–induced seizures do not respond to the usual anticonvulsants used for status epilepticus, including phenytoin, phenobarbital, carbamazepine, valproic acid, and lamotrigine (Chap. 349). The only class of anticonvulsants that has been shown to stop this form of status are the benzodiazepines. Diazepam is the only benzodiazepine approved for seizures in humans, although other FDA-approved benzodiazepines work well against nerve agent–induced seizures in animal models. Diazepam, therefore, is manufactured in 10-mg injectors for intramuscular use and given to U.S. forces for this purpose (Fig. 206-3*B*). Civilian agencies are stockpiling this field product (convulsive antidote for nerve agent, "CANA"), which is not generally used in hospital practice. Extrapolation from animal studies indicates that adults will probably require 30 to 40 mg diazepam, intramuscularly, to stop nerve agent–induced status epilepticus. In the hospital, or in a small child unable to receive the autoinjector, intravenous diazepam may be used at similar doses. The clinician may confuse seizures with the neuromuscular signs of nerve agent poisoning. In the hospital, early electroencephalography is recommended in order to distinguish between nonconvulsive status epilepticus, actual seizures, and postictal paralysis. Recent studies have shown that the most effective benzodiazepine in this situation is midazolam, which is not FDA-approved for seizures.

Peripheral neuropathy and the so-called intermediate syndrome, prominent long-term effects of insecticide poisoning, are not described in nerve agent survivors.

Recent research has explored approaches leading to a transient "immunity" or drugs that would provide protection against lethal nerve agents yet be devoid of side effects. A novel approach is to use enzymes to scavenge these highly toxic nerve agents before they attack their intended targets. The total body of studies has shown that if a scavenger is present at the time of nerve agent exposure, rapid reduction of toxicant levels is observed. This reduction is so rapid and profound that the need to administer a host of pharmacologically active drugs as antidotes is, in theory, eliminated.

207 RADIATION BIOTERRORISM

Zelig A. Tochner, Ofer Lehavi, Eli Glatstein

Terror attacks using nuclear or radiation-related devices are an unequivocal threat in the twenty-first century and are capable of unique medical and psychological effects. In this chapter we will focus on the most probable scenarios of possible attacks and the medical principles of handling such threats.

There are two major categories of potential terrorist incidents with widespread radiologic consequences. The first is the use of radiologic dispersal devices. This could cause a purposeful dissemination of radioactive material without nuclear detonation by using conventional explosives with radionuclides, attacking fixed nuclear facilities, or attacking nuclear powered surface vessels or submarines. Malfunctioning nuclear weapons that are detonated with no nuclear yield (nuclear "duds") and/or installation of radionuclides in food or water are also a possible means of generating a terror attack. The second, and less probable, scenario is the actual use of nuclear weapons. Each scenario has its own medical aspects, including "conventional" blast or thermal injury, introduction to a radiation field, and exposure to either external or internal contamination from a radioactive explosion.

TYPES OF RADIOISOTOPIC RADIATION

Isotopes of atoms with uneven numbers of protons and/or neutrons are typically unstable; such isotopes discharge particles or energy to matter, a process that we define as *radiation*. The main radiation types are alpha, beta, gamma, and neutrons.

Alpha (α) radiation consists of heavy, positively charged particles containing two protons and two neutrons. Alpha particles are usually emitted from isotopes with an atomic number of $\geq$82, such as uranium or plutonium. Due to their large size, alpha particles have limited penetrating power. Fine obstacles such as cloth or human skin can usually stop them from penetrating into the body, and they represent a small risk to external exposure due to their limited penetration. If they somehow are internalized, then alpha particles can cause significant cellular damage within their immediate proximity.

Beta (β) radiation consists of electrons, which are small, light, negatively charged particles (about 1/2000 the mass of a neutron or proton). They can travel only a short finite distance in tissue, depending on their energy. Exposure to beta particles is common in many radiation accidents. Radioactive iodine, released in nuclear plant accidents, is the best known member of this group. Plastic layers and clothing can stop most beta particles, and their penetration is measured

to be a few millimeters. A large quantum of energy to the basal stratum of the skin can cause a burn that is similar to a thermal burn and is treated as such.

Gamma (γ) rays and *x-rays* (both photons) are similar. Gamma rays are uncharged electromagnetic radiation discharged from a nucleus as a wave or photons of energy. X-rays are the result of abrupt mechanical deceleration of electrons striking a heavy target such as tungsten. Gamma and x-rays have similar properties, i.e., no charge and no mass, just energy. Both travel easily through matter, sometimes called *penetrating radiation*, and are the principal type of radiation to cause total-body exposure.

Neutrons (η) particles are heavy and uncharged, often emitted during nuclear detonation. They possess a wide energy range; their ability to penetrate tissues is variable, depending upon their energy. They are less likely to be present in most scenarios of radiation bioterrorism.

The ionization resulting from protons, electrons, and gamma rays is either a direct or indirect (i.e., mediated through water) effect of particles or photons on DNA. Ionization of DNA resulting from neutrons is secondary to the neutrons knocking electrons out of their atomic orbit and the formation of free radicals, which can also damage DNA directly.

The commonly used units of radiation are the rad and the gray (Gy). The rad (radiation absorbed dose) is energy deposited within living matter and is equal to 100 ergs/g of tissue. It is a simple concept but difficult to measure directly. The traditional rad has been replaced by the Système Internationale (SI) unit of the gray; 100 rad = 1 Gy.

TYPES OF EXPOSURE

Whole-body exposure represents deposition of radiation energy over the entire body. Alpha and beta particles have limited penetration and do not cause significant noncutaneous injury unless emission results from an internalized source. Whole-body exposure from gamma rays, x-rays, or neutrons, which can penetrate through the body (depending on their energy), can result in damage to multiple tissues and organs. The tissue damage is proportional to the radiation exposure of that organ or tissue.

External contamination is a result of fallout of radioactive particles that land on the body surface, clothing, skin, and hair. This is the dominant element to consider in the mass casualty situation resulting from a radioactive terrorist strike. The common contaminants will primarily emit alpha and beta radiation. Alpha particles do not penetrate beyond the skin and thus have minimal systemic effects. Beta emitters can cause significant cutaneous burns and scarring. Gamma emitters may not only cause local damage but can also cause whole-body radiation exposures and injury. The medical treatment is primarily decontamination of the body, including wounds and burns, to prevent the contamination from becoming internalized. Removing the contaminated clothing reduces the contamination significantly and is a first step in the decontamination process. Generally patients will not constitute a significant radiation hazard to health care providers, and life-saving treatment should not be delayed for fear of secondary contamination of the medical team. Any damage to health care personnel will depend directly on the duration of exposure and will be inversely proportional to the square of the distance from any radioactive source. Gowns that can be removed are essential to protect health-care personnel.

Internal contamination will occur when radioactive material is inhaled, ingested, or able to enter the body through open wounds or burns or via skin absorption. In principle, any externally contaminated casualty should be evaluated for internal contamination. Some isotopes may have toxic effects on specific target organs due to their chemical properties, in addition to radiologic injury. The respiratory system is the main portal of entrance for internal contamination, and the lung is the organ at greatest risk. Aerosol particles <5 μm can reach the alveoli, whereas larger particles will remain in proximal airways. The tiny particles can be absorbed by the lymphatic system or the bloodstream, continuing to irradiate (depending on their biologically active half-life) until being exhaled. Bronchial lavage is often helpful treatment in this situation. Radioactive material entering the gastrointestinal (GI) tract will be absorbed according to its chemical structure and solubility. The insoluble radionuclides may affect the lower GI tract. Intact skin is normally a good barrier to most radionuclides. Penetration through the skin usually takes place when wounds or burns have altered the skin barriers. Therefore, any skin erosion should be cleaned and decontaminated promptly.

Absorbed radioactive materials will travel throughout the body. Liver, kidney, adipose tissue, and bone tend to bind and retain the radioactive material more than other tissues. The medical treatment includes preventing absorption, reducing incorporation, and enhancing elimination (see below).

Localized exposure means close contact between a highly radioactive source and a part of the body, causing discrete damage to the skin and deeper tissues, similar to a thermal burn. Later signs include epilation, erythema, moist desquamation, ulceration, blistering, or necrosis in proportion to exposure. Alopecia, transient or permanent, is dose-related and starts at cutaneous doses >3 Gy. Overt tissue damage can take weeks and even months to develop; the healing process can also be very slow and last for months. Long-term cutaneous changes, including keratosis, fibrosis, and telangiectasias, may appear years after the exposure. Treatment is based on analgesia and infection prophylaxis. Nevertheless, severe burns can often require grafting or even amputation. Long-term radiation effects are characterized by cell loss and cell death.

RADIOLOGIC DISPERSAL EVENTS

Radiologic dispersal incidents are generally of two types resulting from: (1) small, usually localized sources; or (2) wide dispersals over large areas. The radioactive materials can take the form of solid state, aerosol, gas, or liquid. They can be put into food or water, released from vehicles, or be spread by explosion. The principal route of exposure is usually by direct contact between the victim's skin and the radioactive particles, although internal contamination could occur if the material were inhaled or ingested. The radiation field is also a potential source of whole-body exposure. The psychosocial effects that accompany such an event are significant and are beyond the scope of this chapter. A list of radioactive materials, including information on their major properties and medical treatment, is shown in Table 207-1.

In a localized event, the amount and spread of the radioactive materials are usually limited and can be treated like a spill of hazardous material. Protective clothing prevents or minimizes the contamination of emergency responders.

The use of explosives coupled with a large amount of radioactive materials can result in wide dispersion of radiation, which is of far greater concern. Other potential sources of radiation are nuclear reactors, spent nuclear fuel, and transport vehicles. Less probable but still possible is the use of a large source of penetrating radiation without explosion. It is expected that most exposures would be low, and the principal health and psychosocial effects would be similar to the former scenario but on a larger scale.

Whenever an explosion is involved, conventional life-saving treatment should be given first priority. Only then should decontamination and specific treatment be given for the radiation exposure.

Silent exposure represents a scenario in which a powerful radiologic source could be hidden in a crowded place or radiologic materials spread without any awareness or announcement. It might take a long time to recognize the event and the source of exposure. One of the major clues to this situation is the appearance of unusual clinical manifestations in many individuals; such manifestations are often nonspecific and include symptoms of acute radiation sickness (see below) such as headache, fatigue, malaise, and opportunistic infections. GI phenomena such as diarrhea, nausea, vomiting, and anorexia may occur. Dermatologic symptoms (burns, ulceration, and epilation) and hematopoietic manifestations such as bleeding tendency, thrombocy-

TABLE 207-1 *Internal Contaminant Radionuclides: Properties and Treatment*

Isotope Name	Symbol	Common Usage	Radiation Type $t_{1/2}$ Radiologic $t_{1/2}$ Biologic, days	Exposure Type	Mode of Contamination	Focal Accumulation in Body	Treatment
Manganese	Mn-56	Reactors, research laboratories	β, γ 2.6 h 5.7	External, internal	N/A	Liver	N/A
Cobalt	Co-60	Medical radiotherapy devices, commercial food irradiators	β, γ 5.26 y 9.5	External, internal	Lungs	Liver	Gastric lavage, purgatives; penicillamine in severe cases
Strontium	Sr-90	Fission product of uranium	β 28 y 18,000	Internal	Moderate GI tract	Bones—similar to calcium	Strontium, calcium, ammonium chloride
Molybdenum	Mo-99	Hospitals—scans	β, γ 66.7 h 3	External, internal	N/A	Kidneys	N/A

Phosphorus	P-32	Research laboratories, medical facilities	β 14.3 d 1155	Internal	Inhalation, GI tract, wounds	Bones, bone marrow, rapidly replicating cells	Lavage, aluminum hydroxide, phosphate

Note: N/A, not available; h, hours; y, years; GI, gastrointestinal

topenia, purpura, lymphopenia, or neutropenia are also possible and dose-related. Careful epidemiologic studies may be necessary to identify the source of such exposure.

NUCLEAR WEAPONS

The most likely scenario of nuclear terror would be the detonation of a single low-yield device. The estimated yield of such device is anywhere between 0.01 and 10 kiloton of TNT, although the probability would more likely be toward the lower yield. Coping with such an event is certainly possible. The effects of such an explosion are a combination of several components: ground shock, air blast, thermal radiation, initial nuclear radiation, residual nuclear radiation, crater formation, and radioactive fallout.

The nuclear detonation, like a conventional explosion, will produce a shock wave that can further damage structures and cause many casualties. In addition, the detonation can produce an extremely hot fireball that can ignite materials and cause severe burns. The detonation also releases an intense pulse of ionizing radiation, mainly gamma rays and neutrons. The radiation produced in the first minute is termed *initial radiation*, while the ongoing radiation due to fallout is termed

residual radiation. Both types of radiation can cause acute radiation sickness (ARS; see below). The $LD_{50/30}$ (i.e., a dose that causes 50% mortality at 30 days) is ~4 Gy for whole-body exposure without medical support; with medical support, the $LD_{50/30}$ ranges between 8 and 10 Gy. Winds can carry fallout and contaminate large areas.

On top of its effects, a massive blast forms a crater in the soil and usually produces a ground shock compounding the damage and number of casualties. Inhalation of large amounts of radioactive dust causes pneumonitis that can lead to pulmonary fibrosis. Use of a mask covering the mouth and nose can be very helpful. The intense flash of infrared and visible light can cause either temporary or permanent blindness. Cataracts can develop months to years later among those who survive.

ACUTE RADIATION SICKNESS

Radiation interactions with atoms can result in ionization and the formation of free radicals that damage tissue by disrupting chemical bonds and molecular structures in the cell, including DNA. Radiation damage can lead to cell death; those cells that recover may be mutated and at higher risk for subsequent cancer. Cell sensitivity increases as the replication rate increases and the cell differentiation decreases. Bone marrow and mucosal surfaces of the GI tract, which have vast mitotic activity, are significantly more sensitive to radiation than slowly dividing tissues such as bones and muscles. Following exposure of either all or most of the human body to ionizing radiation, ARS can develop. The clinical manifestations of ARS reflect the dose and type of radiation as well as the part of the body exposed.

CLINICAL MANIFESTATIONS ARS manifests as three major groups of signs and symptoms: gastrointestinal, hematopoietic, and neurovascular. There are four major stages in ARS: prodrome, latent phase, illness, and either recovery or death. The higher the radiation doses, the shorter and more severe each stage. The prodrome appears a few hours to 4 days postexposure; lasts between a few hours to a few days; and can include nausea, vomiting, anorexia, and diarrhea. At the end of the prodrome, ARS progresses to the latent phase. Minimal or no symptoms are present during the latent phase, which commonly lasts up to 2.5 weeks, but can last up to 6 weeks. The duration depends on the radiation dose, the health of the patient, and the coexisting illness or injury. Following the latent phase, the exposed person manifests illness that may eventuate in recovery or lead to death.

With exposure to doses <1 Gy, ARS is generally mild. At this dose symptoms can be minimal or nonexistent, even if the entire body is exposed to penetrating radiation. The clinical picture will mainly be transient depression of bone marrow that lasts up to 2 to 3 weeks and then recovers.

ARS is significantly more acute and severe with exposure to very high doses—>30 Gy. At this dose the prodrome appears in minutes and is followed by 5 to 6 h of latency before a cardiovascular collapse occurs secondary to irreversible damage to the microcirculation.

The type and dose of radiation and the part of the body exposed will determine not only the timing of the different stages of ARS but also the dominant clinical picture. At low radiation doses of 0.7 to 4 Gy, hematopoietic depression due to bone marrow suppression takes place and constitutes the main illness. The patient may develop infections and bleeding secondary to low leukocyte and platelet counts, respectively. The bone marrow will eventually recover in almost all patients if they are supported with transfusions and fluids; antibiotics are often needed in addition. With exposure to 6 to 8 Gy, the clinical picture is significantly more complicated. At these doses the bone marrow will not always recover and death may ensue. A GI syndrome may also accompany the hematopoietic manifestations and further worsen the patient's condition. Compromise of the absorptive layer of the gut alters absorption of fluids, electrolytes, and nutrients. GI injury can lead to diarrhea, hemorrhage, sepsis, and electrolyte and fluid imbalance in a patient whose blood counts are compromised for a period of weeks, often leading to death. Whole-body exposure to doses >9 to 10 Gy is almost always fatal. Crucial elements of the bone marrow simply will not recover. In addition to the GI syndrome associated with very large exposures, patients may develop a neurovascular syndrome; the latter dominates with whole-body doses >20 Gy. Vascular collapse, seizures, and death are usually seen. In this variant the prodrome and latent phase both shorten to a few hours.

TREATMENT

The treatment of ARS is focused on maintaining homeostasis, giving damaged organs the chance to recover. Aggressive support is given to every damaged system. Treatment for the hematopoietic system includes mainly therapy for neutropenia and infection, transfusion and blood products as needed, and hematopoietic growth factors. The value of bone marrow transplantation in this situation is questionable. None of the transplants that were performed among the victims of the nuclear reactor accident in Chernobyl proved successful. Another major component of the treatment of ARS is partial or total parenteral nutrition, to bypass the damaged GI system. For blast and thermal injuries, standard therapy for trauma is given. Psychological support is essential in many cases.

MEDICAL MANAGEMENT OF RADIATION BIOTERRORISM

Victims of radiation bioterrorism can suffer from conventional thermal or blast injuries, exposure to radiation, and contamination by radioactive materials. Many will have combinations of the above, which can be synergistic and cause higher morbidity and mortality than when they occur alone. The number of casualties will be the major factor in determining the response of the medical system to an act of radiation bioterrorism. If only a few people are affected, then no significant changes and adaptation of the system are needed to treat the victims. However, if a terror attack results in a large number (hundreds or more) of casualties, then an organized disaster plan at the local and state levels must be invoked to deal with the crisis properly. Medical personnel should have a prior assignment and be prepared to function in a scenario with which they are familiar. Stockpiles of specific equipment and medications have to be preplanned (see the Centers for Disease Control and Prevention website—*http://www.bt.cdc.gov*). One needs to recognize that one of the goals of terrorists is to overwhelm medical facilities and to minimize the salvage of casualties.

Initial management consists of *primary triage and transportation* of the wounded to emergency rooms for treatment. The rationale behind the triage is to sort patients into classes according to the severity of injury, for the purpose of expediting clinical care and maximizing the use of the available clinical services and facilities. Triage requires determination of the level of emergency care needed. The higher the number and range of casualties, the more complex and difficult triage becomes. The mildly wounded and victims of contamination only can be sent to evacuation, registration with disaster response teams, and decontamination and treatment centers. In this way, the hospitals themselves can avoid being directly overwhelmed, and those who are severely wounded can receive better treatment. Emergency treatment will be administered initially according to the presence of conventional injuries such as wounds, trauma, and thermal or chemical burns. Individuals with such injuries should be stabilized, if possible, and immediately transported to a medical facility. Removing the victim's clothes and wrapping him or her in clean blankets or nylon sheets reduces both the exposure of the patient and the contamination risk to the staff. However, the possibility of contamination needs to be determined. Less severely injured victims should receive a preliminary decontamination before or during evacuation to a hospital.

One must remember that radionuclide contamination of the skin is commonly not an acute life-threatening situation to the patient or the personnel who care for the patient. Only powerful gamma emitters are likely to cause real damage from contamination. It is important to emphasize that exposure to a radiation field alone does not necessarily create any contamination. The exposed person, if not contaminated, is not radioactive and does not directly emit any radiation.

In order to protect the staff, protective gear (gowns, gloves, masks, and caps) should be used. NBC masks with filters and chemically pro-

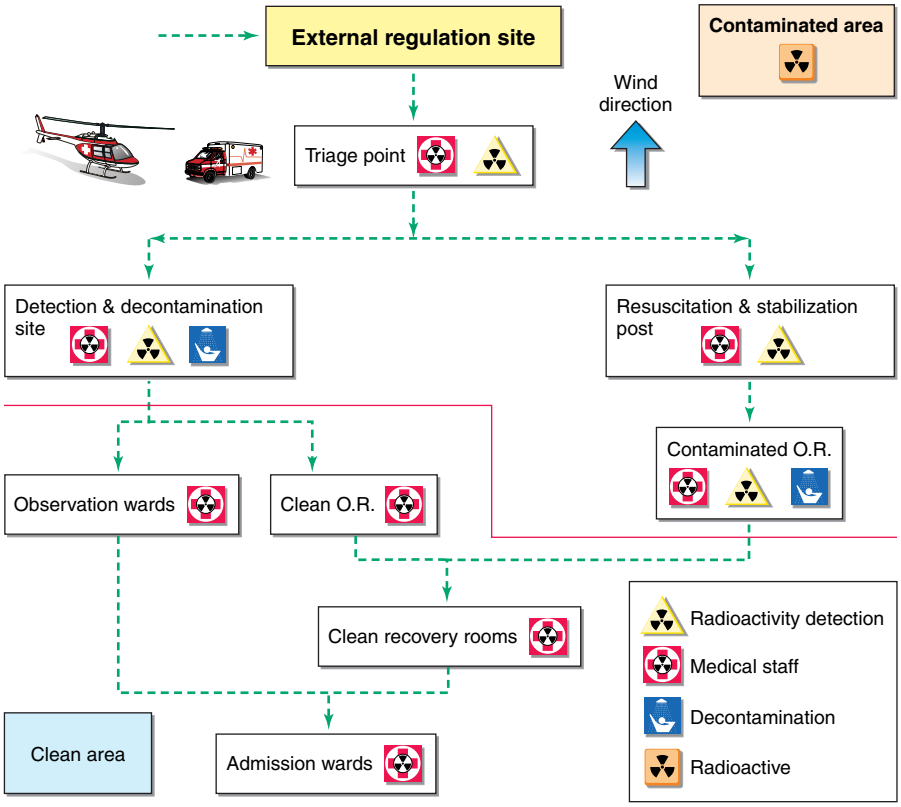

FIGURE 207-1 Flow chart of hospital triage. O.R., operating room.

tective overgarments provide excellent protection from contamination. Waterproof shoe covers are also important. Remaining in the contaminated area and dealing with life-saving procedures should take place according to the "ALARA" principle: as low as reasonably achievable. It is better to send many people for short exposure times than to send a few people for longer periods of time to do the same job.

Decontamination of victims should take place in the field prior to their arrival at medical facilities, but radiologic decontamination should never interfere with medical care. Removal of outer clothing and shoes will usually reduce the patient's contamination by 80 to 90%. Contaminated clothes should be carefully removed by rolling them over themselves, placing them in marked plastic bags, and removing them to a predefined area for contaminated clothes and equipment. A radiation detector should then be used to check for the presence of any residual radiologic contamination on the patient's body. In order to prevent internalization of the radioactive materials, one should cover open wounds prior to decontamination. Showering or washing of the entire skin and hair is very important. The skin is dried and reassessed for residual contamination until no radiation is found. Contamination-removing chemical agents are more than sufficient to remove radiologic contamination.

Wound decontamination should be as conservative as possible. The main goal is to prevent both extensive local damage and internal contamination through lacerated skin. The bandages should be removed and the wounds flushed. The wound should then be dried and assessed for radiation. This procedure can be repeated again and again until contamination is undetectable. Excision of contaminated wounds should be attempted only when surgically necessary.

In the hospital, staff can wear normal hospital barrier clothing, including two pairs of gloves, a gown, shoe covers, a head cover, and a face mask. Eye protection is recommended. Decontamination of medical personnel is obligatory following emergency treatment and decontamination of the patient. All protective clothing should be placed after use in a designated container for contaminated clothing.

Radiation intensity decays rapidly with the square of the distance from the source, and increasing the distance from the source and decreasing the time spent near it are basic principles of radiation safety. Shielding with lead can be used as protection from small radioactive gamma sources. Geiger counters can detect gamma and beta radiation. Pocket chamber (pencil) dosimeters, film badges, and thermoluminescent dosimeters can measure accumulated exposure to gamma radiation. All of these detectors are in common use in medical facilities and should be used to help and define the level of contamination. Alpha radiation is harder to detect due to its poor penetration. An alpha scintillation counter, which is capable of detecting alpha radiation, is not commonly used in medical facilities.

GUIDELINES FOR HOSPITAL MANAGEMENT

Figure 207-1 illustrates a model for hospital arrangement for triage. Persons contaminated either externally or internally should be identified, externally decontaminated, and, if needed, treated immediately and specifically for internal contamination. In all other cases, the need for treatment of radiation injuries does not constitute a medical emergency. Early actions, such as blood sampling both for assessing the degree of severity of the exposure and for blood type and cross-matching for possible transfusion, need to be promptly taken if ARS is evident.

In the hospital entrance, a distinct decontamination area should be set up promptly. Separation between clean and contaminated areas is essential. Medical personnel in this area should wear protective gear as noted above. They also should be rotated in their assignments every 1 to 2 h to ensure minimal exposure to radiation. If patients are critically wounded and require either surgery or resuscitation, they need to pass directly to "contaminated" operating rooms or resuscitation sites for life-saving procedures. Once such patients are stable, they should then be decontaminated. It is important to obtain details concerning the exposure, to look for prodromal signs of radiation sickness, and to do a physical examination. One of the best ways to estimate exposure clinically is to measure the time of prodromal appearance. The earlier the prodromal signs and symptoms appear, the higher the dose of radiation exposure. A few laboratory tests need to be routinely taken, such as blood count and urinalysis. If internal contamination is suspected, specific treatment should be given, as outlined below.

℞ TREATMENT

Treatment for internal radionuclide contamination should begin within hours of exposure. The goal is to leave the smallest amount of radionuclides as possible in the body. Treatment is given in order to reduce absorption and to enhance elimination and excretion. Many of the drugs for these indications are not approved by the U.S. Food and Drug Administration and are used as investigational drugs.

Clearance of the GI tract may be achieved by stomach lavage, emetics (such as apomorphine, 5 to 10 mg, or ipecac, 1- to 2-g capsules or 15 mL in syrup), or by using purgatives, laxatives, ion exchangers, and aluminum antacids. Prussian blue, 1 g tid for ≥3 weeks, is an ion exchanger used to treat cesium 137 internal contamination. Aluminum antacids (such as aluminum phosphate gel, 100 mL) may reduce strontium uptake in the gut if given immediately after exposure. Aluminum hydroxide, 60 to 100 mL, is less effective.

Prevention or reversal of radionuclide interaction with tissues can be done by blocking, diluting, mobilizing, and chelating agents. *Blocking agents* prevent entrance of radioactive materials. A good example is potassium iodide (KI), which blocks the uptake of radioactive iodine (^{131}I) by the thyroid. KI is most effective if taken within the first hour

after exposure and is still effective 6 h after exposure. The effectiveness subsequently declines until 24 h after exposure; however, it is recommended that KI be taken up to 48 h postexposure. The KI dose is based on age, predicted thyroid exposure, and pregnancy and lactation status. Adults between the ages of 18 to 40 should receive 130 mg/d for 7 to 14 days if exposed to ≥10 cGy of radioactive iodine. Other thyroid-blocking agents include prophylthiouracil, 100 mg tid for 8 days, or methimazole, 10 mg tid for 2 days followed by 5 mg tid for 6 days, but they are somewhat less effective.

Diluting agents decrease the absorption of the radionuclide; for example, water may be used as a diluting agent in the treatment for tritium (^{3}H) contamination. The recommended amount is 3 to 4 L/d for at least 3 weeks.

Mobilizing agents are most effective when given immediately; however, they may be effective for up to 2 weeks after exposure. These include antithyroid drugs, parathyroid extract, glucocorticoids, ammonium chloride, diuretics, expectorants, and inhalants. All of them should induce the release of radionuclides from tissues.

Chelating agents can bind many radioactive materials, after which the complexes are excreted from the human body. In this regard, diethylenetriaminepentaacetic acid (DTPA) is superior to ethylenediamine tetraacetic acid (EDTA); it chelates plutonium, berkelium, californium, americium, curium, or any material with an atomic number >92. The dose is 1 g of Ca-DTPA or Zn-DTPA, dissolved in 250 mL of normal saline or 5% glucose, given intravenously over 1 hour daily for up to 5 days. DTPA can also be administrated by inhalation; 1 g is given in 1:1 dilution with water or saline over 15 to 20 min. Treating uranium contamination with DTPA is contraindicated, due to its synergistic damage to the kidneys.

Lung lavage can reduce radiation-induced pneumonitis and is indicated only when a large amount of radionuclide enters the lungs and has the potential for acute radiation injury. The procedure requires anesthesia. Table 207-2 summarizes the common treatment regimens for internal radionuclide contamination.

TABLE 207-2 *Common Drugs[a] for Treatment of Internal Contamination*

Medication	Administered for Radionuclides	Route of Administration	Dosage	Duration	Mechanism of Action
KI	Iodine-131	PO	130 mg/d for adults >40 with thyroid exposure >500 cGy 130 mg/d for adults 18–40 with thyroid exposure >10 cGy 130 mg/d for pregnant or lactating women with thyroid exposure >5 cGy 65 mg/d for children and adolescents 3–18 with thyroid exposure >5 cGy 32.5 mg/d for infants 1 month to 3 years with thyroid exposure >5 cGy 16 mg/d for neonates from birth to 1 month with thyroid exposure >5 cGy	7–14 days	Blocking agent
Zn-DTPA	Plutonium, trans-plutonium, yttrium, americium, curium	IV	1 g in 250 mL NS or 5% glucose, given in 1–2 h, *or* bolus over 3–4 min	Up to 5 days	Chelating agent
		Inhalation	1 g in 1:1 dilution with water or NS over 15–20 min		
		IM	1 g; not recommended because of pain		
Ca-DTPA	Plutonium, *trans*-plutonium, yttrium, americium, curium	IV	1 g in 250 mL NS or 5% glucose, given in 1–2 h, *or* bolus over 3–4 min	Up to 5 days	Chelating agent
		Inhalation	1 g in 1:1 dilution with water or NS over 15–20 min		
		IM	1 g; not recommended because of pain		
Bicarbonate	Uranium	IV	2 ampules sodium bicarbonate (44.3 meq each, 7.5%) in 1000 mL NS, 125 mL/L, *or* 1 ampule of sodium bicarbonate (44.3 meq, 7.5%) in 500 mL NS, 500 mL/h	Usually IV for the first 24 h, PO for additional 2 days; continuation of treatment for >3 days is rare and can be done according to titration of uranium amounts in the body	Increased excretion via the kidneys
		PO	2 tablets every 4 h until urine pH = 7–8, *or* 4 g (8 tablets) 3 tid		
Prussian blue	Cesium-137	PO	1 g tid with 100–200 mL water, up to 10 g/d	≥3 weeks titrated by urine and fecal bioassay and whole-body counting	Ion exchanger
Water	Tritium (H-3)	PO	>3–4 L per day	3 weeks	Excretion of water
Aluminum phosphate gel	Strontium	PO	100 mL immediately after exposure	Once	Decreased gut absorption
Aluminum hydroxide		PO	60–100 mL	Once	Decreased gut absorption

[a] Excluding KI, these drugs have not been approved for this purpose by the U.S. Food and Drug Administration at the time of publication.
Note: NS, normal saline

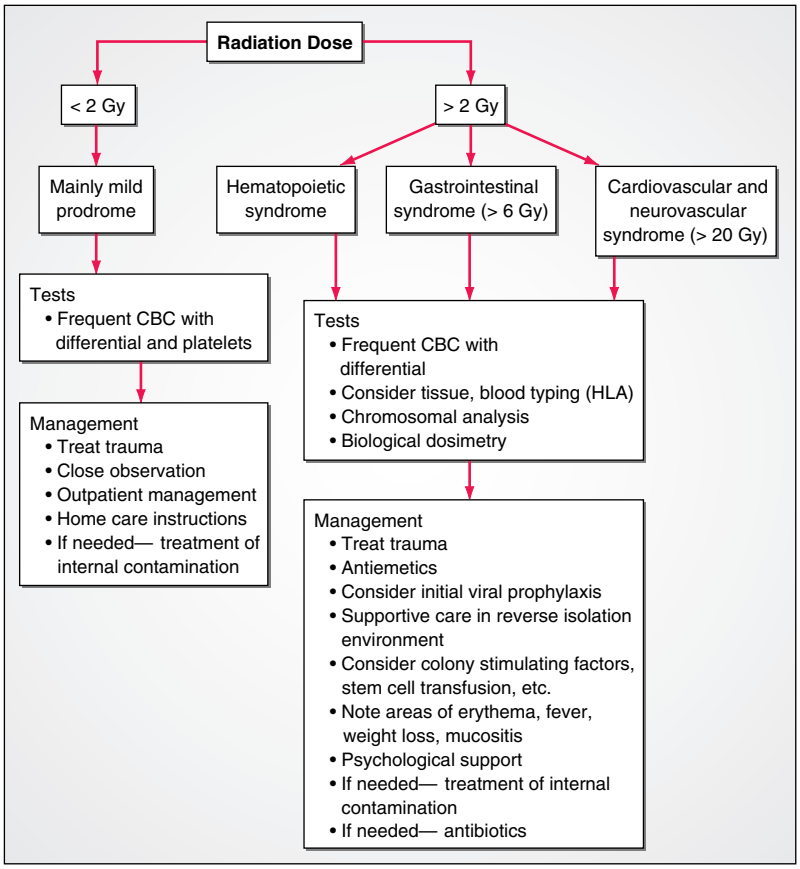

FIGURE 207-2 General guidelines for treatment of radiation casualties. CBC, complete blood count.

MEDICAL ASSAY OF THE RADIATION-EXPOSED PATIENT

One of the major difficulties in treating victims exposed to radiation is the determination of the amount of exposure. Clinical assessment of the patient is the best approach. Appearance of an early prodrome indicates high exposure to radiation. Victims who arrive at the hospital complaining of severe weakness, nausea, vomiting, diarrhea, or seizures probably will not survive despite support measures. Decontamination and the use of radiation-detection equipment are both very important. Few tests can be performed in order to estimate the radiation exposure and the contamination. Baseline laboratory tests should include a complete blood count with differential and platelet count, renal evaluation, and determination of electrolytes. Urine and stool samples should be obtained if internal contamination is suspected. Baseline samples should be taken and repeated every 24 h. Nasal swabs should be taken from each nostril for determination of inhalation of radionuclides. After exhalation, each swab is labeled and sealed in a plastic bag and sent for analysis to appropriate laboratories.

Follow-up complete blood counts including platelets are important on a daily basis as they reflect the bone marrow status. Patients exposed to 0.7 to 4 Gy will develop pancytopenia from as early as 10 days to as long 8 weeks postexposure. Lymphocytes show the most rapid decline, while other leukocytes and platelets decline less rapidly. Erythrocytes are the least vulnerable blood elements.

Absolute lymphocyte counts should be taken every 12 h for 3 days; they are the most valuable early indicator because they are recognized to be a sensitive marker for radiation damage and correlate with both the exposure and prognosis. A 50% drop in absolute lymphocyte count within the first 24 h indicates a significant injury. HLA typing is necessary whenever there is suspicion of irreversible bone marrow damage. Lymphocyte chromosomal analysis can detect radiation exposure as low as 0.03 to 0.06 Gy, and 15 mL of blood should be drawn early as possible in a heparinized collection tube and kept cool. Radiation-induced chromosomal aberrations in peripheral blood lymphocytes include dicentric chromosomes that last for a few weeks. By calibrating a dose-response curve, the radiation dose can be as sessed.

Another method for estimating exposure is the micronucleus (MN/Mni) scoring, which is simple and fast but still empirical. An algorithm for the treatment of radiation casualties is provided in Figure 207-2.

FOLLOW-UP

It is desirable to continue follow-up in some circumstances, such as in cases of internal contamination, especially with exposure from uranium with its nephrotoxic properties; in cases of radiation exposure to distinct organs; and in cases where there is risk for carcinogenicity.

PART VIII DISORDERS OF THE CARDIOVASCULAR SYSTEM

Section 1 Diagnosis of Cardiovascular Disorders

208 APPROACH TO THE PATIENT WITH CARDIOVASCULAR DISEASE

Eugene Braunwald

THE MAGNITUDE OF THE PROBLEM

Cardiovascular diseases comprise the most prevalent serious disorders in the developed nations. The American Heart Association has reported that in 2002, 62 million Americans—32 million females and 30 million males (i.e., more than one in five persons)—had a cardiovascular disease (including hypertension). The prevalence rises progressively with age from 5% at age 20 to 75% at age >75 years.

Discharges from U.S. hospitals for cardiovascular disorders have been rising steadily and now exceed 6 million per year. Despite substantial progress in the primary and secondary prevention of coronary heart disease, approximately 6.5 million Americans suffer from angina pectoris and more than 1 million experience a myocardial infarction each year. About 4.8 million Americans have congestive heart failure and more than half a million new cases occur each year. Hospitalizations for heart failure have risen from 400,000 to 950,000 per year in the past 20 years. More than 1.4 million patients undergo cardiac catheterization each year, and approximately 1.2 million undergo revascularization (either percutaneous coronary intervention or coronary artery bypass grafting). There are approximately 1 million Americans with congenital heart disease now alive, and 40,000 babies with congenital heart disease are born each year. The annual total costs of cardiovascular diseases are estimated at $280 billion—$170 billion in direct costs and $110 billion in indirect costs in lost productivity.

Although age-adjusted death rates for coronary heart disease have declined by two-thirds from their peak in 1965, cardiovascular diseases remain the most common causes of death, responsible for 40% of all deaths, almost 1 million deaths each year. Approximately one-fourth of these deaths are sudden. Among developed nations, death rates from cardiovascular diseases are highest in the nations of the former Soviet Union, are intermediate in the United States and Western Europe, and lowest in Japan. The prevalence of cardiovascular disease, especially coronary artery disease, is rising alarmingly in China, India, Pakistan, and the Middle East, as nutritional and infectious causes of death decline in these regions. It has been projected that by 2020 cardiovascular diseases will be the leading causes of death worldwide.

CARDIAC SYMPTOMS

The symptoms caused by heart disease result most commonly from myocardial ischemia, from disturbance of the contraction and/or relaxation of the myocardium, from obstruction to blood flow, or from an abnormal cardiac rhythm or rate. Ischemia is manifest most frequently as chest discomfort, while reduction of the pumping ability of the heart commonly leads to fatigability and shortness of breath or, when severe, produces cyanosis, hypotension, syncope, and elevated intravascular pressure behind a failing ventricle. The latter results in abnormal fluid accumulation, which in turn leads to dyspnea, orthopnea, and systemic or pulmonary edema. Obstruction to blood flow, as in valvular stenosis, can cause symptoms resembling those resulting from congestive heart failure. Cardiac arrhythmias often develop suddenly, and the resulting signs and symptoms—palpitation, dyspnea, hypotension, presyncope, and syncope—generally occur abruptly and may disappear as rapidly as they develop. Ischemic heart disease, by far the most common form of heart disease in adults, may present with chest discomfort but also as heart failure, tachyarrhythmia, and sudden cardiac death.

Myocardial or coronary function that may be adequate at rest may be inadequate during exertion. Thus chest discomfort and/or dyspnea that appear only during activity are characteristic of heart disease, while the opposite pattern, i.e., the appearance of these symptoms at rest and their remission during exertion, is rarely observed in patients with organic heart disease.

Many patients with cardiocirculatory disease may also be asymptomatic, both at rest and during exertion, but may present an abnormal physical finding, such as a heart murmur, elevated arterial pressure, or an abnormality of the electrocardiogram (ECG) or of the cardiac silhouette on the chest roentgenogram. Patients may exhibit asymptomatic ischemia on an exercise stress test. In some asymptomatic patients the first clinical event may be catastrophic—sudden cardiac death, acute myocardial infarction, or stroke.

FEAR OF HEART DISEASE

Diseases of the heart and circulation are so common and the laity is so well acquainted with the major symptoms resulting from these disorders that patients, and occasionally physicians, erroneously attribute many noncardiac complaints to cardiovascular disease. The combination of the widespread fear of heart disease with the deep-seated emotional connotations concerning this organ's function results in the frequent development of symptoms that mimic those of organic disease in persons with normal cardiovascular systems. The unraveling of symptoms and signs due to organic heart disease from those not directly related is an important and challenging task in such patients.

Patients in whom heart disease has been confirmed, especially those who have experienced a major cardiovascular event such as a myocardial infarction or a serious arrhythmia, are often frightened and anxious about hospital discharge and resuming normal activity, including sexual relations. Attention to these matters is vital in the care of cardiac patients.

Dyspnea, one of the cardinal manifestations of heart failure, is not limited to patients with heart disease but is also observed in conditions as diverse as pulmonary disease, marked obesity, and anxiety (Chap. 29). Similarly, chest discomfort may result from a variety of causes other than myocardial ischemia (Chap. 12). Whether heart disease is responsible for these symptoms can frequently be determined by carrying out a careful clinical examination. Noninvasive testing using electrocardiography at rest and during exercise (Chap. 210), echocardiography (Chap. 211), roentgenography, and myocardial imaging usually provides important additional information to permit the correct interpretation of symptoms; more specialized invasive examinations (catheterization and angiography; Chap. 212) are occasionally necessary.

DIAGNOSIS

As outlined by the New York Heart Association, the elements of a complete cardiac diagnosis include consideration of the following:

1. *The underlying etiology*. Is the disease congenital, infectious, hypertensive, or ischemic in origin?
2. *The anatomic abnormalities*. Which chambers are involved? Are they hypertrophied, dilated, or both? Which valves are affected? Are they regurgitant and/or stenotic? Is there pericardial involvement? Has there been a myocardial infarction?
3. *The physiologic disturbances*. Is an arrhythmia present? Is there evidence of congestive heart failure or of myocardial ischemia?
4. *Functional disability*. How strenuous is the physical activity

required to elicit symptoms? The classification provided by the New York Heart Association has been found to be useful in describing functional disability (Table 208-1).

One example may serve to illustrate the importance of establishing a complete diagnosis. In a patient who presents with exertional chest pain, the identification of myocardial ischemia as the etiology is of great clinical importance. However, the simple recognition of ischemia is insufficient to formulate a therapeutic strategy or prognosis until the underlying anatomic abnormalities responsible for the myocardial ischemia, e.g., coronary atherosclerosis or aortic stenosis, are identified and a judgment made as to whether other physiologic disturbances that cause an imbalance between myocardial oxygen supply and demand, such as severe anemia, thyrotoxicosis, or supraventricular tachycardia, play a contributory role. Finally, the severity of the disability will govern the extent and tempo of the workup and strongly influence the therapeutic strategy that is selected.

The establishment of a correct and complete cardiac diagnosis often commences with the history and physical examination (Chap. 209). Indeed, the clinical examination remains the basis for the diagnosis of a wide variety of disorders (Table 208-2). The clinical examination may then be supplemented by four types of laboratory tests: (1) ECG (Chap. 210); (2) chest roentgenogram; (3) noninvasive graphic examinations (echocardiogram, radionuclide and imaging techniques; Chap. 211); and occasionally (4) specialized invasive examinations, i.e., cardiac catheterization, angiocardiography, and coronary angiography (Chap. 212).

THE DIAGNOSTIC PROCESS In the diagnostic process, the results obtained from each of these several modalities should be analyzed independently of one another as well as together. Only in this way can one avoid overlooking a subtle, though important, finding. For example, an ECG should be obtained in every patient suspected of heart disease. It may provide the critical clue in establishing the correct diagnosis, e.g., the finding of a mild atrioventricular conduction disturbance in a patient with unexplained syncope, even when all other methods of examination reveal no abnormal findings, can be the clue that advanced heart block and asystole might be the cause and can dictate electrophysiologic testing. On the other hand, when combined intelligently with the results of other methods of examination, the ECG may provide essential confirmatory data. Thus, the knowledge that a patient has an apical diastolic rumbling murmur may direct particular attention to the P waves, and the recognition of electrocardiographic left atrial enlargement supports the suggestion that the murmur is caused by mitral stenosis. The diagnosis can then be confirmed by echocardiography, a technique that can also determine the severity of the obstruction and its effects on pulmonary artery pressure and on right and left ventricular function.

FAMILY HISTORY In eliciting the history of a patient with known or suspected cardiovascular disease, particular attention should be directed to the family history. Familial clustering is common in many forms of heart disease. Mendelian transmission of single-gene defects may occur, as in hypertrophic cardiomyopathy (Chap. 221), the Marfan syndrome (Chap. 342), and sudden death associated with a prolonged QT syndrome (Chap. 214). Essential hypertension or coronary atherosclerosis are often polygenic disorders. While familial transmission may be less obvious than in the single-gene disorders, it is also helpful in assessing risk and prognosis. Familial clustering of cardiovascular diseases may occur not only on a genetic basis but may also be related to familial dietary or behavior patterns, such as excessive ingestion of salt or calories or cigarette smoking.

TABLE 208-1 New York Heart Association Functional Classification

Class I	Class III
No limitation of physical activity	Marked limitation of physical activity
No symptoms with ordinary exertion	Less than ordinary activity causes symptoms
Class II	Asymptomatic at rest
Slight limitation of physical activity	Class IV
Ordinary activity causes symptoms	Inability to carry out any physical activity without discomfort
	Symptoms at rest

Source: Modified from The Criteria Committee of the New York Heart Association.

TABLE 208-2 Conditions in Which Clinical Examination Is an Important Determinant of Diagnosis: Confirmation by Echocardiography Is Often Useful

Mitral valve prolapse	Tricuspid regurgitation
Congestive heart failure	Aortic stenosis
Cardiac tamponade	Acute pulmonary hypertension
Hypertension	Chronic pulmonary hypertension
Mitral stenosis	High-output states
Chronic mitral regurgitation	Atrial septal defect
Chronic aortic regurgitation	Anginal syndrome

ASSESSMENT OF FUNCTIONAL IMPAIRMENT When an attempt is made to determine the severity of functional impairment in a patient with heart disease, it is helpful to ascertain with as much precision as possible the level of activity and the rate at which it is performed before symptoms develop. Thus, it is not sufficient to state that the patient complains of dyspnea. The breathlessness that occurs after running up two long flights of stairs denotes far less functional impairment than similar symptoms occurring after taking a few steps on the level. Also, the degree of customary physical activity at work and during recreation should be considered. The development of two-flight dyspnea in a well-conditioned marathon runner may be far more significant than the development of one-flight dyspnea in a previously sedentary person. Similarly, the history must include a detailed consideration of the patient's therapeutic regimen. For example, the persistence or development of edema, breathlessness, and other manifestations of heart failure in a patient whose diet is rigidly restricted in sodium content and who is receiving optimal doses of diuretics is far more grave than are similar manifestations in the absence of these measures. In an effort to determine the progression of symptoms, and thereby the severity of the underlying illness, it may be useful to ascertain what, if any, specific tasks the patient could carry out 1 year earlier that he or she cannot carry out at present.

THE PATIENT WITH A HEART MURMUR (Fig. 208-1) The cause of a heart murmur can often be readily elucidated from a systematic evaluation of its major attributes: timing, duration, intensity, quality, frequency, configuration, location, radiation, and response to maneuvers when considered in the light of the history, general physical examination, and other features of the cardiac examination, as described in Chap. 209.

The majority of heart murmurs are midsystolic and soft (grades I to II/VI). When such a murmur occurs in an asymptomatic child or young adult *without* other evidence of heart disease on clinical examination, it is usually benign and echocardiography is not generally required. On the other hand, two-dimensional and Doppler echocardiography (Chap. 211) are indicated in patients with loud systolic murmurs (grades ≥III/VI), especially those that are holosystolic or late systolic; in most patients with diastolic or continuous murmurs; and in patients with additional unexplained abnormal physical findings on cardiac examination.

ELECTROCARDIOGRAM (See also Chap. 210) Although an ECG should be recorded in every patient with known or suspected heart disease, with the exception of the identification of arrhythmias and of acute myocardial infarction, it rarely permits establishment of a specific diagnosis. The range of normal electrocardiographic findings is wide, and the tracing can be affected significantly by many noncardiac factors, such as age, body habitus, and serum electrolyte concentrations. In the absence of other abnormal findings, electrocardiographic changes must not be overinterpreted.

