Patients with diabetic nephropathy normally have many other complications, the problems increasing as the stage of nephropathy advances. Almost all have retinopathy, often proliferative, and they have a tenfold increased risk of blindness compared with patients without proteinuria. A very high proportion have coronary artery disease, with an excess risk of death many times higher than in patients without proteinuria. They are also more at risk of peripheral vascular disease (often with vascular calcification, peripheral and autonomic neuropathy, foot ulceration, and amputation.

Radiograph of a hand showing extensive vascular calcification

Primary prevention

Poor diabetic control predisposes to the development of nephropathy, although it is not the only factor, and genetic components also predispose to this disease. Tight control of diabetes early in its course helps to delay development of nephropathy (see chapter 10). Many patients will never acquire proteinuria even after several decades. Blood pressure management at all stages is crucial (see below).

Early detection and diagnosis

Testing urine samples for the presence of protein or microalbuminuria should be routine practice at every clinic visit and is obligatory at the annual review. If proteinuria develops it is important to distinguish the onset of nephropathy from other causes of renal disease.

Microalbuminuria is detected by measurement of the albumin/creatinine ratio or urinary albumin concentration. The test is best performed on the first morning urine sample. If albuminuria is discovered for the first time, confirmation is required within one month if proteinuria is present, and if microalbuminuria is detected it should be confirmed twice within the ensuing months. All laboratory and near patient commercial tests specifically designed for microalbuminuria have satisfactory sensitivity (>80%) and specificity (>90%).

If proteinuria has evolved gradually over several years in the presence of retinopathy, and there are no unusual features such as haematuria, unequal size kidneys, or a history of urinary tract complaints, then extensive investigation is not necessary. In Type 2 diabetes, however, there is a greater chance of non-diabetic renal disease being present, and renal biopsy may be needed, especially if there are atypical features. In both Type 1 diabetes and Type 2 diabetes the absence of retinopathy should make one suspect other causes of renal failure. Indeed, rapid onset of proteinuria in any patient is never due to diabetes and should always be fully investigated, including a biopsy.

The characteristic pathological lesion is diabetic glomerulosclerosis, including basement membrane thickening, mesangial expansion, and in the later stages, the classical Kimmelstiel-Wilson nodules, together with hyalinisation of efferent and afferent arterioles. Mesangial expansion, which requires an experienced pathologist to interpret, correlates well with renal function.

Management

- Tight diabetic control delays the onset and slows the progression chiefly in the early phase of the disease, with a smaller effect in fully established disease.
- Established microalbuminuria (—that is three positive samples) is managed with ACE inhibitors:
 - (a) in Type 1 diabetes treatment is commenced regardless of blood pressure which should in any case be maintained < 130/80 mm Hg, or 125/75 mm Hg, in younger patients
 - (b) in Type 2 diabetes treatment aims to maintain a blood pressure < 130/80 mm Hg.

ACE inhibitors and angiotensin receptor blockers always reduce microalbuminuria and delay the onset of established proteinuria.

- Established proteinuria (proteinuria > 500 mg/24 h or albuminuria > 300 mg/24 h).

Diagnostic categories

Microalbuminuria

- Albumin creatinine ratio >2.5 mg/mmol/l (men) >3.5 mg/mmol/l (women)
- Urinary albumin concentration >20 mg/l
- Urinary albumin excretion rate 30-300 mg/24 h, or 20-200 µg/min in an overnight specimen

Proteinuria

- Urinary albumin excretion rate >300 mg/24 h
- Urinary protein excretion >500 mg/24 h (albumin creatinine ration >30 mg/min; albumin concentration >200 mg/l)

Investigations in a patient with proteinuria

- Midstream urine
- 24 hour urine protein
- Renal ultrasonography
- Blood count
- Erythrocyte sedimentation rate
- Antinuclear factor
- Serum complement
- Serum lipids
- (Renal biopsy only as indicated)

Diabetic glomerulosclerosis showing Kimmelstiel-Wilson nodules

This phase is always managed by vigorous hypotensive treatment now aiming where possible for a blood pressure of <130/80 mm Hg or even less (125/75 mm Hg) in younger patients. This both reduces (or occasionally eliminates) proteinuria and slows progression of the declining glomerular filtration rate, best demonstrated in Type 1 diabetes, and is also