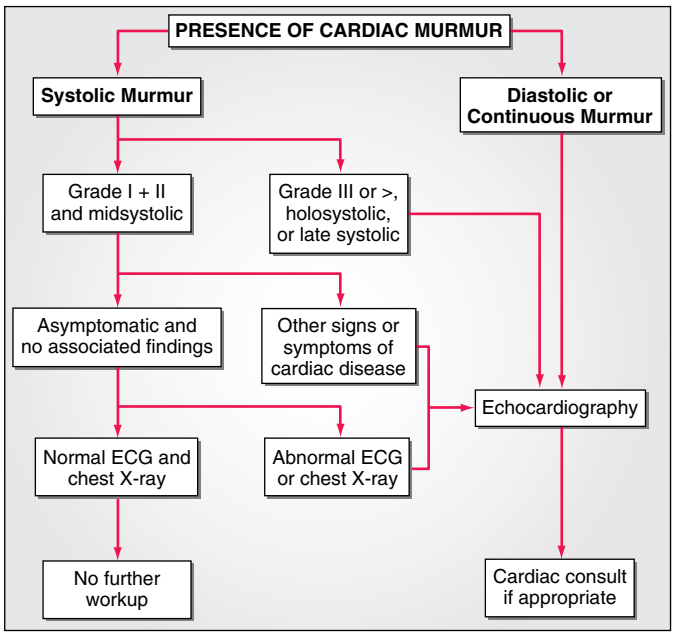

FIGURE 208-1 An alternative "echocardiography first" approach to the evaluation of a heart murmur that also uses the results of the electrocardiogram (ECG) and chest x-ray in asymptomatic patients with soft midsystolic murmurs and no other physical findings. This algorithm is useful to patients over age 40 years in whom the prevalence of coronary artery disease and aortic stenosis increases as the cause of systolic murmur. *[From RA O'Rourke, in E Braunwald, L Goldman (eds): Primary Cardiology, 2d ed. Philadelphia, Saunders, 2003.]*

NATURAL HISTORY Cardiovascular disorders often present acutely, as in a previously asymptomatic patient with extensive coronary atherosclerosis who develops an acute myocardial infarction (Chap. 228) or the previously asymptomatic patient with hypertrophic cardiomyopathy (Chap. 221) whose first clinical manifestation is syncope or even sudden death. However, in both instances, the alert physician may recognize the patient at risk of these complications long before they occur and can often take measures to prevent their occurrence. For example, the patient with acute myocardial infarction may well have had risk factors for atherosclerosis for many years. Had these been recognized, their elimination or reduction might have delayed or even prevented the infarction. Similarly, the patient with hypertrophic cardiomyopathy may have had a heart murmur for years, and a positive family history might have led to an echocardiographic examination and the recognition of the condition and appropriate therapy long before the acute manifestations.

PITFALLS IN CARDIOVASCULAR MEDICINE

Increasing subspecialization in internal medicine and the perfection of advanced diagnostic techniques in cardiology can lead to several undesirable consequences. Examples include:

1. Failure by the *noncardiologist* to recognize important cardiac manifestations of systemic illnesses. Examples of the latter are (a) stroke (secondary to atrial fibrillation or mitral stenosis); (b) skeletal muscular dystrophies (associated with cardiomyopathy); (c) hemochromatosis (associated with myocardial infiltration and restrictive cardiomyopathy); (d) congenital deafness (associated with prolonged QT interval and serious cardiac arrhythmias); (e) Raynaud's disease (associated with primary pulmonary hypertension and coronary vasospasm); (f) connective tissue disorders, e.g., the Marfan syndrome (aortic dilatation and aneurysm, prolapsed mitral valve); (g) hyperthyroidism (heart failure, atrial fibrillation); (h) hypothyroidism (pericardial effusion, coronary artery disease); (i) rheumatoid arthritis (pericarditis, aortic valve disease); (j) scleroderma (cor pulmonale, myocardial fibrosis, pericarditis); (k) systemic lupus erythematosus (valvulitis, myocarditis, pericarditis); and (l) sarcoidosis (arrhythmias, cardiomyopathy). In patients with these and other systemic disorders, a cardiovascular examination should be carried out to identify and estimate the severity of cardiovascular involvement.

2. Failure by the cardiologist to recognize underlying systemic disorders, such as those listed above, in patients with a cardiac disorder. Patients with heart disease should be assessed for the frequent *noncardiac* manifestations of systemic disorders with cardiovascular manifestations. For example, hyperthyroidism should be considered in an elderly patient with unexplained heart failure and atrial fibrillation. Similarly, Lyme disease should be considered in patients with unexplained fluctuating atrioventricular block. A cardiovascular abnormality may provide the clue critical to the recognition of some systemic disorders. For instance, unexplained atrial fibrillation may provide the first clue to the diagnosis of thyrotoxicosis.

3. Overreliance on and overutilization of laboratory tests, particularly invasive techniques for the examination of the cardiovascular system. Cardiac catheterization and coronary arteriography (Chap. 212) provide precise diagnostic information under many circumstances. For example, they aid in establishing a specific anatomic diagnosis, which, in turn, may be critical to developing a therapeutic plan in patients with known or suspected ischemic heart disease. Although a great deal of attention has been lavished on these expensive examinations, it should be recognized that they serve to *supplement*, not *supplant*, a careful examination carried out by clinical and noninvasive techniques. A coronary arteriogram should not be carried out in lieu of a careful history in patients with chest pain suspected of having ischemic heart disease. Although coronary arteriography may establish whether the coronary arteries are obstructed, the results often do not provide a definite answer to the question of whether a patient's complaint of chest pain is attributable to coronary arteriosclerosis. Catheterization of the left side of the heart is all too frequently employed to assess patients with valvular heart disease when echocardiographic examination would actually provide more useful information.

Despite the enormous value of these invasive tests in certain circumstances, they entail some small risk to the patient, involve discomfort and substantial cost, and place a strain on medical facilities. Therefore, they should be carried out only if, after clinical examination and assessment by noninvasive tests, the results of the invasive examination can be expected to modify the patient's management.

MANAGEMENT

After a complete diagnosis has been established, a number of management options are usually available. Several examples may be used to demonstrate some of the principles of cardiovascular therapeutics:

1. In the absence of evidence of heart disease, a clear, definitive statement to that effect should be made and the patient should *not* be asked to return at intervals for repeated examinations. If there is no evidence for disease, such continued attention may lead to the patient developing inappropriate anxiety and fixation on the heart.

2. If there is no evidence of cardiovascular disease but the patient has one or more risk factors for the development of ischemic heart disease (Chap. 224), a plan for their reduction should be developed and the patient should be retested at intervals to assess that he or she is complying and that these risk factors are in fact being reduced.

3. Asymptomatic or mildly symptomatic patients with valvular heart disease that is anatomically severe should be evaluated periodically, every 6 to 12 months, by clinical and noninvasive examinations. Early signs of deterioration of ventricular function can be detected in this manner and in appropriate patients may signify the need for surgical treatment before the development of disabling symptoms, irreversible myocardial damage, and excessive risk of surgical treatment (Chap. 219).

4. It is critical to establish clear criteria for deciding on the form of treatment (medical, percutaneous coronary intervention, or surgical revascularization) in patients with ischemic heart disease (Chap. 226). Mechanical revascularization, i.e., the latter two modalities, is proba-

bly being employed too frequently in the United States; the mere presence of angina pectoris and/or the demonstration of critical coronary arterial narrowing at angiography should not reflexly evoke a decision to treat the patient by revascularization. Instead, this approach should be limited to those patients with ischemic heart disease whose angina has not responded adequately to medical treatment or in whom revascularization has been shown to improve the natural history (e.g., acute coronary syndrome, or multivessel coronary artery disease with left ventricular dysfunction).

209 PHYSICAL EXAMINATION OF THE CARDIOVASCULAR SYSTEM

Robert A. O'Rourke, Eugene Braunwald

A meticulous physical examination is an often inadequately utilized low-cost method for assessing the cardiovascular system and frequently provides important information for the appropriate selection of additional tests. First, the general physical appearance should be evaluated. The patient may appear tired because of a chronic low cardiac output; the respiratory rate may be rapid in cases of pulmonary venous congestion. Central cyanosis, often associated with clubbing of the fingers and toes, indicates right-to-left cardiac or extracardiac shunting or inadequate oxygenation of blood by the lungs. Cyanosis in the distal extremities, cool skin, and increased sweating result from vasoconstriction in patients with severe heart failure (Chap. 31). Noncardiovascular details can be equally important. For example, infective endocarditis is the likely diagnosis in patients with petechiae, Osler's nodes, and Janeway lesions (Chap. 109).

The blood pressure should be taken in both arms and with the patient supine and upright; the heart rate should be timed for 30 s. Orthostatic hypotension and tachycardia may indicate a reduced blood volume, while resting tachycardia may be due to heart failure.

EXAMINATION OF THE RETINA

Inspection of the smaller vessels of the body is possible in the retina. The optic disc should be observed first, with a search for evidence of edema and blurred margins and for cupping with sharp contours. Neovascularization or the pallor of optic atrophy should be ruled out. Next, the examiner should scan along the superior temporal arcade, inspecting the arteries carefully for embolic plaques at each bifurcation and noting the arteriovenous crossing for evidence of obscuration of the vein and for pronounced nicking and banking of the vessels.

Early diabetic microaneurysms, a manifestation of diabetic microvascular disease, are found just temporal to the fovea, along the horizontal raphe, and cotton-wool infarcts are found circularly around the disc (see Fig. 323-9). Thus, the retina can be searched efficiently for evidence of cardiovascular disease.

Variations in the caliber of a single vessel are more important than determinations of arteriovenous ratios. These changes may take the form of focal narrowing, sometimes called *beading*, and are seen in hypercholesterolemia or spasm. In severe hypertension, hypertensive retinopathy with scattered flame-shaped hemorrhages, very constricted arterioles, and cotton-wool spots are evident (see Fig. 25-8).

Retinal emboli have particular cardiovascular significance. Of these, platelet emboli are both the most common and the most evanescent. Hollenhorst cholesterol plaques may be identified at the same bifurcations for months to years after the embolic shower. Platelet emboli, Hollenhorst plaques, and calcium emboli are usually seen along the course of a retinal artery, and their appearance indicates that a patient is shedding from the heart, aorta, great vessels, or carotid arteries (see Fig. 25-6). Roth spots and fat emboli may not appear to be intravascular and may not be associated with a vessel that is ophthalmoscopically visible.

EXAMINATION OF THE ABDOMEN

The diameter of the *abdominal* aorta should be estimated. An abdominal aortic aneurysm may be missed if the examiner fails to assess the area above the umbilicus.

Specific abnormalities of the abdomen may be secondary to heart disease. A large, tender liver is common in patients with heart failure or constrictive pericarditis. Systolic hepatic pulsations are frequent in patients with tricuspid regurgitation. A palpable spleen is a late sign in patients with severe heart failure and is also often present in patients with infective endocarditis.

Ascites may occur with heart failure alone, although it is less common with the use of diuretic therapy. Severe tricuspid regurgitation often results in an enlarged pulsating liver and ascites. Constrictive pericarditis should be considered when the ascites is out of proportion to peripheral edema. When there is an arteriovenous fistula, a continuous murmur may be heard over the abdomen. Fistulas due to trauma and surgery may occur.

A systolic bruit heard over the kidney areas may signify renal artery stenosis in patients with systemic hypertension.

EXAMINATION OF THE EXTREMITIES

Examination of the upper and lower extremities may provide important diagnostic information. Palpation of the peripheral arterial pulses in the upper and lower extremities is necessary to define the adequacy of systemic blood flow and to detect the presence of occlusive arterial lesions. Atherosclerosis of the peripheral arteries may produce intermittent claudication of the buttock, calf, thigh, or foot, with severe disease resulting in tissue damage of the toes. Peripheral atherosclerosis is an important risk factor for coincident ischemic heart disease.

Thrombophlebitis often causes pain (in the calf or thigh) or edema, and when present, pulmonary emboli should be considered as well. Edema is a late sign of heart failure; it frequently involves the right leg prior to the left. However, edema of the lower extremities may be secondary to local factors, such as varicose veins or thrombophlebitis, or to the removal of veins at coronary artery bypass surgery. Under such circumstances, the edema is often unilateral.

ARTERIAL PRESSURE PULSE

The normal central aortic pulse wave is characterized by a fairly rapid rise to a somewhat rounded peak (Fig. 209-1). The anacrotic shoulder, present on the ascending limb, occurs at the time of peak rate of aortic flow just before maximum pressure is reached. The less steep descending limb is interrupted by a sharp downward deflection, coincident with aortic valve closure, called the *incisura*. As the pulse wave is transmitted peripherally, the initial upstroke becomes steeper, the anacrotic shoulder becomes less apparent, and the incisura is replaced by the smoother dicrotic notch. Accordingly, palpation of a peripheral arterial pulse (e.g., the radial pulse) frequently gives less information than examination of a more central pulse (e.g., the carotid pulse) re-

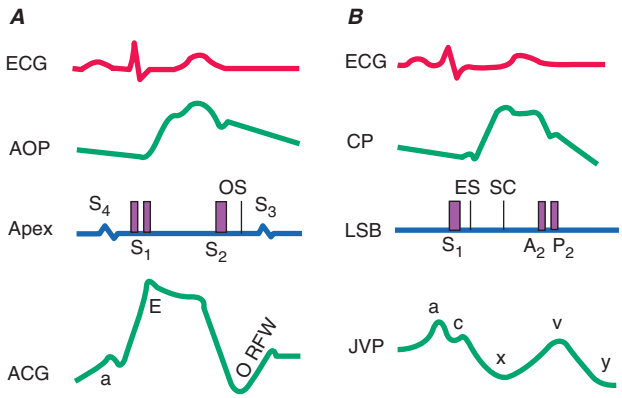

FIGURE 209-1 *A*. Schematic representation of electrocardiogram, aortic pressure pulse (AOP), phonocardiogram recorded at the apex, and apex cardiogram (ACG). On the phonocardiogram, S_1, S_2, S_3, and S_4 represent the first through fourth heart sounds; OS represents the opening snap of the mitral valve, which occurs coincident with the O point of the apex cardiogram. S_3 occurs coincident with the termination of the rapid-filling wave (RFW) of the ACG, while S_4 occurs coincident with the *a* wave of the ACG. *B*. Simultaneous recording of electrocardiogram, indirect carotid pulse (CP), phonocardiogram along the left sternal border (LSB), and indirect jugular venous pulse (JVP). ES, ejection sound; SC, systolic click.

garding alterations in left ventricular ejection or aortic valve function. However, certain findings, such as the bisferiens pulse of aortic regurgitation or pulsus alternans, are more evident in peripheral arteries (Fig. 209-2).

The carotid pulse is best examined with the sternocleidomastoid muscle relaxed and with the patient's head rotated slightly toward the examiner. In palpating the brachial arterial pulse, the examiner can support the patient's relaxed elbow with the right arm while compressing the brachial pulse with the thumb. The usual technique is to compress the artery with the thumb or forefinger until the maximum pulse is sensed. Varying degrees of pressure should then be applied while concentrating on the separate phases of the pulse wave. This method, known as *trisection*, is useful for assessing the sharpness of the upstroke, systolic peak, and diastolic slope of the arterial pulse. In most normal persons, a dicrotic wave is not palpable.

A small weak pulse, *pulsus parvus*, is common in conditions with a diminished left ventricular stroke volume, a narrow pulse pressure, and increased peripheral vascular resistance (Fig. 209-2). A *hypokinetic* pulse may be due to hypovolemia, to left ventricular failure, to restrictive pericardial disease, or to mitral valve stenosis. In aortic valve stenosis, the delayed systolic peak, *pulsus tardus*, results from obstruction to left ventricular ejection. In contrast, a large, bounding (*hyperkinetic*) pulse is usually associated with an increased left ventricular stroke volume, a wide pulse pressure, and a decrease in peripheral vascular resistance. This pattern occurs characteristically in patients with an elevated stroke volume, as in complete heart block; with hyperkinetic circulation due to anxiety, anemia, exercise, or fever; or with a rapid runoff of blood from the arterial system (as caused by a patent ductus arteriosus or peripheral arteriovenous fistula). Patients with mitral regurgitation or a ventricular septal defect may also have a bounding pulse, since vigorous left ventricular ejection produces a rapid upstroke in the arterial pulse, even though the duration of systole and the forward stroke volume may be reduced. In aortic regurgitation, the rapidly rising, bounding arterial pulse results from an increased left ventricular stroke volume and an increased rate of ventricular ejection.

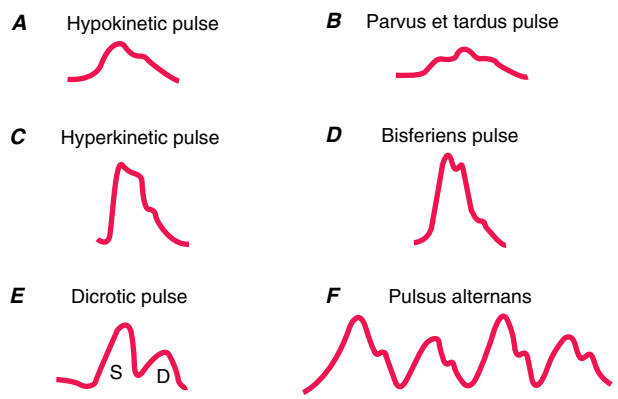

FIGURE 209-2 Schematic representation of arterial pulse waveforms that occur with alterations in cardiac hemodynamics, which may result from normal physiologic responses or may be due to cardiac disease. S, systole; D, diastole. *[Modified from RA O'Rourke, in Hurst's The Heart, 10th ed, V Fuster et al (eds). New York, McGraw-Hill, 2001, with permission.]*

The *bisferiens pulse*, which has two systolic peaks, is characteristic of aortic regurgitation (with or without accompanying stenosis) and of hypertrophic cardiomyopathy (Chap. 221). In the latter condition, the pulse wave upstroke rises rapidly and forcefully, producing the first systolic peak ("percussion wave"). A brief decline in pressure follows because of the sudden midsystolic decrease in the rate of left ventricular ejection, when severe obstruction often develops. This pressure trough is followed by a smaller and more slowly rising positive pulse wave ("tidal wave") produced by continued ventricular ejection and by reflected waves from the periphery. The *dicrotic pulse* has two palpable waves, one in systole and one in diastole. It usually denotes a very low stroke volume, particularly in patients with dilated cardiomyopathy.

Pulsus alternans is a pattern in which there is regular alteration of the pressure pulse amplitude, despite a regular rhythm (Fig. 209-2). It is due to alternating left ventricular contractile force, usually indicates severe impairment of left ventricular function, and commonly occurs in patients who also have a loud third heart sound. Pulsus alternans may also occur during or following paroxysmal tachycardia or for several beats following a premature beat in patients without heart disease. In *pulsus bigeminus*, there is also a regular alteration of pressure pulse amplitude, but it is caused by a premature ventricular contraction that follows each regular beat. In *pulsus paradoxus*, the decrease in systolic arterial pressure that normally accompanies the reduction in arterial pulse amplitude during inspiration is accentuated. In patients with pericardial tamponade (Chap. 222), airway obstruction, or superior vena cava obstruction, the decrease in systolic arterial pressure frequently exceeds the normal decrease of 10 mmHg and the peripheral pulse may disappear completely during inspiration.

Simultaneous palpation of the radial and femoral arterial pulses, which normally are virtually coincident, is important to rule out aortic coarctation, in which the latter pulse is weakened and delayed (Chap. 218).

JUGULAR VENOUS PULSE (JVP)

The two main objectives of the examination of the neck veins are inspection of their waveform and estimation of the central venous pressure (CVP). In most patients, the right internal jugular vein is best for both purposes. Usually, the pulsation of the internal jugular vein is greatest when the trunk is inclined by less than 30°. In patients with elevated venous pressure, it may be necessary to elevate the trunk further, sometimes to as much as 90°. When the neck muscles are relaxed, shining a beam of light tangentially across the skin overlying the vein exposes the pulsations of the internal jugular vein. Simultaneous palpation of the left carotid artery aids the examiner in deciding which pulsations are venous and in relating the venous pulsations to their timing in the cardiac cycle.

The normal JVP reflects phasic pressure changes in the right atrium and consists of two or sometimes three positive waves and two negative troughs (Fig. 209-1). The positive presystolic *a* wave is produced by venous distention due to right atrial contraction and is the dominant wave in the JVP, particularly during inspiration. Large *a* waves indicate that the right atrium is contracting against an increased resistance (Fig. 209-3), such as occurs with tricuspid stenosis or more commonly

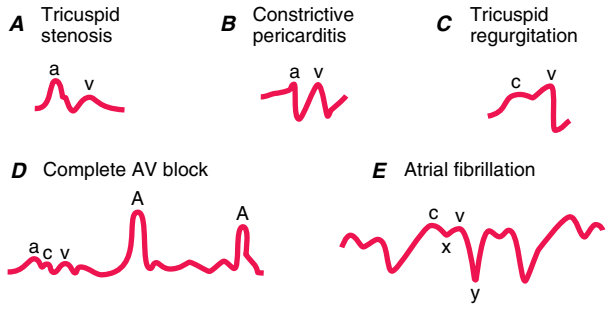

FIGURE 209-3 Abnormal jugular venous pulse waveforms commonly present in patients with cardiac disease and/or arrhythmias. See text. *[Modified from RA O'Rourke, in Hurst's The Heart, 10th ed, V Fuster et al (eds). New York, McGraw-Hill, 2001, with permission.]*

with increased resistance to right ventricular filling (pulmonary hypertension or pulmonic stenosis). Large *a* waves also occur during arrhythmias whenever the right atrium contracts while the tricuspid valve is closed by right ventricular systole. Such "cannon" *a* waves may occur regularly (as during junctional rhythm) or irregularly (as in atrioventricular dissociation with ventricular tachycardia or complete heart block). The *a* wave is absent in patients with atrial fibrillation, and there is an increased delay between the *a* wave and the carotid arterial pulse in patients with first-degree atrioventricular block.

The *c* wave, often observed in the JVP, is a positive wave produced by the bulging of the tricuspid valve into the right atrium during right ventricular isovolumetric systole and by the impact of the carotid artery adjacent to the jugular vein. The *x* descent is due both to atrial relaxation and to the downward displacement of the tricuspid valve during ventricular systole. The *x* descent wave during systole is often accentuated in patients with constrictive pericarditis (Fig. 209-3), but the nadir of this wave is reduced with right ventricular dilation and is often reversed in tricuspid regurgitation. The positive, late systolic *v* wave results from the increasing volume of blood in the right atrium during ventricular systole when the tricuspid valve is closed. Tricuspid regurgitation causes the *v* wave to be more prominent; when tricuspid regurgitation becomes severe, the combination of a prominent *v* wave and obliteration of the *x* descent results in a single large positive systolic wave. After the *v* wave peaks, the right atrial pressure falls because of the decreased bulging of the tricuspid valve into the right atrium as right ventricular pressure declines and the tricuspid valve opens (Fig. 209-3).

This negative descending limb—the *y* descent of the JVP—is produced mainly by the opening of the tricuspid valve and the subsequent rapid inflow of blood into the right ventricle. A rapid, deep *y* descent in early diastole occurs with severe tricuspid regurgitation. A venous pulse characterized by a sharp *y* descent, a deep *y* trough, and a rapid ascent to the baseline is seen in patients with constrictive pericarditis or with severe right-sided heart failure and a high venous pressure. A slow *y* descent in the JVP suggests an obstruction to right ventricular filling, as occurs with tricuspid stenosis or right atrial myxoma.

The right internal jugular is the best vein to use for accurate estimation of the CVP. The sternal angle is used as the reference point, because the center of the right atrium lies approximately 5 cm below the sternal angle in the average patient, regardless of body position. The patient is examined at the optimal degree of trunk elevation for visualization of venous pulsations. The vertical distance between the top of the oscillating venous column and the level of the sternal angle is determined; generally it is less than 3 cm (3 cm + 5 cm = 8 cm blood). The most common cause of a high venous pressure is an elevated right ventricular diastolic pressure.

In patients suspected of having right ventricular failure who have a normal CVP at rest, the *abdominojugular reflux test* may be helpful. The palm of the examiner's hand is placed over the abdomen, and firm pressure is applied for 10 s or more. In normal persons, this maneuver does not alter the jugular venous pressure significantly, but when right heart function is impaired, the upper level of venous pulsation usually increases. A positive abdominojugular test is best defined as an increase in JVP during 10 s of firm midabdominal compression followed by a rapid drop in pressure of 4 cm blood on release of the compression. The most common cause of a positive test is right-sided heart failure secondary to elevated left heart filling pressures. Also, abdominal compression may elicit the JVP pattern typical of tricuspid regurgitation when the resting pulse wave is normal. *Kussmaul's sign*—an increase rather than the normal decrease in the CVP during inspiration—is most often caused by severe right-sided heart failure; it is a frequent finding in patients with constrictive pericarditis or right ventricular infarction.

PRECORDIAL PALPATION

The location, amplitude, duration, and direction of the cardiac impulse usually can be best appreciated with the fingertips. The normal left ventricular apex impulse is located at or medial to the left midclavicular line in the fourth or fifth intercostal space and is a tapping, early systolic outward thrust localized to a point usually less than 2.5 cm in diameter. It is due primarily to recoil of the heart as blood is ejected and should be evaluated with the patient supine and in the left lateral position. Left ventricular hypertrophy results in exaggeration of the amplitude, duration, and often size of the normal left ventricular thrust. The impulse may be displaced laterally and downward into the sixth or seventh intercostal space, particularly in patients with a left ventricular volume load such as occurs in cases of aortic regurgitation or dilated cardiomyopathy.

Additional abnormal features that are detectable at the left ventricular apex include (1) marked presystolic distention of the left ventricle, usually accompanied by a fourth heart sound in patients with an excessive left ventricular pressure load or myocardial ischemia/infarction; and (2) a prominent early diastolic rapid-filling wave, often accompanied by a third heart sound in patients with left ventricular failure or mitral valve regurgitation (Fig. 209-1). A double systolic apical impulse is palpable in many patients with hypertrophic cardiomyopathy.

Right ventricular hypertrophy often results in a sustained systolic lift at the lower left parasternal area, which starts in early systole and is synchronous with the left ventricular apical impulse.

Abnormal precordial pulsations occur during systole in patients with left ventricular dyssynergy due to ischemic heart disease or to diffuse myocardial disease from some other cause. These pulsations often occur in patients with a recent myocardial infarction and may be present in some patients only during episodes of angina. They are most commonly felt in the left midprecordium one or two interspaces above and/or 1 to 2 cm medial to the left ventricular apex. A systolic bulge occurring in the region of the apex is difficult to distinguish from the impulse of left ventricular hypertrophy.

A left parasternal lift is frequently present in patients with severe mitral regurgitation. This pulsation occurs distinctly later than the left ventricular apical impulse, is synchronous with the *v* wave in the left atrial pressure curve, and is due to anterior displacement of the right ventricle by an enlarged, expanding left atrium. A similar impulse occurs to the right of the sternum in some patients with severe tricuspid regurgitation and a giant right atrium. Pulsation of the right sternoclavicular joint may indicate a right-sided aortic arch or aneurysmal dilation of the ascending aorta. Pulmonary artery pulsation is often visible and palpable in the second left intercostal space. While it may be normal in children or thin young adults, this pulsation usually denotes pulmonary hypertension, increased pulmonary blood flow, or poststenotic pulmonary artery dilation.

Thrills are palpable, low-frequency vibrations associated with heart murmurs. The systolic murmur of mitral regurgitation may be palpated at the cardiac apex. When the palm of the hand is placed over the precordium, the thrill of aortic stenosis crosses the palm toward the right side of the neck, while the thrill of pulmonic stenosis radiates more often to the left side of the neck. The thrill due to a ventricular

septal defect is usually located in the third and fourth intercostal spaces near the left sternal border.

Percussion should be performed in each patient to identify normal or abnormal position of the heart, stomach, and liver. However, in patients with a normal cardiac situs, percussion adds little to careful inspection and palpation in the recognition of cardiac enlargement.

CARDIAC AUSCULTATION

To obtain the most information from cardiac auscultation, the observer should keep in mind several principles: (1) Auscultation should be performed in a quiet room to avoid the distracting noises of normal activity. (2) For optimal auscultation, attention must be focused on the phase of the cardiac cycle during which the auscultatory event is expected to occur. (3) The timing of a heart sound or murmur can be determined accurately from its relation to other observable events in the cardiac cycle—the carotid arterial pulse, the apical impulse, or the JVP. (4) To define the significance of a cardiac sound or murmur, it is often necessary to observe alterations in its timing or intensity during various physiologic and/or pharmacologic interventions (Table 209-1).

HEART SOUNDS

The major components of heart sounds are vibrations associated with the abrupt acceleration or deceleration of blood in the cardiovascular system. Studies using simultaneous echocardiographic-phonocardiographic recordings indicate that the first and second heart sounds are produced primarily by the closure of the atrioventricular (AV) and semilunar valves and the events that accompany these closures. The intensity of the *first heart sound* (S_1) is influenced by (1) the position of the mitral leaflets at the onset of ventricular systole; (2) the rate of rise of the left ventricular pressure pulse; (3) the presence or absence of structural disease of the mitral valve; and (4) the amount of tissue, air, or fluid between the heart and the stethoscope. S_1 is louder if diastole is shortened because of tachycardia, if AV flow is increased because of high cardiac output or prolonged because of mitral stenosis, or if atrial contraction precedes ventricular contraction by an unusually short interval, reflected in a short PR interval. The loud S_1 in mitral stenosis usually signifies that the valve is pliable and that it remains open at the onset of isovolumetric contraction because of the elevated left atrial pressure. A soft S_1 may be due to poor conduction of sound through the chest wall, a slow rise of the left ventricular pressure pulse, a long PR interval, or imperfect closure due to reduced valve substance, as in mitral regurgitation. S_1 is also soft when the anterior mitral leaflet is immobile because of rigidity and calcification, even in the presence of predominant mitral stenosis.

Splitting of the two high-pitched components of S_1 by 10 to 30 ms is a normal phenomenon (Fig. 209-1). The first component of S_1 is usually attributed to mitral valve closure, and the second to tricuspid valve closure. Widening of the S_1 is due most often to complete right bundle branch block and the resulting delay in onset of the right ventricular pressure pulse. Reversed splitting of the S_1, in which the mitral component follows the tricuspid component, may be present in patients with severe mitral stenosis, left atrial myxoma, and left bundle branch block.

SPLITTING OF THE *SECOND HEART SOUND* This sound (S_2) normally splits into audibly distinct aortic (A_2) and pulmonic (P_2) components during inspiration, when the augmented inflow into the right ventricle increases its stroke volume and ejection period and thus delays closure of the pulmonic valve. P_2 is coincident with the incisura of the pulmonary artery pressure curve, which is separated from the right ventricular pressure tracing by an interval termed the *hangout time*. The absolute value of this interval reflects the resistance to pulmonary blood flow and the impedance characteristics of the pulmonary vascular bed. This interval is prolonged, and physiologic splitting of S_2 is accentuated, in conditions associated with right ventricular volume overload and a distensible pulmonary vascular bed. However, in patients with an increase in pulmonary vascular resistance, the hangout time is markedly reduced, and narrow splitting of S_2 is present. Splitting that persists with expiration (heard best at the pulmonic area or left sternal border) is usually abnormal when the patient is in the upright position. Such splitting may be due to many causes: delayed activation of the right ventricle (right bundle branch block); left ventricular ectopic beats; a left ventricular pacemaker; prolongation of right ventricular contraction with an increased right ventricular pressure load (pulmonary embolism or pulmonic stenosis); or delayed pulmonic valve closure because of right ventricular volume overload associated with right ventricular failure or diminished impedance of the pulmonary vascular bed and a prolonged hangout time (atrial septal defect).

In pulmonary hypertension, P_2 is loud, and splitting of the second heart sound may be diminished, normal, or accentuated, depending on the cause of the pulmonary hypertension, the pulmonary vascular resistance, and the presence or absence of right ventricular decompensation. Early aortic valve closure, occurring with mitral regurgitation or a ventricular septal defect, may also produce splitting that persists during expiration. It may also occur with constrictive pericarditis. In patients with an atrial septal defect, the proportion of right atrial filling contributed by the left atrium and the venae cavae varies reciprocally during the respiratory cycle, so that right atrial inflow remains relatively constant. Therefore, the volume and duration of right ventricular ejection are not significantly increased by inspiration, and there is little inspiratory exaggeration of the splitting of S_2. This phenomenon, termed *fixed splitting* of the second heart sound, is of considerable diagnostic value.

TABLE 209-1 *Effects of Physiologic and Pharmacologic Interventions on the Intensity of Heart Murmurs and Sounds*

Respiration	Systolic murmurs due to TR or pulmonic blood flow through a normal or stenotic valve and diastolic murmurs of TS or PR generally increase with inspiration, as do right-sided S_3 and S_4. Left-sided murmurs and sounds usually are louder during expiration.
Valsalva maneuver	Most murmurs decrease in length and intensity. Two exceptions are the systolic murmur of HCM, which usually becomes much louder, and that of MVP, which becomes longer and often louder. Following release of the Valsalva maneuver, right-sided murmurs tend to return to control intensity earlier than left-sided murmurs.
After VPB or AF	Murmurs originating at normal or stenotic semilunar valves increase in the cardiac cycle following a VPB or in the cycle after a long cycle length in AF. By contrast, systolic murmurs due to AV valve regurgitation either do not change, diminish (papillary muscle dysfunction), or become shorter (MVP).
Positional changes	With *standing*, most murmurs diminish, two exceptions being the murmur of HCM, which becomes louder, and that of MVP, which lengthens and often is intensified. With *squatting*, most murmurs become louder, but those of HCM and MVP usually soften and may disappear. Passive leg raising usually produces the same results.
Exercise	Murmurs due to blood flow across normal or obstructed valves (e.g., PS, MS) become louder with both isotonic and submaximal isometric (handgrip) exercise. Murmurs of MR, VSD, and AR also increase with handgrip exercise. However, the murmur of HCM often decreases with near maximum handgrip exercise. Left-sided S_4 and S_3 are often accentuated by exercise, particularly when due to ischemic heart disease.
Pharmacologic interventions	During the initial relative hypotension following amyl nitrite inhalation, murmurs of MR, VSD, and AR decrease, while murmurs of aortic stenosis or sclerosis increase. During the later tachycardia phase, murmurs of MS and right-sided lesions also increase. The response in MVP often is biphasic (first softer and then louder than control). The arterial constrictor phenylephrine tends to produce the opposite effects.
Transient arterial occlusion	Transient external compression of both arms by bilateral cuff inflation to 20 mmHg over peak systolic pressure augments the murmurs of MR, VSD, and AR, but not murmurs due to other causes.

Note: TR, tricuspid regurgitation; TS, tricuspid stenosis; PR, pulmonic regurgitation; HCM, hypertrophic cardiomyopathy; MVP, mitral valve prolapse; PS, pulmonic stenosis; MS, mitral stenosis; MR, mitral regurgitation; VSD, ventricular septal defect; AR, aortic regurgitation; VPB, ventricular premature beat; and AF, atrial fibrillation.

A delay in aortic valve closure causing P_2 to precede A_2 results in so-called reversed (paradoxic) splitting of S_2. Splitting is then maximal in expiration and decreases during inspiration with the normal delay of pulmonic valve closure. The most common causes of reversed splitting of S_2 are left bundle branch block and delayed excitation of the left ventricle from a right ventricular ectopic beat. Mechanical prolongation of left ventricular systole, resulting in reversed splitting of S_2, may also be caused by severe aortic outflow obstruction, a large aorta-to-pulmonary artery shunt, systolic hypertension, and ischemic heart disease or cardiomyopathy with left ventricular failure. P_2 is normally softer than A_2 in the second left intercostal space; a P_2 that is greater than A_2 in this area suggests pulmonary hypertension, except in patients with atrial septal defect.

SYSTOLIC SOUNDS The *ejection sound* is a sharp, high-pitched event occurring in early systole and closely following the first heart sound. Ejection sounds occur in the presence of semilunar valve stenosis and in conditions associated with dilation of the aorta or pulmonary artery. The aortic ejection sound is usually heard best at the left ventricular apex and the second right intercostal space; the pulmonary ejection sound is loudest at the upper left sternal border. The latter, unlike most other right-sided acoustical events, is heard better during expiration.

Nonejection clicks, or *midsystolic clicks*, occurring with or without a late systolic murmur, often denote prolapse of one or both leaflets of the mitral valve (Chap. 219). They also may be caused by tricuspid valve prolapse. They probably result from chordae tendineae that are functionally unequal in length on either or both AV valves and are heard best along the lower left sternal border and at the left ventricular apex. Systolic clicks may be single or multiple, and they may occur at any time in systole but are usually later than the systolic ejection sound.

DIASTOLIC SOUNDS The *opening snap* (OS) is a brief, high-pitched, early diastolic sound, which is usually due to stenosis of an AV valve, most often the mitral valve. It is generally heard best at the lower left sternal border and radiates well to the base of the heart. The A_2-OS interval is inversely related to the height of the mean left atrial pressure and ranges from 0.04 to 0.12 s. In the second intercostal space, an OS is often confused with P_2. However, careful auscultation will reveal both components of S_2, followed by the OS. The OS of tricuspid stenosis occurs later in diastole than the mitral OS and is often overlooked in patients with more prominent mitral valve disease.

The *third heart sound* (S_3) is a low-pitched sound produced in the ventricle 0.14 to 0.16 s after A_2, at the termination of rapid filling. This sound is frequent in normal children and in patients with high cardiac output. However, in patients over 40 years old, an S_3 usually indicates impairment of ventricular function, AV valve regurgitation, or other conditions that increase the rate or volume of ventricular filling. The left-sided S_3 is best heard with the bell piece of the stethoscope at the left ventricular apex during expiration and with the patient in the left lateral position. The right-sided S_3 is best heard at the left sternal border or just beneath the xiphoid and is usually louder with inspiration. Often it is accompanied by the systolic murmur of functional tricuspid regurgitation. Third heart sounds often disappear with treatment of heart failure.

An S_3 that is earlier (0.10 to 0.12 s after A_2) and higher-pitched than normal (a pericardial knock) often occurs in patients with constrictive pericarditis (Chap. 222); its presence depends on the restrictive effect of the adherent pericardium, which abruptly halts diastolic filling.

The *fourth heart sound* (S_4) is a low-pitched, presystolic sound produced in the ventricle during ventricular filling; it is associated with an effective atrial contraction and is best heard with the bell piece of the stethoscope. The sound is absent in patients with atrial fibrillation. The S_4 occurs when diminished ventricular compliance increases the resistance to ventricular filling, and it is frequently present in patients with systemic hypertension, aortic stenosis, hypertrophic cardiomyopathy, ischemic heart disease, and acute mitral regurgitation. Most patients with an acute myocardial infarction and sinus rhythm have an audible S_4. The fourth heart sound is frequently accompanied by visible and palpable presystolic distention of the left ventricle. It is loudest at the left ventricular apex when the patient is in the left lateral position and is accentuated by mild isotonic or isometric exercise in the supine position. The right-sided S_4 is present in patients with right ventricular hypertrophy secondary to either pulmonic stenosis or pulmonary hypertension and frequently accompanies a prominent presystolic *a* wave in the JVP.

An S_4 frequently accompanies delayed AV conduction even in the absence of clinically detectable heart disease. The incidence of an audible S_4 increases with increasing age. Whether an audible S_4 in adults without other evidence of cardiac disease is abnormal remains controversial. Both left-sided S_3 and S_4 sounds increase with isometric exercise and both may radiate to the subclavian and carotid arteries.

HEART MURMURS

Cardiac murmurs result from vibrations set up in the bloodstream and the surrounding heart and great vessels as a result of turbulent blood flow, the formation of eddies, and cavitation (bubble formation as a result of sudden decrease in pressure).

The evaluation of the patient with a heart murmur may vary greatly depending on many of the considerations discussed below. These include the intensity of the cardiac murmur, its timing in the cardiac cycle, its location and radiation, and its response to various physiologic maneuvers. Also of importance are the presence or absence of cardiac and noncardiac symptoms and whether other cardiac or noncardiac physical findings suggest that the cardiac murmur is clinically significant. The skill and confidence of the cardiac auscultator, the relative costs of various diagnostic approaches, and the accuracy and reliability of additional tests in the laboratory where they are performed are also important factors.

The intensity (loudness) of murmurs may be graded from I to VI. A grade I murmur is so faint that it can be heard only with special effort; a grade IV murmur is commonly accompanied by a thrill; and a grade VI murmur is audible with the stethoscope removed from contact with the chest. The configuration of a murmur may be crescendo, decrescendo, crescendo-decrescendo (diamond-shaped), or plateau (Fig. 209-4). The precise time of onset and time of cessation of a murmur depend on the instant in the cardiac cycle at which an adequate pressure difference between two chambers arises and disappears (Fig. 209-5).

The location on the chest wall where the murmur is best heard and the areas to which it radiates can aid in identifying the cardiac structure from which the murmur originates. For example, the murmur of aortic valve stenosis is usually loudest in the second right intercostal space and radiates to the carotid arteries. By contrast, the murmur of mitral regurgitation is most often loudest at the cardiac apex. It may radiate to the left sternal border and base of the heart when the posterior mitral leaflet is predominantly involved or to the axilla and back when the anterior leaflet is more severely affected. In the latter case, the regurgitant blood is directed toward the posterior left atrial wall.

EFFECTS OF PHYSIOLOGIC INTERVENTIONS It is often difficult to classify a cardiac murmur with certainty on the basis of its timing, configuration, location, radiation, pitch, or intensity. However, by noting changes in the characteristics of the murmur during maneuvers that alter cardiac hemodynamics, the auscultator can often identify its correct origin and significance (Table 209-1).

Accentuation of a murmur during inspiration (a maneuver that augments systemic venous return) implies that it originates on the right side of the circulation; expiratory exaggeration has less significance. Prolonged expiratory pressure against a closed glottis (i.e., the Valsalva maneuver) reduces the intensity of most murmurs by diminishing both right and left ventricular filling (i.e., ventricular preload). The systolic murmur associated with *hypertrophic cardiomyopathy* and the late systolic murmur due to *mitral valve prolapse* are exceptions and may be paradoxically accentuated during the Valsalva maneuver. Mur-

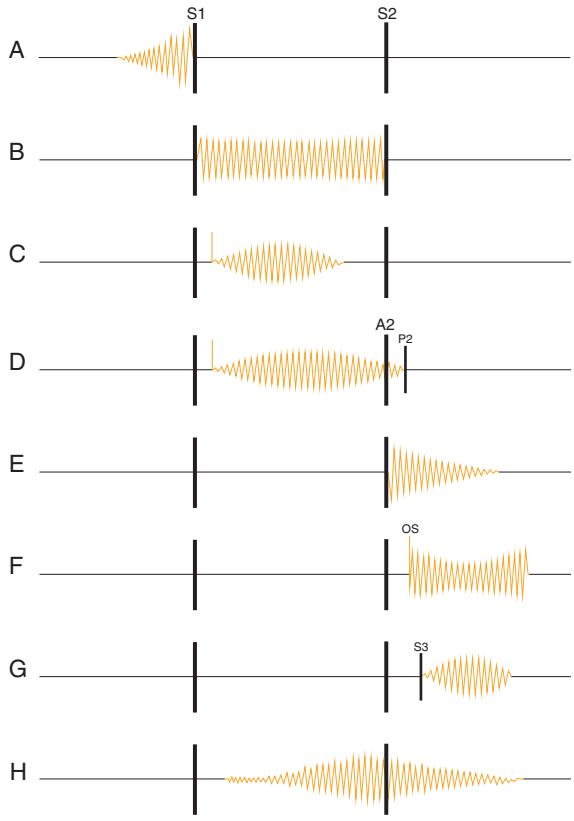

FIGURE 209-4 Diagram depicting principal heart murmurs. *A*. Presystolic murmur of mitral or tricuspid stenosis. *B*. murs due to flow across a normal or obstructed semilunar valve increase in intensity in the cycle following a premature ventricular beat or a long RR interval in atrial fibrillation. In contrast, murmurs due to AV valve regurgitation or a ventricular septal defect do not change appreciably during the beat following a prolonged diastole. Standing, which decreases left ventricular volume, accentuates the murmur of hypertrophic cardiomyopathy and occasionally the murmur due to mitral valve prolapse. Squatting, which increases both venous return and systemic arterial resistance and thus ventricular afterload, increases most murmurs, except those due to hypertrophic cardiomyopathy and mitral regurgitation due to a prolapsed mitral valve, which often decrease. In the patient who cannot squat, jackknifing the legs will produce the same response. Sustained handgrip exercise, which increases systemic arterial pressure and heart rate, often accentuates the murmurs of mitral regurgitation, aortic regurgitation, and mitral stenosis but usually diminishes those due to aortic stenosis or hypertrophic cardiomyopathy.

SYSTOLIC MURMURS ■ Holosystolic (Pansystolic) Murmurs These are generated when there is flow between two chambers that have widely different pressures throughout systole, such as the left ventricle and either the left atrium or the right ventricle (Fig. 209-5). The pressure gradient occurs early in contraction and lasts until relaxation is almost complete. Therefore, holosystolic murmurs begin before aortic ejection, and at the area of maximal intensity they begin with S_1 and end after S_2 (Fig. 209-4*B*). Holosystolic murmurs accompany mitral or tricuspid regurgitation, ventricular septal defect, and, under certain circumstances, aortopulmonary shunts. Although the typical high-pitched murmur of mitral regurgitation usually continues throughout systole, the shape of the murmur may vary considerably. The holosystolic murmurs of mitral regurgitation and ventricular septal defect are augmented by transient exercise.

The murmur of tricuspid regurgitation associated with pulmonary hypertension is holosystolic and frequently increases during inspiration. Not all patients with mitral or tricuspid regurgitation or ventricular septal defect have holosystolic murmurs. Often, a mild valvular regurgitant jet, detected by color flow Doppler techniques (Chap. 211), is not associated with an audible murmur despite optimal auscultation. Such regurgitant jets usually do not indicate clinical heart disease. Trivial mitral regurgitation can be detected by Doppler in up to 45% of normal individuals; tricuspid regurgitation in up to 70%; and pulmonic regurgitation in up to 88%. Aortic regurgitation is encountered much less frequently in normal persons, and its incidence increases with advancing age. An overinterpretation of the significance of mild regurgitation by echocardiographers often results in a misdiagnosis of "echocardiographic heart disease," resulting in unnecessary patient anxiety and infective endocarditis prophylaxis.

Midsystolic Murmurs These also called *systolic ejection murmurs*, which are often crescendo-decrescendo in shape, and occur when blood is ejected across the aortic or pulmonic outflow tracts (Figs. 209-4*C* and 209-5). The murmur starts shortly after S_1, when the ventricular pressure becomes high enough to open the semilunar valve. As the velocity of ejection increases, the murmur gets louder; as ejection declines, it diminishes. The murmur ends before the ventricular pressure falls enough to permit closure of the aortic or pulmonic leaflets. When the semilunar valves are normal, an increased flow rate (as occurs in states of elevated cardiac output), ejection into a dilated vessel beyond the valve, or increased transmission of sound through a thin chest wall may be responsible for this murmur. Most benign, functional murmurs are midsystolic and originate from the pulmonary outflow tract. Valvular or subvalvular obstruction of either ventricle may also cause such a midsystolic murmur, the intensity being related to the flow rate.

The murmur of aortic stenosis is the prototype of the left-sided midsystolic murmur. The location and radiation of this murmur are influenced by the direction of the high-velocity jet within the aortic

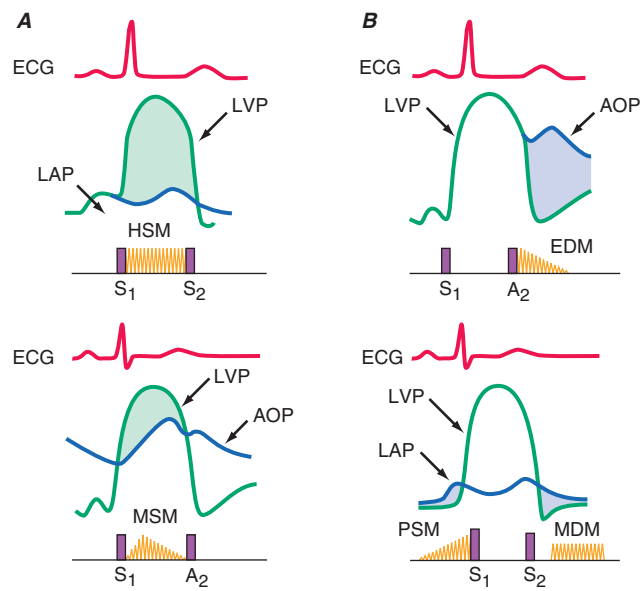

FIGURE 209-5 *A*. Schematic representation of ECG, aortic pressure (AOP), left ventricular pressure (LVP), and left atrial pressure (LAP). The shaded areas indicate a transvalvular pressure difference during systole. HSM, holosystolic murmur; MSM, midsystolic murmur. *B*. Graphic representation of ECG, aortic pressure (AOP), left ventricular pressure (LVP), and left atrial pressure (LAP) with shaded areas indicating transvalvular diastolic pressure difference. EDM, early diastolic murmur; PSM, presystolic murmur; MDM, middiastolic murmur.

root. In *valvular aortic stenosis*, the murmur is usually maximal in the second right intercostal space, with radiation into the neck. In *supravalvular aortic stenosis*, the murmur is occasionally loudest even higher, with disproportionate radiation into the right carotid artery. In hypertrophic cardiomyopathy, the midsystolic murmur originates in the left ventricular cavity and is usually maximal at the lower left sternal edge and apex, with relatively little radiation to the carotids. When the aortic valve is immobile (calcified), the aortic closure sound (A_2) may be soft and inaudible so that the length and configuration of the murmur are difficult to determine. Midsystolic murmurs also occur in patients with mitral regurgitation or, less frequently, tricuspid regurgitation resulting from papillary muscle dysfunction. Such murmurs due to mitral regurgitation are often confused with those originating in the aorta, particularly in elderly patients.

The patient's age and the area of maximal intensity aid in determining the significance of midsystolic murmurs. Thus, in a young adult with a thin chest and a high velocity of blood flow, a faint or moderate midsystolic murmur heard only in the pulmonic area is usually without clinical significance, while a somewhat louder murmur in the aortic area may indicate congenital aortic stenosis. In elderly patients, pulmonic flow murmurs are rare, while aortic systolic murmurs are common and may be due to aortic dilation, to a significant degree of valvular aortic stenosis, or to nonstenotic thickening of the aortic valve leaflets. Midsystolic aortic and pulmonic murmurs are intensified after amyl nitrite inhalation and during the cardiac cycle following a premature ventricular beat, while those due to mitral regurgitation are unchanged or softer. Aortic systolic murmurs are diminished by interventions that increase aortic impedance, such as transient arterial occlusion. Echocardiography or cardiac catheterization may be necessary to separate a prominent and exaggerated functional murmur from one due to congenital or acquired semilunar valve stenosis.

Early Systolic Murmurs These murmurs begin with the first heart sound and end in midsystole. In *large ventricular septal defects with pulmonary hypertension*, the shunting at the end of systole may be small or absent, resulting in an early systolic murmur. A similar murmur may occur with very small *muscular ventricular septal defects*, the shunt being interrupted in late systole. An early systolic murmur is a feature of *tricuspid regurgitation occurring in the absence of pulmonary hypertension*. This lesion is common in narcotics abusers with infective endocarditis, in whom a tall regurgitant right atrial *v* wave reaches the level of the normal right ventricular pressure in late systole, confining the murmur to early systole. Patients with acute mitral regurgitation into a noncompliant left atrium and a large *v* wave often have a loud early systolic murmur that diminishes as the pressure gradient between the left ventricle and left atrium decreases in late systole (Chap. 219).

Late Systolic Murmurs These murmurs are faint or moderately loud, high-pitched apical murmurs that start well after ejection and do not mask either heart sound. They are probably related to papillary muscle dysfunction caused by infarction or ischemia of these muscles or to their distortion by left ventricular dilation. They may appear only during angina but are common in patients with myocardial infarction or diffuse myocardial disease. Late systolic murmurs following midsystolic clicks are due to late systolic mitral regurgitation caused by prolapse of the mitral valve into the left atrium (Chap. 219).

DIASTOLIC MURMURS ■ Early Diastolic Murmurs (Figs. 209-4*E*, 209-5) These murmurs begin with or shortly after S_2, as soon as the corresponding ventricular pressure falls enough below that in the aorta or pulmonary artery. The high-pitched murmurs of aortic regurgitation or of pulmonic regurgitation due to pulmonary hypertension are generally decrescendo, since there is a progressive decline in the volume or rate of regurgitation during diastole. Faint, high-pitched murmurs of aortic regurgitation are difficult to hear unless they are specifically sought by applying firm pressure with the diaphragm over the left midsternal border while the patient sits leaning forward and holds a breath in full expiration. The diastolic murmur of aortic regurgitation is enhanced by an acute elevation of the arterial pressure, such as occurs with handgrip exercise; it diminishes with a decrease in arterial pressure, as with amyl nitrite inhalation. The diastolic murmur of congenital pulmonic regurgitation without pulmonary hypertension is low- to medium-pitched. The onset of this murmur is delayed because the regurgitant flow is minimal at the onset of pulmonic valve closure when the reverse pressure gradient responsible for the regurgitation is negligible.

Middiastolic Murmurs These usually arise from the mitral or tricuspid valves, occur during early ventricular filling, and are due to disproportion between valve orifice size and flow rate. Such murmurs may be quite loud (grade III), despite only slight AV valve stenosis, when there is normal or increased blood flow. Conversely, the murmurs may be soft or even absent despite severe obstruction if the cardiac output is markedly reduced. When stenosis is marked, the diastolic murmur is prolonged, and the duration of the murmur is more reliable than its intensity as an index of the severity of valve obstruction.

The low-pitched, middiastolic murmur of mitral stenosis characteristically follows the OS (Fig. 209-4*F*). It should be specifically sought by placing the bell of the stethoscope at the site of the left ventricular impulse, which is best localized with the patient on the left side. Frequently, the murmur of mitral stenosis is present only at the left ventricular apex, and it may be increased in intensity by mild supine exercise or by inhalation of amyl nitrite. In tricuspid stenosis, the middiastolic murmur is localized to a relatively limited area along the left sternal edge and may be louder during inspiration.

Middiastolic murmurs may be generated across the mitral valve in cases of mitral regurgitation, patent ductus arteriosus, or ventricular septal defect, and across the tricuspid valve in cases of tricuspid regurgitation or atrial septal defect. These murmurs are related to the very rapid flow across an AV valve, usually follow an S_3 (Fig. 209-4*G*), and tend to occur with large left-to-right shunts or severe AV valve regurgitation. A soft middiastolic murmur may sometimes be heard in patients with acute rheumatic fever (Carey-Coombs murmur). It has been attributed to inflammation of the mitral valve cusps or excessive left atrial blood flow as a consequence of mitral regurgitation.

In acute, severe aortic regurgitation, the left ventricular diastolic pressure may exceed the left atrial pressure, resulting in a middiastolic murmur due to "diastolic mitral regurgitation." In severe, chronic aortic regurgitation, a murmur is frequently present that may be either middiastolic or presystolic (Austin-Flint murmur). This murmur appears to originate at the anterior mitral valve leaflet when blood enters the left ventricle simultaneously from both the aortic root and the left atrium.

Presystolic Murmurs (Fig. 209-4*A*) These murmurs begin during the period of ventricular filling that follows atrial contraction and therefore occur in sinus rhythm. They are usually due to AV valve stenosis and have the same quality as the middiastolic filling rumble, but they are usually crescendo, reaching peak intensity at the time of a loud S_1. The presystolic murmur corresponds to the AV valve gradient, which may be minimal until the moment of right or left atrial contraction. It is the presystolic murmur that is most characteristic of tricuspid stenosis and sinus rhythm. A right or left *atrial myxoma* may occasionally cause either middiastolic or presystolic murmurs that resemble the murmurs of mitral or tricuspid stenosis.

CONTINUOUS MURMURS These begin in systole, peak near S_2, and continue into all or part of diastole (Fig. 209-4*H*). These murmurs result from continuous flow due to a communication between high- and low-pressure areas that persists through the end of systole and the beginning of diastole. A *patent ductus arteriosus* causes a continuous murmur as long as the pressure in the pulmonary artery is much below that in the aorta. The murmur is intensified by elevation of the systemic arterial pressure. When pulmonary hypertension is present, the diastolic portion may disappear, leaving the murmur confined to systole. A continuous murmur is uncommon in cases of aortopulmonary septal

defect, which usually is associated with severe pulmonary hypertension. Surgically produced connections and the subclavian–pulmonary artery anastomosis result in murmurs similar to that of a patent ductus.

Continuous murmurs may result from congenital or acquired *systemic arteriovenous fistula*, *coronary arteriovenous fistula*, anomalous origin of the left coronary artery from the pulmonary artery, and *communications between the sinus of Valsalva and the right side of the heart*. Continuous murmurs may also occur in patients with a small atrial septal defect with a high left atrial pressure. Murmurs associated with *pulmonary arteriovenous fistulas* may be continuous but are usually only systolic. Continuous murmurs may also be due to disturbances of flow pattern in constricted systemic (e.g., renal) or pulmonary arteries when marked pressure differences between the two sides of the narrow segment persist; a continuous murmur in the back may be present in *coarctation of the aorta*; *pulmonary embolism* may cause continuous murmurs in partially occluded vessels.

In nonconstricted arteries, continuous murmurs may be due to rapid flow through a tortuous bed. Such murmurs typically occur within the bronchial arterial collateral circulation in cyanotic patients with severe pulmonary outflow obstruction. The "mammary souffle," an innocent murmur heard over the breasts during late pregnancy and in the early postpartum period, may be systolic or continuous. The innocent cervical venous hum is a continuous murmur usually audible over the medial aspect of the right supraclavicular fossa with the patient upright. The hum is usually louder during diastole and can be abolished instantaneously by digital compression of the ipsilateral internal jugular vein. Transmission of a loud venous hum to the area below the clavicles may result in a mistaken diagnosis of patent ductus arteriosus.

PERICARDIAL FRICTION RUB These adventitious sounds may have presystolic, systolic, and early diastolic scratchy components and may be confused with a murmur or extracardiac sound when heard only in systole. A pericardial friction rub is best appreciated with the patient upright and leaning forward and may be accentuated during expiration.

210 ELECTROCARDIOGRAPHY

Ary L. Goldberger

The electrocardiogram (ECG or EKG) is a graphic recording of electric potentials generated by the heart. The signals are detected by means of metal electrodes attached to the extremities and chest wall and are then amplified and recorded by the electrocardiograph. ECG *leads* actually display the instantaneous *differences* in potential between these electrodes.

The clinical utility of the ECG derives from its immediate availability as a noninvasive, inexpensive, and highly versatile test. In addition to its use in detecting arrhythmias, conduction disturbances, and myocardial ischemia, electrocardiography may reveal other findings related to life-threatening metabolic disturbances (e.g., hyperkalemia) or increased susceptibility to sudden cardiac death (e.g., QT prolongation syndromes). The advent of coronary thrombolysis or angioplasty in the early therapy of acute myocardial infarction (Chap. 228) has refocused particular attention on the sensitivity and specificity of ECG signs of myocardial ischemia.

ELECTROPHYSIOLOGY (See also Chaps. 213 and 214)

Depolarization of the heart is the initiating event for cardiac contraction. The electric currents that spread through the heart are produced by three components: cardiac pacemaker cells, specialized conduction tissue, and the heart muscle itself. The ECG, however, records only the depolarization (stimulation) and repolarization (recovery) potentials generated by the atrial and ventricular myocardium.

The depolarization stimulus for the normal heartbeat originates in the *sinoatrial* (SA) *node* (Fig. 210-1), or *sinus node*, a collection of *pacemaker cells*. These cells fire spontaneously; that is, they exhibit *automaticity*. The first phase of cardiac electrical activation is the spread of the depolarization wave through the right and left atria, followed by atrial contraction. Next, the impulse stimulates pacemaker and specialized conduction tissues in the atrioventricular (AV) nodal and His-bundle areas; together, these two regions constitute the AV junction. The bundle of His bifurcates into two main branches, the right and left bundles, which rapidly transmit depolarization wavefronts to the right and left ventricular myocardium by way of Purkinje fibers. The main left bundle bifurcates into two primary subdivisions, a left anterior fascicle and a left posterior fascicle. The depolarization wavefronts then spread through the ventricular wall, from endocardium to epicardium, triggering ventricular contraction.

Since the cardiac depolarization and repolarization waves have direction and magnitude, they can be represented by vectors. *Vectorcardiograms* that measure and display these instantaneous potentials are no longer used much in clinical practice. However, the general principles of vector analysis remain fundamental to understanding the genesis of normal and pathologic ECG waveforms. Vector analysis illustrates a central concept of electrocardiography—that the ECG re-

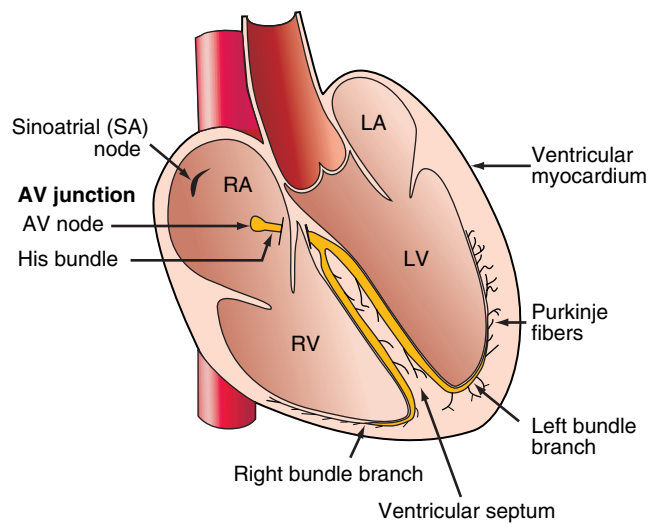

FIGURE 210-1 Schematic of the cardiac conduction system.

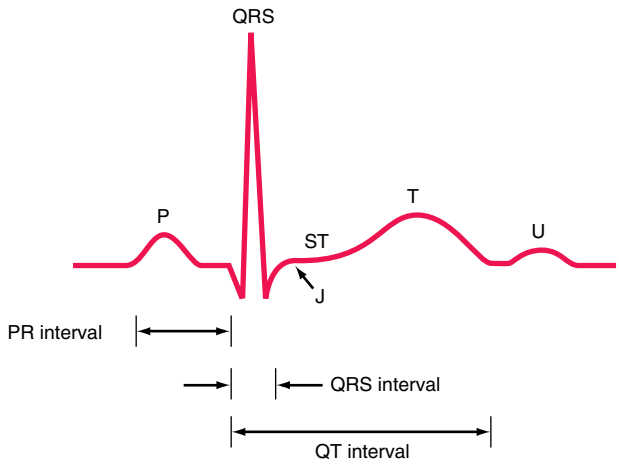

FIGURE 210-2 Basic ECG waveforms and intervals. Not shown is the R-R interval, the time between consecutive QRS complexes.

cords the complex spatial and temporal summation of electrical potentials from multiple myocardial fibers conducted to the surface of the body. This principle accounts for inherent limitations in both ECG *sensitivity* (activity from certain cardiac regions may be canceled out or may be too weak to be recorded) and *specificity* (the same vectorial sum can result from either a selective gain or a loss of forces in opposite directions).

ECG WAVEFORMS AND INTERVALS

The ECG waveforms are labeled alphabetically, beginning with the P wave, which represents atrial depolarization (Fig. 210-2). The QRS complex represents ventricular depolarization, and the ST-T-U complex (ST segment, T wave, and U wave) represents ventricular repolarization. The J point is the junction between the end of the QRS complex and the beginning of the ST segment. Atrial repolarization is usually too low in amplitude to be detected, but it may become apparent in such conditions as acute pericarditis or atrial infarction.

The QRS-T waveforms of the surface ECG correspond in a general way with the different phases of simultaneously obtained ventricular *action potentials*, the intracellular recordings from single myocardial fibers (see Fig. 213-2). The rapid upstroke (phase 0) of the action potential corresponds to the onset of QRS. The plateau (phase 2) corresponds to the isoelectric ST segment, and active repolarization (phase 3) to the inscription of the T wave. Factors that decrease the slope of phase 0 by impairing the influx of Na^+ (e.g., drugs such as flecainide or procainamide, or hyperkalemia) tend to increase QRS duration. Conditions that prolong phase 2 (use of amiodarone, hypocalcemia) increase the QT interval. In contrast, shortening of ventricular repolarization (phase 2), as by digitalis administration or hypercalcemia, abbreviates the ST segment.

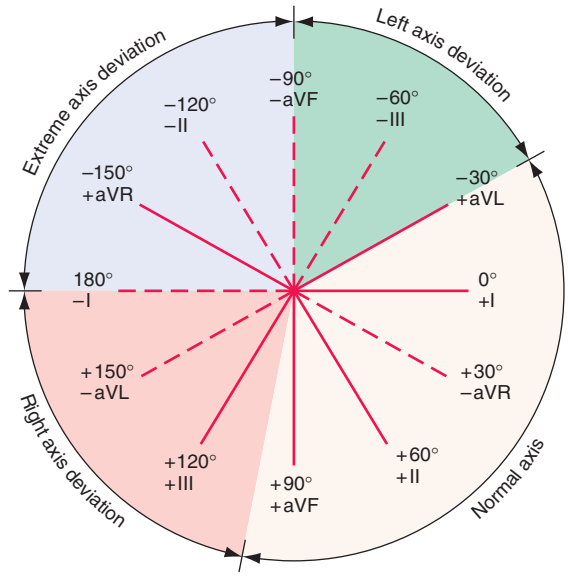

FIGURE 210-4 The frontal plane (extremity or limb) leads are represented on a hexaxial diagram. Each ECG lead has a specific spatial orientation and polarity. The positive pole of each lead axis (*solid line*) and negative pole (*hatched line*) are designated by their angular position relative to the positive pole of lead I (0°). The mean electrical axis of the QRS complex is measured with respect to this display.

The electrocardiogram is ordinarily recorded on special graph paper which is divided into 1-mm^2 gridlike boxes. Since the ECG paper speed is generally 25 mm/s, the smallest (1 mm) horizontal divisions correspond to 0.04 s (40 ms), with heavier lines at intervals of 0.20 s (200 ms). Vertically, the ECG graph measures the amplitude of a given wave or deflection (1 mV = 10 mm with standard calibration; the voltage criteria for hypertrophy mentioned below are given in millimeters). There are four major ECG intervals: R-R, PR, QRS, and QT (Fig. 210-2). The heart rate (beats per minute) can be readily computed from the interbeat (R-R) interval by dividing the number of large (0.20 s) time units between consecutive R waves into 300 or the number of small (0.04 s) units into 1500. The PR interval measures the time (normally 120 to 200 ms) between atrial and ventricular depolarization, which includes the physiologic delay imposed by stimulation of cells in the AV junction area. The QRS interval (normally 100 ms or less) reflects the duration of ventricular depolarization. The QT interval includes both ventricular depolarization and repolarization times and varies inversely with the heart rate. A rate-related ("corrected") QT interval, QT_c, can be calculated as $QT/\sqrt{R\text{-}R}$ and normally is $\leq$0.44 s.

The QRS complex is subdivided into specific deflections or waves. If the initial QRS deflection in a given lead is negative, it is termed a *Q wave*; the first positive deflection is termed an *R wave*. A negative deflection after an R wave is an *S wave*. Subsequent positive or negative waves are labeled R′ and S′, respectively. Lowercase letters (qrs) are used for waves of relatively small amplitude. An entirely negative QRS complex is termed a *QS wave*.

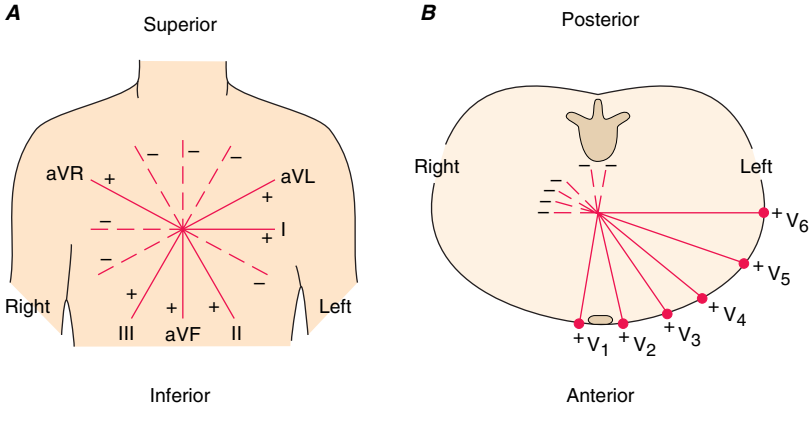

FIGURE 210-3 The six frontal plane (*A*) and six horizontal plane (*B*) leads provide a three-dimensional representation of cardiac electrical activity.

ECG LEADS

The 12 conventional ECG leads record the difference in potential between electrodes placed on the surface of the body. These leads are divided into two groups: six extremity (limb) leads and six chest (precordial) leads. The extremity leads record potentials transmitted onto the *frontal plane* (Fig. 210-3*A*), and the chest leads record potentials transmitted onto the *horizontal plane* (Fig. 210-3*B*). The six extremity leads are further subdivided into three *bipolar leads* (I, II, and III) and three *unipolar*

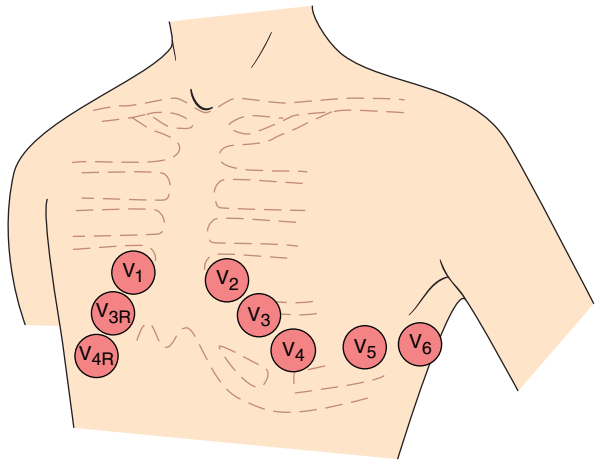

FIGURE 210-5 The horizontal plane (chest or precordial) leads are obtained with electrodes in the locations shown.

leads (aVR, aVL, and aVF). Each bipolar lead measures the difference in potential between electrodes at two extremities: lead I = left arm − right arm voltages, lead II = left leg − right arm, and lead III = left leg − left arm. The unipolar leads measure the voltage (V) at one locus relative to an electrode (called the *central terminal* or *indifferent electrode*) that has approximately zero potential. Thus, aVR = right arm, aVL = left arm, and aVF = left leg (foot). The lowercase *a* indicates that these unipolar potentials are electrically augmented by 50%. The right leg electrode functions as a ground. The spatial orientation and polarity of the six frontal plane leads is represented on the hexaxial diagram (Fig. 210-4).

The six chest leads (Fig. 210-5) are unipolar recordings obtained by electrodes in the following positions: lead V_1, fourth intercostal space, just to the right of the sternum; lead V_2, fourth intercostal space, just to the left of the sternum; lead V_3, midway between V_2 and V_4; lead V_4, midclavicular line, fifth intercostal space; lead V_5, anterior axillary line, same level as V_4; and lead V_6, midaxillary line, same level as V_4 and V_5.

Together, the frontal and horizontal plane electrodes provide a three-dimensional representation of cardiac electrical activity. Each lead can be likened to a different camera angle "looking" at the same events—atrial and ventricular depolarization and repolarization—from different spatial orientations. The conventional 12-lead ECG can be supplemented with additional leads under special circumstances. For example, right precordial leads V_3R, V_4R, etc. are useful in detecting evidence of acute right ventricular ischemia. Bedside monitors and ambulatory ECG (Holter) recordings usually employ only one or two modified leads. →***Intracardiac electrocardiography and electrophysiologic testing are discussed in Chaps. 213 and 214.***

The ECG leads are configured so that a positive (upright) deflection is recorded in a lead if a wave of depolarization spreads toward the positive pole of that lead, and a negative deflection if the wave spreads toward the negative pole. If the mean orientation of the depolarization vector is at right angles to a given lead axis, a biphasic (equally positive and negative) deflection will be recorded.

GENESIS OF THE NORMAL ECG

P WAVE

The normal atrial depolarization vector is oriented downward and toward the subject's left, reflecting the spread of depolarization from the sinus node to the right and then the left atrial myocardium. Since this vector points toward the positive pole of lead II and toward the negative pole of lead aVR, the normal P wave will be positive in lead II and negative in lead aVR. By contrast, activation of the atria from an ectopic pacemaker in the lower part of either atrium or in the AV junction region may produce retrograde P waves (negative in lead II, positive in lead aVR).

QRS COMPLEX

Normal ventricular depolarization proceeds as a rapid, continuous spread of activation wavefronts. This complex process can be divided into two major, sequential phases, and each phase can be represented by a mean vector (Fig. 210-6). The first phase is depolarization of the interventricular septum from the left to the right and anteriorly (vector 1). The second results from the simultaneous depolarization of the right and left ventricles; it is normally dominated by the more massive left ventricle, so that vector 2 points leftward and posteriorly. Therefore, a right precordial lead (V_1) will record this biphasic depolarization process with a small positive deflection (septal r wave) followed by a larger negative deflection (S wave). A left precordial lead, e.g., V_6, will record the same sequence with a small negative deflection (septal q wave) followed by a relatively tall positive deflection (R wave). Intermediate leads show a relative increase in R-wave amplitude (normal R-wave progression) and a decrease in S-wave amplitude progressing across the chest from the right to left. The precordial lead where the R and S waves are of approximately equal amplitude is referred to as the *transition zone* (usually V_3 or V_4) (Fig. 210-7).

The QRS pattern in the extremity leads may vary considerably from one normal subject to another depending on the *electrical axis* of the QRS, which describes the mean orientation of the QRS vector with reference to the six frontal plane leads. Normally, the QRS axis ranges from −30° to +100° (Fig. 210-4). An axis more negative than −30° is referred to as *left axis deviation*, while an axis more positive than +100° is referred to as *right axis deviation*. Left axis deviation may

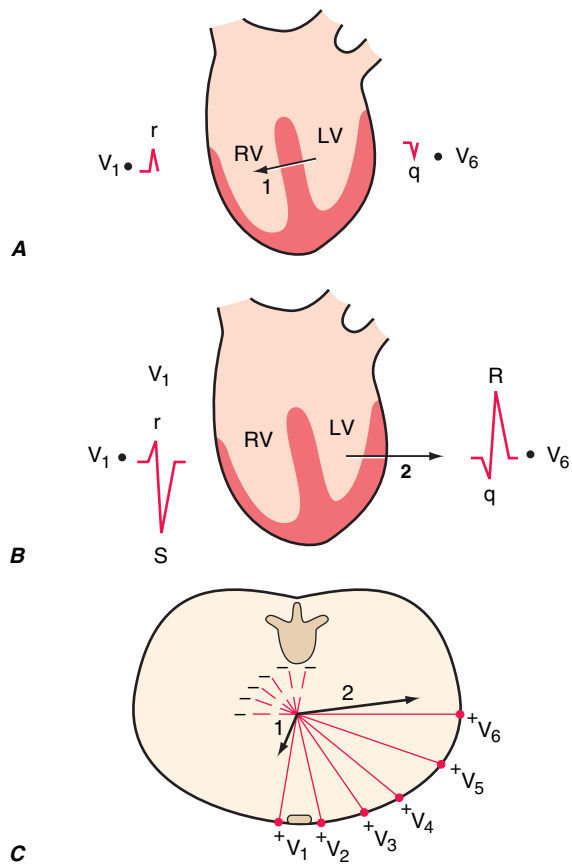

FIGURE 210-6 Ventricular depolarization can be divided into two major phases, each represented by a vector. *A*. The first phase (*arrow 1*) denotes depolarization of the ventricular septum, beginning on the left side and spreading to the right. This process is represented by a small "septal" r wave in lead V_1 and a small septal q wave in lead V_6. *B*. Simultaneous depolarization of the left and right ventricles (LV and RV) constitutes the second phase. Vector 2 is oriented to the left and posteriorly, reflecting the electrical predominance of the LV. *C*. Vectors (*arrows*) representing these two phases are shown in reference to the horizontal plane leads. (*After Goldberger, 1999.*)

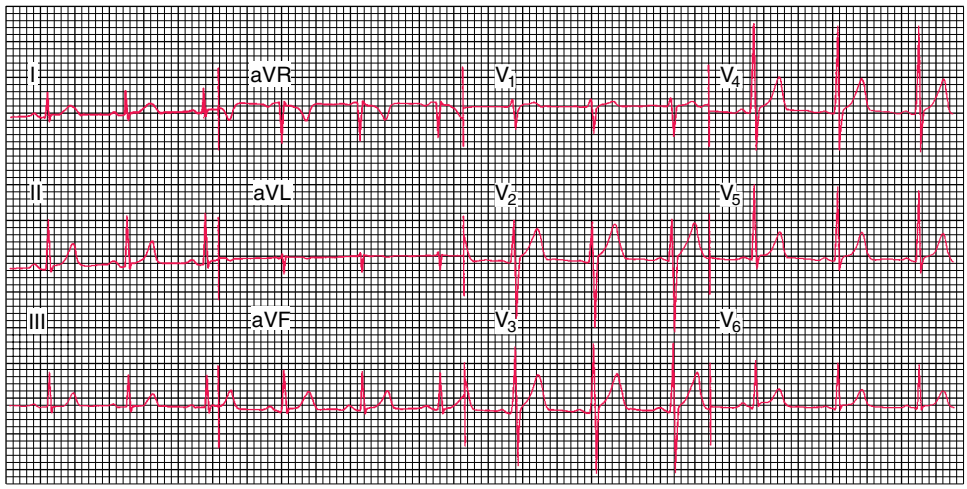

FIGURE 210-7 Normal electrocardiogram from a healthy subject. Sinus rhythm is present with a heart rate of 75 beats per minute. PR interval is 0.16 s; QRS interval (duration) is 0.08 s; QT interval is 0.36 s; the mean QRS axis is about +70°. The precordial leads show normal R-wave progression with the transition zone (R wave = S wave) in lead V_3.

occur as a normal variant but is more commonly associated with left ventricular hypertrophy, a block in the anterior fascicle of the left bundle system (left anterior fascicular block or hemiblock), or inferior myocardial infarction. Right axis deviation may also occur as a normal variant (particularly in children and young adults); as a spurious finding due to reversal of the left and right arm electrodes; or in conditions such as right ventricular overload (acute or chronic), infarction of the lateral wall of the left ventricle, dextrocardia, left pneumothorax, or left posterior fascicular block.

T WAVE AND U WAVE

Normally, the mean T-wave vector is oriented roughly concordant with the mean QRS vector. Since depolarization and repolarization are electrically opposite processes, this normal QRS–T-wave vector concordance indicates that repolarization must normally proceed in the reverse direction from depolarization (i.e., from ventricular epicardium to endocardium). The normal U wave is a small, rounded deflection (≤1 mm) that follows the T wave and usually has the same polarity as the T wave. An abnormal increase in U-wave amplitude is most commonly due to drugs (e.g., quinidine, procainamide, disopyramide) or hypokalemia. Very prominent U waves are a marker of increased susceptibility to the *torsades de pointes* type of ventricular tachycardia (Chap. 214). Inversion of the U wave in the precordial leads is abnormal and may be a subtle sign of ischemia.

MAJOR ECG ABNORMALITIES

CARDIAC ENLARGEMENT AND HYPERTROPHY

Right atrial overload (acute or chronic) may lead to an increase in P-wave amplitude (≥2.5 mm) (Fig. 210-8). Left atrial overload typically produces a biphasic P wave in V_1 with a broad negative component or a broad (≥120 ms), often notched P wave in one or more limb leads (Fig. 210-8). This pattern may also occur with left atrial conduction delays in the absence of actual atrial enlargement, leading to the more general designation of *left atrial abnormality*.

Right ventricular hypertrophy due to a pressure load (as from pulmonic valve stenosis or pulmonary artery hypertension) is characterized by a relatively tall R wave in lead V_1 (R ≥ S wave), usually with right axis deviation (Fig. 210-9); alternatively, there may be a qR pattern in V_1 or V_3R. ST depression and T-wave inversion in the right to midprecordial leads are also often present. This so-called ventricular strain pattern is attributed to repolarization abnormalities in hypertrophied muscle. Right ventricular hypertrophy due to ostium secundum–type atrial septal defects, with the accompanying right ventricular volume overload, is commonly associated with an incomplete or complete right bundle branch block pattern with a rightward QRS axis.

Acute cor pulmonale due to pulmonary embolism (Chap. 244), for example, may be associated with a normal ECG or a variety of abnormalities. Sinus tachycardia is the most common arrhythmia, although other tachyarrhythmias, such as atrial fibrillation or flutter, may occur. The QRS axis may shift to the right, sometimes in concert with the so-called $S_1Q_3T_3$ pattern (prominence of the S wave in lead I, Q wave in lead III, with T-wave inversion in lead III). Acute right ventricular dilation may also be associated with poor R-wave progression and T-wave inversions in V_1 to V_4 (right ventricular "strain") simulating acute anterior infarction. A right ventricular conduction disturbance may appear.

Chronic cor pulmonale due to obstructive lung disease (Chap. 220) usually does not produce the classic ECG patterns of right ventricular hypertrophy noted above. Instead of tall right precordial R waves, chronic lung disease more typically is associated with small R waves in right to midprecordial leads (poor R-wave progression) due in part to downward displacement of the diaphragm and the heart. Low-voltage complexes are commonly present, owing to hyperaeration of the lungs.

A number of different voltage criteria for *left ventricular hypertrophy* (Fig. 210-9) have been proposed on the basis of the presence of tall left precordial R waves and deep right precordial S waves [e.g., SV_1 + (RV_5 or RV_6) ≥ 35 mm; or (RV_5 or RV_6) ≥ 25 mm]. Repolarization abnormalities (ST depression with T-wave inversions) may

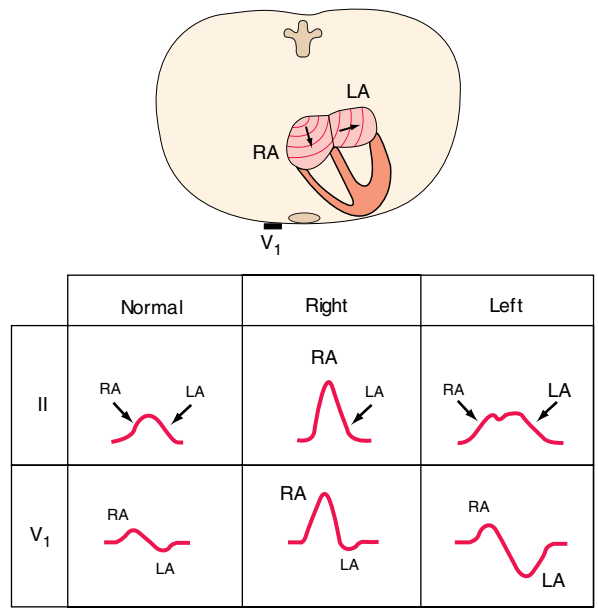

FIGURE 210-8 Right atrial (RA) overload may cause tall, peaked P waves in the limb or precordial leads. Left atrial (LA) abnormality may cause broad, often notched P waves in the limb leads and a biphasic P wave in lead V_1 with a prominent negative component representing delayed depolarization of the LA. (*After MK Park, WG Guntheroth: How to Read Pediatric ECGs, 3d ed. St. Louis, Mosby–Year Book, 1992.*)

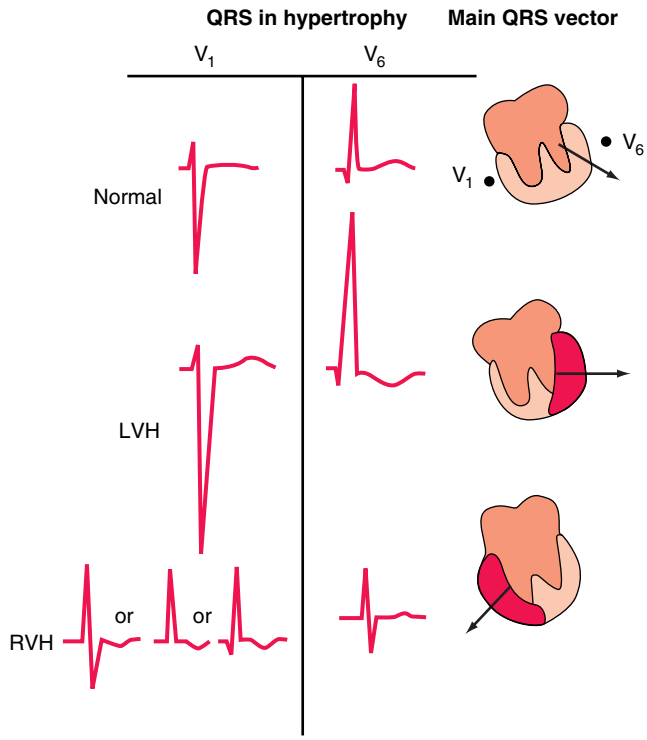

FIGURE 210-9 Left ventricular hypertrophy (LVH) increases the amplitude of electrical forces directed to the left and posteriorly. In addition, repolarization abnormalities may cause ST-segment depression and T-wave inversion in leads with a prominent R wave ("strain" pattern). Right ventricular hypertrophy (RVH) may shift the QRS vector to the right; this effect usually is associated with an R, RS, or qR complex in lead V_1. T-wave inversions may be present in right precordial leads ("strain" pattern).

also appear (left ventricular "strain" pattern) in leads with prominent R waves. However, prominent precordial voltages may occur as a normal variant, especially in athletic or young individuals. Left ventricular hypertrophy may increase limb lead voltage (e.g., RaVL $\geq$ 11 to 13 mm, RaVF $\geq$ 20 mm; $R_I + S_{III} \geq 25$ mm) with or without increased precordial voltage. The presence of left atrial abnormality increases the likelihood of underlying left ventricular hypertrophy in cases with borderline voltage criteria. Left ventricular hypertrophy often progresses to incomplete or complete left bundle branch block. The sensitivity of conventional voltage criteria for left ventricular hypertrophy is decreased in obese persons and in smokers. ECG evidence for left ventricular hypertrophy is a major noninvasive marker of increased risk of cardiovascular morbidity and mortality, including sudden cardiac death. However, because of false-positive and false-negative diagnoses, the ECG is of limited utility in diagnosing atrial or ventricular enlargement. More definitive information is provided by echocardiography (Chap. 211).

BUNDLE BRANCH BLOCKS

Intrinsic impairment of conduction in either the right or left bundle system (intraventricular conduction disturbances) leads to prolongation of the QRS interval. With complete bundle branch blocks the QRS interval is $\geq$120 ms in duration; with incomplete blocks the QRS interval is between 100 and 120 ms. The QRS vector is usually oriented in the direction of the myocardial region where depolarization is delayed (Fig. 210-10). Thus, with right bundle branch block, the terminal QRS vector is oriented anteriorly and to the right (rSR′ in V_1 and qRS in V_6, typically). Left bundle branch block alters both early and later phases of ventricular depolarization. The major QRS vector is directed to the left and posteriorly. In addition, the normal early left-to-right pattern of septal activation is disrupted such that septal depolarization proceeds from right to left as well. As a result, left bundle branch block generates wide, predominantly negative (QS) complexes in lead V_1 and entirely positive (R) complexes in lead V_6. A pattern identical to that of left bundle branch block, preceded by a sharp spike, is seen in most cases of electronic right ventricular pacing because of the relative delay in left ventricular activation.

Bundle branch block may occur in a variety of conditions. In subjects without structural heart disease, right bundle branch block is seen more commonly than left bundle branch block. Right bundle branch block also occurs with heart disease, both congenital (e.g., atrial septal defect) and acquired (e.g., valvular, ischemic). Left bundle branch block is often a marker of one of four underlying conditions: coronary heart disease (often with impaired left ventricular function), hypertensive heart disease, aortic valve disease, and cardiomyopathy. Bundle branch blocks may be chronic or intermittent. A bundle branch block may be rate-related; for example, it often occurs when the heart rate exceeds some critical value.

Bundle branch blocks and depolarization abnormalities secondary to artificial pacemakers not only affect ventricular depolarization (QRS) but are also characteristically associated with *secondary repolarization* (ST-T) abnormalities. With bundle branch blocks, the T wave is typically opposite in polarity to the last deflection of the QRS (Fig. 210-10). This discordance of the QRS–T-wave vectors is caused by the altered sequence of repolarization that occurs secondary to altered depolarization. In contrast, *primary repolarization* abnormalities are independent of QRS changes and are related instead to actual alterations in the electrical properties of the myocardial fibers themselves (e.g., in the resting membrane potential or action potential duration), not just to changes in the sequence of repolarization. Ischemia, electrolyte imbalance, and drugs such as digitalis all cause such primary ST–T-wave changes. Primary and secondary T-wave changes may coexist. For example, T-wave inversions in the right precordial leads with left bundle branch block or in the left precordial leads with right bundle branch block may be important markers of underlying ischemia or other abnormalities.

Partial blocks ("hemiblocks") in the left bundle system (left anterior or posterior fascicular blocks) generally do not prolong the QRS duration substantially but instead are associated with shifts in the frontal plane QRS axis (leftward or rightward, respectively). More complex combinations of fascicular and bundle branch blocks may occur involving the left and right bundle system. Examples of *bifascicular*

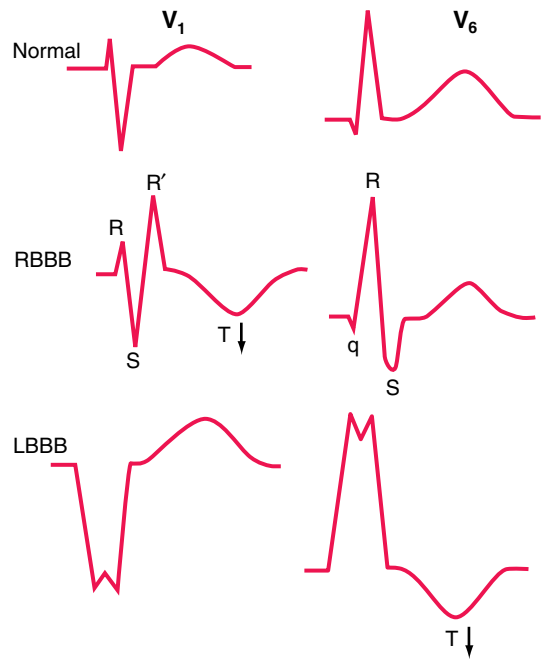

FIGURE 210-10 Comparison of typical QRS-T patterns in right bundle branch block (RBBB) and left bundle branch block (LBBB) with the normal pattern in leads V_1 and V_6. Note the secondary T-wave inversions (*arrows*) in leads with an rSR′ complex with RBBB and in leads with a wide R wave with LBBB.

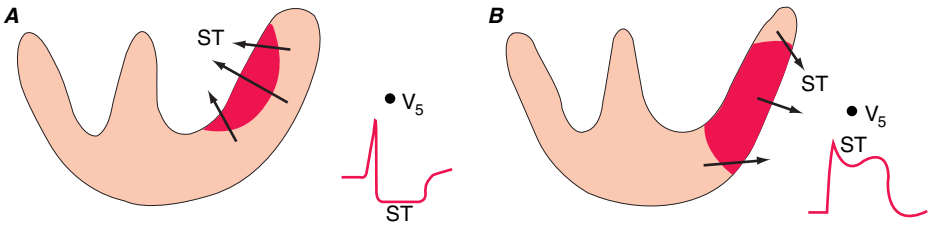

FIGURE 210-11 Acute ischemia causes a current of injury. With predominant subendocardial ischemia (*A*), the resultant ST vector will be directed toward the inner layer of the affected ventricle and the ventricular cavity. Overlying leads therefore will record ST depression. With ischemia involving the outer ventricular layer (*B*) (transmural or epicardial injury), the ST vector will be directed outward. Overlying leads will record ST elevation.

block include right bundle branch block and left posterior fascicular block, right bundle branch block with left anterior fascicular block, and complete left bundle branch block. Chronic bifascicular block in an asymptomatic individual is associated with a relatively low risk of progression to high-degree AV heart block. In contrast, new bifascicular block with acute anterior myocardial infarction carries a much greater risk of complete heart block. Alternation of right and left bundle branch block is a sign of *trifascicular disease*. However, the presence of a prolonged PR interval and bifascicular block does not necessarily indicate trifascicular involvement, since this combination may arise with AV node disease and bifascicular block. Intraventricular conduction delays can also be caused by extrinsic (toxic) factors that slow ventricular conduction, particularly hyperkalemia or drugs (class 1 antiarrhythmic agents, tricyclic antidepressants, phenothiazines).

Prolongation of QRS duration does not necessarily indicate a conduction delay but may be due to *preexcitation* of the ventricles via a bypass tract, as in the Wolff-Parkinson-White (WPW) syndrome (Chap. 214) and related variants. The diagnostic triad of WPW consists of a wide QRS complex associated with a relatively short PR interval and slurring of the initial part of the QRS (delta wave), the latter effect due to aberrant activation of ventricular myocardium. The presence of a bypass tract predisposes to reentrant supraventricular tachyarrhythmias.

MYOCARDIAL ISCHEMIA AND INFARCTION (See also Chap. 228)

The ECG is a cornerstone in the diagnosis of acute and chronic ischemic heart disease. The findings depend on several key factors: the nature of the process [reversible (i.e., ischemia) versus irreversible (i.e., infarction)], the duration (acute versus chronic), extent (transmural versus subendocardial), and localization (anterior versus inferoposterior), as well as the presence of other underlying abnormalities (ventricular hypertrophy, conduction defects).

Ischemia exerts complex time-dependent effects on the electrical properties of myocardial cells. Severe, acute ischemia lowers the resting membrane potential and shortens the duration of the action potential. Such changes cause a voltage gradient between normal and ischemic zones. As a consequence, current flows between these regions. These currents of injury are represented on the surface ECG by deviation of the ST segment (Fig. 210-11). When the acute ischemia is *transmural*, the ST vector is usually shifted in the direction of the outer (epicardial) layers, producing ST elevations and sometimes, in the earliest stages of ischemia, tall, positive so-called hyperacute T waves over the ischemic zone. With ischemia confined primarily to the *subendocardium*, the ST vector typically shifts toward the subendocardium and ventricular cavity, so that overlying (e.g., anterior precordial) leads show ST-segment depression (with ST elevation in lead aVR). Multiple factors affect the amplitude of acute ischemic ST deviations. Profound ST elevation or depression in multiple leads usually indicates very severe ischemia. From a clinical viewpoint, the division of acute myocardial infarction into ST segment elevation and non-ST elevation types is useful since the efficacy of acute reperfusion therapy is limited to the former group.

The ECG leads are more helpful in localizing regions of ST elevation than non-ST elevation ischemia. For example, acute transmural anterior (including apical and lateral) wall ischemia is reflected by ST elevations or increased T-wave positivity (Fig. 210-12) in one or more of the precordial leads (V_1 to V_6) and leads I and aVL. Inferior wall ischemia produces changes in leads II, III, and aVF. Posterior wall ischemia may be indirectly recognized by *reciprocal* ST depressions in leads V_1 to V_3. Prominent reciprocal ST depressions in these leads also occur with certain inferior wall infarcts, particularly those with posterior or lateral wall extension. Right ventricular ischemia usually produces ST elevations in right-sided chest leads (Fig. 210-5). When ischemic ST elevations occur as the earliest sign of acute infarction, they are typically followed within a period ranging from hours to days by evolving T-wave inversions and often by Q waves occurring in the same lead distribution. (T-wave inversions due to evolving or chronic ischemia correlate with prolongation of repolarization and are often associated with QT lengthening.) Reversible transmural ischemia, for example, due to coronary vasospasm (Prinzmetal's variant angina), may cause transient ST-segment elevations without development of Q waves. Depending on the severity and duration of such ischemia, the ST elevations may either resolve completely in minutes or be followed by T-wave inversions that persist for hours or even days. Patients with ischemic chest pain who present with deep T-wave inversions in multiple precordial leads (e.g., V_1 to V_4) with or without cardiac enzyme elevations typically have severe obstruction in the left anterior descending coronary artery system (Fig. 210-13). In contrast, patients whose baseline ECG already shows abnormal T-wave inversions may develop T-wave normalization (pseudonormalization) during episodes of acute transmural ischemia.

With infarction, depolarization (QRS) changes often accompany repolarization (ST-T) abnormalities. Necrosis of sufficient myocardial tissue may lead to decreased R-wave amplitude or abnormal Q waves in the anterior or inferior leads (Fig. 210-14). Previously, abnormal Q waves were considered to be markers of transmural myocardial in-

FIGURE 210-12 Hyperacute phase of anteroseptal myocardial infarction (MI). Note the tall positive T waves (V_2 to V_3) along with ST-segment elevations and Q waves (V_1 to V_3).

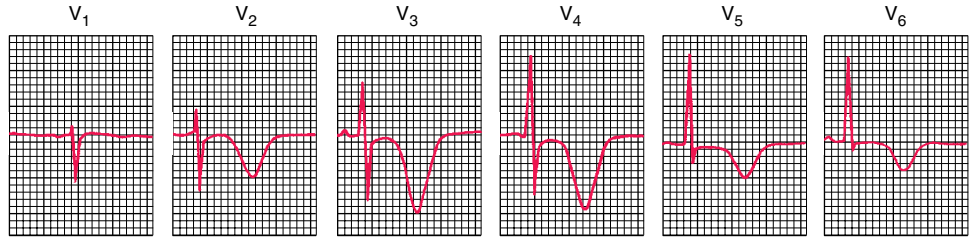

FIGURE 210-13 Severe anterior wall ischemia (with or without infarction) may cause prominent T-wave inversions in the precordial leads. This pattern is usually associated with a high-grade stenosis of the left anterior descending coronary artery.

farction, while subendocardial infarcts were thought not to produce Q waves. However, careful ECG-pathology correlative studies have indicated that transmural infarcts may occur without Q waves and that subendocardial (nontransmural) infarcts may sometimes be associated with Q waves. Therefore, infarcts are more appropriately classified as "Q-wave" or "non-Q-wave." The major acute ECG changes in syndromes of ischemic heart disease are schematically summarized in Fig. 210-15. Loss of depolarization forces due to posterior or lateral infarction may cause reciprocal increases in R-wave amplitude in leads V_1 and V_2 without diagnostic Q waves in any of the conventional leads. Atrial infarction may be associated with PR-segment deviations due to an atrial current of injury, changes in P-wave morphology, or atrial arrhythmias. In the weeks and months following infarction, these ECG changes may persist or begin to resolve. Complete normalization of the ECG following Q-wave infarction is uncommon but may occur, particularly with smaller infarcts. In contrast, ST-segment elevations that persist for several weeks or more after a Q-wave infarct usually correlate with a severe underlying wall motion disorder (akinetic or dyskinetic zone), although not necessarily a frank ventricular aneurysm.

ECG changes due to ischemia may occur spontaneously or may be provoked by various exercise protocols (stress electrocardiography) (Chap. 226). In patients with severe ischemic heart disease, exercise testing is most likely to elicit signs of subendocardial ischemia (horizontal or downsloping ST depression in multiple leads). ST-segment elevation during exercise is most often observed after a Q-wave infarct. This repolarization change does not necessarily indicate active ischemia but correlates strongly with the presence of an underlying ventricular wall motion abnormality. However, in patients *without* prior infarction, transient ST-segment elevation with exercise is a reliable sign of transmural ischemia.

The ECG has important limitations in both sensitivity and specificity in the diagnosis of ischemic heart disease. Although a single normal ECG does not exclude ischemia or even acute infarction, a normal ECG *throughout* the course of an acute infarct is distinctly uncommon. Prolonged chest pain without diagnostic ECG changes, therefore, should always prompt a careful search for other noncoronary causes of chest pain (Chap. 12). Furthermore, the diagnostic changes of acute or evolving ischemia are often masked by the presence of left bundle branch block, electronic ventricular pacemaker patterns, and WPW preexcitation. On the other hand, clinicians may overdiagnose ischemia or infarction based on the presence of ST-segment elevations or depressions, T-wave inversions, tall positive T waves, or Q waves *not* related to ischemic heart disease (pseudoinfarct patterns). For example, ST-segment elevations simulating ischemia may occur with acute pericarditis (Fig. 210-16) or myocarditis, as a normal variant ("early repolarization" pattern), or in a variety of other conditions (Table 210-1). Similarly, tall, positive T waves do not invariably represent hyperacute ischemic changes but may also be caused by normal variants, hyperkalemia, cerebrovascular injury, and left ventricular volume overload due to mitral or aortic regurgitation, among other causes. ST-segment elevations and tall, positive T waves are common findings in leads V_1 and V_2 in left bundle branch block or left ventricular hypertrophy in the absence of ischemia. The differential diagnosis of Q waves (Table 210-2) includes physiologic or positional variants, ventricular hypertrophy, acute or chronic noncoronary myocardial injury, hypertrophic cardiomyopathy, and ventricular conduction disorders. Digitalis, ventricular hypertrophy, hypokalemia, and a variety of other

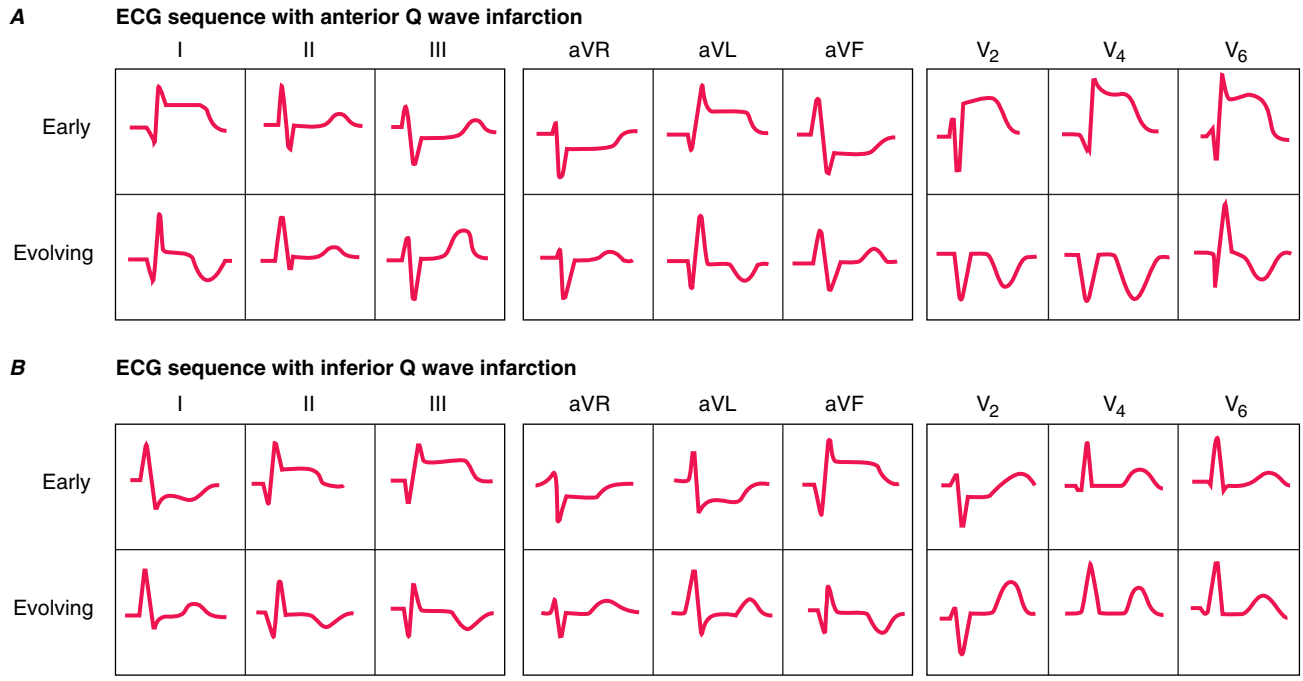

FIGURE 210-14 54Sequence of depolarization and repolarization changes with (*A*) acute anterior and (*B*) acute inferior wall Q-wave infarctions. With anterior infarcts, ST elevation in leads I, aVL, and the precordial leads may be accompanied by reciprocal ST depressions in leads II, III, and aVF. Conversely, acute inferior (or posterior) infarcts may be associated with reciprocal ST depressions in leads V_1 to V_3. (*After Goldberger, 1999.*)

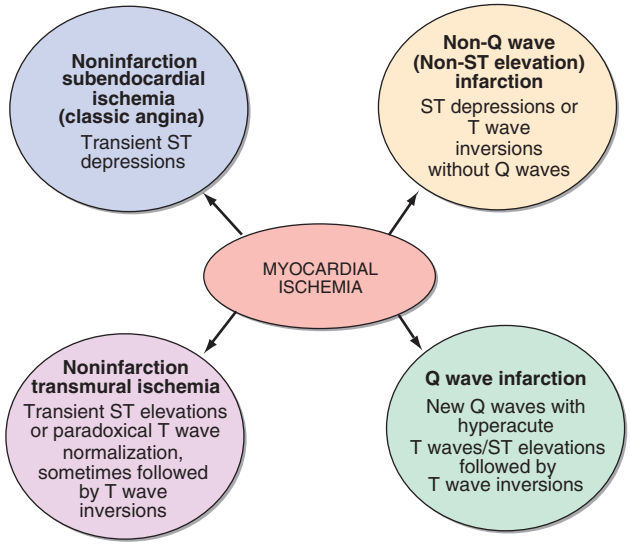

FIGURE 210-15 Variability of ECG patterns with acute myocardial ischemia. The ECG also may be normal or nonspecifically abnormal. Furthermore, these categorizations are not mutually exclusive. For example, a non-ST elevation infarct may evolve into a Q-wave infarct; ST elevations may be followed by a non-Q-wave infarct; or ST depressions and T-wave inversions may be followed by a Q-wave infarct. (*After Goldberger, 1991.*)

factors may cause ST-segment depression mimicking subendocardial ischemia. Prominent T-wave inversion may occur with ventricular hypertrophy, cardiomyopathy, myocarditis, and cerebrovascular injury (particularly intracranial bleeds; Fig. 210-17), among many other conditions.

METABOLIC FACTORS AND DRUG EFFECTS

A variety of metabolic and pharmacologic agents alter the ECG and, in particular, cause changes in repolarization (ST-T-U) and sometimes QRS prolongation. Certain life-threatening electrolyte disturbances may be diagnosed initially and monitored from the ECG. *Hyperkalemia* produces a sequence of changes usually beginning with narrowing and peaking (tenting) of the T waves. Further elevation of extracellular K^+ leads to AV conduction disturbances, diminution in P-wave amplitude, and widening of the QRS interval. Severe hyperkalemia eventually causes cardiac arrest with a slow sinusoidal type of mechanism ("sine-wave" pattern) followed by asystole. *Hypokalemia* (Fig. 210-17) prolongs ventricular repolarization, often with prominent U waves.

TABLE 210-1 Differential Diagnosis of ST Segment Elevations

Ischemia/myocardial infarction
Noninfarction, transmural ischemia (Prinzmetal's angina pattern)
Acute myocardial infarction
Postmyocardial infarction (ventricular aneurysm pattern)
Acute pericarditis
Normal variant ("early repolarization" pattern)
Left ventricular hypertrophy/left bundle branch block[a]
Other (rarer)
Brugada syndrome (right bundle branch block-like pattern with ST elevations in right precordial leads)[a]
Class 1C antiarrhythmic drugs[a]
DC cardioversion
Hypercalcemia[a]
Hyperkalemia[a]
Hypothermia (J wave/Osborn wave)
Myocardial injury
Myocarditis
Tumor invading left ventricle
Trauma to ventricles

[a] Usually localized to V_1-V_2 or V_3

TABLE 210-2 Differential Diagnosis of Q Waves (with Selected Examples)

Physiologic or positional factors
1. Normal variant "septal" q waves
2. Normal variant Q waves in V_1 to V_2, aVL, III, and aVF
3. Left pneumothorax or dextrocardia: loss of lateral R-wave progression
Myocardial injury or infiltration
1. Acute processes: myocardial ischemia or infarction, myocarditis, hyperkalemia
2. Chronic processes: myocardial infarction, idiopathic cardiomyopathy, myocarditis, amyloid, tumor, sarcoid, scleroderma, Chagas' disease, echinococcus cyst
Ventricular hypertrophy/enlargement
1. Left ventricular (poor R-wave progression[a])
2. Right ventricular (reversed R-wave progression[b] or poor R-wave progression[a], particularly with chronic obstructive lung disease)
3. Hypertrophic cardiomyopathy (may simulate anterior, inferior, posterior, or lateral infarcts)
Conduction abnormalities
1. Left bundle branch block (poor R-wave progression[a])
2. Wolff-Parkinson-White patterns

[a] Small or absent R waves in the right to midprecordial leads.
[b] Progressive decrease in R-wave amplitude from V_1 to the mid- or lateral precordial leads.

Source: After Goldberger, 1991.

FIGURE 210-16 Acute pericarditis often produces diffuse ST-segment elevations (in this case in leads I, II, aVF, and V_2 to V_6) due to a ventricular current of injury. Note also the characteristic PR-segment deviation (opposite in polarity to the ST segment) due to a concomitant atrial injury current.

Prolongation of the QT interval (Fig. 210-17) is also seen with drugs that increase the duration of the ventricular action potential—class 1A antiarrhythmic agents and related drugs (e.g., quinidine, disopyramide, procainamide, tricyclic antidepressants, phenothiazines) and class III agents (amiodarone, sotalol, ibutilide). Marked QT prolongation, sometimes with deep, wide T-wave inversions, may occur with intracranial bleeds, particularly subarachnoid hemorrhage ("CVA T-wave" pattern) (Fig. 210-17). Systemic *hypothermia* (Fig. 210-17) also prolongs repolarization, usually with a distinctive convex elevation of the J point (Osborn wave). *Hypocalcemia* typically prolongs the QT interval (ST portion), while *hypercalcemia* shortens it (Fig. 210-18). Digitalis glycosides also shorten the QT interval, often with a characteristic "scooping" of the ST–T-wave complex (*digitalis effect*).

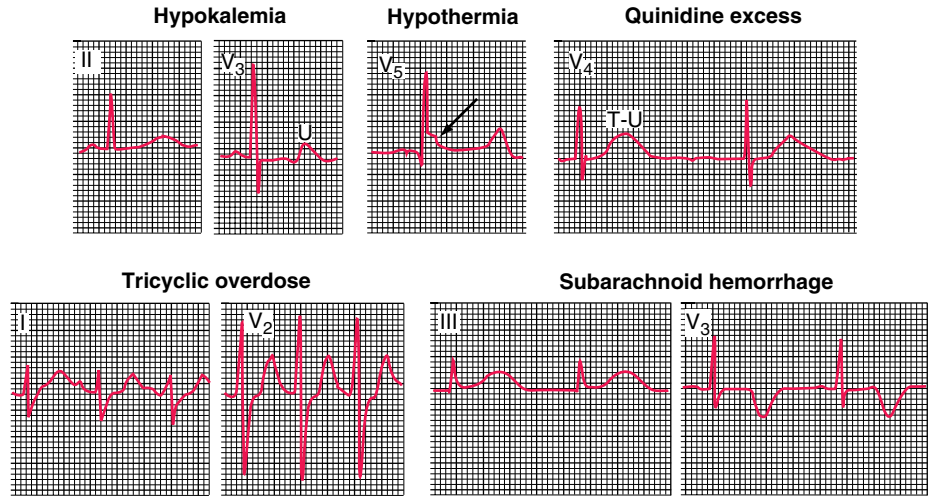

FIGURE 210-17 A variety of metabolic derangements, drug effects, and other factors may prolong ventricular repolarization with QT prolongation or prominent U waves. Repolarization prolongation, particularly if due to hypokalemia or pharmacologic agents, indicates increased susceptibility to *torsades de pointes* type ventricular tachycardia. Hypothermia is associated with a distinctive convex "hump" at the J point (Osborn wave, *arrow*). Note QRS and QT prolongation along with sinus tachycardia in the case of tricyclic antidepressant overdose.

Many other factors are associated with ECG changes, particularly alterations in ventricular repolarization. T-wave flattening, minimal T-wave inversions, or slight ST-segment depression ("nonspecific ST–T-wave changes") may occur with a variety of electrolyte and acid-base disturbances, a variety of infectious processes, central nervous system disorders, endocrine abnormalities, many drugs, ischemia, hypoxia, and virtually any type of cardiopulmonary abnormality. While subtle ST–T-wave changes may be markers of ischemia, transient nonspecific repolarization changes may also occur following a meal or with postural (orthostatic) change, hyperventilation, or exercise in healthy individuals.

ELECTRICAL ALTERNANS

Electrical alternans—a beat-to-beat alternation in one or more components of the ECG signal—is a common type of nonlinear cardiovascular response to a variety of hemodynamic and electrophysiologic perturbations. Total electrical alternans (P-QRS-T) with sinus tachycardia is a relatively specific sign of pericardial effusion, usually with cardiac tamponade. The mechanism relates to a periodic swinging motion of the heart in the effusion at a frequency exactly one-half the heart rate. Repolarization (ST-T) alternans is a sign of electrical instability and may precede ventricular tachyarrhythmias.

CLINICAL INTERPRETATION OF THE ECG

Accurate analysis of ECGs requires thoroughness and care. The patient's age, gender, and clinical status should always be taken into account. For example, T-wave inversions in leads V_1 to V_3 are more likely to represent a normal variant in a healthy young adult woman ("persistent juvenile T-wave pattern") than in an elderly man with chest discomfort. Similarly, the likelihood that ST-segment depression during exercise testing represents ischemia depends partly on the prior probability of coronary artery disease.

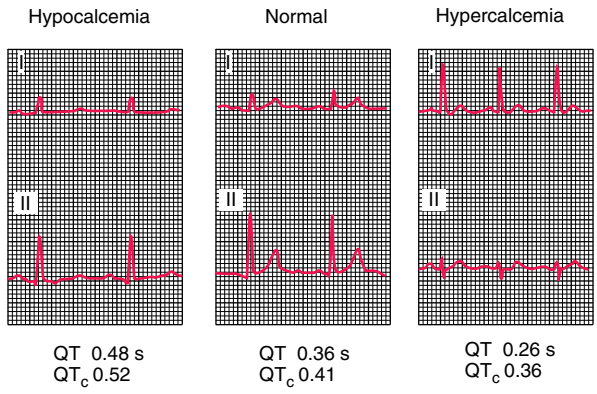

FIGURE 210-18 Prolongation of the Q-T interval (ST-segment portion) is typical of hypocalcemia. Hypercalcemia may cause abbreviation of the ST segment and shortening of the QT interval.

Many mistakes in ECG interpretation are errors of omission. Therefore, a systematic approach is desirable. The following 14 points should be analyzed carefully in every ECG: (1) standardization (calibration) and technical features (including lead placement and artifacts); (2) heart rate; (3) rhythm; (4) PR interval; (5) QRS interval; (6) QT interval; (7) mean QRS electrical axis; (8) P waves; (9) QRS voltages; (10) precordial R-wave progression; (11) abnormal Q waves; (12) ST segments; (13) T waves; (14) U waves.

Only after analyzing all these points should the interpretation be formulated. Where appropriate, important clinical correlates or inferences should be mentioned. For example, the combination of left atrial abnormality (enlargement) and signs of right ventricular hypertrophy suggests mitral stenosis. Low voltage with sinus tachycardia raises the possibility of pericardial tamponade or chronic obstructive lung disease. Sinus tachycardia with QRS and QT (U) prolongation suggests tricyclic antidepressant overdose (Fig. 210-17). Comparison with previous ECGs is essential. →***The diagnosis and management of specific cardiac arrhythmias and conduction disturbances are discussed in Chaps. 213 and 214.***

COMPUTERIZED ELECTROCARDIOGRAPHY

Computerized ECG systems are widely used. Digital systems provide for convenient storage and immediate retrieval of thousands of ECG records. Despite advances, computer interpretation of ECGs has important limitations. Incomplete or inaccurate readings are most likely with arrhythmias and complex abnormalities. Therefore, computerized interpretation (including measurements of basic ECG intervals) should not be accepted without careful physician review.

211 NONINVASIVE CARDIAC IMAGING: ECHOCARDIOGRAPHY, NUCLEAR CARDIOLOGY, AND MRI/CT IMAGING

Rick A. Nishimura, Raymond J. Gibbons, James F. Glockner, A. Jamil Tajik

Cardiovascular imaging has significantly enhanced the practice of cardiology over the past few decades. Two-dimensional (2D) echocardiography is able to visualize the heart directly in real time using ultrasound, providing instantaneous assessment of the myocardium, cardiac chambers, valves, pericardium, and great vessels. Doppler echocardiography measures the velocity of moving red blood cells and has become a noninvasive alternative to cardiac catheterization for assessment of hemodynamics. Transesophageal echocardiography (TEE) provides a unique window for high-resolution imaging of posterior structures of the heart, particularly the left atrium, mitral valve, and aorta. Nuclear cardiology uses isotopes to assess myocardial perfusion and function and has contributed greatly to the evaluation of patients with ischemic heart disease. Cardiac magnetic resonance imaging (MRI) and computed tomography (CT) can delineate cardiac structure and function with high resolution. They are particularly useful in the examination of cardiac masses, the pericardium, and the great vessels and there is growing interest in their utility in patients with suspected coronary artery disease (CAD). This chapter provides an overview of the basic concepts of these cardiac imaging modalities, as well as the clinical indications for each procedure.

ECHOCARDIOGRAPHY

TWO-DIMENSIONAL ECHOCARDIOGRAPHY ■ Basic Principles 2D echocardiography uses the principle of ultrasound reflection off cardiac structures to produce images of the heart (Table 211-1). The imaging is performed from multiple acoustic windows with different transducer rotations so that the entire heart and great vessels can be displayed in real time and in various 2D planes. Most information from a study is obtained from a visual analysis of the 2D images, although objective measurements of cardiac dimensions can be obtained. For a transthoracic echocardiogram (TTE), the imaging is performed with a handheld transducer placed directly on the chest wall. In selected patients, a TEE may be performed, in which an ultrasound transducer is mounted on the tip of an endoscope placed in the esophagus and directed toward the cardiac structures, so that high-resolution images of the posterior structures are obtained.

Current echocardiographic machines are portable; they can be wheeled directly to the patient's bedside. Thus, a major advantage of echocardiography over other imaging modalities is the ability to obtain instantaneous images of the cardiac structures for immediate interpretation, even in emergency or trauma units or in critical care settings.

TABLE 211-1 Clinical Uses of Echocardiography

Two-Dimensional Echocardiography	**Doppler Echocardiography**
Cardiac chambers	Valve stenosis
Chamber size	Gradient
Left ventricular	Valve area
Hypertrophy	Valve regurgitation
Regional wall motion abnormalities	Semiquantitation
Valve	Intracardiac pressures
Morphology and motion	Volumetric flow
Pericardium	Diastolic filling
Effusion	Intracardiac shunts
Tamponade	**Transesophageal Echocardiography**
Masses	Inadequate transthoracic images
Great vessels	Aortic disease
Stress Echocardiography	Infective endocarditis
Two-dimensional	Source of embolism
Myocardial ischemia	Valve prosthesis
Viable myocardium	Intraoperative
Doppler	
Valve disease	

"Handheld" echocardiographic units weighing less than 6 lb have now become available, further enhancing the ease and portability of echocardiography. These units can easily be carried to the bedside of the patient. Although prototype instruments had only 2D echocardiographic capabilities, there are now units that can also perform pulsed Doppler, continuous-wave Doppler, and color-flow Doppler imaging. As these units become smaller and more functional, they may soon become an essential part of the physical examination.

A limitation of a 2D echocardiogram performed via a transthoracic approach is the inability to obtain high-quality images in all patients, especially those with a thick chest wall or severe lung disease. Ultrasound waves are poorly transmitted through lung parenchyma. The diagnostic accuracy of an echocardiogram is highly dependent on both the operator of the echocardiographic equipment and the interpreter of the study.

Chamber Size and Function 2D echocardiography is an ideal imaging modality for assessing left ventricular (LV) size and function (Fig. 211-1). A qualitative assessment of the cavity size of the ventricle and systolic function can be made directly from the 2D image by experienced observers (Fig. 211-2). Quantitative assessment of LV size and function can be made by electronic calipers (measuring systolic and diastolic dimensions of the short axis of the LV) or quantitative 2D echocardiography. With quantitative 2D echocardiography, endocardial outlines of the LV cavity are traced in systole and diastole and the LV cavity areas are then fitted to computer models of the LV to obtain systolic and diastolic volumes. The presence or absence of regional wall motion abnormalities can be visually assessed by examining endocardial motion as well as wall thickening. 2D echocardiography is useful in the diagnosis of LV hypertrophy, seen as an

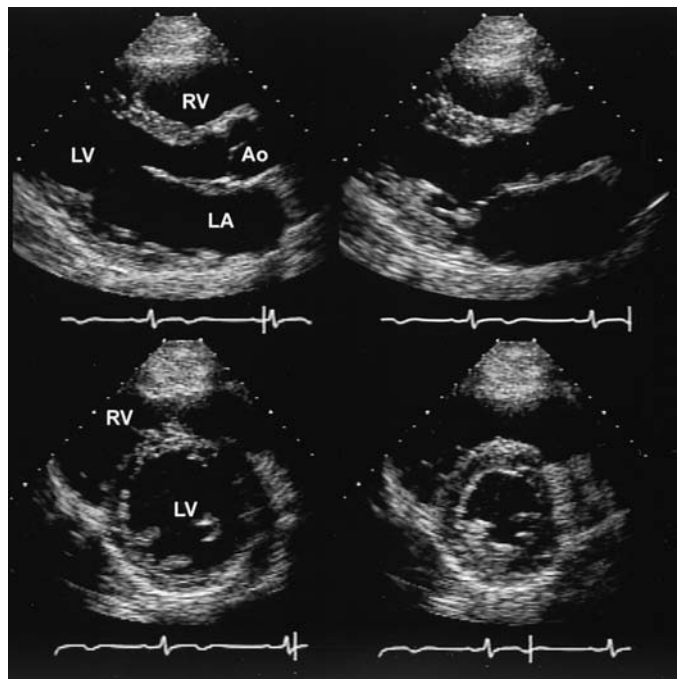

FIGURE 211-1 Two-dimensional echocardiographic still-frame images from a normal patient with a normal heart. *Upper*: Parasternal long axis view during systole and diastole (*left*) and systole (*right*). During systole, there is thickening of the myocardium and reduction in the size of the left ventricle (LV). The valve leaflets are thin and open widely. *Lower*: Parasternal short axis view during diastole (*left*) and systole (*right*) demonstrating a decrease in the left ventricular cavity size during systole as well as an increase in wall thickening. LA, left atrium; RV, right ventricle; Ao, aorta.

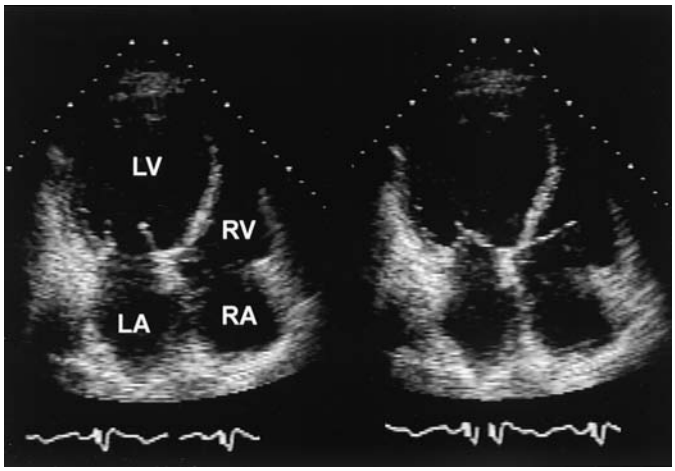

FIGURE 211-2 Apical four-chamber view from a patient with a dilated cardiomyopathy. The left ventricle (LV) is dilated, and there is little change in the LV cavity size from diastole (*left*) to systole (*right*). RV, right ventricle; RA, right atrium; LA, left atrium.

increase in wall thickness. Other chamber sizes are assessed by visual analysis, including the left atrium and right-sided chambers. There is no method for quantitative analysis of right ventricular size and function by 2D echocardiography, due to the complex geometry of the right ventricle.

Valve Abnormalities (See also Chap. 219) 2D echocardiography is the gold standard for imaging valve morphology and motion (Fig. 211-1). Leaflet thickness and mobility, valve calcification, and the appearance of subvalvular and supravalvular structures can be assessed. Valve stenosis is reliably diagnosed by the thickening and decreased mobility of the valve. 2D echocardiography is the gold standard for the diagnosis of mitral stenosis, which produces typical tethering and diastolic doming. The severity of the stenosis can be obtained from a direct planimeter measurement of the mitral valve orifice from the short axis view. The presence and etiology of stenosis of the semilunar valves can be made by 2D echocardiography. Estimating the severity of the stenosis by 2D echocardiography alone is less reliable and requires Doppler echocardiography. The diagnosis of valvular regurgitation must be made by Doppler echocardiography, but 2D echocardiography is valuable for determining the etiology of the regurgitation. Annular dilatation, prolapse, flail leaflets, vegetation, and rheumatic involvement can be diagnosed and the LV response to volume overload can be assessed by 2D echocardiography.

Pericardial Effusion (See also Chap. 222) 2D echocardiography is the imaging modality of choice for the detection of pericardial effusion, which is easily visualized as a black echolucent ovoid structure surrounding the heart. In the hemodynamically unstable patient with pericardial tamponade, typical echo findings of right ventricular collapse, right atrial collapse, and a dilated inferior vena cava are seen (see Fig. 222-2). In patients with subclinical tamponade, these 2D echocardiographic features may not be present, but the diagnosis of elevated pericardial pressure can be made by Doppler findings of variations of inflow velocities with respiration (see Fig. 222-3). Echocardiographically guided pericardiocentesis has now become a standard of care. A 2D echocardiogram can directly visualize the location of the pericardial fluid in relationship to the entry point, and this technique has led to a low complication rate. Increased thickness of the pericardium is difficult to assess by 2D echocardiography. Subtle clues to pericardial constriction can be seen on 2D echocardiography from enhanced ventricular interaction, but Doppler imaging is required for confirmation of this diagnosis.

Intracardiac Masses (See also Chap. 223) Intracardiac masses can be visualized on 2D echocardiography, provided that image quality is adequate. Solid masses appear as echo-dense structures, which can be located inside the cardiac chambers or infiltrating into the myocardium or pericardium (see Fig. 223-1). Although an echocardiographic examination cannot provide pathologic confirmation of the etiology of a mass, there are several instances in which the diagnosis of the mass can be suspected from its appearance, mobility, attachments, and the concomitant abnormalities seen. *LV* thrombus appears as an echo-dense structure, usually in the apical region associated with regional wall motion abnormalities. The appearance and mobility of the thrombus are predictive of embolic events. *Atrial myxoma* can be diagnosed by the appearance of a well-circumscribed mobile mass with attachments to the atrial septum. Prominent benign structures, such as *lipomatous infiltration of the atrial septum* and a *calcified mitral annulus*, may appear as cardiac masses. The high-resolution images provided by TEE may be required for further delineation of myocardial masses.

Aortic Disease (See also Chap. 231) 2D echocardiography can provide extremely useful information on diseases of the aorta. The proximal ascending aorta, the arch, and the distal descending aorta can usually be visualized via the transthoracic approach. For patients in whom a dilated aorta is well visualized, 2D echocardiography can be used for serial follow-up. Aortic dissection can be diagnosed when an intimal flap is visualized on a TTE. However, the definitive diagnosis of an aortic dissection usually requires a TEE.

DOPPLER ECHOCARDIOGRAPHY ■ Basic Principles Doppler echocardiography uses ultrasound reflecting off moving red blood cells to measure the velocity of blood flow across valves, within cardiac chambers, and through the great vessels. Normal and abnormal blood flow patterns can be assessed noninvasively. Color-flow Doppler imaging (Fig. 211-3) displays the blood velocities in real time superimposed upon a 2D echocardiographic image. The different colors indicate the direction of blood flow (red toward and blue away from the transducer), with green superimposed when there is turbulent flow. Thus regurgitant lesions and shunts may be assessed by color-flow Doppler. Pulsed-wave Doppler measures the blood flow velocity in a specific location on the 2D echocardiographic image and displays the velocities in a spectral pattern using time as the *x*-axis. Continuous-wave Doppler

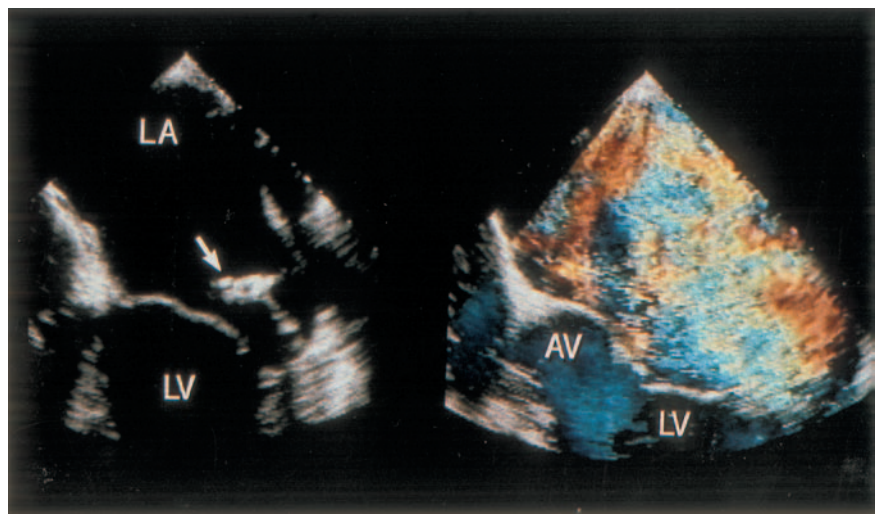

FIGURE 211-3 *Left:* Transesophageal echocardiographic view of a patient with severe mitral regurgitation due to a flail posterior leaflet. The arrow points to the portion of the posterior leaflet that is unsupported and moves into the left atrium during systole. *Right:* Color-flow imaging demonstrating a large mosaic jet of mitral regurgitation during systole. LA, left atrium; LV, left ventricle; AV, aortic valve.

echocardiography can measure high velocities of blood flow directed along the line of the Doppler beam, such as occur in the presence of valve stenosis, valve regurgitation, or intracardiac shunts. These high velocities can be used to determine intracardiac pressure gradients by a modified Bernoulli equation:

$$\text{Pressure change} = 4 \times (\text{velocity})^2$$

The derived pressure gradient can be used to determine intracardiac pressures and stenosis severity.

Tissue Doppler echocardiography measures the velocity of the myocardium. The velocity of myocardium is several magnitudes lower than the velocity of moving red blood cells. Analysis of specific myocardial motion allows for quantification of regional myocardial contraction and relaxation.

Valve Gradients (See also Chap. 219) In the presence of valvular stenosis, there is an increase in the velocity of blood flow across the stenotic valve. A continuous-wave Doppler beam can be placed into this jet of blood, and the measured velocity used to determine an instantaneous gradient across the valve by applying the modified Bernoulli equation. Integration of this velocity over time provides an accurate measurement of the mean gradient across the valve. Since the valve gradient is dependent upon transvalvular flow, a calculated "valve area" is of clinical benefit and can be derived noninvasively.

Valvular Regurgitation (See also Chap. 219) Valvular regurgitation is diagnosed by Doppler echocardiography when there is an abnormal retrograde flow across the valve. Color-flow imaging is the Doppler method used most frequently to detect valve regurgitation by visualization of a high-velocity turbulent jet in the chamber proximal to the regurgitant valve. The sensitivity of Doppler echocardiography for the detection of regurgitant lesions is high, and even trivial or mild regurgitation in the absence of clinical auscultatory evidence of a regurgitant murmur may be detected. The size and extent of the color-flow jet into the receiving cardiac chamber provide a semiqualitative estimate of the severity of regurgitation, but there are many limitations to using color jet size alone.

Intracardiac Pressures These can be calculated from the peak continuous-wave Doppler signal of a regurgitant lesion. The Bernoulli equation is applied to the peak velocity to obtain the pressure gradient between two cardiac chambers. This is commonly applied to a tricuspid regurgitant jet, from which the systolic pressure gradient between the right atrium and right ventricle can be calculated. Adding an assumed right atrial pressure to this gradient will give a derived right ventricular systolic pressure, which provides the pulmonary artery systolic pressure in the absence of right ventricular outflow tract obstruction. Change in pressure over time during isovolumic contraction can be derived from a mitral regurgitation signal. This measurement provides an index of systolic contractility.

Cardiac Output Volume flow rates can be reliably measured noninvasively from Doppler echocardiography. Using the hydrodynamic principle of flow through a rigid tube, the volume of flow can be calculated from the area of an orifice through which blood flows multiplied by the time of the velocity. The most accurate site for this measurement is through the LV outflow tract. The product of the outflow area and velocity provides a beat-to-beat measurement of stroke volume, which, when multiplied by heart rate, provides a measurement of cardiac output.

Diastolic Filling (See also Chap. 215) Doppler echocardiography allows noninvasive evaluation of ventricular diastolic filling. The transmitral velocity curves reflect the relative pressure gradients between the left atrium and LV throughout the diastolic filling period. They are influenced by the rate of ventricular relaxation, the driving force across the valve, and the compliance of the LV. There is a progression of diastolic dysfunction in disease states, which can be assessed by Doppler flow velocity curves (Fig. 211-4). In the early phase of diastolic dysfunction there is primarily an abnormality of relaxation, with decreased early transmitral flow and a compensatory increase in flow during atrial contraction. As disease progresses, there is a higher left atrial pressure and reduced compliance of the LV, resulting in a higher early transmitral velocity and shortening of the deceleration of flow in early diastole, termed *restriction to filling*. These transmitral flow curves can be used to estimate ventricular filling pressures and to determine prognosis in certain disease entities. The addition of Doppler interrogation of pulmonary venous flow, analysis of Doppler tissue velocities of annular motion, and right-sided chamber flow velocities provides further information concerning the diastolic properties. Grading of the severity of diastolic dysfunction is now possible based on the Doppler velocities (Grades I–IV).

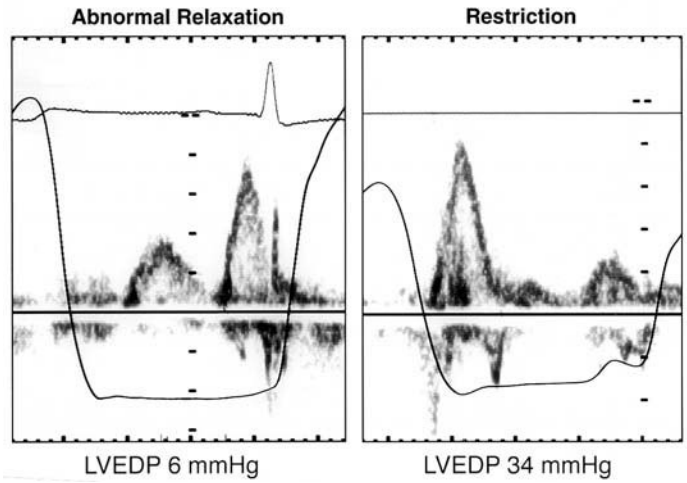

FIGURE 211-4 High-fidelity left ventricular pressure curve superimposed on a mitral inflow velocity curve obtained by Doppler echocardiography. The ratio of early and late diastolic flows is termed an *E:A ratio*. *Left*: In early stages of diastolic dysfunction, there is an abnormality of relaxation. There is a decrease in the early diastolic filling and an increase with filling at atrial contraction, resulting in a low E:A ratio of 0.5, with deceleration time (DT) of 280 ms. In this instance, the left ventricular end-diastolic pressure (LVEDP) is low at 6 mmHg. *Right*: As diastolic dysfunction progresses, there is a restriction to filling, in which there is a high early diastolic velocity and low velocity at atrial contraction resulting in a high E:A ratio of 3.0, with DT of 120 ms. In this instance, the LVEDP is markedly elevated to 34 mmHg. The DT reflects the rate of decline of the early velocity and is a measure of the effective operative compliance of the left ventricle. (See text for explanation.)

Congenital Heart Disease (See also Chap. 218) Doppler echocardiography has been useful in the evaluation of patients with congenital heart disease. Congenital stenotic or regurgitant valve lesions can be assessed. The detection and semiquantitation of intracardiac shunts is possible by Doppler echocardiography. Patency of surgical shunts and conduits can be determined.

STRESS ECHOCARDIOGRAPHY (See also Chap. 226) 2D and Doppler echocardiography are usually performed in the resting state. Further information can be obtained by reimaging during either exercise or pharmacologic stress. The primary indications for stress echocardiography are to confirm the suspicion of CAD and estimate its severity. Stress echocardiography using both 2D echocardiography and Doppler echocardiography provides additional information for the patient with valvular heart disease.

The response of the myocardium to ischemia consists of a cascade of events. A decrease in systolic contraction of the ischemic area, termed a *regional wall motion abnormality*, occurs before symptoms or electrocardiographic changes. During a stress echocardiogram, 2D echocardiographic images at rest and during stress are digitized and displayed in a side-by-side format so that induced regional wall motion abnormalities may be detected. Changes in overall systolic function as well as end-systolic volume are also assessed. New regional wall motion abnormalities, a decline in ejection fraction, and an increase in end-systolic volume with stress are all indicators of myocardial ischemia (Fig. 211-5).

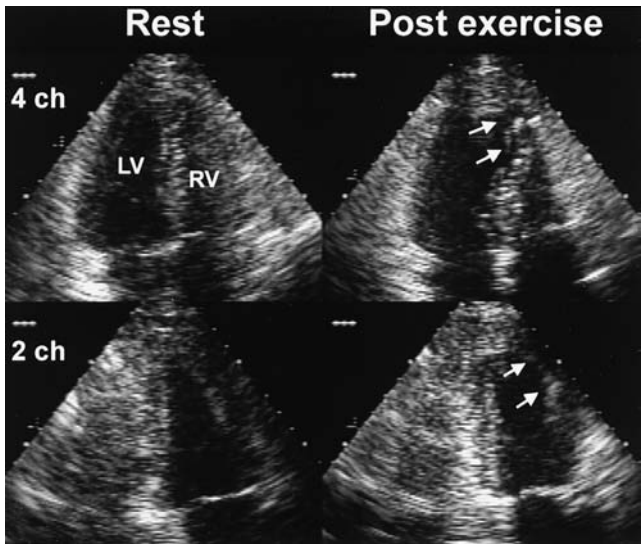

FIGURE 211-5 Stress echocardiographic images in a patient with known coronary artery disease. *Left*: The systolic views from a patient in the resting state is shown. The upper frame is taken from a four-chamber view and the lower frame is taken from a two-chamber view. *Right*: The systolic views are shown immediately after exercise. The arrows point to the appearance of a regional wall motion abnormality in the anterior and apical segments. LV, left ventricle; RV, right ventricle. *(From JK Oh et al, The Echo Manual, 2d ed. Philadelphia, Lippincott, Williams & Wilkins, 1999; with permission.)*

Exercise stress testing is usually done with exercise protocols using either upright treadmill or bicycle exercise. The echocardiographic imaging is done at baseline and then immediately after exercise. In patients who are not able to exercise, pharmacologic testing can be performed by infusion of dobutamine to increase myocardial oxygen demand. Dobutamine echocardiography has also been used to assess myocardial viability in patients with poor systolic function and concomitant CAD. In this type of study, dobutamine is started at a low dose of 5 to 10 μg/kg per min and then incrementally increased every few minutes. In the presence of viable myocardium, an increase in the systolic contraction of the myocardium is evident at low doses of dobutamine, and is followed by an ischemic response at higher doses.

It is important that the images be obtained as soon as possible after exercise is stopped since regional wall motion abnormalities may dissipate rapidly with time. Interpretation of the images is highly operator-dependent, and thus this technique requires an experienced echocardiographer.

Doppler echocardiography can be used at rest and during exercise in patients with valvular heart disease to determine the hemodynamic response to stress. Gradients across stenotic valves can be measured at rest and immediately after exercise; this provides information previously obtained by right heart catheterization during exercise. Pulmonary pressures can be obtained from the tricuspid regurgitation velocities at rest and during exercise.

TRANSESOPHAGEAL ECHOCARDIOGRAPHY This technique has provided an additional window to the heart (see Fig. 211-3). Because of the close proximity of the esophagus to the heart, high-resolution images of posterior structures are consistently obtained. TEE should be performed when further information is required after comprehensive 2D and Doppler transthoracic echocardiograms. Diseases of the aorta, such as aortic dissection, can be readily diagnosed and quantitated by TEE (Fig. 211-6; Chap. 231). Defining the source of embolism is a common indication for TEE, as abnormalities such as atrial thrombi, patent foramen ovale, and aortic debris can be detected. Other masses, particularly those in the atria, can be visualized. The presence of vegetations for the diagnosis of infective endocarditis and its complications can be assessed by TEE (Chap. 109). The evaluation of suspected abnormalities of a mitral prosthesis is an indication for TEE, as the posterior imaging window will avoid the problems of acoustic reflection caused by the prosthetic valve seen with TTE. TEE can be used during cardiac surgery to guide various operations, such as mitral valve repair and septal myectomy. When limited information is obtained from a TTE due to poor imaging windows, TEE can be useful.

Patients presenting with atrial fibrillation of indeterminate duration pose a difficult therapeutic challenge. Cardioversion may be the preferred treatment modality for these patients but if the time of onset of the atrial fibrillation is either greater than 48 h or unclear, there may be a higher risk of an embolic event at the time of cardioversion. In this situation, TEE has been used before cardioversion to look for a thrombus in the left atrium or left atrial appendage. If no thrombus is present, cardioversion can be safely performed emergently, as long as there is full dose anticoagulation before, during, and after the procedure.

EMERGENCY ECHOCARDIOGRAPHY A major advantage of echocardiography is the ability to obtain instantaneous images of the cardiac structures for immediate interpretation at the patient's bedside. Thus, echocardiography has become an ideal imaging modality for cardiac emergencies.

Unstable Hemodynamics For the patient with unstable hemodynamics, echocardiography can determine left ventricular size and function, right ventricular size and function, and the presence of acute valvular regurgitation and pericardial tamponade. Echocardiography is especially useful in the hemodynamically unstable patient following myocardial infarction, where acute mechanical complications (e.g., papillary muscle rupture, ventricular septal defect, myocardial perforation with tamponade, and right ventricular infarction) can be diagnosed and need to be differentiated from severe left ventricular systolic dysfunction. An enlarged right ventricle in a hemodynamically unstable patient can indicate the presence of acute right ventricular pressure overload, which is seen in acute pulmonary embolism. Echocardiography is the imaging modality of choice for the diagnosis of pericardial tamponade. 2D echocardiography can also be used to guide emergency pericardiocentesis.

Chest Pain Syndromes (See also Chap. 12) Echocardiography can be useful in selected patients with chest pain syndromes. For those patients who have an equivocal electrocardiogram, the presence of regional wall motion abnormalities on an echocardiogram can lead to the diagnosis of myocardial ischemia as an etiology for the pain. Other

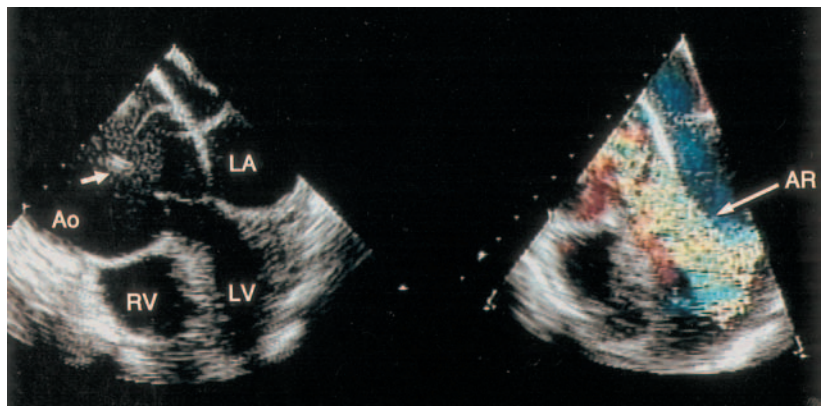

FIGURE 211-6 Transesophageal echocardiographic view of a patient with a dilated aorta, aortic dissection, and severe aortic regurgitation. The arrow points to the intimal flap that is seen in the dilated ascending aorta. *Left:* The long axis apex down view of the black and white two-dimensional image in diastole. *Right:* Color-flow imaging that demonstrates a large mosaic jet of aortic regurgitation. Ao, aorta; RV, right ventricle; AR, aortic regurgitation.

etiologies of chest pain, such as acute dissection or pericarditis with effusion, can also be diagnosed by echocardiography.

NUCLEAR CARDIOLOGY

BASIC PRINCIPLES OF NUCLEAR CARDIOLOGY All nuclear cardiology studies depend on the injection into the patient of an isotope that emits photons, generally gamma rays generated during radioactive decay when the nucleus of an isotope changes from one energy level to a lower one. Radionuclide imaging uses a special camera that images these photons. A common problem with all nuclear studies is that photons are emitted in all directions from the point of origin, and scattering, attenuation, and absorption of the photons can occur. The higher the energy of the isotope, the less chance for scatter or absorption. The two most commonly used isotopes are technetium 99m (^{99m}Tc) and thallium 201 (^{201}Tl).

ASSESSMENT OF VENTRICULAR FUNCTION Equilibrium radionuclide angiography, also known as *multiple-gated blood pool imaging*, is useful for the noninvasive assessment of ventricular function. It involves the imaging of ^{99m}Tc-labeled albumin or red cells that are uniformly distributed throughout the blood volume. Resting images of the blood pool of isotopes within the cardiac chambers are obtained by electrocardiographic gating through multiple cycles, so that sufficient counts can be detected to obtain an image. This requires that the heart rate be reasonably constant without significant arrhythmia. It provides an accurate, reproducible method for assessment of LV function. Other clinical variables that can be obtained include size and function of the right ventricle, size of atrial chambers and great vessels, diastolic filling parameters, and the severity of valvular regurgitation.

First-pass radionuclide angiography is an alternative method for the noninvasive assessment of ventricular function that involves the recording of the movement of a bolus of radionuclide during its "first pass" through the central circulation. This does not require labeling of red blood cells. ^{99m}Tc is utilized because of its low cost and short half-life. During this testing, the passage of the radioisotope through the right atrium, right ventricle, pulmonary circulation, left atrium, left ventricle, and aorta is recorded with a high-count (usually multicrystal) camera. The high count rates allow temporal definition of the passage of the bolus. The disadvantage of first-pass radionuclide angiography compared to equilibrium testing is its poorer resolution of ventricular wall motion.

Gated single-photon emission computed tomography (SPECT) can also be used to assess ejection fraction and regional wall motion (usually poststress) by gating the acquisition of SPECT myocardial perfusion images (see below). Although this can potentially be done using ^{201}Tl, ^{99m}Tc- labeled compounds are preferable because of their higher count rates. An automated technique determines the endocardial borders of the LV cavity and a geometric model is used to calculate the ejection fraction. As for equilibrium radionuclide angiography, the heart rhythm should be regular without significant arrhythmia.

ASSESSMENT OF MYOCARDIAL PERFUSION Myocardial perfusion imaging by nuclear techniques is now widely applied for the evaluation of ischemic heart disease (Chap. 226). Injection of radioisotopes at rest and during stress is performed to produce images of myocardial regional uptake proportional to regional blood flow. With maximal exercise, myocardial blood flow is increased up to fivefold above the resting condition. In the presence of a fixed coronary stenosis, there is an inability to increase myocardial perfusion in the territory supplied by the stenosis, creating a flow differential and inhomogeneous distribution of the isotope. In patients who are unable to exercise, pharmacologic agents are used to increase blood flow and create similar inhomogeneities. The preferred pharmacologic agents are adenosine or dipyridamole, which increase blood flow to a similar degree as exercise. In patients with bronchospastic lung disease, which is a contraindication to the use of adenosine or dipyridamole, dobutamine may be used as an alternative, although it does not increase blood flow to the same extent.

^{201}Tl is a potassium analogue and is avidly taken up by viable myocardial cells. The degree of uptake is related directly to the coronary blood flow. An initial injection is usually performed at peak exercise, and hypoperfused myocardium will have less thallium uptake than a region of normal perfusion. Over the next several hours, a complex process occurs that is known as "redistribution." There is a continuous input of thallium into the myocardium from a large reservoir of thallium in the blood pool. At the same time, thallium continuously washes out of portions of the myocardium at a rate that is dependent on local myocardial perfusion. The final result is that a region of ischemia that initially appears as an area of reduced uptake becomes apparently normal over time; this redistribution is seen on delayed imaging. In regions of fibrosis (infarction), there will be no redistribution on delayed imaging. A "reinjection" of additional thallium before acquisition of the delayed images enhances the detection of ischemia. The presence of redistribution in areas of hypokinesia has been associated with recovery of LV function after revascularization.

Other findings on thallium imaging may be of considerable clinical importance. Increased lung uptake of thallium may be seen immediately after stress and assessed either quantitatively or qualitatively. This finding reflects increased pulmonary capillary wedge pressure during stress. It occurs in the presence of severe CAD and/or LV dysfunction. It provides important adverse prognostic information that is incremental to other clinical, stress, and coronary angiographic variables. Thallium images may also show evidence of transient poststress LV dilatation. This finding is also associated with severe CAD and/or LV dysfunction as well as with an adverse prognosis.

^{99m}Tc-labeled compounds have a higher photon energy and shorter half-life than ^{201}Tl, permitting the injection of larger doses (Fig. 211-7). As a result, these compounds generally provide higher quality scans with fewer artifacts. Three technetium-labeled agents have been approved for general use: teboroxime, tetrofosmin, and sestamibi. The last is the best studied of these agents and is currently used most frequently. Like thallium, sestamibi distributes to the myocardium in relation to blood flow, and its uptake requires a viable myocardial cell and an intact cell membrane. It is transported through the cytoplasm and bound to the mitochondria in a nearly irreversible fashion. Compared to thallium, there is far less redistribution. As a result, the agent must generally be injected twice—once at rest and once during stress.

COMPARISON OF THALLIUM AND TECHNETIUM Both ^{201}Tl- and ^{99m}Tc-labeled compounds provide clinically useful myocardial perfusion images in the majority of patients. The choice between the two is often dictated by local experience and economics. However, in selected patients, there may be factors that suggest a clear advantage for one or the other. The relative advantages of both agents are listed in Table 211-2.

POSITRON EMISSION TOMOGRAPHY The underlying physics of positron emission tomography (PET) scanning is quite different from that involved in the standard radionuclide techniques described above. The annihilation of the positron leads to the simultaneous emission of two very high energy (511 keV) photons in opposite directions. These can then be imaged by a series of detectors placed in a ring around the patient. The very high energy of the photons results in far less scatter and attenuation than with conventional nuclear cardiology techniques. PET cameras are considerably more expensive than conventional nuclear cardiology cameras. The radiopharmaceuticals involved require a cyclotron for production and generally have half-lives that are so short that transportation beyond the immediate local region is not feasible. Although the initial availability of PET was limited, the increasing role of PET imaging in oncology has increased its availability for cardiac imaging.

Positron emitters can be employed to study both myocardial blood flow and myocardial metabolism. Nitrogen-13 ammonia, oxygen-15 water, and rubidium-82 have all been employed to assess myocardial blood flow. They permit measurement of absolute regional blood flows, in contrast to the relative blood flows that are assessed with

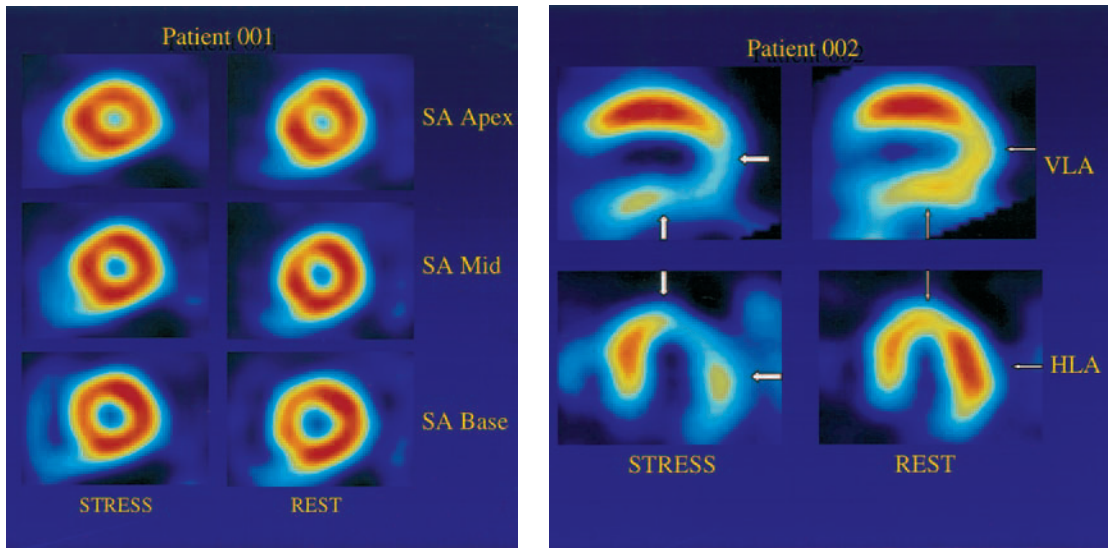

FIGURE 211-7 *A.* Exercise sestamibi study on a 71-year-old, white female with atypical angina. *Left:* Stress images; *right:* rest images. The images are normal. There is even sestamibi update throughout the myocardium at rest and during stress. *B.* Exercise sestamibi study on a 75-year-old male with a history of typical angina. *Left:* Stress images; *right:* rest images. The stress images show a large defect involving the apex, lateral, and inferior walls (thick arrows), which improves at rest (thin arrows). Subsequent coronary angiography demonstrates severe three-vessel coronary artery disease. SA, short axis; Mid, middle of the left ventricle; VLA, vertical long axis; HLA, horizontal long axis.

^{201}Tl- or ^{99m}Tc-labeled compounds. This advantage has been utilized for research purposes but has not yet been exploited clinically. Myocardial metabolism is most often assessed using fluorine-18 deoxyglucose. This agent permits the detection and quantification of exogenous glucose utilization in areas of hypoperfused myocardium.

The clinical application of PET scanning that has been most well studied is the assessment of myocardial viability. The pattern of enhanced fluorodeoxyglucose uptake in regions of decreased perfusion (termed *glucose/blood flow "mismatch"*) indicates the presence of ischemic myocardium that has preferentially shifted its metabolic substrate toward glucose rather than fatty acid or lactate. This pattern identifies regions of ischemic or hibernating myocardium that are likely to improve in function after revascularization (Chap. 226).

Careful studies have consistently shown the ability of PET to identify ischemic or hibernating myocardium in 10 to 20% of regions that would be classified as fibrotic (infarcted) by ^{201}Tl- or ^{99m}Tc-labeled compounds. For that reason, this technique is generally regarded as the gold standard for the assessment of myocardial viability. When large fixed defects (infarcts) are detected by ^{201}Tl- or ^{99m}Tc-labeled-compounds in patients who are candidates for coronary revascularization, PET imaging can suggest if the risk of revascularization is justified by the potential benefit.

Within the past few years, specially modified conventional gamma cameras have been employed to image fluorodeoxyglucose in an attempt to avoid the expense related to cameras dedicated to PET. The limited evidence available suggests that this approach is inferior to standard PET.

TABLE 211-2 Relative Advantages of Thallium 201 and Technetium 99m Sestamibi

THALLIUM
Lower radiopharmaceutical cost
Measurement of increased pulmonary uptake
Detection of resting ischemia (hibernating myocardium)
SESTAMIBI
Better image quality (particularly in obese patients or female patients with breast attenuation)
Ventricular function assessment (first-pass or gated SPECT)
Shorter imaging times (lower cost)
Shorter imaging protocols (patient/scheduling convenience)
Acute imaging in myocardial infarction (myocardium at risk) and unstable angina (chest pain triage)
Superior quantification, particularly of resting perfusion defect (infarct size)

Note: SPECT, single-photon emission computed tomography.

OVERVIEW OF STRESS TESTING

CHOOSING THE APPROPRIATE INITIAL STRESS TEST The choice of an initial stress testing modality should be based on the evaluation of the patient's resting electrocardiogram, the physical ability to perform exercise, and the local expertise and technology available in an institution. For the standard risk assessment of CAD, the exercise electrocardiographic test (Chap. 226) should be the initial mode of stress testing in patients with a normal electrocardiogram who are not taking digoxin and who are able to exercise. If there are resting electrocardiographic abnormalities (ST depression >1 mm, LV hypertrophy, bundle branch block, paced rhythm, pre-excitation) or the patient is taking digoxin or has had a prior coronary revascularization, an imaging modality (either nuclear imaging or echocardiography) should be used for initial evaluation. Pharmacologic stress testing with imaging should be used in patients who are unable to exercise.

When an imaging modality is appropriate, the decision as to whether to use an echocardiographic or a nuclear test is dependent not only on the patient's situation but also on the local expertise and technology available in the institution. Both echocardiography and nuclear imaging require expertise in the performance and interpretation of the tests and the best information is obtained from the imaging modality in which there is most expertise and experience. There are, however, certain situations in which one imaging modality has an advantage over the other.

Echocardiography provides additional structural information. Therefore, if there is a question of concomitant valve disease, pericardial disease, or aortic disease, echocardiography is able to provide information regarding these issues. The major limitation of echocardiography is the inability to obtain diagnostic images in all patients, especially those with chronic obstructive pulmonary disease or severe obesity. Tissue harmonic imaging and contrast injection may help in further delineating endocardial motion in these patients. However, if there is inadequate definition of endocardial motion on the resting echocardiogram, stress echocardiography should not be performed. If the patient has had a previous infarction and one needs to determine whether a specific area of the myocardium is ischemic, nuclear imaging is the preferred modality. Nuclear imaging using ^{99m}Tc-labeled compounds is preferred in obese patients and those with severe lung disease. Nuclear imaging is more sensitive and less specific than echocardiography for the detection of myocardial ischemia.

There are certain instances in which there are false-positives with imaging stress testing. In patients with left bundle branch block, exercise may provoke abnormalities in regional perfusion and regional ventricular function in the absence of CAD. Therefore, the modality of choice in these patients is pharmacologic perfusion imaging.

STRESS TESTING FOR PROGNOSIS Exercise electrocardiography, stress nuclear imaging, and stress echocardiography can all provide important information regarding diagnosis and the patient's subsequent risk for cardiac death. The results are often pivotal in defining the need for coronary angiography and coronary revascularization. For the exercise electrocardiogram, the Duke treadmill score is a well-validated index that is useful for both diagnosis and prognosis. Patients who exercise for $>$ 5 min on the treadmill using a Bruce protocol without angina or ST segment changes have a low risk of subsequent cardiac death ($<$ 1% annual mortality). In contrast, patients with markedly abnormal stress tests are at high risk for subsequent death ($>$ 3% annual mortality); coronary angiography and possible revascularization are appropriate. For the exercise electrocardiogram, a high-risk Duke score consists of a low exercise workload with angina and early ST segment changes.

The imaging tests can add further prognostic information, especially when the results of an exercise electrocardiogram fall into an intermediate risk category. For nuclear imaging, normal stress (exercise) or pharmacologic myocardial perfusion scans (p. 1325) are highly predictive of the absence of significant coronary disease and a low risk of subsequent cardiac death. For stress (exercise or dobutamine) echocardiography, an increase in ejection fraction and a decrease in end-systolic volume at a high workload predict the absence of significant coronary disease and a low risk of subsequent cardiac death. For nuclear imaging, large stress-induced defects, multiple stress-induced defects of moderate size, or a large fixed defect with LV dilatation or increased ^{201}Tl lung uptake are high-risk findings. For stress echocardiography, patients with a drop in ejection fraction, the appearance of multiple regional wall motion abnormalities, and an increase in end-systolic volume are at high risk.

MRI AND CT IMAGING

MRI MRI is a technique based on the magnetic properties of hydrogen nuclei. In the presence of a large magnetic field, nuclear spin transitions from the ground state to excited states can be induced, and as the nuclei relax and return to their ground state, they release energy in the form of electromagnetic radiation that is detected and processed into an image. Contrast agents are frequently employed in MRI to provide magnetic resonance angiograms (MRAs). These provide enhanced soft-tissue contrast as well as the opportunity to obtain rapid angiographic images during the first pass of contrast through the vascular system. Cardiac MRI is particularly challenging because of the rapid physiologic motion of the heart and coronary arteries. Both static and cine images can be obtained using electrocardiographic triggering, often within a short breath-hold of 10 to 15 s (Fig. 211-8). Cine images can be acquired in any plane with excellent blood-myocardial contrast, and these images can be used to quantify ejection fraction, end-systolic and end-diastolic volumes, and cardiac mass with high accuracy and reliability.

Clinical Utility The multiplanar capabilities of MRI, coupled with excellent contrast and spatial resolution, are often valuable in defining anatomic relationships in patients with complex congenital heart disease. Cardiac masses can be characterized and their relationship to normal anatomic structures defined. Likewise, MRI is often the examination of choice to determine whether a mediastinal or pulmonary mass has invaded the pericardium or heart. The entire pericardium can be visualized in multiple planes, and MRI has proved useful in characterization of pericardial effusions, pericardial thickening, and constrictive pericarditis in patients with indeterminate results on echocardiography. MRI is an important technique for evaluation of patients with suspected arrhythmogenic right ventricular dysplasia, where fatty infiltration of the right ventricular free wall can be identified, as can right ventricular dilatation and dyskinesis.

MRA is a standard technique for imaging the aorta and large vessels of the chest and abdomen, with results essentially identical to conventional catheter-based angiography. MRA of the coronary arteries is a much more difficult challenge, both because of the small size of these vessels and because of their rapid and complex motion during the cardiac cycle. Although promising results have been achieved, coronary MRA is not yet an accurate and reliable clinical technique.

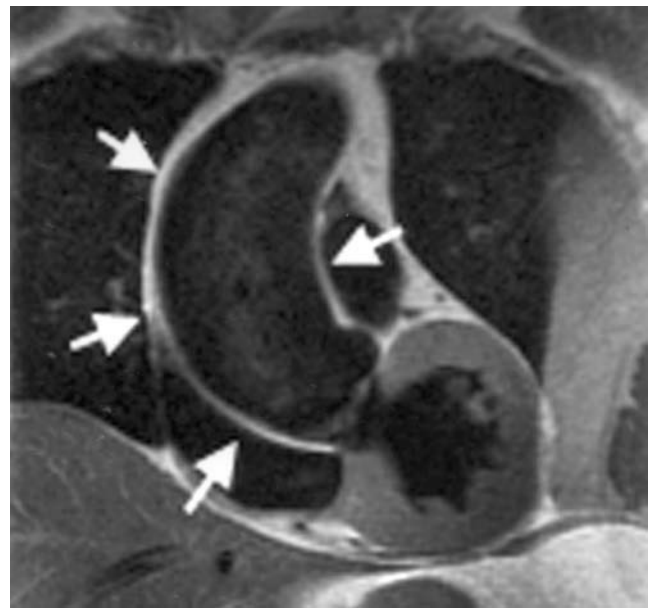

FIGURE 211-8 Axial dark-blood MRI from a patient with aortic stenosis and dilatation of the ascending aorta (arrows). Image was acquired in approximately 10 s during suspended respiration.

MRI is a promising technology for the evaluation of myocardial perfusion. Myocardial perfusion is evaluated by injecting a bolus of contrast and then continuously scanning the heart as the contrast passes through the cardiac chambers and into the myocardium. Relative perfusion deficits are reflected as regions of low signal intensity within the myocardium. Myocardial viability may be determined by imaging the heart 10 to 20 min after contrast injection, as infarcted tissue retains contrast by virtue of its larger extracellular volume. Specialized pulse sequences have been designed to measure the velocity of blood in each pixel of the image, so that flow across valves and within blood vessels may be accurately determined. These techniques may allow characterization of the severity of valvular disease as well as quantification of shunt volumes.

Cardiac MRI has several limitations. Absolute contraindications include the presence of pacemakers, internal defibrillators, or cerebral aneurysm clips. A small percentage of patients are claustrophobic and unable to tolerate the examination within the relatively confined quarters of the magnet bore. Examination of clinically unstable patients is problematic, since close monitoring is difficult.

CT IMAGING CT is fast, simple, and noninvasive, and it provides images with excellent spatial resolution and good soft-tissue contrast. Imaging the heart is a more difficult problem, however, because image acquisition times for conventional CT have until recently been on the order of 1 s, far too long to freeze cardiac motion.

Electron-beam CT employs a fixed detector array and radiation source. The x-rays are generated by an electron beam sweeping continuously across the target anode ring. This is accomplished very rapidly, on the order of 50 to 100 ms. The electron beam can be triggered by the electrocardiogram trace, and single static images or cine images are generated with excellent temporal resolution.

Clinical Applications Cardiac CT has several clinical applications. Pericardial calcification is an important sign of constrictive pericarditis and is easily detected by CT. CT is useful in characterizing cardiac masses, particularly those containing fat or calcium. The ability to detect small amounts of fat with high spatial resolution makes CT an

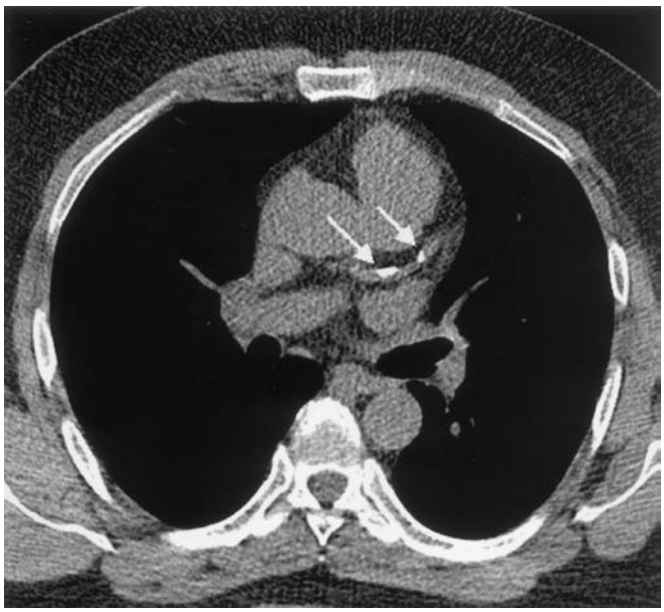

FIGURE 211-9 Noncontrast image from electron-beam CT revealing small foci of calcification in the left anterior descending coronary artery (arrow).

attractive technique for imaging patients with suspected arrhythmogenic right ventricular dysplasia. Cine images can be used to evaluate wall motion and determine ejection fraction, end-diastolic and end-systolic volumes, and cardiac mass.

CT angiography (CTA) has demonstrated accuracy similar to MRA in imaging the aorta and great vessels, and CTA is rapidly becoming the examination of choice in the evaluation of patients with suspected pulmonary embolus. Coronary CTA with multidetector spiral CT is in the developmental stage. Both CT and MRI are valuable in delineating the presence and course of anomalous coronary vessels; however, the clinical utility of either technique in detecting and grading coronary artery stenoses has not been widely demonstrated.

Coronary Calcification Calcium in the coronary arteries occurs in atherosclerosis and is absent in the normal coronary artery. CT is very sensitive for the detection of coronary artery calcification and is being promoted as a noninvasive modality for the screening and diagnosis of CAD (Fig. 211-9). The amount of coronary calcification (coronary calcium score) is related to the severity of coronary disease. However, although CT has a very high sensitivity for the detection of CAD, it has a low specificity. The overall predictive accuracy for angiographic obstructive coronary disease in a typical CAD patient population is similar to other imaging modalities, such as SPECT. Due to its low specificity, CT should not be used for the diagnosis of obstructive coronary disease. However, in asymptomatic patients, more severe coronary atherosclerosis (and thus a higher calcium score) is associated with a higher risk of future cardiac events. Nonetheless, there are no data to show that the information from CT is additive to standard clinical assessment of the risk of CAD and coronary events. The results of properly designed outcomes research studies are required for determination of the ultimate clinical role of CT scanning in patients with known or suspected CAD.

Limitations of CT Limitations of CT include ionizing radiation and the need for iodinated contrast, which is problematic in patients with renal insufficiency or contrast allergy. Radiation doses tend to increase as the spatial and temporal resolution improve; however, the dose for cardiac CT is almost always significantly lower than the dose delivered during cardiac catheterization.

212 DIAGNOSTIC CARDIAC CATHETERIZATION AND ANGIOGRAPHY

Donald S. Baim, William Grossman

Despite progressive improvements in noninvasive techniques, cardiac catheterization remains a key clinical tool for assessing the anatomy and physiology of the heart and its associated vasculature. It involves the insertion of small (diameter, 2 to 3 mm), hollow plastic tubes or catheters into a peripheral artery or vein under local anesthesia, and passage of their tips into the heart for pressure measurement or for the injection of a liquid radiographic contrast agent. The findings of diagnostic cardiac catheterization characterize the extent and severity of cardiac disease and thereby help in deciding on the most appropriate plan for medical, surgical, or catheter-based treatment. While the majority of patients with coronary artery disease (CAD) or valvular disease can be managed using only clinical and noninvasive data, more than 2 million cardiac catheterization and angiographic procedures are performed each year for diagnostic or interventional purposes, or both. This chapter focuses on the uses of cardiac catheterization as a diagnostic tool. →***For further discussion of catheter-based interventions, see Chap. 229.***

INDICATIONS, CONTRAINDICATIONS, AND COMPLICATIONS

INDICATIONS Given the expense and small, but real, risks of cardiac catheterization, its performance is not routine whenever cardiac disease is diagnosed or suspected. Instead, cardiac catheterization is recommended only when there is a need to confirm the presence of a clinically suspected condition, define its anatomic and physiologic severity, and determine whether important associated conditions are present. This need most commonly arises when a patient is experiencing limiting or escalating symptoms of cardiac dysfunction (Chap. 216) or myocardial ischemia (Chap. 226) or when objective measures (such as exercise testing or echocardiography) suggest that the patient has a high risk of progressing to rapid functional deterioration, myocardial infarction, or other adverse events. Under these circumstances, catheterization may serve as a checkpoint prior to treatment by cardiac surgery or a catheter-based intervention. While cardiac catheterization was previously considered mandatory in *all* patients being considered for cardiac surgery, currently many patients with congenital or valvular

TABLE 212-1 Relative Contraindications to Cardiac Catheterization and Angiography

Uncontrolled ventricular irritability: increased risk of ventricular tachycardia and fibrillation during catheterization if ventricular irritability is uncontrolled
Uncorrected hypokalemia or digitalis toxicity
Uncorrected hypertension: predisposes to myocardial ischemia and/or heart failure during angiography
Intercurrent febrile illness
Decompensated heart failure: especially acute pulmonary edema, unless catheterization can be done with patient sitting up
Anticoagulated state: prothrombin time >18 s
Severe allergy to radiographic contrast agent
Severe renal insufficiency and/or anuria: unless dialysis is planned to remove fluid and radiographic contrast load

heart disease undergo surgical correction based solely on clinical and noninvasive test data. Cardiac catheterization and coronary arteriography still remain, however, the only way to define *coronary anatomy* with sufficient precision to inform decisions regarding coronary surgery or catheter-based interventions in patients with CAD. In patients with other forms of heart disease (e.g., dilated cardiomyopathy, valvular heart disease), cardiac catheterization can provide hemodynamic characterization essential for the design of an appropriate medical regimen, or to assess prognosis.

CONTRAINDICATIONS When there is a clinical "need to know," there are very few absolute contraindications to diagnostic cardiac catheterization in a patient who understands and accepts the associated risks. Some relative contraindications to cardiac catheterization, however, are listed in Table 212-1. Most center on factors that increase the risk of the procedure above the baseline mortality risk of roughly 1 in 1000 for clinically stable patients. For example, risk is increased more than tenfold in patients with severe symptoms, certain types of coronary anatomy, valve disease, left ventricular dysfunction, or severe noncardiac disease, as outlined in Table 212-2.

COMPLICATIONS Beyond the mortality risk, cardiac catheterization carries a 1 in 1000 risk of stroke or myocardial infarction. Other problems, such as transient tachy- or bradyarrhythmias or bruising or bleeding at the catheter insertion site, occur in fewer than 1% of patients and respond to drug therapy, countershock, or vascular surgical repair, without long-term sequelae. Although serious, problems such as cardiac perforation or arterial dissection are very rare in the modern era of cardiac catheterization.

Some patients, however, are intolerant of the iodinated contrast agents used for angiography, which may produce transient deterioration in renal function (particularly in patients with baseline renal dysfunction or proteinuria who are not adequately prehydrated) or *allergic reactions* ranging from urticaria to frank anaphylaxis in sensitive patients. These allergic reactions can be suppressed by pretreatment with glucocorticoids (prednisone, 20 to 40 mg every 6 h), conventional antihistamines (e.g., diphenhydramine, 25 mg every 6 h), and H_2 antagonists (cimetidine, 300 mg every 6 h), starting 18 to 24 h prior to the procedure. Despite these precautions, anaphylactic reactions during radiographic contrast angiography may require emergency treatment with intravenous epinephrine. In contemporary practice, however, use of newer nonionic contrast agents has almost eliminated these severe allergic reactions. Compared to the original high-osmolar agents, the newer contrast agents also have a lesser myocardial depressant effect and produce fewer side effects (hypotension, nausea, bradycardia, or a sensation of marked warmth following injection).

TABLE 212-2 Patient Characteristics Associated with Increased Mortality from Cardiac Catheterization

Age Infants (<1 month old) and the elderly (>85 years old) are at increased risk of death during cardiac catheterization. Elderly women appear to be at higher risk than elderly men.
Functional class Mortality in class IV patients is more than 10 times greater than in class I–II patients.
Severity of coronary obstruction Mortality for patients with left main coronary artery disease is more than 10 times greater than in patients with one- or two-vessel disease.
Valvular heart disease Especially when severe and combined with coronary disease, is associated with a higher risk of death at cardiac catheterization than coronary artery disease alone.
Left ventricular dysfunction Mortality in patients with a left ventricular ejection fraction <30% is more than 10 times greater than in patients with an ejection fraction ≥50%.
Severe noncardiac disease Patients with renal insufficiency, insulin-requiring diabetes, advanced cerebrovascular and/or peripheral vascular disease, or severe pulmonary insufficiency have an increased incidence of death and other major complications from cardiac catheterization.

TECHNIQUES

Cardiac catheterization is performed with the patient in the fasting state and awake but lightly sedated. Typical preprocedure sedatives include diazepam (Valium, 5 to 10 mg orally) or midazolam (Versed, 1 mg intravenously). Although cardiac catheterization was previously performed exclusively as an inpatient procedure, current practice is to perform most elective procedures on an *outpatient* basis, with the patient discharged 2 to 4 h after the procedure is completed. Since cardiac catheterization is a sterile procedure, prophylactic antibiotics are not necessary. To minimize the risks of bleeding at the local catheter insertion site, patients who have been anticoagulated chronically with warfarin should have this agent discontinued at least 48 h prior to the procedure, so that the INR falls below 2. Oral aspirin (325 mg per day) is recommended in patients undergoing diagnostic catheterization for suspected coronary disease, since aspirin pretreatment is required if a coronary intervention is to be performed.

Most (>95%) cardiac catheterizations are performed by the percutaneous femoral technique, in which a needle puncture is performed in the femoral artery (for left heart catheterization) and the femoral vein (for right heart catheterization). A flexible guidewire is inserted through this needle, over which a vascular access sheath is placed, through which the desired catheters can be advanced. This percutaneous technique has been modified for other sites, including the brachial and radial artery. The brachial or radial approach has an advantage in the patient with peripheral vascular disease involving the abdominal aorta and iliac or femoral arteries or in whom immediate postprocedure ambulation is desired, but it involves some limitations in the range of devices that can be used if the diagnostic procedure evolves into a catheter-based intervention. With these alternatives, the original cut-down, or Sones, technique of cardiac catheterization by direct exposure of the brachial artery and vein in the antecubital fossa is rarely used.

Cardiac catheterization may include a variety of different measurements of pressure and flow (hemodynamics) as well as a variety of different contrast injections recorded as x-ray movies (angiography). The exact types of testing performed in any given procedure depend on the nature of the clinical problem being evaluated. In patients with CAD, the procedure may include only left ventriculography and coronary angiography, while in patients with valvular heart disease, full left and right heart hemodynamic studies may be performed.

RIGHT HEART CATHETERIZATION

Measurement of the pressures in the right side of the heart was once a routine part of each cardiac catheterization, but it is now used in fewer than 25% of procedures since it adds little to the evaluation of the patient with CAD. It is still useful, however, when significant left and/or right ventricular dysfunction, valve disease, myopericardial disease, or intracardiac shunting is suspected. The right heart catheterization procedure is similar to the placement of a Swan-Ganz catheter at the bedside in the intensive care unit, except that it is performed under fluoroscopic guidance. A balloon flotation catheter is advanced from a suitable vein (femoral, brachial, subclavian, or internal jugular)

into the superior vena cava, where blood is sampled for oximetry. The catheter is then positioned in the right atrium, where pressure is measured. The balloon is inflated with air (or carbon dioxide, if intracardiac shunting is suspected) and advanced sequentially into the right ventricle, pulmonary artery, and pulmonary artery wedge position. Pressure is recorded at each of these locations, with normal values for pressures measured during cardiac catheterization summarized in Table 212-3. After recording the pulmonary wedge pressure (which approximates left atrial pressure), the balloon is deflated so that pulmonary artery pressure can be monitored and blood samples obtained for oximetry. Comparison of oxygen saturations in the superior and inferior vena cava, the chambers of the right heart, and pulmonary artery permits assessment of the presence of a left-to-right shunt at the atrial, ventricular, or pulmonary artery level, which will be manifested as an increase ("step-up") in oxygen saturation of blood as it traverses these vessels and chambers.

MEASUREMENT OF CARDIAC OUTPUT Measurements of the pulmonary artery and aortic oxygen content and oxygen consumption allow calculation of the cardiac output by the Fick principle, which states that

$$Q\ (\text{L/min}) = \frac{O_2\ \text{consumption (mL/min)}}{\text{arteriovenous } O_2\ \text{difference (mL/L)}}$$

In order to compare individuals of different body weights and sizes, cardiac output (Q) is commonly divided by body surface area to yield the cardiac index (CI). Normal values for O_2 consumption and cardiac output are given in Table 212-3. It should be noted, however, that dividing the O_2 consumption by the arteriovenous O_2 difference across the lungs (estimated pulmonary venous–pulmonary arterial O_2 content) actually measures the *pulmonary* blood flow (Q_p). In patients with an intracardiac left-to-right shunt at the atrial, ventricular, or pulmonary artery levels, this calculated pulmonary blood flow overestimates systemic blood flow by the amount flowing through the shunt. In such cases, calculation of systemic blood flow (Q_s) requires dividing O_2 consumption by the *systemic* arteriovenous O_2 difference, estimated as the systemic arterial blood O_2 content minus the mixed venous blood O_2 content derived from the chamber immediately proximal to the level of the shunt. The Fick method is most dependable when the cardiac output is low and a large arteriovenous oxygen difference can be measured.

Another approach to the measurement of cardiac output during right heart catheterization is the thermodilution technique, in which a thermistor is mounted on the tip of a balloon flotation catheter and positioned in the pulmonary artery. An aliquot (10 mL) of room temperature or chilled intravenous solution is then injected into the vena cava or right atrium via a proximal port on the catheter. The resulting change in temperature at the thermistor is monitored, and the integral of temperature drop at the thermistor is calculated electronically. By conservation of heat, this temperature integral is inversely proportional to the volume flow rate past the thermistor, allowing calculation of the

TABLE 212-3 Normal Values for Hemodynamic Parameters

Pressures (mmHg)	
Systemic arterial	
Peak systolic/end-diastolic	100–140/60–90
Mean	70–105
Left ventricle	
Peak systolic/end-diastolic	100–140/3–12
Left atrium (or pulmonary capillary wedge)	
Mean	2–10
a wave	3–15
v wave	3–15
Pulmonary artery	
Peak systolic/end-diastolic	15–30/4–12
Mean	9–18
Right ventricle	
Peak systolic/end-diastolic	15–30/2–8
Right atrium	
Mean	2–8
a wave	2–10
v wave	2–10
Resistances [(dyn·s)/cm^5]	
Systemic vascular resistance	700–1600
Pulmonary vascular resistance	20–130
Cardiac index [(L/min)/m^2]	2.6–4.2
Oxygen consumption index [(L/min)/m^2]	110–150
Arteriovenous oxygen difference (mL/L)	30–50

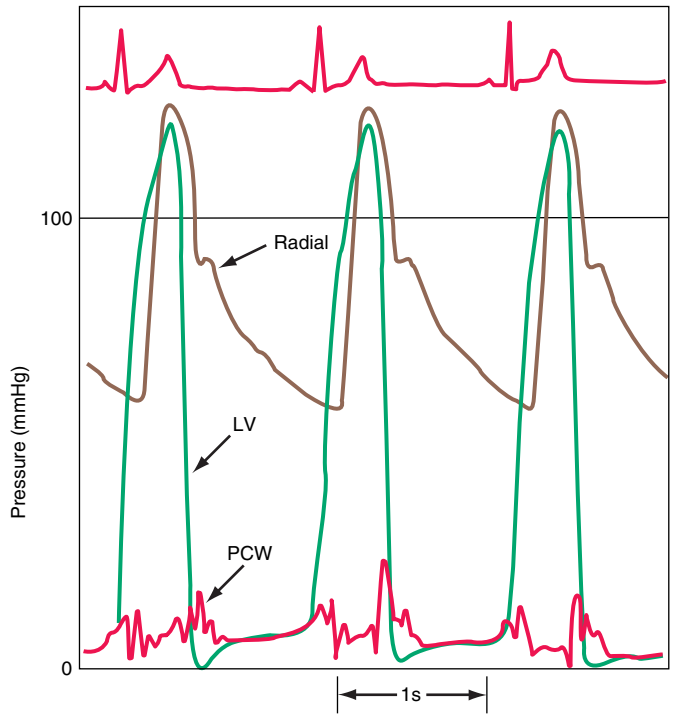

FIGURE 212-1 Left ventricular (LV), radial artery, and pulmonary capillary wedge (PCW) pressures in a patient with normal cardiovascular function. Note the absence of a pressure gradient between the LV and radial artery in systole and between the LV and PCW in diastole.

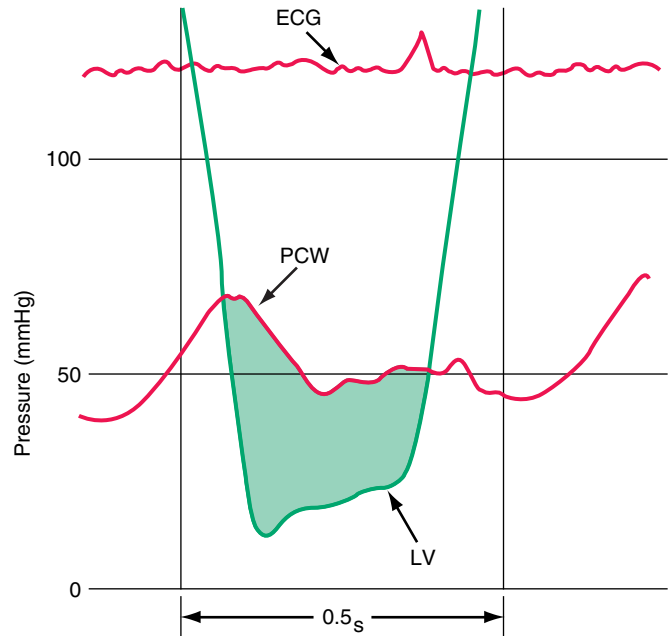

FIGURE 212-2 Pulmonary capillary wedge (PCW) and left ventricular (LV) pressure tracings in a 40-year-old woman with mitral stenosis. This patient also had systemic hypertension and significant elevation of her LV diastolic pressure. *[From BA Carabello, W Grossman, in Grossman's Cardiac Catheterization, Angiography, and Intervention, 6th ed, DS Baim, W Grossman (eds). Baltimore, Lippincott Williams & Wilkins, 2000.]*

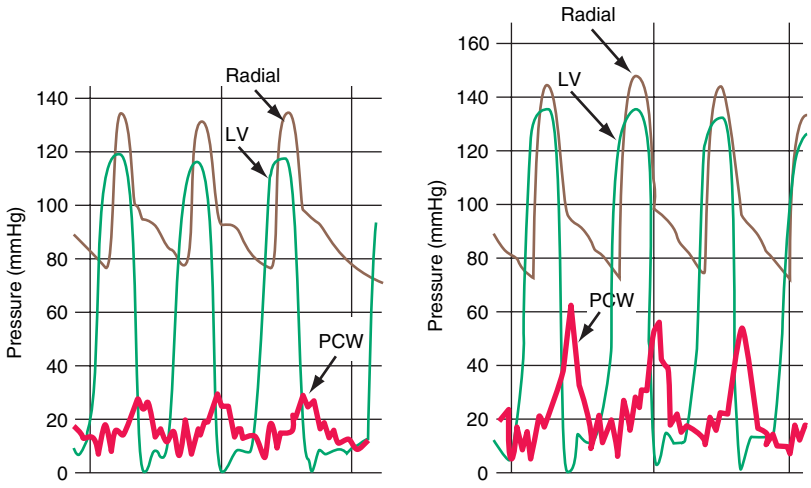

FIGURE 212-3 Hemodynamic findings at rest and during exercise in a patient with mitral regurgitation. Left ventricular (LV), pulmonary capillary wedge (PCW), and radial artery pressure tracings are shown before (*left*) and during (*right*) the sixth minute of supine bicycle exercise. PCW mean pressure and *v* wave increase substantially with exercise. *[From BH Lorell, W Grossman, in Grossman's Cardiac Catheterization, Angiography, and Intervention, 6th ed, DS Baim, W Grossman (eds). Baltimore, Lippincott Williams & Wilkins, 2000.]*

corresponding pulmonary blood flow. In contrast to the Fick method, the indicator-dilution method is least reliable when the cardiac output is low and transit of the cold bolus through the right heart is delayed.

LEFT HEART CATHETERIZATION

Whether performed using the femoral, brachial, or radial approach, the left heart catheter is advanced under fluoroscopic guidance into the central aorta, where pressure is measured and recorded. Next, the catheter is advanced in retrograde fashion across the aortic valve into the left ventricle, where pressure is measured. If a right heart catheter is in place, this is an appropriate time for simultaneous measurement and recording of left heart, right heart, and peripheral arterial pressures together with a determination of cardiac output by either thermodilution or the Fick method. This hemodynamic "snap-shot" allows assessment of possible pressure gradients across the mitral and aortic valves and calculation of systemic and pulmonary vascular resistances. The resistance to blood flow through the systemic vascular bed is

$$SVR = 80(MAP - RA)/SBF$$

where *SVR* is systemic vascular resistance [(dyn·s)/cm^5], *MAP* and *RA* are mean aortic and right atrial pressures (mmHg), 80 is a constant for converting to metric units, and *SBF* is systemic blood flow (L/min). Resistance to blood flow through the pulmonary vascular bed is

$$PVR = 80(PA - PCW \text{ or } LA)/PBF$$

where *PVR* is pulmonary vascular resistance [(dyn·s)/cm^5]; *PA*, *PCW*, and *LA* are pulmonary artery, pulmonary capillary wedge, and left atrial mean pressures, respectively (mmHg); and *PBF* is pulmonary blood flow (L/min). Normal values for pulmonary and systemic vascular resistances are given in Table 212-3.

When valvular stenosis is present, the measurements of the upstream and downstream pressures and flow allow calculation of the valve orifice using the Gorlin formula

$$A = flow/K\sqrt{\Delta P}$$

where A is the valve orifice area (cm^2), *flow* is the blood flow (mL/s) across the stenotic valve; ΔP is the mean pressure gradient (mmHg) during the period of blood flow; and K is a constant (44.3 for the aortic valve and 37.7 for the mitral valve).

In the normal heart, left ventricular and aortic pressures should be essentially equal during systole, while left atrial (pulmonary capillary wedge) and left ventricular pressures should be equal during diastole, as seen in Fig. 212-1. The presence of a systolic pressure gradient between the left ventricle and aorta indicates obstruction at the level of the aortic valve (e.g., calcific *aortic stenosis*) or at subaortic level (e.g., *hypertrophic obstructive cardiomyopathy*). Similarly, the presence of a diastolic pressure gradient between the left atrium (or pulmonary capillary wedge pressure) and the left ventricle generally indicates *mitral stenosis*, although it may also be seen in rare conditions such as cor triatriatum and left atrial myxoma. An example of a large diastolic pressure gradient in a patient with mitral stenosis is seen in Fig. 212-2. As seen in Fig. 212-3, patients with significant mitral regurgitation may have a prominent *v* wave in the pulmonary capillary wedge pressure, which often increases substantially during modest exercise. Severe *aortic regurgitation* produces a widening of the aortic pulse pressure, with equilibration of aortic and left ventricular pressures in diastole (Fig. 212-4). In the presence of valvular heart disease affecting the tricuspid or pulmonic valves, right-sided pressures exhibit characteristic deformities. In patients with severe *tricuspid regurgitation*, the right atrial pressure resembles the right ventricular pressure closely in appearance. Mean right atrial pressure and right ventricular end-diastolic pressure are both elevated in tricuspid regurgitation. In *tricuspid stenosis*, there is a pressure gradient between the right atrium and ventricle during diastole.

In *cardiac tamponade* or *pericardial constriction* (Chap. 222), there is equalization of left and right ventricular diastolic pressures. In pericardial tamponade, diastolic pressures continue to increase gradually throughout diastole, but in constrictive pericarditis ventricular filling ceases shortly after mitral and tricuspid valve opening. This produces an abrupt rise in ventricular diastolic pressure with a mid- and late-ventricular pressure plateau, giving the so-called square root sign (Fig. 212-5).

Congestive heart failure due to myocardial contractile dysfunction is associated with characteristic alterations in the ventricular pressure waveforms seen at cardiac catheterization. Neither the rise nor the decline in isovolumic pressure is as steep as in the normal heart. The reduced slopes of pressure rise and decline are associated with an abbreviated ejection period, giving the left ventricular pressure tracing a triangular appearance (Fig. 212-6). Also, the pressure decline does not continue to zero, so the minimal left ventricular pressure may be elevated. This hemodynamic finding correlates with an increased ventricular end-systolic volume, which is a sign of depressed contractile function of the left ventricular myocardium.

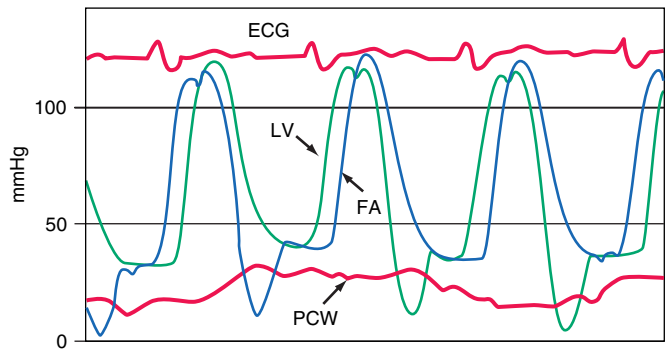

FIGURE 212-4 Severe aortic regurgitation. There is equilibration between the left ventricular (LV) and aortic or femoral artery (FA) pressures in diastole. Also, LV diastolic pressure exceeds pulmonary capillary wedge (PCW) pressure early in diastole, indicating premature closure of the mitral valve (a characteristic feature of severe aortic regurgitation). *[From W Grossman, in Grossman's Cardiac Catheterization, Angiography, and Intervention, 6th ed, DS Baim, W Grossman (eds). Baltimore, Lippincott Williams & Wilkins, 2000.]*

CARDIAC ANGIOGRAPHY

LEFT VENTRICULOGRAPHY

Following the measurement of cardiac pressures, the angiographic portion of the cardiac catheterization usually begins with left ventriculography—the injection of radiographic contrast material directly into the left ventricular cavity. A power injector is used to inject 30 to 45 mL of radiographic contrast material into the left ventricular chamber at a rate of 10 to 12 mL/s. The resulting radiographic images are recorded, and the left ventricular silhouette is defined at end-diastole and end-systole. This permits calculation of the left ventricular chamber volumes and ejection fraction, as well as qualitative assessment of regional wall motion abnormalities. The normal left ventricle ejects 50 to 80% of its end-diastolic volume with each beat; i.e., its *ejection fraction* is 0.50 to 0.80. In adults, normal values for left ventricular volumes are, for end-diastolic volume, 72 ± 15 mL/m^2 (mean ± standard deviation) and, for end-systolic volume, 20 ± 8 mL/m^2. Regional abnormalities of wall motion are illustrated in Fig. 212-7 and include diminished inward motion of a myocardial segment (*hypokinesis*), absence of inward movement of a myocardial segment (*akinesis*), and paradoxical systolic expansion of a regional myocardial segment (*dyskinesis*).

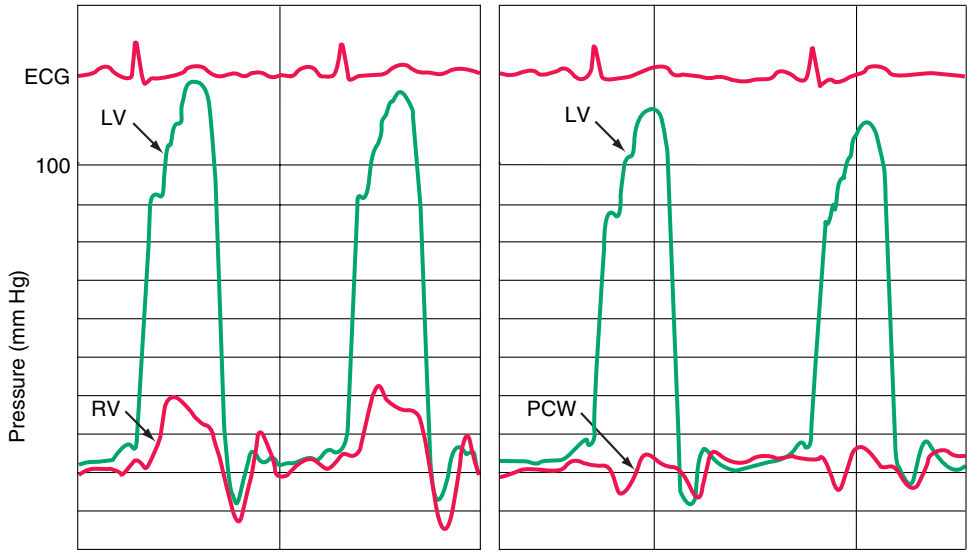

FIGURE 212-5 Left ventricular (LV), right ventricular (RV), and pulmonary capillary wedge (PCW) pressure tracings in a patient with severe constrictive pericarditis. Note the diastolic dip and plateau ("square root sign") pattern for left and right ventricular diastolic pressures (*left*). The wedge pressure (*right*) shows early systolic and early diastolic dips.

Performing left ventriculography in the right anterior oblique projection allows assessment of the mitral and aortic valves. Mitral regurgitation is easily visualized as the leakage of radiographic contrast material back into the left atrium during left ventricular systole. Its severity can be estimated qualitatively using a grading system of 1+ (mild; radiographic contrast material clears with each beat and never opacifies the entire left atrium) to 4+ (severe; opacification of the entire left atrium occurs within one beat, and contrast material can be seen refluxing into the pulmonary veins).

On occasion, left ventriculography may also be performed in the *left* anterior oblique projection to evaluate contraction of the septal or lateral walls or to detect abnormal communications such as ventricular septal defect (Chap. 218). In the most common form of hypertrophic cardiomyopathy (idiopathic hypertrophic subaortic stenosis; Chap. 221), left ventriculography in this projection shows anterior motion of the anterior leaflet of the mitral valve during systole and bulging of the interventricular septum into the left ventricular cavity, especially in the subaortic region. Mural thrombi within the left ventricular chamber may be well visualized during left ventriculography; they occur most commonly in the left ventricular apex.

It should be pointed out, however, that many of these findings could

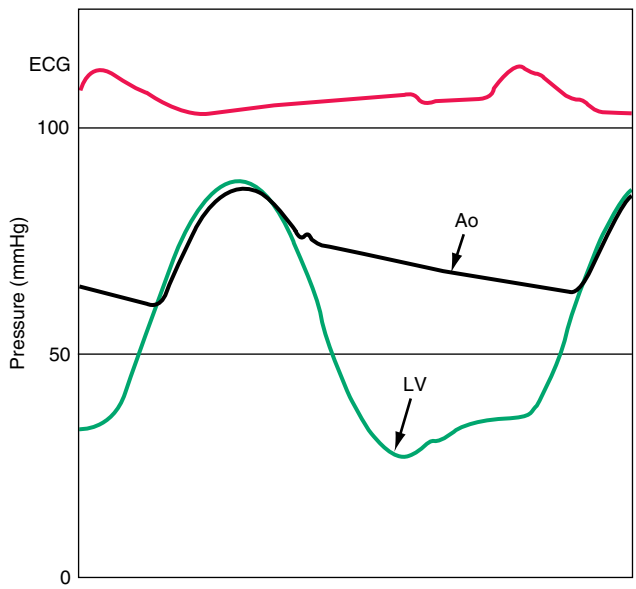

FIGURE 212-6 Left ventricular (LV) and aortic (Ao) pressures in a patient with advanced dilated cardiomyopathy. Marked slowing of the rates of LV pressure rise and fall (impairment of contractility and relaxation) give the LV pressure pulse a triangular appearance. Also, the minimal value for LV diastolic pressure is markedly elevated, suggesting an increased end-systolic volume and a reduced LV ejection fraction. *[From W Grossman, in Grossman's Cardiac Catheterization, Angiography, and Intervention, 6th ed, DS Baim, W Grossman (eds). Baltimore, Lippincott Williams & Wilkins, 2000.]*

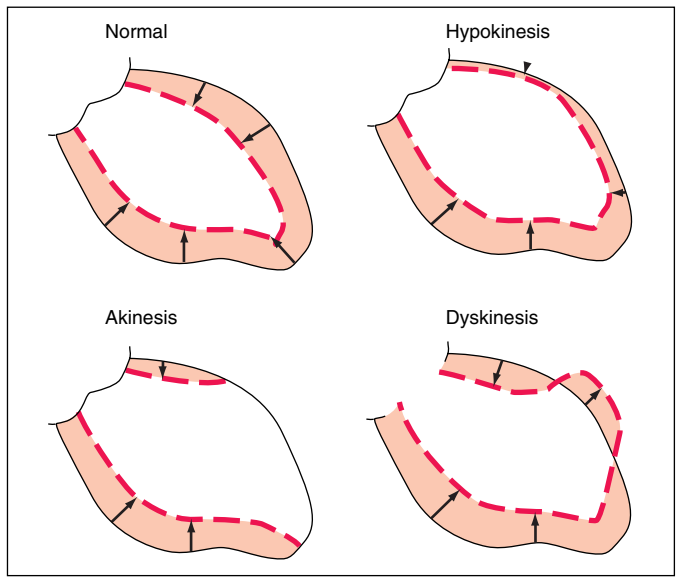

FIGURE 212-7 Diagrammatic representation of end-diastolic (*solid line*) and end-systolic (*dashed line*) silhouettes of left ventricular cineangiograms in various forms of localized wall motion disorder in patients with coronary heart disease. Normal wall motion is symmetric; a patient with *hypokinesis* exhibits reduced contraction, seen here over the anterior and apical surfaces; a patient with *akinesis* exhibits absent wall motion, seen here over the anteroapical surface; a patient with *dyskinesis* exhibits paradoxic bulging of a small portion of the anterior wall with systole.

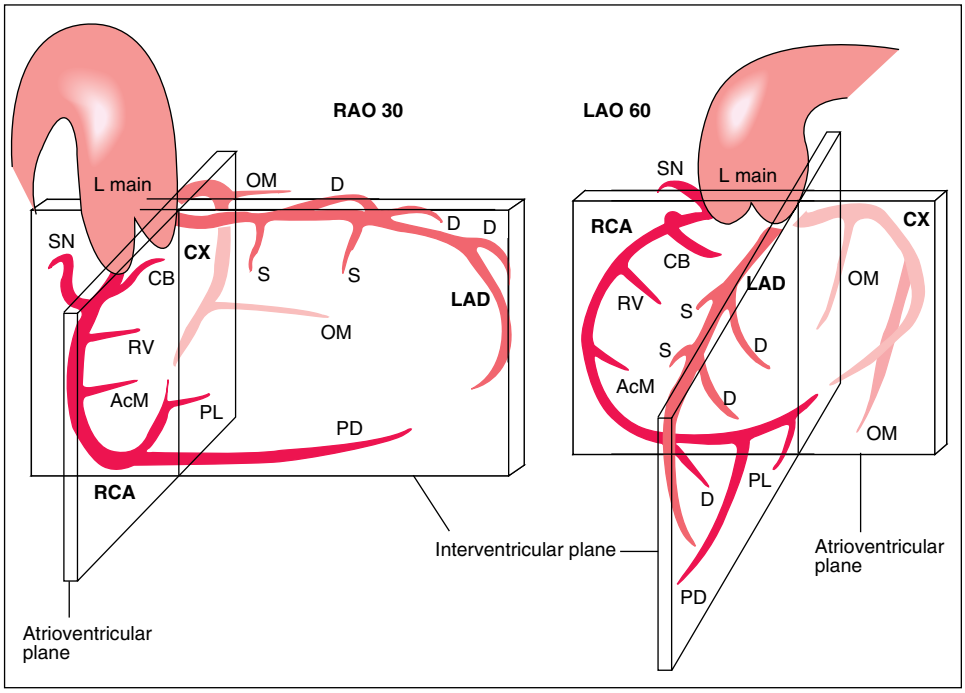

FIGURE 212-8 Representation of coronary anatomy relative to the interventricular and atrioventricular valve planes. Coronary branches are indicated as L Main (left main), LAD (left anterior descending), D (diagonal), S (septal), CX (circumflex), OM (obtuse marginal), RCA (right coronary artery), CB (conus branch), SN (sinus node), AcM (acute marginal), PD (posterior descending), PL (posterolateral left ventricular). RAO, right anterior oblique, LAO, left anterior oblique. *[From DS Baim, W Grossman, in Grossman's Cardiac Catheterization, Angiography, and Intervention, 6th ed, DS Baim, W Grossman (eds). Baltimore, Lippincott Williams & Wilkins, 2000.]*

also be evaluated using either cardiac echo or cardiac magnetic resonance imaging. This allows avoidance of left ventriculography in patients where a reduction in total contrast load is desired.

AORTOGRAPHY

Rapid injection of radiographic contrast material into the ascending aorta allows detection of abnormalities that involve the aorta and aortic valve. When suspected clinically, aortography permits detection and qualitative assessment of the severity of abnormalities such as aortic regurgitation, which is graded using a 1+ to 4+ scale, as for mitral regurgitation. Abnormal communications between the aorta and right side of the heart, such as a patent ductus arteriosus or ruptured aneurysm of a sinus of Valsalva, may be visualized. Aortography can permit identification of aortic aneurysm and of aortic dissection (Chap. 231) by visualizing an intimal flap within the aortic lumen.

CORONARY ANGIOGRAPHY

This common procedure involves the selective injection of a radiographic contrast agent into the coronary arteries. Placement of the catheter tip into the right and left coronary arteries is carried out under fluoroscopic guidance, and contrast agent is injected by hand during recording of the radiographic image. Each coronary artery is usually viewed in several projections to permit assessment of the severity of stenosis and to minimize the overlap of adjacent vessels. In addition to the detection of coronary artery stenoses, coronary angiography evaluates the rapidity of coronary flow, the blush of capillary filling in the myocardium, the presence of congenital abnormalities of the coronary circulation, and patency of any coronary artery bypass grafts. Examples of normal and abnormal coronary anatomy are shown in Figs. 212-8 and 212-9. The location, severity, and morphology of the stenotic lesions can be analyzed in great detail, and the resulting information is essential to planning either bypass surgery or catheter-based intervention (Fig. 212-10). This is usually done by visual estimation of percent diameter stenosis of each lesion relative to the "uninvolved" adjacent reference segment, with stenosis $> 50\%$ taken as being hemodynamically significant (that is capable of interfering with maximal increases in perfusion of the subserved myocardial territory during stress).

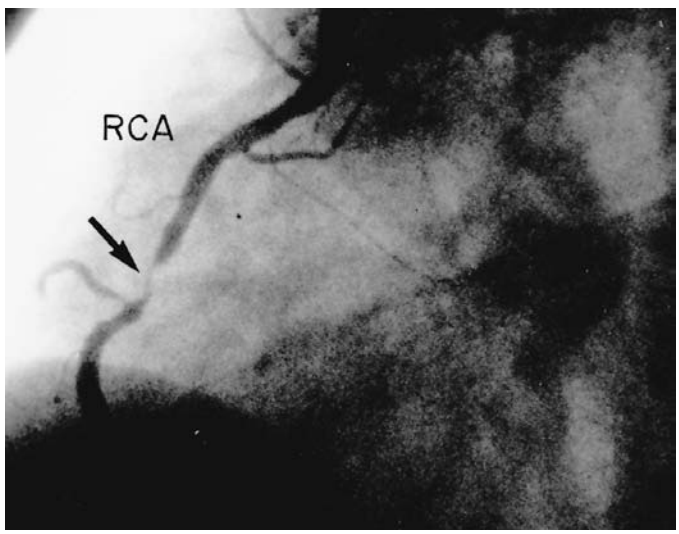

FIGURE 212-9 Coronary angiogram showing a right coronary artery (RCA) with a severe (95%) stenosis at its midpoint (*arrow*).

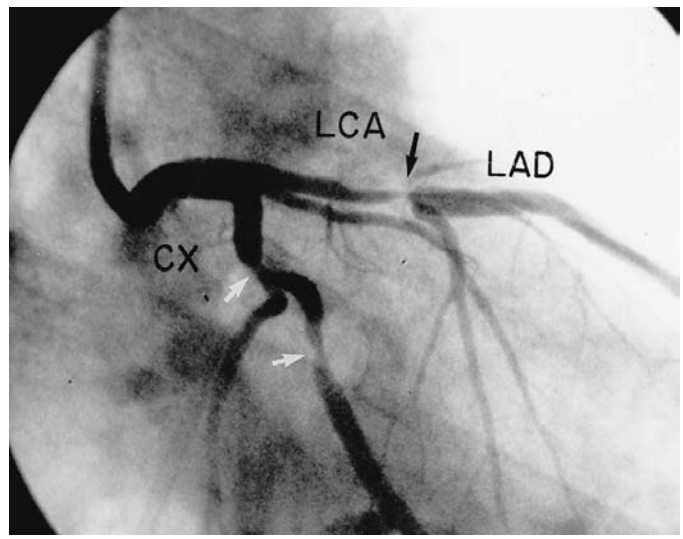

FIGURE 212-10 Coronary angiogram of a left coronary artery (LCA) with a tight stenosis in the proximal left anterior descending (LAD) artery (*black arrow*) immediately prior to the origin of a large septal branch. The circumflex artery (CX) has two moderately severe stenoses (*white arrows*).

POSTPROCEDURE CARE

The average diagnostic cardiac catheterization procedure takes roughly 30 min. Intravenous heparin (2000 to 3000 IU) may be given at the time of catheter insertion and reversed with intravenous protamine at the conclusion, but increasingly diagnostic catheterization is being performed without anticoagulant administration. The vascular sheaths are removed at the end of the procedure, and hemostasis is achieved by applying local pressure over the puncture site for 10 to 15 min, followed by a 2- to 4-h period of bed rest before ambulation and discharge. Alternatively, a variety of devices are now available for sealing the arterial puncture site, to allow a shorter period of bed rest and earlier ambulation. Most patients with suitable anatomy, however, now undergo a catheter-based intervention during the same procedure as the diagnostic cardiac catheterization, entailing an overnight hospital stay (Chap. 229).

213 THE BRADYARRHYTHMIAS: DISORDERS OF SINUS NODE FUNCTION AND AV CONDUCTION DISTURBANCES

Mark E. Josephson, Peter Zimetbaum

ANATOMY OF THE CONDUCTING SYSTEM Under normal conditions, the pacemaker function of the heart resides in the sinoatrial (SA) node, which lies at the junction of the right atrium and superior vena cava. The SA node is approximately 1.5 cm long and 2 to 3 mm wide and is supplied by the sinus node artery, which arises from either the right coronary artery (60%) or the left circumflex coronary artery (40%). Once the impulse exits the sinus node and perinodal tissue, it traverses the atrium until it reaches the atrioventricular (AV) node. The blood supply of the AV node is derived from the posterior descending coronary artery (90%). The AV node lies at the base of the interatrial septum just above the tricuspid annulus and anterior to the coronary sinus. The electrophysiologic properties of the AV node result in slow conduction, which is responsible for the normal delay in AV conduction, i.e., the PR interval.

The bundle of His emerges from the AV node, enters the fibrous skeleton of the heart, and courses anteriorly across the membranous interventricular septum. It has a dual blood supply from the AV nodal artery and a branch of the anterior descending coronary artery. The branching (distal) portion of the bundle of His gives rise to a broad sheet of fibers that course over the left side of the interventricular septum to form the left bundle branch and a narrow cable-like structure on the right side that forms the right bundle branch. The arborization of both the right and left bundle branches gives rise to the distal His-Purkinje system, which ultimately extends throughout the endocardium of the right and left ventricles.

The SA node, atrium, and AV node are significantly influenced by autonomic tone. Vagal influences depress automaticity of the SA node, depress conduction, and prolong refractoriness in the tissue surrounding the SA node; inhomogeneously decrease atrial refractoriness and slow atrial conduction; and prolong AV nodal conduction and refractoriness. Sympathetic influences exert the opposite effect.

ELECTROPHYSIOLOGIC PRINCIPLES

In the resting state, the interior of most cardiac cells, with the exception of the SA and AV nodes, is approximately −80 to −90 mV, negative with respect to a reference extracellular electrode. The resting membrane potential is determined primarily by the concentration gradient of potassium across the cell membrane. Activation of cardiac cells results from movement of ions across the cell membrane, causing a transient depolarization known as the *action potential*. The ionic species responsible for the action potential varies among the cardiac tissues, and the configuration of the action potential is therefore unique to each tissue (Fig. 213-1).

The action potential of the His-Purkinje system has five phases (Fig. 213-2). The rapid depolarizing current (phase 0) is mainly determined by an influx of sodium into myocardial cells followed by a secondary (slower) influx of calcium, which produces a slow inward current. The repolarization phases of the action potential (phases 1 to 3) are primarily related to outward flux of potassium. The resting membrane potential is phase 4. Recent studies have demonstrated hetero-

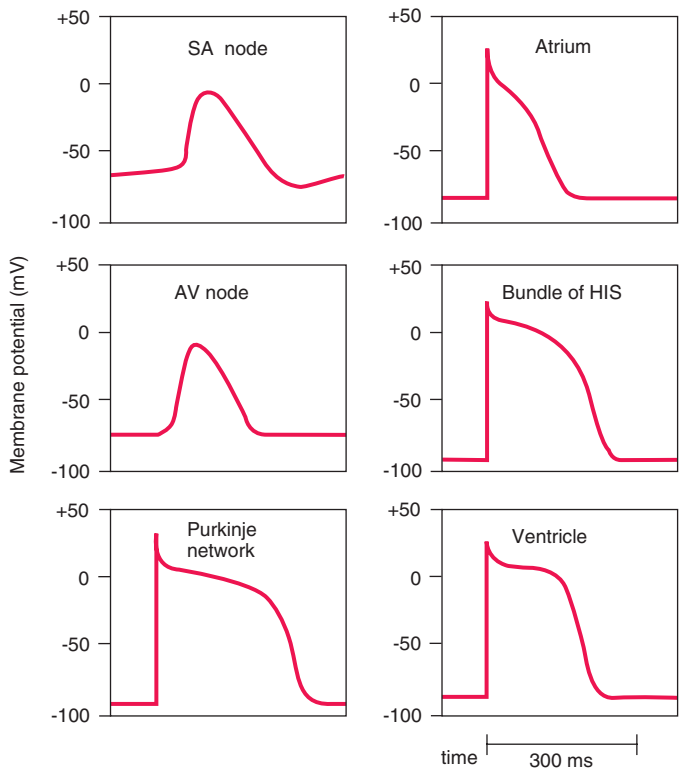

FIGURE 213-1 Action potential configurations in different regions of the mammalian heart. *(From AM Katz, Physiology of the Heart, 2d ed. New York, Raven, 1992, with permission.)*

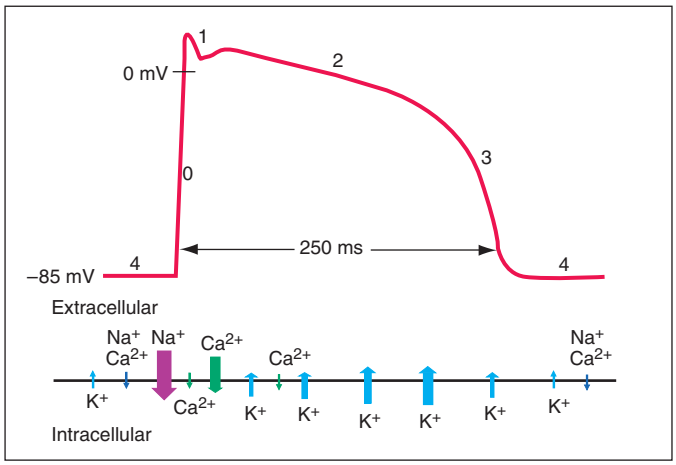

FIGURE 213-2 Schematic representation of the action potential in normal ventricle depicting the direction, strength, and period of flow of the ionic currents underlying the action potential. The arrow's direction and size indicate whether current is inward- or outward-directed and the approximate current strength of the ion identified at the arrow's base. The horizontal position of the arrow corresponds to the same moment in the time course of action potential (see text). The five phases of the action potential are indicated by the numerals placed along the waveform. *(From Ten Eick et al, Prog Cardiovasc Dis 24:157, 1981, with permission.)*

geneity of action potentials in the epicardium, mid-myocardium, and endocardium as well as between right and left ventricles. These differences are due to different ion currents in different layers.

The bradyarrhythmias result from abnormalities either of impulse formation, i.e., automaticity, or of conduction. *Automaticity*, which is normally observed in the sinus node, the specialized fibers of the His-Purkinje system, and some specialized atrial fibers, is the property of a cardiac cell that causes it to depolarize spontaneously during phase 4 of the action potential, leading to the generation of an impulse. To exhibit automaticity, the resting membrane potential must decrease spontaneously until threshold potential is reached and an all-or-none regenerative response occurs. The ionic currents producing spontaneous diastolic depolarization appear to involve the inward currents of sodium and/or calcium and a decreasing outward potassium current.

The velocity of *conduction*, i.e., impulse propagation through cardiac tissues, depends on the magnitude of inward current, which is directly related to the rate of rise and amplitude of phase 0 of the action potential. The more positive the threshold potential and the slower the rate of depolarization toward threshold, the lower is the rate of rise and amplitude of phase 0 of the action potential and the slower is the conduction velocity. Disease states or drugs may result in lower rates of rise of phase 0 at any given membrane potential. Passive membrane properties (e.g., intracellular resistance and intercellular coupling) can also affect impulse propagation. Propagation is more rapid parallel to fiber orientation than transverse to it, a property termed *anisotropic conduction*.

Refractoriness is a property of cardiac cells that defines the period of recovery that cells require after being discharged before they can be reexcited by a stimulus. The *absolute refractory period* is defined by that portion of the action potential during which no stimulus, regardless of its strength, can evoke another response. The *effective refractory period* is that part of the action potential during which a stimulus can evoke only a local, nonpropagated response. The *relative refractory period* extends from the end of the effective refractory period to the time that the tissue is fully recovered. During this time, a stimulus of greater than threshold strength is required to evoke a response, which is propagated more slowly than normal. In the normal His-Purkinje system or ventricular myocytes, excitability is recovered following completion of the action potential, and evoked responses have characteristics similar to the spontaneous normal response. In the AV node, recovery of excitability occurs well after completion of the action potential.

INTRACARDIAC RECORDINGS OF THE SPECIALIZED CONDUCTING SYSTEM Electrode catheters allow the recording of activation of portions of the specialized conducting system, including the bundle of His. To obtain a recording from the bundle of His, the electrode catheter is positioned across the tricuspid valve (Fig. 213-3). The interval from local atrial depolarization in the His bundle recording to the onset of depolarization of the His bundle deflection is called the *AH interval* (normal = 60 to 125 ms) and represents an indirect method of assessing AV nodal conduction time. The interval from the beginning of the His bundle deflection to the earliest onset of ventricular activation, as measured from any of multiple-surface electrocardiogram (ECG) leads or the intracardiac ventricular electrogram, is called the *HV interval* (normal = 35 to 55 ms) and represents conduction time through the His-Purkinje system. Electrode catheters can be positioned in the area of the sinus node to record high right atrial activity. Left atrial activity may be recorded directly via a catheter placed across a patent foramen ovale or indirectly using a catheter inserted into the coronary sinus. The atrial activation sequence may be "mapped," and sites of intra- and interatrial conduction abnormalities may be ascertained.

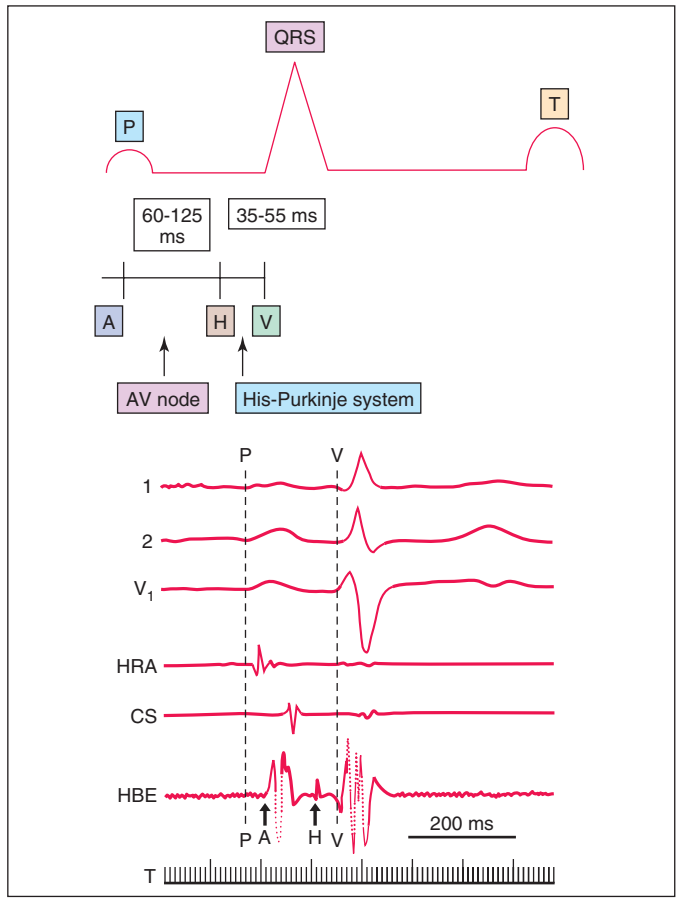

FIGURE 213-3 (*Top*) Schema relating the surface electrocardiogram with intracardiac conduction. The normal AV nodal conduction time (AH interval) is 60–125 ms and normal His-Purkinje conduction time (HV interval) is 35–55 ms. Surface ECG leads I, II, and V_1 are displayed with intracardiac ECGs from the high right atrium (HRA), left atrium from the coronary sinus (CS), and AV junction to obtain a His bundle electrogram (HBE). T, time lines; A, atrial activation; H, His bundle activation; V, ventricular activation. Atrial activation begins in the HRA and spreads inferiorly to the low atrial septum, as recorded in the HBE, and the left atrium, as recorded in the CS. The AH and HV intervals represent AV nodal and His-Purkinje conduction times, respectively. (*Bottom*) Normal intracardiac recording. Normal atrioventricular conduction. Vertical lines at bottom = 0.10 s. *(From ME Josephson, Clinical Cardiac Electrophysiology: Techniques and Interpretations, 3d ed. Philadelphia, Lippincott Williams & Wilkins 2002, with permission.)*

SINUS NODE DYSFUNCTION

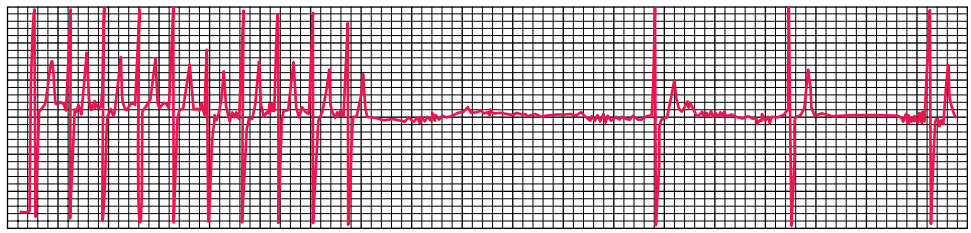

FIGURE 213-4 Tachycardia-bradycardia syndrome. Rhythm strip of ECG lead II showing spontaneous cessation of supraventricular tachycardia followed by a 6-s pause prior to resumption of sinus activity. The patient was asymptomatic during supraventricular tachycardia, but the sinus pause caused severe light-headedness.

The SA node is normally the dominant cardiac pacemaker because its intrinsic discharge rate is the highest of all potential cardiac pacemakers. Its responsiveness to alterations in autonomic nervous system tone is responsible for the normal acceleration of heart rate during exercise and the slowing that occurs during rest and sleep. Increases in sinus rate normally result from an increase in parasympathetic tone acting via muscarinic receptors and/or an increase in sympathetic tone acting via β-adrenergic receptors. Slowing of the heart rate is normally due to opposite alterations. In adults, the normal sinus rate under basal conditions is 60 to 100 beats/min. *Sinus bradycardia* is said to exist when the sinus rate is <60 beats/min, and *sinus tachycardia* when it is >100 beats/min. However, there is wide variation among individuals, and rates <60 beats/min do not necessarily indicate pathologic states. For example, trained athletes often exhibit resting rates <50 beats/min due to increases in vagal tone. Normal elderly individuals may also show marked sinus bradycardia at rest.

ETIOLOGY SA node dysfunction is most often found in the elderly as an isolated phenomenon. Although interruption of the blood supply to the SA node may produce dysfunction, the correlation between obstruction of the sinus node artery and clinical evidence of SA node dysfunction is poor. Specific disease states associated with SA node dysfunction include senile amyloidosis and other conditions associated with infiltration of the atrial myocardium. Sinus bradycardia is associated with hypothyroidism, advanced liver disease, hypothermia, typhoid fever, and brucellosis; it occurs during episodes of hypervagotonia (vasovagal syncope), severe hypoxia, hypercapnia, acidemia, and acute hypertension. However, most cases of SA node dysfunction are due to idiopathic degeneration or are secondary to pharmacologic agents.

MANIFESTATIONS Although marked and/or inappropriate (≤50 beats/min) sinus bradycardia may cause fatigue and other symptoms due to inadequate cardiac output, more commonly sinus node dysfunction is manifest as paroxysmal dizziness, presyncope, or syncope. These symptoms usually result from abrupt, prolonged sinus pauses caused by failure of sinus impulse formation (sinus arrest) or block of conduction of sinus impulses to the surrounding atrial tissue (sinus exit block). In either case, the ECG manifestation is a prolonged period (3 s) of atrial asystole. In some patients, SA node dysfunction is accompanied by abnormalities in AV conduction. In addition to the absence of atrial activity, lower pacemakers fail to emerge during the sinus pauses, resulting in periods of ventricular asystole and syncope. Occasionally, SA node dysfunction is manifested by an inadequate acceleration in sinus rate in response to a stress such as exercise or fever. In some patients, SA node dysfunction may become manifest only in the presence of certain cardioactive drugs: cardiac glycosides, β-adrenergic blocking drugs, calcium channel blockers, amiodarone, and other antiarrhythmic agents. These agents, which do not usually cause sinus node dysfunction in normal individuals, may unmask evidence of sinus node dysfunction in susceptible individuals.

The *sick sinus syndrome* refers to a combination of symptoms (dizziness, confusion, fatigue, syncope, and congestive heart failure) caused by SA node dysfunction and manifested by marked sinus bradycardia, sinoatrial block, or sinus arrest. Because these symptoms are nonspecific, and because ECG manifestations of sinus node dysfunction are often intermittent, it may be difficult to prove that such symptoms are actually caused by SA node dysfunction.

Atrial tachyarrhythmias such as atrial fibrillation, atrial flutter, or atrial tachycardia may be accompanied by SA node dysfunction. The *bradycardia-tachycardia syndrome* refers to paroxysmal atrial arrhythmia that upon termination is followed by prolonged sinus pauses (Fig. 213-4) or in which there are alternating periods of tachyarrhythmia and bradyarrhythmia. Syncope or presyncope may result from failure of the sinus node to recover function following suppression of automaticity by atrial tachyarrhythmia.

DIAGNOSIS *First-degree sinoatrial exit block* denotes a prolonged conduction time from the SA node to the surrounding atrial tissue. It cannot be recognized on a standard (surface) ECG but requires invasive intracardiac recordings, which can detect this condition indirectly, by measuring the sinus response to atrial premature beats, or directly, by recording SA node electrograms. *Second-degree sinoatrial exit block* denotes the intermittent failure of conduction of sinus impulses to the surrounding atrial tissue; it is manifested as the intermittent absence of P waves (Fig. 213-5). *Third-degree*, or *complete, sinoatrial block* is characterized by a lack of atrial activity or by the presence of an ectopic subsidiary atrial pacemaker. On the standard ECG it cannot be distinguished from sinus arrest, but direct intracardiac recordings of SA node activity permit this distinction. The bradycardia-tachycardia syndrome is manifested on the standard ECG as tachyarrhythmias (Fig. 213-4). Most often these are atrial flutter or fibrillation, although any tachycardia during which the atria are activated may cause overdrive suppression of the sinus node, resulting in clinical appearance of this syndrome.

The most important step in the diagnosis of sick sinus syndrome is to correlate symptoms with ECG evidence of SA node dysfunction. While ambulatory ECG (Holter) monitoring remains a mainstay in evaluating sinus node function, most episodes of syncope are paroxysmal and unpredictable. Single and even multiple 24-h Holter monitor recordings may fail to include a symptomatic episode. Caution must be taken in interpreting the Holter monitor results. For instance, a pause during sleep is often a normal finding associated with heightened vagal tone. This should not be interpreted as sinus node dysfunction requiring pacemaker implantation. Continuous-loop event records represent a more specific diagnostic tool. These devices may be worn for prolonged periods of time and allow close correlation between electrocardiographic findings and symptoms. They do require the patient's ability to activate the monitor at the time of symptoms. More recently, an implantable event recorder, which can be interrogated like a pacemaker, has been developed for patients with rare events.

The response to carotid sinus pressure and pharmacologic autonomic "denervation" of the heart may be helpful. Carotid sinus pressure can be particularly useful in patients in whom paroxysmal dizziness or syncope is compatible with the hypersensitive carotid si-

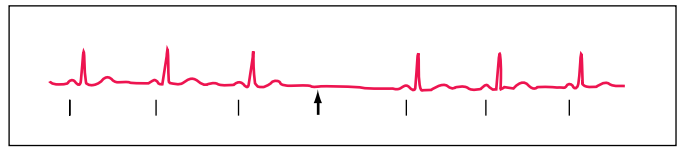

FIGURE 213-5 Second-degree sinoatrial exit block. Surface ECG denoting abrupt absence of P wave during sinus rhythm. Prior to the pause, the sinus rate is regular. The interval of the pause is exactly twice the basal sinus cycle length. The arrow marks the appropriate location for the absent P wave. SA exit block can be 2:1 as above or longer, as shown in Fig. 213-6.

nus syndrome (Chap. 20). In such patients, the response can be dramatic, and sinus pauses in excess of 5 s may occur. Although pauses in excess of 3 s are considered abnormal, in elderly, asymptomatic patients such pauses are common and do not require therapy. This is a major limitation of the use of carotid sinus pressure as a diagnostic test in the elderly. The other noninvasive test of SA node function involves the use of pharmacologic agents to manipulate the autonomic nervous system and assess the balance of parasympathetic and sympathetic activity on the sinus node. Physiologic or pharmacologic maneuvers that are vagomimetic (Valsalva maneuver or phenylephrine-induced hypertension), vagolytic (atropine), sympathomimetic (isoproterenol or hypotension by nitroprusside), or sympatholytic (β-adrenergic blocking agents) can be utilized, singly and in combination. These studies are designed to test the response of the sinus node to autonomic stimulation and inhibition and thereby characterize the status of autonomic regulation of the sinus node. Abnormalities of the autonomic control of sinus function are particularly common in patients in whom asymptomatic sinus bradycardia is documented.

Intrinsic Heart Rate This is a manifestation of the primary activity of the SA node, and its determination requires chemical autonomic blockade of the heart with a combination of atropine and a beta blocker. Normal values of intrinsic heart rate (in beats per minute) are calculated by the formula $118.1 - (0.57 \times \text{age})$. The use of autonomic blockade can separate patients with asymptomatic sinus bradycardia into a group with primary sinus node dysfunction (slow intrinsic heart rate) and a group with autonomic imbalance (normal intrinsic heart rate). Autonomic blockade is particularly useful when combined with invasive assessment of sinus node function. Autonomic blockade may depress conduction in patients with intrinsic disease of the conduction system and should be carried out only in a setting where arrhythmias can be monitored and treated rapidly.

EVALUATION The invasive electrophysiologic investigation of SA node dysfunction should be undertaken in patients who have had symptoms compatible with SA node dysfunction and in whom no documentation of the arrhythmia responsible for these symptoms has been obtained by prolonged monitoring. Asymptomatic patients with sinus bradycardia need not be tested, since no therapy is indicated. Similarly, symptomatic patients with ECG documentation of asystole, sinoatrial block or arrest, or the bradycardia-tachycardia syndrome do not require electrophysiologic tests for diagnosis. However, in symptomatic patients without documentation of an arrhythmia, electrophysiologic assessment of SA node function can yield information that may be used to guide appropriate therapy. The tools most commonly employed are the sinus node recovery time (a response to overdrive atrial pacing) and sinoatrial conduction time calculated indirectly by response to atrial premature complexes or recorded directly by a sinus node electrogram.

The results of electrophysiologic tests of sinus node function must be interpreted with caution. SA node dysfunction coexists frequently with other disorders such as AV conduction disturbances, which may cause symptoms such as syncope. Electrophysiologic evaluation of patients with symptoms such as undiagnosed syncope must not stop with the demonstration of abnormalities of SA node dysfunction or carotid sinus hypersensitivity. Instead, complete evaluation, including His bundle recordings and programmed atrial and ventricular stimulation (Chap. 214), is necessary to search for additional electrophysiologic abnormalities that could be responsible for symptoms.

TREATMENT

Permanent pacemakers (p. 1339) are the mainstay of therapy for patients with symptomatic SA node dysfunction. Patients with intermittent paroxysms of bradycardia or sinus arrest and with the cardioinhibitory form of the hypersensitive carotid sinus syndrome are usually adequately treated by demand ventricular pacemakers. These devices are reliable, relatively inexpensive, and suffice to prevent episodic symptoms due to abrupt bradycardia. Although an atrial demand pacemaker should be adequate for patients with SA node dysfunction, the frequent accompaniment of dysfunction in other portions of the cardiac conduction system mandates placement of a pacemaker also capable of ventricular pacing. Whether dual-chamber pacing offers any advantages to ventricular pacing in such circumstances remains uncertain. Patients with symptomatic chronic sinus bradycardia or frequent prolonged episodes of sinus node dysfunction do better with dual-chamber pacemakers that preserve the normal AV activation sequence. Recent studies suggest that AV sequential pacing may also be useful in preventing atrial fibrillation, an important component of the bradycardia-tachycardia syndrome, and stroke, a known complication of atrial fibrillation.

AV CONDUCTION DISTURBANCES

The specialized cardiac conducting system normally ensures synchronous conduction of each sinus impulse from the atria to the ventricles. Abnormalities of conduction of the sinus impulse to the ventricles may portend the development of heart block, which can ultimately lead to syncope or cardiac arrest. In order to evaluate the clinical significance of conduction abnormalities, the physician must assess (1) the site of conduction disturbance, (2) the risk of progression to complete block, and (3) the probability that a subsidiary escape rhythm arising distal to the site of block will be electrophysiologically and hemodynamically stable. This latter point is perhaps the most important, since the rate and stability of the escape pacemaker determine what symptoms result from heart block. The escape pacemaker following AV nodal block is usually in the His bundle, which generally has a stable rate of 40 to 60 beats/min and is associated with a QRS complex of normal duration (in the absence of a preexisting intraventricular conduction defect). This contrasts with escape rhythms arising in the distal His-Purkinje system, which have lower intrinsic rates (25 to 45 beats/min), manifest wide QRS complexes with prolonged duration, and are unstable. Thus, the most important issue is to assess the risk of infra- or intra-His block (which always mandates a pacemaker) or AV nodal block in which the frequency of the escape pacemaker is not sufficient to meet hemodynamic requirements (Table 213-1). Although prolonged QRS complexes are invariable when the distal His-Purkinje pacemakers form the escape mechanism, wide QRS complexes can also coexist with AV nodal block and a His bundle rhythm. Therefore, QRS morphology alone may not be adequate to identify the site of block.

ETIOLOGY The AV node is supplied by the parasympathetic and sympathetic nervous systems and is sensitive to variations in autonomic tone. Chronic slowing of AV nodal conduction may be seen in highly trained athletes who have hypervagotonia at rest. A variety of diseases and drugs can also influence AV nodal conduction. These include acute processes such as myocardial infarction (particularly inferior); coronary spasm (usually of the right coronary artery); digitalis intoxication; excesses of beta and/or calcium blockers; acute infections such as viral myocarditis, acute rheumatic fever, infectious mononucleosis; and miscellaneous disorders such as Lyme disease, sarcoidosis, amyloidosis, and neoplasms, particularly cardiac mesotheliomas. AV nodal block may also be congenital.

TABLE 213-1 *Atrioventricular Conduction Evaluation*

1. Atrial activation times: Measurement of intraatrial conduction times. Prolonged activation times may be associated with atrial flutter or fibrillation.
2. Measurement of AH and HV intervals: Prolongation of AH interval (>125 ms) or prolongation of the HV interval (>55 ms) may help localize the site of delay.
3. Incremental atrial pacing: To determine the cycle length at which block occurs in the AV node and/or His-Purkinje system. Block below the His bundle at rates of <150 beats per minute portends the development of infra-His block.

Two degenerative diseases are commonly responsible for damage to the specialized conducting system and produce AV block usually associated with bundle branch block (Chap. 210). In *Lev's disease*, there are calcification and sclerosis of the fibrous cardiac skeleton, which frequently involve the aortic and mitral valves, the central fibrous body, and the summit of the ventricular septum. *Lenegre's disease* appears to be a primary sclerodegenerative disease of the conducting system with no involvement of the myocardium or the fibrous skeleton of the heart. These two diseases are probably the most common causes of isolated chronic heart block in adults. Hypertension and aortic and/or mitral stenosis are specific disorders that either accelerate the degeneration of the conducting system or have a direct effect by calcification and fibrosis involving the conducting system.

First-degree AV block, more properly termed *prolonged AV conduction*, is classically characterized by a PR interval >0.20 s, but use of this value may be misleading in terms of clinical significance. Since the PR interval is determined by atrial, AV nodal, and His-Purkinje activation, delay in any one or more of these structures can contribute to a prolonged PR interval. In the presence of a QRS complex of normal duration, a PR interval >0.24 s almost invariably is due to a delay within the AV node. If the QRS is prolonged, delays may be present at any of the levels mentioned above. Delay within the His-Purkinje system is always accompanied by a prolonged QRS duration but can occur with a relatively normal PR interval (Fig. 213-6). However, as indicated below, it is only with intracardiac recordings that the exact site of delay can be determined.

Second-degree heart block (intermittent AV block) is present when some atrial impulses fail to conduct to the ventricles. Mobitz type I second-degree AV block (AV Wenckebach block) is characterized by progressive PR interval prolongation prior to block of an atrial impulse (Fig. 213-7*A*). The pause that follows is less than fully compensatory (i.e., is less than two normal sinus intervals), and the PR interval of the first conducted impulse is shorter than the last conducted atrial impulse prior to the blocked P wave. Usually the difference between the longest and shortest PR intervals exceeds 100 ms. This type of block is almost always localized to the AV node and associated with a normal QRS duration, although bundle branch block may be present. It is seen most often as a transient abnormality with inferior wall infarction or with drug intoxication, particularly digitalis, beta blockers, and occasionally calcium channel antagonists. This type of block can also be observed in normal individuals with heightened vagal tone. Although Mobitz type I block can progress to complete heart block, this is uncommon, except in the setting of acute inferior wall myocardial infarction. Even when it does, however, the heart block is usually well tolerated because the escape pacemaker usually arises in the proximal His bundle and provides a stable rhythm. As a result, the presence of Mobitz type I second-degree AV block rarely mandates aggressive therapy. Therapeutic decisions depend on the ventricular response and the symptoms of the patient. If the ventricular rate is adequate and the patient is asymptomatic, observation is sufficient.

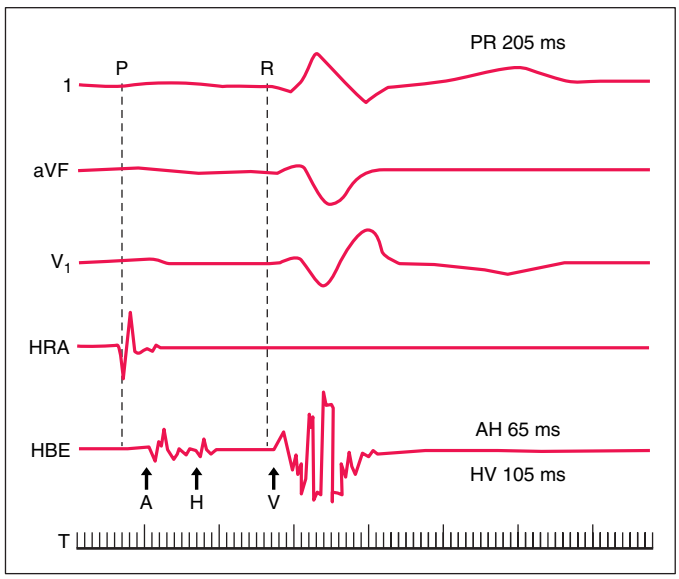

FIGURE 213-6 Example of marked His-Purkinje system disease with a relatively normal PR interval. Surface leads I, aVF, and V_1 are shown with electrograms from the high right atrium (HRA), His bundle electrogram (HBE), and time lines (T). The QRS shows right bundle branch block and left anterior hemiblock; the PR interval is minimally elevated at 205 ms, but the HV interval exceeds 100 ms. Such a prolonged HV interval mandates a pacemaker.

In Mobitz type II second-degree AV block, conduction fails suddenly and unexpectedly without a preceding change in PR intervals (Fig. 213-7*B*). It is generally due to disease of the His-Purkinje system and is most often associated with a prolonged QRS duration. When Mobitz type II block occurs with a normal QRS duration, an intra-His site of block should be expected. It is important to recognize this type of block because it has a high incidence of progression to complete heart block with an unstable, slow, lower escape pacemaker. Therefore, pacemaker implantation is necessary in this condition. Mobitz type II block may occur in the setting of anteroseptal infarction or in the primary or secondary sclerodegenerative or calcific disorders of the fibrous skeleton of the heart. In so-called high-degree AV block there are periods of two or more consecutively blocked P waves, but intermittent conduction can be demonstrated. Block is usually in the His-Purkinje system, but simultaneous block in the AV node may also be present. Regardless of the site of origin of the escape rhythm, if it is slow and the patient is symptomatic, a cardiac pacemaker is mandatory.

Third-degree AV block is present when no atrial impulse propagates to the ventricles. If the QRS complex of the escape rhythm is of normal duration, occurs at a rate of 40 to 55 beats/min, and increases with atropine or exercise, AV nodal block is probable. Congenital complete AV block is usually localized to the AV node. If the block is within the His bundle, the escape pacemaker is usually less responsive to these perturbations. If the escape rhythm of the QRS is wide and associated with rates ≤40 beats/min, block is usually localized in, or distal to, the His bundle and mandates a pacemaker, since the escape rhythm in this setting is unreliable (Fig. 213-8). Some patients with infra-His bundle block are capable of retrograde conduction. In such patients, a "pacemaker syndrome" (see below) may develop if a simple ventricular pacemaker is used. Dual-chamber pacemakers eliminate this potential problem.

AV DISSOCIATION AV dissociation exists whenever the atria and ventricles are under the control of two separate pacemakers and, while present in complete AV block, can occur in the absence of a primary conduction disturbance. AV dissociation unrelated to heart block may occur under two circumstances: First, it may develop with an AV junctional rhythm in response to severe sinus bradycardia. When the sinus rate and the escape rate are similar and the P waves occur just before, in, or following the QRS complex, isorhythmic AV dissociation is said to be present. Treatment usually consists of removal of the offending cause of sinus bradycardia (i.e., discontinuation of digitalis, beta blockers, or calcium antagonists), accelerating the sinus node by vagolytic agents, or insertion of a pacemaker if the escape rhythm is slow and results in symptoms. Second, AV dissociation can be caused by an enhanced lower (junctional or ventricular) pacemaker that competes with normal sinus rhythm and frequently exceeds it. This has been called *interference AV dissociation* because the rapid lower pacemaker results in bombardment of the AV node in a retrograde fashion, rendering it refractory to the normal sinus impulses. Thus failure of antegrade conduction is a physiologic response in this circumstance. Interference dissociation commonly occurs during ventricular tachycardia, accelerated junctional or ventricular rhythms seen with digitalis intoxication, myocardial ischemia and/or infarction, or local irritation following cardiac surgery. The accelerated rhythm should be treated

FIGURE 213-7 *A*. Mobitz type I second-degree AV block. Intracardiac recordings demonstrate that the PR prolongation (320, 615 ms) is localized to the AV node (AH 240, 535 ms, respectively). HBE, His bundle electrogram; A, atrium; H, His; V, ventricle. Time lines (T) = 100 ms. *B*. Mobitz type II second-degree AV block. Intracardiac recordings document block below the His bundle. During sinus rhythm right bundle branch block is present. AV nodal conduction is normal (AH, 85 ms), but His-Purkinje conduction is markedly prolonged (HV, 95 ms). The third sinus P wave suddenly blocks below the recorded His deflection without any preceeding change in AV conduction. *(From ME Josephson, Clinical Cardiac Electrophysiology: Techniques and Interpretations, 3d ed. Philadelphia, Lippincott Williams & Wilkins 2002, with permission.)*

with either antiarrhythmic drugs (Chap. 214), removal of an offending drug, or correction of the metabolic abnormality or ischemia.

INTRACARDIAC ELECTROCARDIOGRAPHIC RECORDINGS IN DIAGNOSIS AND MANAGEMENT The main therapeutic decision in patients with AV conduction disturbance is whether or not a permanent pacemaker is required, and a number of circumstances exist in which His bundle electrocardiography can be a useful diagnostic tool upon which to base this decision. It is unquestionable that patients with symptomatic second- or third-degree AV block should be paced, and therefore these patients do not require electrophysiologic study. However, intracardiac ECG recordings can be useful in at least the following four groups of patients:

1. *Patients with syncope and bundle branch or bifascicular block without documentation of AV block*. In such patients, the demonstration of marked infra-His bundle conduction disturbances, i.e., a prolonged HV interval (>100 ms), may usually be taken as an indication of the need for the insertion of the permanent pacemaker. Complete electrophysiologic evaluation, including atrial and ventricular programmed stimulation, is indicated to help identify other possible cardiac etiologies for the syncope. Since the incidence of significant advanced AV block is low in asymptomatic patients who have bifascicular block, electrophysiologic evaluation or permanent pacemakers are not cost-effective. In this group, observation appears most reasonable.

2. *Patients with 2:1 AV conduction*. Intracardiac recordings are necessary to ascertain the site of the conduction disturbance because the typical ECG features of Mobitz type I or Mobitz type II block cannot be discerned during a 2:1 pattern of AV conduction on the surface ECG. Intracardiac recordings may demonstrate that AV nodal block, intra-His bundle block, infra-His bundle block, or combinations of block may be responsible (Figs. 213-7 and 213-8). A surface ECG finding that suggests an infra-His bundle lesion is the presence of alternating bundle branch block associated with changing PR intervals. Intracardiac recordings in such patients confirm that the block is almost always in the His-Purkinje system. Increasing block with exercise or following atropine suggests intra- or infra-His block (Table 213-2). The finding of infra- or intra-His bundle block in patients with asymptomatic second-degree AV block mandates pacemaker therapy because of the high likelihood of the development of symptomatic high-grade AV block and syncope.

3. *Patients with Wenckebach block in the presence of bundle branch block*. This situation, particularly when the maximal change in PR interval is 50 ms, can suggest intra- or infra-His Wenckebach block, in which case a pacemaker is mandated. Intracardiac recordings are necessary to make this diagnosis.

4. *Asymptomatic patients with third-degree AV block*. In such patients, electrophysiologic studies may be useful in assessing the stability of the junctional pacemaker. Pacing is indicated when the His bundle escape pacemaker is shown to be unstable by an inadequate response to exercise, atropine, or isoproterenol or by a prolonged junctional recovery time following ventricular pacing.

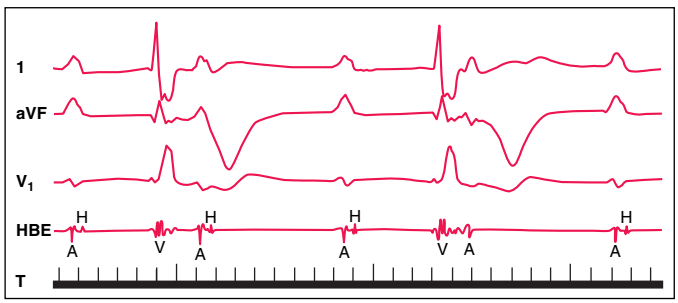

FIGURE 213-8 Third-degree AV block. The figure shows surface leads 1, aVF, V_1, and an intracardiac His bundle recording (HBE). Complete heart block is evident on the surface leads. The intracardiac recording demonstrates an absence of QRS deflection (V) after a His bundle (H) spike. This indicates block below the His bundle. Note that following the second QRS complex (V), there is an atrial (A) deflection indicating retrograde conduction. Retrograde conduction is often present when block is in the His-Purkinje system but is virtually never present when block is in the AV node. *(From ME Josephson, Clinical Cardiac Electrophysiology: Techniques and Interpretations, 3d ed. Philadelphia, Lippincott Williams & Wilkins, 2002, with permission.)*

GENETIC CONSIDERATIONS A number of congenital and familial syndromes involving the cardiac conduction system have been described. An example of a congenital condition that is transmitted but not genetic is congenital complete heart block associated with maternal systemic lupus erythematosus. This disorder is associated with maternal IgG autoantibodies to several ribonucleoproteins that are transplacentally transmitted to the fetus and damage the fetal AV node. The fetal conduction disease is generally clinically evident by the second trimester and is associated with significant fetal mortality and neonatal requirement of cardiac pacing.

The embryonic development of the cardiac septa and conduction system occur together, and clinical disorders have been described, including the *Holt-Oram syndrome*, an autosomal dominant disorder including upper limb dysplasia and atrial septal defect, often with conduction disturbances in the AV node. Studies of families with a high incidence of congenital heart disease, including ostium secundum atrial septal defect and conduction disorders in the AV node, have

TABLE 213-2 *Site of 2:1 Atrioventricular Block*

Characteristic	*Observation—Site of Block*
1. QRS width	BBB—anywhere Normal QRS—in AV node or His bundle
2. PR interval of conducted P wave	>0.30 s—in AV node ≤0.16 s—in HPS or His bundle[a]
3. Atropine or exercise	Improve conduction—in AV node Worsen conduction—in HPS or His bundle[a]
4. CSP	Worsen conduction—in AV node Improve conduction—in HPS or His bundle[a]
5. Retrograde conduction	Present—in HPS or His bundle[a] Absent—may be anywhere

[a] Use of a pacemaker is indicated.
Note: BBB, bundle branch block; HPS, His-Purkinje system; CSP, carotid sinus pressure.

identified the gene NKX2-5 on chromosome 5q35 as important in the regulation of septation and in the development and function of the AV node. A familial syndrome of progressive complete heart block has also long been recognized. The gene for this disorder has been mapped to a region on chromosome 19q13. Familial disorders of SA node function have also been described, but specific details of abnormal genetic sites are not available.

TREATMENT

Pharmacologic Therapy Pharmacologic therapy is usually reserved for acute situations. Atropine (0.5 to 2.0 mg intravenously) and isoproterenol (1 to 4 μg/min intravenously) are useful in increasing heart rate and decreasing symptoms in patients with sinus bradycardia or AV block localized to the AV node. They have an insignificant effect on lower pacemakers. In patients with neurocardiac syncope, beta blockers and disopyramide have been suggested as methods to depress left ventricular function and decrease mechanoreceptor-related reflexes. Mineralocorticoids, midodrine, ephedrine, and theophylline have also been reported to be of benefit to occasional patients. Unfortunately, no controlled study has shown that any of these pharmacologic modalities works in a predictable fashion in all patients. Recently, serotonin-reuptake inhibitors have been shown to benefit some patients. Further work on delineating different mechanisms in different patient groups may allow us to apply pharmacologic agents more appropriately. Long-term therapy of bradyarrhythmias is best accomplished by pacemakers.

Pacemakers External energy sources can be used to stimulate the heart when disorders in impulse formation and/or transmission lead to symptomatic bradyarrhythmias. Pacer stimuli can be applied to the atria and/or ventricles. Indications for pacemaker insertion are listed in the guidelines summarized on p. 1340.

TEMPORARY PACING This is usually instituted to provide immediate stabilization prior to permanent pacemaker placement or to provide pacemaker support when a bradycardia is precipitated by what is presumed to be a transient event such as ischemia or drug toxicity. Temporary pacing is usually achieved by the transvenous insertion of an electrode catheter with the catheter positioned in the right ventricular apex and attached to an external generator. This procedure is associated with a small risk of cardiac perforation, infection at the insertion site, and thromboembolism; the risk of the latter two complications increases markedly if the pacing wire is left in place for >48 h. The development of an entirely external transthoracic cardiac pacing system may preclude the need for transvenous pacing in selected patients. However, occasional failure of ventricular capture and significant discomfort related to the large current required for effective transthoracic ventricular stimulation preclude the uniform use of this approach.

PERMANENT PACING This mode of pacing is instituted for persistent or intermittent symptomatic bradycardia not related to a self-limiting precipitating factor or for documented infranodal second- or third-degree AV block. Permanent pacing leads are usually inserted transvenously through the subclavian or cephalic vein with the leads positioned in the right atrial appendage for atrial pacing and the right ventricular apex for ventricular pacing. The leads are then attached to the pulse generator, which is inserted into a subcutaneous pocket below the clavicle. Epicardial lead placement is used when (1) transvenous access cannot be obtained; (2) the chest is already open, i.e., in the course of a cardiac operation; and (3) adequate endocardial lead placement cannot be achieved. Most pacemaker generators are powered by lithium batteries. The life expectancy of the generator is related to (1) voltage output required for capture, (2) requirement for incessant or intermittent pacing, and (3) number of cardiac chambers paced. Life expectancy of the simple ventricular demand pacemaker can exceed 10 years.

PACING CODE A code consisting of three to five letters has been developed for describing pacemaker type and function (Table 213-3). The first letter indicates the chamber(s) paced and is designated *V* for ventricular pacing, *A* for atrial pacing, or *D* for dual-chamber (both atrial and ventricular) pacing. The second letter indicates the chamber in which electrical activity is sensed and is also indicated by *A*, *V*, or *D*. An additional designation, *O*, has been used when pacemaker discharge is not dependent on a sensed electrical activity. The third letter refers to the response to a sensed electric signal. The letter *O* represents no response to an underlying electric signal, usually related to the absence of associated sensing function; *I* represents inhibition of pacing function; *T* represents triggering of pacing function; and *D* indicates a dual response, i.e., spontaneous atrial and ventricular activity inhibiting atrial and ventricular pacing and atrial activity triggering a ventricular response. Additional fourth and fifth letters of the pacing code have been recommended to indicate whether the pacemaker is programmable and has rate modulation (fourth) and whether special antitachycardia functions are available (i.e., antitachycardia pacing, *T*, and delivery of high- or low-energy shocks). In the fourth category, *M* represents multiprogrammability and *R* represents rate response ("physiologic") pacing.

It follows from the described code that the standard VVIR (ventricular demand pacemaker) paces the ventricle, senses the ventricle, is inhibited by sensed spontaneous ventricular activity, and has rate modulation, while the DDDR pulse generator is capable of sensing and pacing both the atria and ventricles and has a dual response to the sensed atrial and ventricular activity as described above (Fig. 213-9). Both pacemakers have rate modulation (*R*). "Physiologic" pacemakers use sensors (muscular activity, respiratory rate, temperature, O_2 saturation, QT interval, etc.) as methods to allow the pacemaker to increase the heart rate in response to physiologic demands, i.e., exercise. These pacemakers are essential when chronotropic incompetence is present and an increase in heart rate is required to enhance physiologic performance. Studies have shown that such "physiologic" pacemakers improve exercise tolerance and relieve symptoms to a greater degree than fixed-rate pacemakers.

Selection of the appropriate pacemaker and pacing mode depends on the clinical condition and the type of bradyarrhythmia being treated. The two most common pacing mode selections are DDD and VVI. DDD provides AV sequential pacing, which is ideally suited for the relatively young and active patient who has intact sinus node function or intermittent dysfunction and high-grade persistent or intermittent AV block. The DDD mode will allow for physiologic atrial sensed and ventricular paced rates and improve exercise tolerance. AV synchrony and dual-chamber pacing may also be desirable in patients with borderline hemodynamic reserve who are dependent on atrial contribution to cardiac output and in those patients who develop the pacemaker syndrome (see below) in response to ventricular demand pacing.

Rate-responsive DDD (i.e., DDDR) pacing is indicated when chronotropic incompetence is present in a patient who requires AV synchrony. The DDD pacing mode is contraindicated in chronic atrial

SUMMARY OF GUIDELINES FOR PERMANENT PACING (2002 NEW OR REVISED RECOMMENDATIONS)

Acquired AV Block in Adults

Class I
1. Third-degree and advanced second-degree AV block, associated with any one of the following:
   a. Symptomatic bradycardia
   b. Arrhythmias and other conditions that require drugs that result in symptomatic bradycardia
   c. Documented periods of asystole ≥ 3.0 s or any escape rate less than 40 beats/min
   d. After catheter ablation of the AV junction
   e. Postoperative AV block that is not expected to resolve
   f. Neuromuscular diseases

Class IIa
1. Asymptomatic third-degree block with average awake ventricular rates of ≥ 40 beats/min
2. Asymptomatic type II second-degree AV block with a narrow QRS
3. Asymptomatic type I second-degree AV block at intra- or infra-His levels
4. First- or second-degree AV block with symptoms similar to those of pacemaker syndrome

Class IIb
1. Marked first-degree AV block (> 0.3 s) in patients with LV dysfunction in whom a shorter AV interval results in hemodynamic improvement, presumably by decreasing left atrial filling pressure

Class III
1. Intermittent third-degree AV block
2. Asymptomatic type I second-degree AV block at the AV node
3. AV block expected to resolve

Chronic Bifascicular and Trifascicular Block

Class I
1. Intermittent third-degree AV block
2. Type II second-degree AV block
3. Alternating bundle-branch block

Class IIa
1. Syncope when other likely causes have been excluded
2. Incidental finding at EP study of HV interval ≥ 100 ms
3. Incidental finding at EP study

Class IIb
1. Neuromuscular diseases

Class III
1. Fascicular block without AV block or symptoms
2. Fascicular block with first-degree AV block without symptoms

After Acute Myocardial Infarction

Class I
1. Persistent second-degree AV block in the His-Purkinje system with bilateral bundle branch block or third-degree AV block
2. Transient advanced (second- or third-degree) infranodal AV block and associated bundle branch block
3. Persistent and symptomatic second- or third-degree AV block

Class IIb
1. Persistent second- or third-degree AV nodal block

Class III
1. Transient AV block in the absence of intraventricular conduction defects
2. Transient AV block in the presence of isolated left anterior fascicular block
3. Acquired left anterior fascicular block in absence of AV block
4. Persistent first-degree AV block in the presence of old bundle branch block

Sinus Node Dysfunction

Class I
1. With documented symptomatic bradycardia
2. Symptomatic chronotropic incompetence

Class IIa
1. With heart rate < 40 beats/min not associated with symptoms
2. With syncope of unexplained origin

Class IIb
1. With minimal symptoms

Class III
1. Asymptomatic patients
2. In patients with symptoms documented as not associated with a slow heart rate
3. With symptomatic bradycardia due to nonessential drug therapy

Pacemakers That Automatically Detect and Pace to Terminate Tachycardias

Class I
1. Symptomatic recurrent supraventricular tachycardia that is reducibly terminated by pacing after drugs and catheter ablation failure
2. Symptomatic recurrent sustained VT as part of an automatic defibrillator system

Pacing Recommendations to Prevent Tachycardia

Class I
1. Sustained pause-dependent VT

Class IIa
1. High-risk patients with congenital long-QT syndrome

Class IIb
1. AV reentrant or AV node reentrant supraventricular tachycardia not responsive to therapy
2. Prevention of symptomatic, drug-refractory, recurrent atrial fibrillation

Hypersensitive Carotid Sinus Syndrome and Neurocardiogenic Syncope

Class I
1. Recurrent syncope caused by carotid sinus stimulation
2. Minimal carotid sinus pressure induces ventricular asystole of >3 s duration in the absence of any medication that depresses the sinus node or AV conduction

Class IIa
1. Recurrent syncope without clear, provocative events and with a hypersensitive cardioinhibitory response
2. Syncope of unexplained origin when major abnormalities of sinus node function or AV conduction are discovered or provoked in EP studies
3. Significantly symptomatic and recurrent neurocardiogenic syncope associated with bradycardia documented spontaneously or at the time of tilt-table testing

Class IIb
1. Neurally mediated syncope with significant bradycardia reproduced by a head-up tilt

Class III
1. Hyperactive cardioinhibitory response to carotid sinus stimulation in the absence of symptoms
2. Recurrent syncope, lightheadedness, or dizziness in the absence of a hyperactive cardioinhibitory response

Note: Class I: Evidence that procedure/treatment is indicated; Class IIa: Conflicting evidence but weight of evidence in favor; Class IIb: Efficacy less well established; Class III: Evidence that procedure/treatment is not effective; EP: electrophysiologic.

fibrillation or flutter, because rapid and irregular ventricular pacing will occur to the upper rate limit. In some cases this will produce a more rapid ventricular rate than the patient's own rate in the absence of a pacemaker. DDD pacemakers must either automatically switch (i.e., mode-switching function) or be reprogrammed to the VVI mode. Almost all such pacemakers are now combined with some form of rate responsiveness so that when the device functions in the VVI mode, it also will respond to physiologic demands (VVIR).

Chronotropic insufficiency (i.e., the inability of the sinus rate to accelerate) is a contraindication for a DDD pacemaker, since such a pacemaker will act as a "fixed-rate" pacemaker at the programmed lower rate. In these situations, a rate-adaptive or "physiologic" pacemaker is indicated (VVIR or DDDR). In patients with impaired sinus node function or chronic atrial fibrillation, a sensor-driven, rate-adaptive pacemaker must be implanted. As mentioned earlier, these pacemakers automatically adjust ventricular pacing rates to a sensed indicator of exertion. The DDD pacing mode may also be contraindicated in patients with intermittent or persistent ventriculoatrial conduction, who may develop pacemaker-mediated tachycardia (see below).

Specific pacemaker programming is often effective for the management of vasovagal syncope. These algorithms result in rapid pacing (≥100 beats/min) following the detection of an abrupt and significant drop in sinus rates. Biventricular pacing is a new therapy for class 3

TABLE 213-3 *The NASPE/BPEG Generic Pacemaker Code*

and 4 heart failure with QRS prolongation (Chap. 216). This technique involves the addition of a lead placed in the coronary sinus to pace the posterolateral aspect of the left ventricle. The synchronized activation of the lateral (coronary sinus lead) and septal (right ventricular lead) aspects of the left ventricle results in improved hemodynamic function in some patients.

PROGRAMMABILITY OF PACEMAKERS This allows for modification of pacing function after implantation and for adaptation to changes in clinical needs. Pacemaker programming is accomplished by activation of the programming head positioned over the implanted pulse generator after making the desired changes in programmable parameters (Table 213-3). A radio frequency system is routinely used to communicate the program to the pacemaker. A high degree of sophistication is required to recognize the presence and causes of pacemaker malfunction and their treatment.

COMPLICATIONS Adverse effects of permanent pacing are usually associated with failure or malfunction of the pacing system. These problems are usually secondary to over- or undersensing, output failure, and/or lead fracture or displacement. Two other problems may occur. The *pacemaker syndrome* consists of fatigue, dizziness, syncope, and distressing pulsations in the neck and chest and can be associated with adverse hemodynamic effects. The pathophysiologic contributors to the pacemaker syndrome include (1) loss of atrial contribution to ventricular systole; (2) vasodepressor reflex initiated by cannon *a* waves, which are caused by atrial contractions against a closed tricuspid valve and observed in the jugular venous pulse (Chap. 209); and (3) systemic and pulmonary venous regurgitation due to atrial contraction against a closed AV valve. The symptoms associated with the pacemaker syndrome can be prevented by maintaining AV synchrony by dual-chamber pacing or, in the case of a ventricular demand pacemaker, by programming an escape rate 15 to 20 beats/min below that of the paced rate (i.e., hysteresis). As a result of this programming, sinus activity and thus atrial contraction will be less likely to occur at the same time as ventricular pacing and ventricular contraction. The second major problem peculiar to dual-chamber pacemakers is the development of *pacemaker-mediated tachycardia*. In this instance, retrograde depolarization of the atria, resulting from a premature ventricular depolarization or a paced ventricular complex, is sensed and leads to subsequent triggering of ventricular pacing. This, in turn, can result in repetition of the phenomenon of ventriculoatrial conduction with the development of an endless-loop, pacemaker-mediated tachycardia. It may be corrected by reprogramming the atrial refractory period.

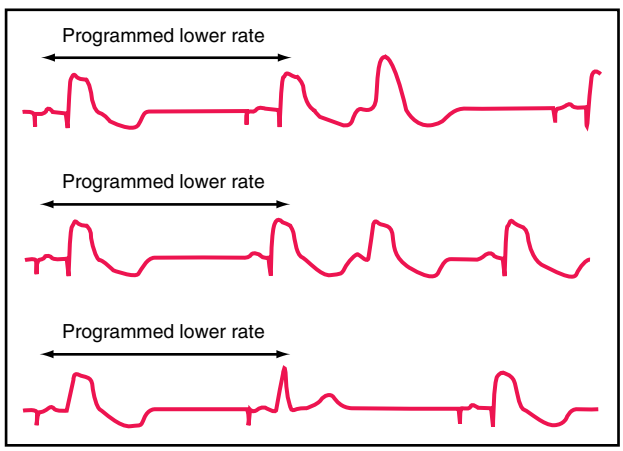

FIGURE 213-9 Normally functioning DDD pacemaker. All three panels show a lead II rhythm strip at 50 mm/s. The programmed lower rate is approximately 55 beats/min. (*Top*) AV sequential pacing with a paced AV interval of 160 ms is shown for the first two complexes. A ventricular premature complex occurs and is sensed, resetting the cycle. (*Middle*) The first beat is AV paced, but spontaneous sinus P waves and atrial premature complex trigger a ventricular paced complex with a sensed P to QRS of 120 ms. (*Bottom*) After the first AV paced complex, a paced atrial complex conducts to the ventricle with a PR of 120 ms, inhibiting the ventricular pacemaker.

214 THE TACHYARRHYTHMIAS

Mark E. Josephson, Peter Zimetbaum

MECHANISMS OF TACHYARRHYTHMIAS

Tachyarrhythmias may be divided into disorders of impulse propagation and disorders of impulse formation.

REENTRY Disorders of impulse propagation (reentry) are generally considered to be the most common mechanism of sustained paroxysmal tachyarrhythmia. The requirements for initiating reentry include (1) electrophysiologic inhomogeneity (i.e., differences in conduction and/or refractoriness) in two or more regions of the heart connected with each other to form a potentially closed loop; (2) unidirectional block in one pathway; (3) slow conduction over an alternative pathway, allowing time for the initially blocked pathway to recover excitability; and (4) reexcitation of the initially blocked pathway to complete a loop of activation (Fig. 214-1). Repetitive circulation of the impulse over this loop can produce a sustained tachyarrhythmia. While anatomic obstacles may underlie reentry and provide an inexcitable center around which the impulse can circulate, they are not essential. Reentrant arrhythmias can be reproducibly initiated and terminated by premature complexes and rapid stimulation. The response of these arrhythmias to stimulation can help distinguish them from arrhythmias caused by triggered activity.

ENHANCED AUTOMATICITY Disorders of impulse formation can be subdivided into tachyarrhythmias caused by enhanced automaticity and those caused by triggered activity. In addition to the sinus node, automatic pacemaker activity can be observed in specialized atrial fibers, fibers of the atrioventricular (AV) junction, and Purkinje fibers (Chap. 213). Myocardial cells do not normally possess pacemaker activity. Enhancement of normal automaticity in latent pacemaker fibers or the development of abnormal automaticity due to partial depolarization of the resting membrane occurs as a consequence of a variety of pathophysiologic states, which include (1) increased endogenous or exogenous catecholamines, (2) electrolyte disturbances (e.g., hypokalemia), (3) hypoxia or ischemia, (4) mechanical effects (e.g., stretch), and (5) drugs (e.g., digitalis). Tachycardia caused by automaticity cannot be started or stopped by pacing.

TRIGGERED ACTIVITY Rhythms due to triggered activity are events that do not occur spontaneously but require a change in cardiac electrical frequency as a trigger. Triggered activity may be caused by early afterdepolarizations, which occur during phases 2 and 3 of the action potential, or delayed afterdepolarizations, which occur following completion of phase 3 of the action potential (Fig. 213-2). Triggered activity has been observed in atrial, ventricular, and His-Purkinje tissue under conditions such as increased local catecholamine concentration, hypercalcemia, and digitalis intoxication (delayed afterdepolarizations) or during bradycardia, hypokalemia, or other situations prolonging action potential duration (early afterdepolarizations). All of these conditions produce an accumulation of intracellular calcium. With increasing amplitude of the afterdepolarizations, threshold can be reached and repetitive activity produced. The exact role of triggered activity in spontaneous clinical arrhythmias is unknown, but tachyarrhythmias associated with digitalis intoxication, accelerated idioventricular rhythm in acute infarction and/or reperfusion, and exercise-induced ventricular tachycardia (VT) are believed to be caused by triggered activity due to delayed afterdepolarizations. *Torsades de pointes* ("twisting of the points"; polymorphic VT associated with long QT intervals) may be caused by triggered activity due to early afterdepolarizations, although reentry may also be operative.

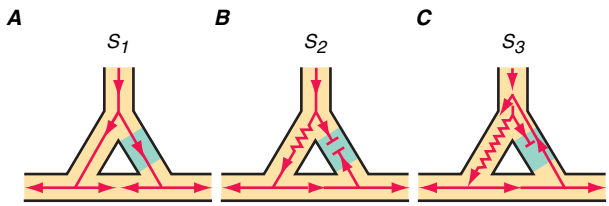

FIGURE 214-1 Schema of reentry. Y branching of the Purkinje system to ventricular muscle is shown in panels *A* through *C*. The right limb (*blue*) of the Purkinje system has a longer refractory period than the left. *A*. During a slow stimulated rate (S_1), conduction proceeds normally over both Purkinje fibers, resulting in collision in the ventricular muscle. *B*. An early premature stimulus (S_2) results in block in the Purkinje fiber on the right and slow conduction down the left. The impulse conducts through the ventricle and attempts to reenter the initial site of block but fails because this site has not fully recovered excitability. *C*. An earlier stimulus (S_3) again results in block on the left. The resulting slower propagation down the left fiber provides enough time for the initial site of block to recur and allows the impulse to conduct through it to produce a reentrant circuit.

The use of electrophysiologic studies, i.e., intracardiac recordings and programmed stimulation, has greatly expanded the understanding of the mechanisms of tachyarrhythmias. In addition to helping diagnose arrhythmias, these techniques may be of value in determining the most appropriate types of therapy because they allow the physician to observe the hemodynamic and symptomatic consequences of the arrhythmia in the presence or absence of therapy. Electrophysiologic studies of tachycardias require the positioning of multiple electrode catheters at critical areas within the heart. These electrodes must be capable of both stimulating and recording from multiple sites in the atria and/or ventricles.

PREMATURE COMPLEXES

ATRIAL PREMATURE COMPLEXES (APCs) APCs can be found on 24-h Holter monitoring in over 60% of normal adults. APCs are usually asymptomatic and benign, although at times they may be associated with palpitations. In susceptible patients, they can initiate paroxysmal supraventricular tachycardias (PSVTs). APCs may originate from any location in either atrium, and they are recognized on the electrocardiogram (ECG) as early P waves with a morphology that differs from the sinus P wave (Fig. 214-2). While APCs usually conduct to the ventricles when they occur late in the cardiac cycle, early APCs may reach the AV conduction system while it is still in its relative refractory period, resulting in a conduction delay manifested by a prolonged PR interval following the premature P wave (Fig. 214-2). Very early APCs may even be blocked in the AV node if this structure is encountered during its effective refractory period. APCs, whether conducted or not, are usually followed by a pause before a return to sinus activity. Most commonly, an APC enters and resets the sinus node, so the sum of the pre- and postextrasystolic PP intervals is less than the sum of two sinus PP intervals (Fig. 214-2). In this case, the pause is said to be less than fully compensatory. The QRS complex following most APCs is normal, although early APCs may be followed by aberrantly conducted QRS complexes due to the premature complex falling within the relative refractory period of the His-Purkinje system.

Since most APCs are asymptomatic, treatment is not required. When they cause palpitations or trigger PSVTs (see below), treatment may be useful. Factors that precipitate APCs, such as alcohol, tobacco, or adrenergic stimulants, should be identified and eliminated; in their absence, mild sedation or the use of a beta blocker may be tried.

AV JUNCTIONAL COMPLEXES The site of origin of these complexes is thought to be in the bundle of His, since the normal AV node in vivo possesses no automaticity. AV junctional complexes are less common than either atrial or ventricular premature complexes and are more often associated with cardiac disease or digitalis intoxication. Junctional premature impulses can conduct both antegradely to the ventricles and retrogradely to the atrium and, on rare occasions, may fail to conduct in either direction. Premature AV junctional complexes can be recognized by normal-appearing QRS complexes that are not preceded by a P wave. Retrograde P waves (inverted in leads II, III, and aVF) may be observed after the QRS complex.

While often asymptomatic, junctional premature complexes may be associated with palpitations and cause cannon *a* waves, which may

result in distressing pulsations in the neck. When symptomatic, they should be treated like APCs.

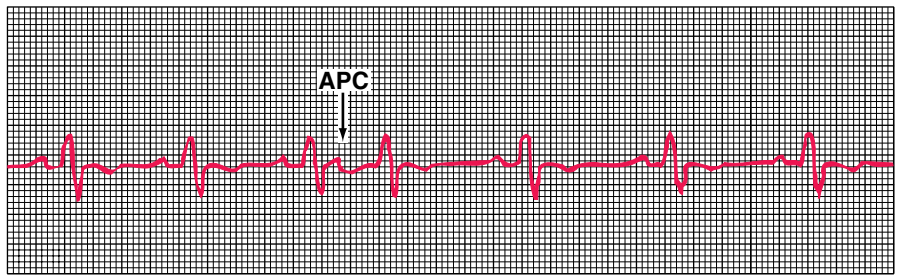

FIGURE 214-2 ECG lead II. Sinus rhythm with one atrial premature complex (*arrow*). Note the difference in P-wave configuration between sinus and the premature atrial complexes. In addition, note that the PR interval of the premature complex is prolonged, due to slowed conduction of the premature impulse through the AV conduction system.

VENTRICULAR PREMATURE COMPLEXES (VPCs)

These are among the most common arrhythmias and occur in patients with and without heart disease. Of adult males, ≥60% will exhibit VPCs during a 24-h Holter monitoring. In patients without heart disease, VPCs have not been shown to be associated with any increased incidence in mortality or morbidity. VPCs may occur in up to 80% of patients with previous myocardial infarction, and in this setting, if frequent (>10 per hour) and/or complex (occurring in couplets), they have been associated with increased mortality. However, cardiac mortality in such patients usually occurs in association with significantly impaired ventricular function. While frequent and complex ventricular ectopy is an independent risk factor, it is not as strong a risk factor as is impaired ventricular function. Moreover, even though VT and/or ventricular fibrillation (VF) may be the basis for the sudden death in these patients, this does not a priori establish a cause-and-effect relation between spontaneous ectopy and life-threatening VT or VF. Very early cycle (R-on-T) VPCs have been stated by some to increase the risk of sudden death. Although this has been observed during acute ischemia and in the setting of QT prolongation, frequently, VT or VF is precipitated by VPCs that occur after the T wave of the prior beat.

VPCs are recognized by wide (usually >0.14 s), bizarre QRS complexes that are not preceded by P waves (Fig. 214-3*A*). However, when they arise in the specialized conduction system (e.g., fascicles) they may be <0.12 s in duration. They may bear a relatively fixed relationship to the preceding sinus complex (i.e., fixed coupled VPCs). When fixed coupling is not present and the interval between VPCs has a common denominator, *ventricular parasystole* is said to be present (Fig. 214-4). Under these circumstances, the VPCs are a manifestation of abnormal automaticity of a protected ventricular focus. Because this focus is not penetrated by sinus impulses, it is not reset by them, and the interectopic intervals remain relatively fixed (≤120 ms variation of mean RR cycle length).

VPCs may occur singly; in patterns of bigeminy, in which every sinus beat is followed by a VPC; in trigeminy, in which two sinus beats are followed by a VPC; in quadrigeminy, etc. Two successive VPCs are termed *pairs* or *couplets*, while three or more consecutive VPCs are termed *ventricular tachycardia* when the rate exceeds 100 beats/min (Fig. 214-3*B*). VPCs may have similar morphologies (monomorphic, or uniform) or different morphologies (polymorphic, or multiformed).

Most commonly, VPCs are not conducted retrogradely to the atrium to reset the sinoatrial node. Thus they result in a fully compensatory pause, i.e., the interval between conducted sinus beats that bracket the VPC equals two basic RR intervals. Ventricular impulses may also manifest retrograde conduction to the atrium and cause inverted P waves in leads II, III, and aVF. This retrograde atrial activation can reset the sinus node, and the pause that results may therefore be less than compensatory. In many instances, the VPC will not be associated with retrograde ventriculoatrial (VA) conduction but may block retrogradely in the AV node. This renders the AV node refractory to the subsequent sinus beat and causes slowed conduction (i.e., prolonged PR interval) or block of the next sinus P wave. This prolonged PR interval is said to be a manifestation of concealed retrograde conduction of the ventricular impulse into the AV node. A VPC that does not produce any manifestation of retrograde concealed conduction and fails to influence the oncoming sinus impulse is termed an *interpolated VPC*.

VPCs can cause palpitations or neck pulsations secondary to either the occurrence of cannon *a* waves or the increased force of contraction due to postextrasystolic potentiation of ventricular contractility. Patients with frequent VPCs or bigeminy may rarely develop syncope or lightheadedness because the VPCs do not result in an adequate stroke volume and the cardiac output is reduced by the "halving" of the heart rate.

TREATMENT

In the absence of cardiac disease, isolated asymptomatic VPCs, regardless of configuration and frequency, need no treatment. When arrhythmias are symptomatic, the symptoms should first be addressed by either allaying the patient's anxiety or, if this is not successful, reducing the frequency of the VPCs with antiarrhythmic agents. β-Adrenergic blockers may be successful in managing VPCs that occur primarily in the daytime or under stressful situations and in specific settings such as mitral valve prolapse and thyrotoxicosis. While other antiarrhythmic agents may be tried should this be unsuccessful, their risk may outweigh any benefits. In patients with cardiac disease, fre-

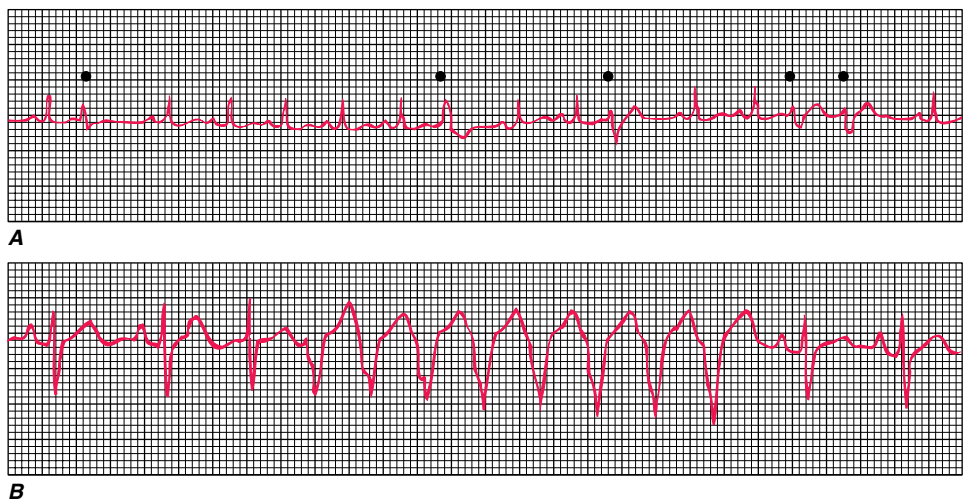

FIGURE 214-3 *A*. Single ventricular ectopy. During sinus rhythm, five premature ventricular complexes (*filled circles*) occur. Note that the QRS configuration is bizarre and different from that during sinus rhythm. The premature ventricular complexes are not preceded by P waves. The QRS widths of the premature complexes are 120–160 ms and multiple morphologies are present. The pause following the premature complexes is fully compensatory, the sinus beat after the premature complex occurring on time. *B*. Nonsustained ventricular tachycardia (VT). Following two sinus beats, an atrial premature contraction with long PR interval initiates an 8-beat run of wide complex tachycardia. Atrial activity can be seen following the fourth and seventh beats. The greater number of QRS complexes compared with P waves confirms the diagnosis of VT.

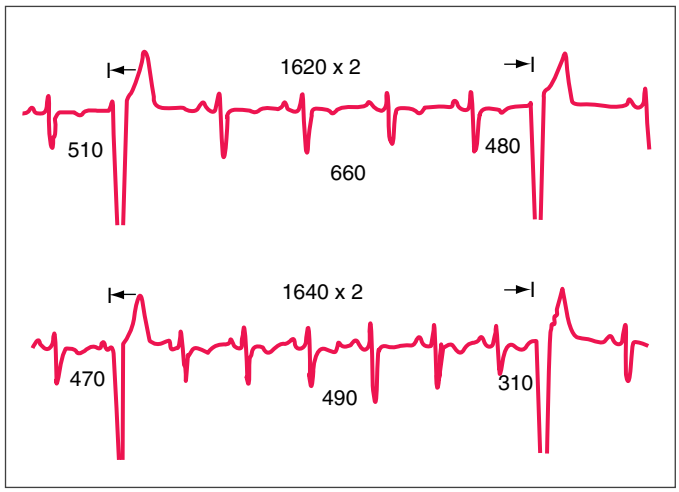

FIGURE 214-4 Ventricular parasystole. At varying sinus cycle lengths during exercise, interectopic intervals remain constant at 1620 to 1640 ms. However, the coupling intervals between sinus and ectopic complexes vary between 510 and 310 ms.

quent VPCs are associated with an increased risk of sudden and nonsudden cardiac death, and many physicians have attempted to eliminate or reduce the frequency of these VPCs in an attempt to reduce this risk. However, the cause-and-effect relationship of the VPCs to fatal events has never been established.

The ability of pharmacologic antiarrhythmic therapy guided by continuous ECG monitoring to reduce the risk of sudden death in postmyocardial infarction patients with frequent (≥6 per minute) VPCs was tested by the Cardiac Arrhythmia Suppression Trial (CAST). This study compared mortality in patients whose ectopy was suppressed by one of three agents (encainide, flecainide, or moricizine) and then randomized to treatment with either the "effective" drug or placebo. After a mean follow-up of 2 years, the study was discontinued because both the sudden death and overall mortality rate were significantly increased in patients receiving antiarrhythmic agents (encainide, flecainide). This study has shown that in patients having the characteristics of the study population, abolition of ventricular ectopy by pharmacologic therapy cannot be used as a marker to define reduction of the risk of sudden death after myocardial infarction and, in fact, may increase mortality.

Recent studies have evaluated the use of electrophysiologic testing and implantable cardioverter/defibrillator (ICD) placement in the management of patients at high risk for sudden death (i.e., those with left ventricular ejection fractions <40% and nonsustained VT). These studies have found that induction of a sustained ventricular arrhythmia through programmed electrical stimulation selects a group of these patients whose prognosis is improved with implantation of a defibrillator. These studies have found no correlation among the rate, morphology, or duration of nonsustained episodes of VT and the likelihood of having a sustained ventricular arrhythmia induced.

Antiarrhythmic agents can also produce the lethal arrhythmias that they are given to prevent (proarrhythmic effects). Thus therapy directed toward VPCs in the setting of chronic cardiac disease may result in an inappropriate and costly use of agents without proven efficacy and with potential side effects in many patients. The high incidence of side effects and the frequent exacerbation of arrhythmias caused by all antiarrhythmic drugs make it mandatory to monitor patients being treated with such agents. Congestive heart failure (CHF) is the most important risk factor for proarrhythmia.

In acute myocardial infarction, the greatest incidence of primary VF occurs within the first 24 h (Chap. 228). Temporary prophylactic antiarrhythmic therapy with lidocaine or procainamide was formerly recommended for all patients with acute infarction, regardless of the presence or degree of spontaneous ectopy. However, failure to improve overall survival and drug toxicity have led most physicians to recommend prophylactic antiarrhythmic therapy only to young patients with complicated infarctions, where a favorable risk-benefit ratio may be obtained. Other studies have shown that intravenous beta blockers may also reduce the incidence of primary VF.

TACHYCARDIAS

Tachycardias refer to arrhythmias with three or more complexes at rates exceeding 100 beats/min; they occur more often in structurally diseased than in normal hearts. Those paroxysmal tachycardias that are initiated by APCs or VPCs are considered to be due to reentry, except some of the digitalis-induced tachyarrhythmias, which are probably due to triggered activity (see below).

If the patient is hemodynamically stable, an attempt should be made to determine the mechanism and origin of the tachycardia, since this will usually lead to an appropriate therapeutic decision. Information to be obtained from the ECG includes (1) the presence, frequency, morphology, and regularity of P waves and QRS complexes; (2) the relationship between atrial and ventricular activity; (3) a comparison of the QRS morphology during sinus rhythm and during the tachycardia; and (4) the response to carotid sinus massage or other vagal maneuvers. It is useful first to compare a 12-lead ECG during the tachycardia with one recorded during sinus rhythm. One can also utilize the electrodes situated at the end of a flexible pacing catheter inserted into the esophagus behind the left atrium to record atrial activity.

Observation of the jugular venous pulse can provide clues to the presence of atrial activity and its relationship to ventricular ectopy. Intermittent cannon *a* waves suggest AV dissociation, while persistent cannon *a* waves suggest 1:1 VA conduction. Flutter waves may be seen or no atrial activity may be apparent, as in the presence of atrial flutter and atrial fibrillation (AF), respectively. The arterial pulse may also manifest AV dissociation or AF by demonstrating variations in amplitude. A first heart sound of variable intensity during a regular rhythm also suggests AV dissociation or AF.

Carotid sinus pressure should be applied only while the patient is electrocardiographically monitored with resuscitative equipment available to manage the rare episode of asystole and/or VF associated with this procedure. Carotid sinus massage should not be performed in patients with carotid arterial bruits. The patient should be positioned flat with the neck extended. Massage of one carotid bulb at a time should be performed by applying firm pressure just underneath the angle of the jaw for up to 5 s. Alternative vagomimetic maneuvers include the Valsalva maneuver, immersion of the face in cold water, and administration of 5 to 10 mg edrophonium.

SINUS TACHYCARDIA In the adult, sinus tachycardia is said to be present when the heart rate exceeds 100 beats/min. Sinus tachycardia rarely exceeds 200 beats/min and is not a primary arrhythmia; instead, it represents a physiologic response to a variety of stresses, such as fever, volume depletion, anxiety, exercise, thyrotoxicosis, hypoxemia, hypotension, or CHF. Sinus tachycardia has a gradual onset and offset. The ECG demonstrates P waves with sinus contour preceding each QRS complex. Carotid sinus pressure usually produces modest slowing with a gradual return to the previous rate upon cessation. This contrasts with the response of PSVTs, which may slow slightly and terminate abruptly.

℞ TREATMENT

Sinus tachycardia should not be treated as a primary arrhythmia, since it is almost always a physiologic response to a demand placed on the heart. As such, therapy should be directed to the primary disorder. However, in the setting of CHF, enhanced sympathetic activity has detrimental effects on myocardial function and merits treatment. Use of beta blockers in this situation decreases the effects of neurohormonal activation that leads to worsening CHF. Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers are additional drugs affecting neurohormonal activation in heart failure whose

use improves outcomes. The other situations in which sinus tachycardia is a consequence (listed above) can all be readily treated.

ATRIAL FIBRILLATION AF is a common arrhythmia that may occur in paroxysmal and persistent forms. It may be seen in normal individuals, particularly during emotional stress or following surgery, exercise, acute alcoholic intoxication, or a prominent surge of vagal tone (i.e., vasovagal response). It may also occur in patients with heart or lung disease who develop acute hypoxia, hypercapnia, or metabolic or hemodynamic derangements. Persistent AF usually occurs in patients with cardiovascular disease, most commonly rheumatic heart disease, nonrheumatic mitral valve disease, hypertensive cardiovascular disease, chronic lung disease, atrial septal defect, and a variety of miscellaneous cardiac abnormalities. AF may be the presenting finding in thyrotoxicosis. So-called lone AF, which occurs in patients without underlying heart disease, often represents the tachycardia phase of the tachycardia-bradycardia syndrome.

The morbidity associated with AF is related to (1) excessive ventricular rate, which in turn may lead to hypotension, pulmonary congestion, or angina pectoris in susceptible individuals, and in some patients can produce a tachycardia-mediated cardiomyopathy; (2) the pause following cessation of AF, which can cause syncope; (3) systemic embolization, which occurs most commonly in patients with rheumatic heart disease (Table 214-1); (4) loss of the contribution of atrial contraction to cardiac output, which may cause fatigue; and (5) anxiety secondary to palpitations. In patients with severe cardiac dysfunction, particularly those with hypertrophied, noncompliant ventricles, the combination of the loss of the atrial contribution to ventricular filling and the abbreviated filling period due to the rapid ventricular rate in AF can produce marked hemodynamic instability, resulting in hypotension, syncope, or heart failure. In patients with mitral stenosis, in whom ventricular filling time is critical, development of AF with a rapid ventricular rate may precipitate pulmonary edema (Chap. 219). AF may also cause a cardiomyopathy related to persistent rapid rates (so-called tachycardia-induced cardiomyopathy).

AF is characterized by disorganized atrial activity without discrete P waves on the surface ECG (Fig. 214-5*A*). Atrial activation is manifested by an undulating baseline or by more sharply inscribed atrial deflections of varying amplitude and frequency ranging from 350 to 600 beats/min. The ventricular response is irregularly irregular. This results from the large number of atrial impulses that penetrate the AV node, making it partially refractory to subsequent impulses. This effect of nonconducted atrial impulses to influence the response to subsequent atrial impulses is termed *concealed conduction*. As a result, the ventricular response is relatively slow, considering the actual atrial rate. AF may convert to atrial flutter, especially in response to antiarrhythmic drugs such as quinidine or flecainide. If AF converts to atrial flutter, which has a slower atrial rate, the effect of concealed conduction may be diminished, and a paradoxical increase in the ventricular response may occur. The main factor determining the rate of the ventricular response is the functional refractory period of the AV node or the most rapid paced rate at which 1:1 conduction through the AV node can be observed.

If, in the presence of AF, the ventricular rhythm becomes regular and slow (e.g., 30 to 60 beats/min), complete heart block is suggested,

Lead V_1 demonstrating an irregular ventricular rhythm associated with poorly defined irregular atrial activity consistent with atrial fibrillation. *B*. Lead II demonstrates atrial flutter, identified by the regular "sawtooth-like" activity (*arrows*) at an atrial rate of 300 beats/min with 2:1 ventricular response.

and if the ventricular rhythm is regular and rapid (e.g., ≥100 beats/min), a tachycardia arising in the AV junction or ventricle should be suspected. Digitalis intoxication is a common cause of both phenomena.

Patients with AF exhibit a loss of *a* waves in the jugular venous pulse and variable pulse pressures in the carotid arterial pulse. The first heart sound usually varies in intensity. On echocardiography, the left atrium is frequently enlarged, and in patients in whom the left atrial diameter >4.5 cm, it may be difficult to convert AF to sinus rhythm and/or maintain the latter, despite therapy.

TREATMENT

In acute AF, a precipitating factor such as fever, pneumonia, alcoholic intoxication, thyrotoxicosis, pulmonary emboli, CHF, or pericarditis should be sought. When such a factor is present, therapy should be directed toward the primary abnormality. If the patient's clinical status is severely compromised, electrical cardioversion is the treatment of choice. In the absence of severe cardiovascular compromise, slowing of the ventricular rate becomes the initial therapeutic goal. This may be most rapidly accomplished with β-adrenergic blockers and/or calcium channel antagonists. Both prolong the refractory period of the AV node and slow conduction within it. When catecholamine levels or sympathetic nervous system tone are likely to be elevated, beta blockers may be favored. Digitalis preparations are less effective, take longer to act, and are associated with more toxicity. Conversion to sinus rhythm may then be attempted. Prior to cardioversion, precautions must be taken to reduce the risk of systemic embolization. Patients should be anticoagulated to an INR of at least 1.8 for the prior 3 consecutive weeks or have had AF for <48 h. Alternatively, for those patients with AF for >48 h who are not anticoagulated, a transesophageal echocardiogram can exclude the presence of left atrial thrombus and allow safe cardioversion. Following cardioversion, anticoagulation must be maintained for at least 4 weeks until atrial mechanical function returns to normal.

Antiarrhythmic medications in either oral or intravenous form may be employed but are only modestly effective in restoring sinus rhythm. When antiarrhythmic agents such as the quinidine-like drugs (class IA) or the flecainide-like agents (class IC) are used (Table 214-2), it is important to increase AV node refractoriness prior to administering

TABLE 214-2 *Classification of Antiarrhythmic Drugs*

Class I	Drugs that reduce maximal velocity of phase of depolarization (V_{max}) due to block of inward Na^+ current in tissue with fast response action potentials
IA	↓ V_{max} at all heart rates and ↑ action potential duration, e.g., quinidine, procainamide, disopyramide
IB	Little effect at slow rates on V_{max} in normal tissue; ↓ V_{max} in partially depolarized cells with fast response action potentials Effects increased at faster rates No change or ↓ in action potential duration, e.g., lidocaine, phenytoin, tocainide, mexiletine
IC	↓ V_{max} at normal rates in normal tissue Minimal effect on action potential duration, e.g., flecainide, propafenone, moricizine
Class II	Antisympathetic agents, e.g., propranolol and other β-adrenergic blockers: ↓ SA nodal automaticity, ↑ AV nodal refractoriness, and ↓ AV nodal conduction velocity
Class III	Agents that prolong action potential duration in tissue with fast-response action potentials, e.g., bretylium, amiodarone, sotalol, ibutilide, dofetilide
Class IV	Calcium (slow) channel blocking agents: ↓ conduction velocity and ↑ refractoriness in tissue with slow-response action potentials, e.g., verapamil, diltiazem
Drugs that cannot be classified by this schema: Digitalis, Adenosine	

Note: SA, sinoatrial; AV, atrioventricular.

such drugs because their vagolytic effect and/or their ability to convert AF to atrial flutter may reduce the concealed conduction in the AV node and lead to an excessively rapid ventricular response. β-Adrenergic blockers are especially useful in this regard. Intravenous ibutilide, a class III agent, is reasonably effective in converting new-onset AF to sinus rhythm.

Direct-current (DC) electrical cardioversion is a highly effective method to restore sinus rhythm, either as a primary method of therapy or following the failure of antiarrhythmic medications. DC cardioversion is accomplished through the delivery of at least 200 W·s of energy between electrodes placed to the right of the sternum and the cardiac apex or to the left of the scapula. New methods of cardioversion using biphasic waveforms have increased the efficacy of transthoracic cardioversion to >90%. If external cardioversion is unsuccessful, internal cardioversion with energy delivered between two catheters inside the heart or one inside and a patch outside the heart may prove effective. Recent studies suggest pretreatment with ibutilide can facilitate cardioversion.

It is unlikely that patients with chronic AF will convert to and remain in sinus rhythm in the presence of long-standing rheumatic heart disease and/or when the atria are markedly enlarged. The goal of therapy in patients in whom AF cannot be converted to sinus rhythm is control of the ventricular response. This can usually be accomplished by beta blockers, calcium channel blockers, or digitalis, singly or in combination. In occasional patients, the ventricular response cannot be controlled by pharmacologic therapy alone. In such patients, the creation of complete heart block by radiofrequency catheter ablation of the AV junction followed by permanent pacemaker implantation is appropriate.

If sinus rhythm is restored electrically or pharmacologically, quinidine or related agents as well as the class IC agents (e.g., flecainide or propafenone), sotalol, dofetilide, or amiodarone may be used to prevent recurrence. In patients in whom cardioversion is unsuccessful or in whom AF has recurred or is likely to recur despite antiarrhythmic therapy, it is probably wisest to allow the patient to remain in AF and to control the ventricular response with calcium antagonists, β-adrenergic blockers, or digitalis glycosides. Since such patients are always at risk of systemic embolization, particularly in the presence of organic heart disease, chronic anticoagulation must be considered (Table 214-3). Chronic anticoagulation is particularly important in the elderly, where the attributable risk of AF for stroke approaches 30%. Several

TABLE 214-3 *Recommendations for Long-Term Anticoagulation in Patients with Chronic Atrial Fibrillation*

Age, years	Risk Factors[a]	Recommendations
<65	Absent	Aspirin
	Present	Warfarin [target INR 2.5 (range 2.0–3.0)]
65–75	Absent	Aspirin or warfarin
	Present	Warfarin [target INR 2.5 (range 2.0–3.0)]
>75	All patients	Warfarin [target INR 2.5 (range 2.5–3.0)]

[a] Risk factors are prior transient ischemic attack, systemic embolus or stroke, hypertension, poor left ventricular function, rheumatic mitral valve disease, prosthetic heart valve, congestive heart failure.

Source: From ACC/AHA/ESC.

studies have now demonstrated conclusively that the incidence of embolization in patients with AF not associated with valvular heart disease is reduced by chronic anticoagulation with warfarin-like agents. Recommendation for chronic anticoagulation should be instituted based on clinical risk factors for stroke regardless of whether or not an antiarrhythmic medication is utilized. Studies have demonstrated that antiarrhythmic drugs are not associated with stroke reduction perhaps because of asymptomatic (unrecognized) recurrences. Aspirin also may be effective for this purpose in patients who are not at high risk for stroke. Although anticoagulation may be associated with hemorrhagic complications, the risk is largely associated with INRs above the recommended range of 2.0 to 3.0. Recommendations for the selection of antiarrhythmic medications to prevent the recurrence of AF are shown in Fig. 214-6.

Ablation therapy for cure of AF is an active area of investigation. This therapy is generally employed for patients with paroxysmal AF. This type of AF is often triggered by automatic foci located in the pulmonary veins. Ablation around the pulmonary veins to prevent electrical transit of impulses from the pulmonary veins to and from the left atrium may be curative. While ablation or isolation of these foci is possible, the procedure can result in pulmonary vein stenosis, pulmonary hypertension, and stroke. The MAZE procedure is a surgical approach to cure AF through the creation of multiple scars in the right and left atria to compartmentalize the electrical conduction in these chambers and disallow the propagation of fibrillatory waves. The

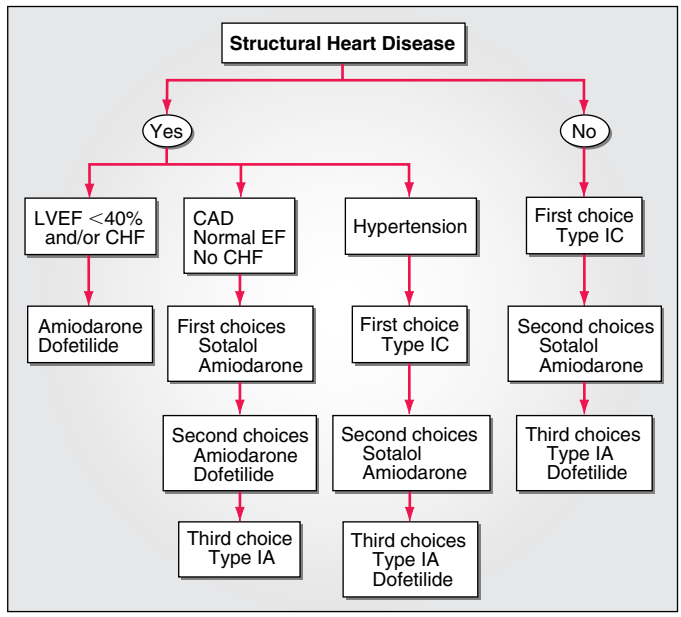

FIGURE 214-6 Recommendations for the selection of antiarrhythmic medications to prevent the recurrence of atrial fibrillation. See Tables 214-2 and 214-4 for definition of class IA and IC drugs. An atrioventricular nodal blocking agent (i.e., beta blocker, calcium channel blocker, or digoxin) should be added to all class IC and IA agents as well as to dofetilide. LVEF, left ventricular ejection fraction; CHF, congestive heart failure; CAD, coronary artery disease; EF, ejection fraction.

morbidity, mortality, and success rate of such catheter-based procedures render them experimental at this time.

ATRIAL FLUTTER This arrhythmia occurs most often in patients with organic heart disease. Flutter may be paroxysmal, in which case there is usually a precipitating factor, such as pericarditis or acute respiratory failure, or it may be persistent. Atrial flutter (as well as AF) is very common during the first week following open-heart surgery. Atrial flutter is usually less long-lived than is AF, although on occasion it may persist for months to years. Often, if it lasts for more than a week, atrial flutter will convert to AF. Systemic embolization is less common in atrial flutter than in AF.

Atrial flutter is characterized by an atrial rate between 250 and 350 beats/min. Typically, the ventricular rate is half the atrial rate, i.e., ~150 beats/min because of 2:1 block in the AV node. If the atrial rate is slowed to <220 beats/min by antiarrhythmic agents such as quinidine, which also possess vagolytic properties, the ventricular rate may rise suddenly because of the development of 1:1 AV conduction. Classically, flutter waves are seen as regular sawtooth-like atrial activity, most prominent in the inferior leads (Fig. 214-5*B*). When the ventricular response is regular and not a simple fraction of the atrial rate, complete AV block is present, which may be a manifestation of digitalis toxicity. Activation mapping suggests that atrial flutter is a form of atrial reentry localized to the right atrium.

℞ TREATMENT

The most effective treatment of atrial flutter is DC cardioversion, which can be accomplished at low energy (25 to 50 W·s) under mild sedation. Higher energies (100 to 200 W·s) are often used because they are less likely to cause AF, which not infrequently occurs following lower energy delivery. Although atrial flutter is associated with a slightly lower risk of embolization than AF, the same precautions should be followed in regard to anticoagulation as are used with AF. The reason for the increased risk of emboli in atrial flutter is uncertain, but the coexistence of AF is common. In patients who develop atrial flutter following open-heart surgery or recurrent flutter in the setting of acute myocardial infarction, particularly if they are being treated with digitalis, atrial pacing (using temporary pacing wires implanted at the time of operation or a pacing lead inserted into the atrium pervenously) at rates of 115 to 130% of the atrial flutter rate can usually convert the atrial flutter to sinus rhythm. Atrial pacing may also result in the conversion of atrial flutter to AF, which allows for easier control of the ventricular response.

If immediate conversion of atrial flutter is not mandated by the patient's clinical status, the ventricular response should first be slowed by blocking the AV node with a beta blocker, calcium antagonist, or digitalis. Digitalis is the least effective and occasionally converts atrial flutter into AF. Once AV nodal conduction is slowed with any of these drugs, an attempt to convert flutter to sinus rhythm using a class I (A or C) agent or amiodarone should be made. Increasing doses of the drug selected are administered until the rhythm converts or side effects occur. Ibutilide is a new antiarrhythmic agent that is administered intravenously and appears to be particularly effective for conversion of atrial flutter to sinus rhythm.

Quinidine, other class IA drugs, flecainide, propafenone, sotalol, dofetilide, and amiodarone (Table 214-4) may be useful in preventing recurrences of atrial flutter. Radiofrequency ablation is a highly effective treatment for patients with the most typical forms of atrial flutter, which are due to reentry around the tricuspid valve in a counterclockwise or clockwise fashion. The coronary sinus and inferior vena cava cause the wavefront of activation to pass between them and the tricuspid valve. Ablation of the narrowed isthmus using radiofrequency energy can cure flutter in >85% of cases. This is far more successful than the response to drugs. As such, ablation is considered by many to be the therapy of choice for recurrent atrial flutter.

PAROXYSMAL SUPRAVENTRICULAR TACHYCARDIAS (Fig. 214-7) In most cases, functional differences in conduction and refractoriness in the AV node or the presence of an AV bypass tract provide the substrate for the development of PSVT (previously termed *paroxysmal atrial tachycardia*). Electrophysiologic studies have demonstrated that reentry is responsible for the vast majority of cases of PSVT. Reentry has been localized to the sinus node, atrium, AV node, or a macroreentrant circuit involving conduction in the antegrade direction through the AV node and retrograde through an AV bypass tract (Fig. 214-8). Such a bypass tract may also conduct antegradely, in which case the Wolff-Parkinson-White (WPW) syndrome is said to be present. When the bypass tract manifests only retrograde conduction, it is termed a *concealed bypass tract* (Fig. 214-7*B*). In these cases, the QRS complex during sinus rhythm is normal. In the absence of the WPW syndrome, reentry through the AV node or through a concealed bypass tract makes up nearly 90% of all PSVTs. Atrial tachycardias due to automaticity are not paroxysmal and often present as an incessant arrhythmia.

AV NODAL REENTRANT TACHYCARDIA There is no age or disease predisposition for the development of AV nodal reentrant tachycardia, the most common cause of supraventricular tachycardia. It is, however, more commonly observed in women. It usually presents as a regular narrow QRS complex tachycardia at rates of 120 to 250 beats/min. APCs that initiate the arrhythmia are almost always associated with a prolonged PR interval. Retrograde P waves may be absent, buried in the QRS complex, or appear as distortions at the terminal parts of the QRS complex (Fig. 214-7*A*).

AV nodal reentrant PSVT (Fig. 214-7*A*) can be reproducibly initiated and terminated by appropriately timed atrial premature stimuli. The onset of the tachycardia is almost always associated with prolongation of the PR interval due to marked AV nodal conduction delay (prolonged AH interval) following the APC that is critical for the genesis of the arrhythmia. The sudden prolongation of the AH interval is consistent with the concept of dual AV nodal pathways: a *fast pathway*, which exhibits rapid conduction and a long refractory period, and a *slow pathway*, which has a short refractory period but conducts slowly. During sinus rhythm, only conduction over the fast pathway is manifest, resulting in a normal PR interval (Fig. 214-8). Atrial extrastimuli at a critical coupling interval are blocked in the fast pathway because of its longer refractory period and are conducted slowly through the slow pathway. If conduction down the slow pathway is slow enough to allow the previously refractory fast pathway time to recover excitability, a single atrial (echo) reentrant beat or sustained tachycardia ensues. A critical balance between conduction velocity and refractoriness within the node is required to sustain AV nodal reentry. Retrograde atrial and antegrade ventricular activation occur simultaneously, explaining why P waves may not be apparent on the surface ECG.

Clinical Features AV nodal reentry may produce palpitations, syncope, and heart failure depending on the rate and duration of the arrhythmia and the presence and severity of any underlying heart disease. Hypotension and syncope may occur due to both the sudden loss of the atrial contribution to ventricular filling and a reflex baroreceptor response to simultaneous atrial and ventricular contraction, which produce high atrial pressures. This situation can also result in acute pulmonary edema.

℞ TREATMENT

In patients without hypotension, vagal maneuvers, particularly carotid sinus massage, can terminate the arrhythmia in 80% of cases. If these maneuvers are unsuccessful, adenosine (12 mg intravenously) is the agent of choice. Beta blockers may also be used to slow or terminate the tachycardia but are agents of second choice. Digitalis glycosides have a slower onset of action and should *not* be used for acute therapy. When these drugs fail to terminate the tachycardia, or when the tachycardia is recurrent, atrial or ventricular pacing via a temporary pacemaker inserted pervenously may be used to terminate the arrhythmia.

TABLE 214-4 *Drugs Used to Treat Cardiac Tachyarrhythmias*

Drug	Mode of Administration	$t_{1/2}$ (oral), h	Route of Metabolism	Clinical Effects and/or Indications for Use
Digoxin	IV, 0.25–1.5 mg Oral, 0.75–1.5 mg loading dose over 12–24 h Maintenance, 0.23–0.50 mg/kg	36	Renal	Slowing of ventricular rate during AF, flutter, and other atrial tachycardias in the absence of preexcitation; slowing, termination, and/or prevention of SVT due to AV nodal reentry and AV reentry utilizing bypass tracts; may terminate or prevent intraatrial reentrant tachycardias; ineffective in prevention of automatic atrial tachycardias
Adenosine	IV bolus, 6–12 mg	<10s		Acute termination of regular reentrant SVT involving the AV node
Quinidine (class IA)	Oral, 200–400 mg q6h	8–9	Hepatic, 80% Renal, 20%	Atrial and ventricular tachyarrhythmias; all types of SVT; control of ventricular rate in patients with preexcitation and AF and flutter
Procainamide (class IA)	IV, 40–50 mg/min to total of 10–20 mg/kg		Hepatic, 50% Renal, 50%	Same as quinidine
	Oral, 500–1000 mg q6h (sustained-release forms)	3–5		
Disopyramide (class IA)	Oral, 100–300 mg q6h	8–9	Hepatic, 50% Renal, 50%	Same as quinidine
Lidocaine (class IB)	IV, 20–50 mg/min to total of 5 mg/kg loading dose, followed by 1–4 mg/kg	1–2	Hepatic	VT and VF, especially during acute ischemia and myocardial infarction
Phenytoin (class IB)	IV, 20 mg/kg to total dose of 1000 mg Oral, 1000-mg loading dose over 24 h Maintenance, 100–400 mg/d	18–36	Hepatic	Tachyarrhythmias induced by digitalis; occasionally effective for ventricular tachyarrhythmias not induced by digitalis alone or in combination with other antiarrhythmic agents; polymorphic VT associated with increased QT interval
Mexiletine (class IB)	Oral, 100–300 mg q6–8h	9–12	Hepatic	Ventricular tachyarrhythmias; secondary agent in combination with other class I medication
Flecainide (class IC)	Oral, begin at 50–100 mg bid, increase by ≤50 mg in 4-day intervals to a maximum of mg daily	7–23	Hepatic, 75% Renal, 25%	Supraventricular tachyarrhythmias including atrial fibrillation and flutter; also ventricular arrhythmias refractory to other medications or radiofrequency ablation
Propafenone (class IC)	Oral, 150–300 mg q8h	5–8	Hepatic	Same as flecainide
Moricizine (class IC)	Oral, 200–400 mg q8h	2–6	Hepatic	Same as flecainide
Beta blockers (class II) e.g., metoprolol	IV, load with 5–10 mg q5min for 3 doses, then 3 mg q6h		Hepatic	Slowing of ventricular rate during AF, atrial flutter, and other atrial tachyarrhythmias in the absence of preexcitation; SVT due to AV nodal reentry; reentry utilizing bypass tracts; arrhythmias (e.g., VT) induced by exercise or occurring in the presence of hyperthyroidism; polymorphic VT associated with congenital long QT syndrome
	Oral, 25–100 mg bid	3–4		
Bretylium (class III)	IV, 1–2 mg/kg per min to total load, 5–10 mg/kg Maintenance, 0.5–2 mg/kg	8–14	Renal	Refractory VT and VF, especially due to acute ischemia
Amiodarone (class III)	IV, 5–10 mg/kg load over 20 min, then 1 g/24 h		Hepatic	Sustained VT and VF
	Oral, load 800–1600 mg/d for 1 week, then 400–600 mg/d for 3 weeks, then 200–400 mg/d thereafter	13–103		AF and atrial flutter, other types of SVT, VT, VF
Sotalol (class III)	Oral, 80–320 mg q12h	10–20	Renal, 90% Hepatic, 10%	Atrial and ventricular tachyarrhythmias
Ibutilide (class III)	IV, <60 kg: 0.01 mg/kg over 10 min IV, ≥60 kg: 1 mg over 10 min, repeat after 10 min if no effect	2–6	Hepatic	AF, atrial flutter, and other SVTs including preexcitation tachycardias
Dofetilide	125–250 mg PO bid	8–12	Renal	AF, atrial flutter, and other SVTs
Calcium channel blockers (class IV) e.g., verapamil	IV, 2.5–10 mg over 1–2 min to total of 0.15 mg/kg		Hepatic	Slowing of ventricular rate during AF and flutter, and other SVTs in the absence of preexcitation; idiopathic VT
	Oral, 240–480 qd	6–24		
Diltiazem	IV, load with 0.25 mg/kg over 2 min; if needed, repeat after 15 min with 0.35 mg over 2 min Maintenance, 10–15 mg/h		Hepatic	Same as verapamil

Note: AF, atrial fibrillation; AV, atrioventricular; SVT, supraventricular tachycardia; VF, ventricular fibrillation; VT, ventricular tachycardia.

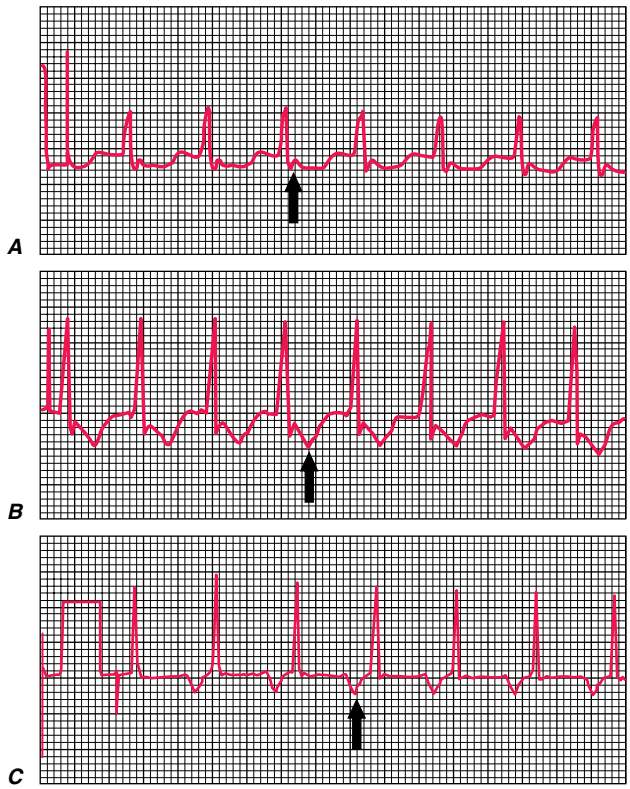

FIGURE 214-7 Examples of supraventricular tachycardia (SVT). Arrows indicate P waves. *A*. AV nodal reentry. Upright P waves are visible at the end of the QRS complex. *B*. AV reentry using a concealed bypass tract. Inverted retrograde P waves are superimposed on the T waves. *C*. Automatic atrial tachycardia. Inverted P waves follow the T waves and precede the QRS complex.

However, if severe ischemia and/or hypotension is caused by the tachycardia, (DC) cardioversion should be considered.

AV nodal reentry can usually be prevented by the use of drugs that act primarily on the antegrade slow pathway (such as digitalis, beta blockers, or calcium channel antagonists) or on the fast pathway (class IA or IC; Table 214-4). We favor initial therapy with beta blockers, calcium channel antagonists, or digoxin because the risk-benefit ratio associated with treatment with these agents is more favorable than that of IA or IC agents. Drugs most likely to avert recurrences prevent induction of the arrhythmias by programmed stimulation. This technique utilizes temporary pacemaker catheters connected to a physiologic stimulator capable of variable rate pacing and stimulation with one or more precisely timed premature impulses. In the past decade it has been recognized that in symptomatic patients who require chronic therapy, radiofrequency catheter modification of the AV node should be considered the treatment of choice. This technique can cure AV nodal reentry in >95% of cases and has been proven to be safe, although a 1 to 2% risk of AV block requiring a permanent pacemaker exists.

AV REENTRANT TACHYCARDIA PSVT due to AV reentry incorporates a concealed AV bypass tract as part of the tachycardia circuit. Thus the impulse passes antegradely from the atria through the AV node and His-Purkinje system to the ventricles and then retrogradely through the (concealed) bypass tract back to the atrium. Patients with this disorder manifest the same type of PSVT as do patients with the WPW syndrome (see below), but the bypass tract cannot conduct in an antegrade direction during sinus rhythm or other atrial tachyarrhythmias.

AV reentrant tachycardia can be initiated and terminated by either APCs or VPCs. Initiation of PSVT by a VPC is virtually diagnostic of AV reentry. Alternation of the QRS complexes occurs in approximately one-third of such tachycardias. Since atrial activation must follow ventricular activation during AV reentry, the P wave usually occurs after the QRS complex (Fig. 214-7*B*).

Atrial activation mapping is of major value in evaluating the origin of these tachycardias. Most concealed bypass tracts are left-sided. Thus, during PSVT or during ventricular pacing, the earliest activation sequence is recorded in the left atrium, usually via a catheter in the coronary sinus. This eccentric atrial activation is quite distinct from the normal retrograde activation sequence in which the earliest activation of the atria is in the area of the AV junction. The ability of a ventricular stimulus to conduct to the atrium at a time when the bundle of His is refractory or more specifically terminate the tachycardia without depolarizing the atria is diagnostic of retrograde conduction over a concealed bypass tract.

Rx TREATMENT

This is similar to the treatment for AV nodal reentry tachycardia. Although pharmacologic agents may be used, patients who require chronic therapy should be considered candidates for radiofrequency catheter ablation of the bypass tract. This requires detailed electrophysiologic study to exclude other arrhythmias that may be responsible for patients' symptoms and to determine the location of the bypass tract(s). The efficacy of this procedure exceeds 90%, with minimal risks. In the remaining small number of patients failing catheter ablation, surgical ablation or pharmacologic therapy can be used.

SINUS NODE REENTRY AND OTHER ATRIAL TACHYCARDIAS Reentry in the region of the sinus node or within the atria is invariably initiated by APCs. These arrhythmias are less common than AV nodal or AV

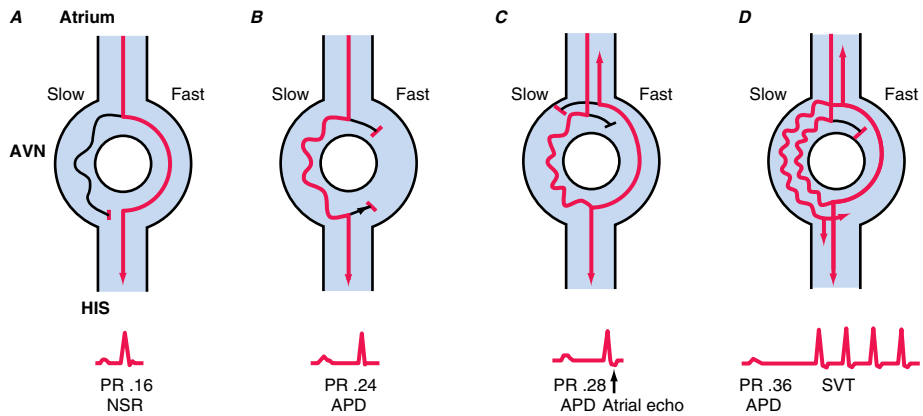

FIGURE 214-8 Mechanism of AV nodal reentry: The atrium, AV node (AVN), and His bundle are shown schematically. The AV node is longitudinally dissociated into two pathways, slow and fast, with different functional properties (see text). In each panel of this diagram, red lines denote excitation in the AV node, which is manifest on the surface electrocardiogram (ECG), while black lines denote conduction that is concealed and not apparent on the surface electrocardiogram. *A*. During sinus rhythm (NSR) the impulse from the atrium conducts down both pathways. However, only conduction over the fast pathway is manifest on the surface ECG, producing a normal PR interval of 0.16 s. *B*. An atrial premature depolarization (APD) blocks in the fast pathway. The impulse conducts over the slow pathway to the His bundle and ventricles, producing a PR interval of 0.24 s. Because the impulse is premature, conduction over the slow pathway occurs more slowly than it would during sinus rhythm. *C*. A more premature atrial impulse blocks in the fast pathway, conducting with increased delay in the slow pathway, producing a PR interval of 0.28 s. The impulse conducts retrogradely up the fast pathway producing a single atrial echo. Sustained reentry is prevented by subsequent block in the slow pathway. *D*. A still more premature atrial impulse blocks initially in the fast pathway, conducting over the slow pathway with increasing delay, producing a PR interval of 0.36 s. Retrograde conduction occurs over the fast pathway and reentry occurs, producing a sustained tachycardia (SVT). *(After ME Josephson: Clinical Cardiac Electrophysiology, 2d ed. Phildelphia, Lea & Febiger, 2002; with permission.)*

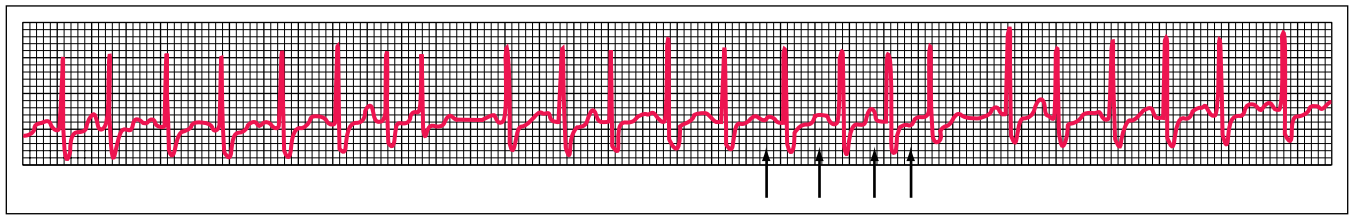

FIGURE 214-9 Multifocal atrial tachycardia. A lead I rhythm strip demonstrates a multifocal atrial tachycardia defined by ≥3 consecutive P waves of variable morphology and rate >100 beats/min (*arrows*).

reentry and are more often associated with underlying cardiac disease. During sinus node reentry, the P-wave morphology is identical to that occurring in sinus rhythm, but the PR interval is prolonged. This is in contrast to sinus tachycardia, in which the PR interval tends to shorten. With intraatrial reentry, the P-wave configuration differs from that during sinus rhythm, and the PR interval is prolonged.

℞ TREATMENT

Sinus node and atrial reentrant arrhythmias are managed like other reentrant PSVTs, except that catheter ablation is less successful because multiple foci may be present.

NONREENTRANT ATRIAL TACHYCARDIAS These may be a manifestation of digitalis intoxication or may be associated with severe pulmonary or cardiac disease, with hypokalemia, or with the administration of theophylline or adrenergic drugs. Multifocal atrial tachycardia (MAT) (Fig. 214-9) is particularly common following theophylline administration. By definition, MAT requires three or more consecutive P waves of different morphologies at rates greater than 100 beats/min. MAT usually has an irregular ventricular rate because of varying AV conduction. There is a high incidence of AF (50 to 70%) in patients with MAT.

℞ TREATMENT

Treatment should be directed at the underlying disorder. The digitalis-induced arrhythmias are caused by triggered activity. In such atrial tachycardias with AV block secondary to digitalis intoxication, the atrial rate rarely exceeds 180 beats/min, and 2:1 block is typically present. Atrial arrhythmias precipitated by digitalis can usually be treated by withdrawal of the drug.

Automatic atrial tachycardias not caused by digitalis are difficult to terminate, and in such cases the main goal of therapy should be to control the ventricular response, either by drugs that affect the AV node, such as digitalis, beta blockers, or calcium channel antagonists, or by ablation techniques. Catheter ablation and surgery have been employed to eradicate the arrhythmia's focus or create heart block for rate control. Catheter ablation can cure incessant atrial tachycardia in <75% of cases and reverse tachycardia-mediated cardiomyopathy. Ablation should be considered for all patients with incessant atrial tachycardia.

PREEXCITATION (WPW) SYNDROME The most frequently encountered type of ventricular preexcitation is that associated with AV bypass tracts. These connections are composed of strands of atrial-like muscle, which may occur almost anywhere around the AV rings. The term *Wolff-Parkinson-White syndrome* is applied to patients with both preexcitation on the ECG and paroxysmal tachycardias. AV bypass tracts can be associated with certain congenital abnormalities, the most important of which is Ebstein's anomaly.

AV bypass tracts that conduct in an antegrade direction produce a typical ECG pattern of a short PR interval (<0.12 s), a slurred upstroke of the QRS complex (delta wave), and a wide QRS complex. This pattern results from a fusion of activation of the ventricles over both the bypass tract and the AV nodal His-Purkinje system (Fig. 214-10). The relative contribution of activation over each system determines the amount of preexcitation.

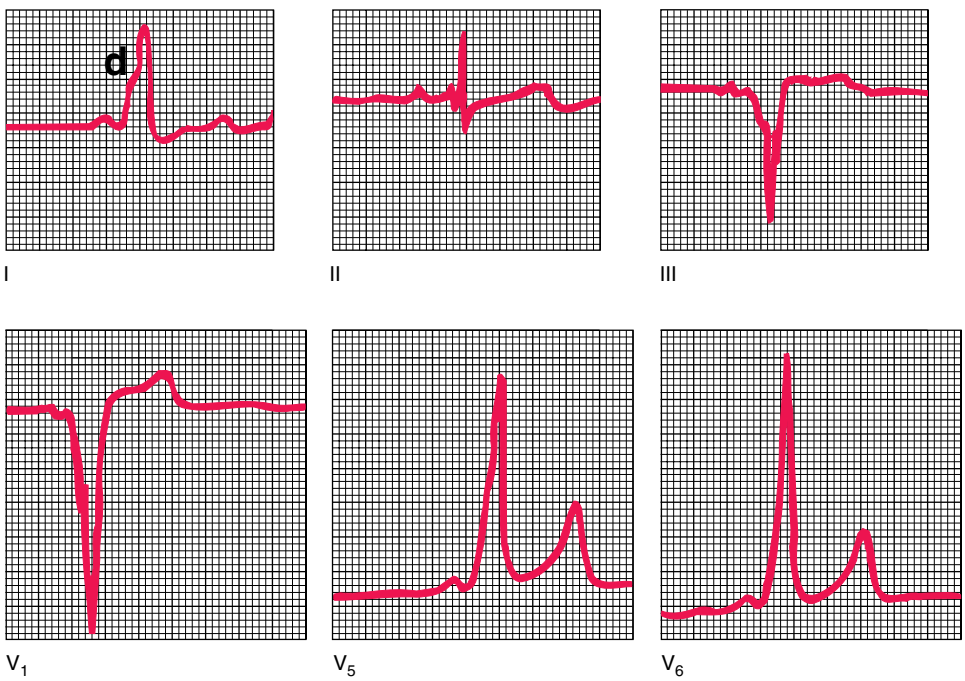

FIGURE 214-10 ECG in Wolff-Parkinson-White syndrome. There is a short PR interval (0.11 s), a wide QRS complex (0.12 s), and slurring on the upstroke of the QRS produced by early ventricular activation over the bypass tract (delta wave, d in lead I). The negative delta waves in V_1 are diagnostic of a right-sided bypass tract. Note the Q wave (negative delta wave) in lead III, mimicking myocardial infarction.

During PSVT in WPW, the impulse is usually conducted antegradely over the normal AV system and retrogradely through the bypass tract. The characteristics are identical to those described on p. 1347. Rarely (~5%), tachycardias occurring in patients with WPW will exhibit a reverse pattern with antegrade conduction through the bypass tract and retrograde conduction through the normal AV system. This produces a tachycardia with a wide QRS complex in which the ventricles are totally activated by the bypass tract. Atrial flutter and AF also occur commonly in patients with WPW syndrome. Since the bypass tract does not have the same decremental conducting properties as the AV node, the ventricular responses during atrial flutter or fibrillation may be unusually rapid and may cause VF.

The goals of electrophysiologic evaluation in patients suspected of having the WPW syndrome are (1) to confirm the diagnosis, (2) to localize the bypass tract and determine how many

bypass tracts are present, (3) to demonstrate the role of the bypass tract in the genesis of the arrhythmias, (4) to determine the potential for the development of possibly life-threatening rates during atrial flutter or fibrillation, and (5) to evaluate therapeutic options.

TREATMENT

Pharmacologic therapy is aimed at altering the electrophysiologic properties (i.e., refractoriness or conduction velocity) of one or more components of the reentrant circuit. This is most often accomplished by agents such as beta blockers or calcium channel blockers that slow conduction and increase refractoriness of the AV node or by agents such as quinidine or flecainide that slow conduction and increase refractoriness primarily in the bypass tract. Some drugs may affect multiple sites.

Acute management of episodes of PSVT in patients with WPW syndrome is similar to that of PSVT in patients with concealed bypass tracts.

In patients with the WPW syndrome and AF, DC cardioversion should be carried out if there is a life-threatening, rapid ventricular response. In non-life-threatening situations, lidocaine (3 to 5 mg/kg) or procainamide (15 mg/kg) administered intravenously over 15 to 20 min will usually slow the ventricular response. More recently, ibutilide has become available as an alternative therapy for preexcitation tachycardia. Caution should be employed when using digitalis or intravenous verapamil in patients with the WPW syndrome and AF, since these drugs can shorten the refractory period of the accessory pathway and can increase the ventricular rate, thereby placing the patient at increased risk for VF. Chronic oral therapy with verapamil is not associated with this risk. In addition to these drugs, beta-blocking agents are of no utility in controlling the ventricular response during AF when conduction proceeds over the bypass tract. Although atrial or ventricular pacing can almost always terminate PSVT in patients with the WPW syndrome, they can induce AF. As such, chronic pacemaker therapy is to be discouraged.

While surgical ablation of bypass tracts offers a permanent cure of supraventricular tachycardia (SVT) and most AFs associated with SVT, the advent of radiofrequency catheter ablation has virtually eliminated the need for surgery. Catheter ablation of bypass tracts is possible in >90% of patients and is the treatment of choice in patients with symptomatic arrhythmias. It is safer, more cost-effective, and just as successful as surgery. Nevertheless, surgical ablation may be required in the occasional patient in whom catheter ablation fails.

NONPAROXYSMAL JUNCTIONAL TACHYCARDIA This rhythm usually results from conditions that produce enhanced automaticity or triggered activity in the AV junction and is most commonly due to digitalis intoxication, inferior wall myocardial infarction, myocarditis, endogenous or exogenous catecholamine excess, acute rheumatic fever, or valve surgery.

The onset of nonparoxysmal junctional tachycardia is usually gradual, with a "warm-up" period prior to stabilization of the rate, which can range from 70 to 150 beats/min, faster rates usually being associated with digitalis intoxication. Nonparoxysmal junctional tachycardia is recognized by a QRS complex identical to that of sinus rhythm. The rate can be influenced by autonomic tone and can be increased by catecholamines, vagolytic agents, or exercise and slowed somewhat by carotid sinus pressure. When this rhythm is due to digitalis intoxication, it usually is associated with AV block and/or dissociation. Soon after cardiac surgery, retrograde conduction is more likely to be present because of the heightened sympathetic state.

TREATMENT

This is directed toward elimination of the underlying etiologic factors. Since digitalis is the most common cause of this rhythm, discontinuation of this drug is indicated. If the rhythm is associated with other serious manifestations of digitalis intoxication, such as ventricular or atrial irritability, active intervention with lidocaine or a beta blocker may be useful, and in some instances use of digitalis antibodies (Fab fragments) should be considered. Cardioversion of this rhythm should not be attempted, particularly in the setting of digitalis intoxication. When AV conduction is intact, atrial pacing can capture and override the junctional focus and provide the AV synchrony necessary to maximize cardiac output. Nonparoxysmal junctional tachycardia is usually not a chronic, recurrent problem, and attention to the acute precipitating events can often resolve the tachycardia.

VENTRICULAR TACHYCARDIA *Sustained ventricular tachycardia* is defined as VT that persists for >30 s or requires termination because of hemodynamic collapse. VT generally accompanies some form of structural heart disease, most commonly chronic ischemic heart disease associated with a prior myocardial infarction. Sustained VT may also be associated with nonischemic cardiomyopathies, metabolic disorders, drug toxicity, or prolonged QT syndrome, and it occurs occasionally in the absence of heart disease or other predisposing factors. Nonsustained VT (three beats to 30 s) is also associated with cardiac disease but occurs in its absence more often than the sustained arrhythmia. While nonsustained VT usually does not produce symptoms, sustained VT is almost always symptomatic and is often associated with marked hemodynamic compromise and/or the development of myocardial ischemia. A fixed anatomic substrate, not acute ischemia, is responsible for most recurrent episodes of sustained uniform VT. Acute ischemia appears to have little role in the genesis of sustained uniform VT associated with chronic infarction but may play a role in the degeneration of stable VT into VF or initiation of polymorphic VT. Most episodes of VF begin with VT.

The ECG diagnosis of VT is suggested by a wide-complex QRS tachycardia at a rate exceeding 100 beats/min. The QRS configuration during any episode of VT may be uniform (monomorphic) or it may vary from beat to beat (polymorphic). *Bidirectional tachycardia* refers to VT that shows an alternation in QRS axis. Typically this appears as a QRS with a right bundle branch block pattern with alternating superior (leftward) and inferior axes (rightward). While the rhythm is usually quite regular, slight irregularity may exist. Atrial activity may be dissociated from ventricular activity, or the atria may be depolarized retrogradely. The onset of the tachycardia is generally abrupt, but in nonparoxysmal tachycardias it can be gradual. Paroxysmal VT is usually initiated by a VPC.

It is important to distinguish SVT with aberration of intraventricular conduction from VT because the clinical implications and management of these two arrhythmias are totally different. The most important clinical predictor of VT is the presence of structural heart disease. The observation of intermittent cannon *a* waves and varying first heart sounds suggests AV dissociation and is diagnostic of VT. In a majority of cases, the diagnosis can and should be made by close examination of the 12-lead ECG. Pharmacologic maneuvers, such as administration of intravenous verapamil or adenosine, can be hazardous and should be avoided. It is always useful to have a 12-lead ECG recorded during sinus rhythm for comparison with that during tachycardia. When the tracing obtained during sinus rhythm demonstrates the same morphologic features as those during the tachycardia, the diagnosis of PSVT with aberration is favored. An infarction pattern on the sinus rhythm tracing suggests the potential presence of the anatomic substrate necessary for VT.

Characteristics of the 12-lead ECG during the tachycardia that suggest a ventricular origin for the arrhythmia are (1) a QRS complex >0.14 s in the absence of antiarrhythmic therapy, (2) AV dissociation (with or without fusion or captured beats) or variable retrograde conduction (Fig. 214-11), (3) a superior QRS axis in the presence of a right bundle branch block pattern, (4) concordance of the QRS pattern in all precordial leads (i.e., all positive or all negative deflections), and (5) other QRS patterns (morphology) with prolonged duration that are inconsistent with typical right or left bundle branch block patterns (Table 214-5). A wide, complex, bizarre tachycardia that is very ir-

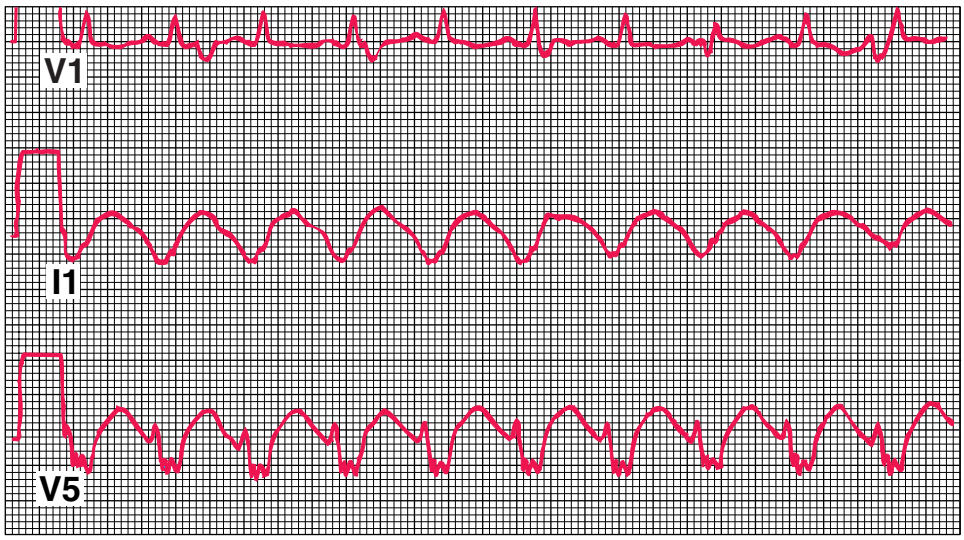

FIGURE 214-11 Ventricular tachycardia with AV dissociation. P waves are dissociated from the underlying wide complex rhythm (best seen on lead V_1).

regular suggests AF with conduction over an AV bypass tract. Similarly, a QRS complex in excess of 0.20 s is uncommon during VT in the absence of drug therapy and is more common with preexcitation. Intravenous verapamil will stop most recalcitrant SVTs involving the AV junction, but it is rarely effective for VT. Because of this property, verapamil has been utilized to attempt to differentiate SVT with aberrant conduction from VT. However, this is extremely hazardous, since intravenous verapamil can precipitate cardiac arrest in patients with VT. A similar caveat can be made for use of adenosine. This agent can produce a coronary stent in patients with multivessel disease and produce a cardiac arrest.

It has been possible to replicate sustained uniform VT in >95% of patients with this arrhythmia using programmed electrical stimulation. In most patients the tachycardia is initiated with ventricular premature stimuli. A sustained monomorphic VT with a morphology identical to that of the spontaneous arrhythmia is the rule. The clinical significance of polymorphic VT initiated by programmed stimulation is not clear, since more aggressive stimulation (i.e., the use of three or four extrastimuli) can induce polymorphic VT and even VF in some normal subjects and in patients who have never had a clinical arrhythmia.

Sustained uniform VT can be terminated by programmed stimulation or rapid pacing in at least 75% of patients; the remainder require cardioversion. The ability to reproducibly initiate and terminate a sustained, uniform VT permits assessment of pharmacologic and electrical therapy of these arrhythmias.

The reproducible termination of VT by programmed stimulation permits evaluation of the effectiveness of antitachycardia pacemakers for long-term therapy of paroxysmal episodes of arrhythmia. Unfortunately, rapid pacing, the most effective form of therapy, can accelerate the tachycardia and/or produce VF. Therefore, antitachycardia pacing is a viable form of therapy only when the pacing device includes backup defibrillation capabilities.

Clinical Features Symptoms resulting from VT depend on the ventricular rate, duration of the tachycardia, and presence and extent of underlying cardiac disease. When the tachycardia is rapid and associated with severe myocardial dysfunction and cerebrovascular disease, hypotension and syncope are common. However, the presence of hemodynamic stability does not preclude a diagnosis of VT. The rate, loss of the atrial contribution to ventricular filling, and abnormal sequence of ventricular activation are important factors producing a decreased cardiac output during VT.

The *prognosis* of VT depends on the underlying disease state. If sustained VT develops within the first 6 weeks following acute myocardial infarction, the prognosis is poor, with a 75% mortality rate at 1 year. Patients with nonsustained VT following myocardial infarction have a threefold greater risk of death than a comparable group of patients without this arrhythmia. However, a cause-and-effect relationship between the nonsustained tachycardia and subsequent sudden death has not been established. Patients without heart disease who have uniform VT have a good prognosis and an extremely low risk of sudden death.

TREATMENT

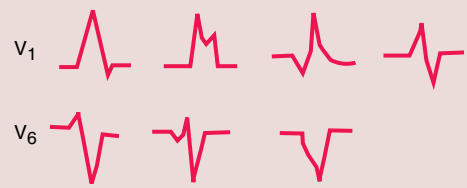
The risk-benefit ratio of treating each specific type of VT should be considered before beginning therapy. This is important because antiarrhythmic agents can produce or exacerbate the very arrhythmias that they are given to prevent. In general, patients with VT but without organic heart disease have a benign course; such patients with asymptomatic, nonsustained VT need not be treated because their prognosis will not be affected. An exception is the patient with congenital long QT syndrome. Such patients have recurrent polymorphic VT and a high mortality from sudden death if untreated. Patients with sustained VT in the absence of heart disease usually require therapy because the arrhythmia causes symptoms. These tachycardias may respond to beta blockers; verapamil; class IA, IC, or III agents; or amiodarone.

In patients with VT and organic heart disease, if marked hemodynamic compromise is present or if there is evidence of ischemia, CHF, or central nervous system hypoperfusion, the rhythm should be promptly terminated by (DC) cardioversion (see below). If the patient with organic heart disease tolerates the VT well, pharmacologic therapy may be tried. Procainamide is probably the most effective agent

TABLE 214-5 *Wide Complex Tachycardia*

ECG CRITERIA THAT FAVOR VENTRICULAR TACHYCARDIA

1. AV dissociation
2. QRS width: >0.14 s with RBBB configuration
   >0.16 s with LBBB configuration
3. QRS axis: Left axis deviation with RBBB morphology
   Extreme left axis deviation (northwest axis) with LBBB morphology
4. Concordance of QRS in precordial leads
5. Morphologic patterns of the QRS complex
   RBBB: Mono- or biphasic complex in V_1
   RS (*only with left axis deviation*) or QS in V_6



LBBB: Broad R wave in V_1 or V_2 ≥0.04 s
Onset of QRS to nadir of S wave in V_1 or V_2 of ≥0.07 s
Notched downslope of S wave in V_1 or V_2
Q wave in V_6

Note: AV, atrioventricular; BBB, bundle branch block.
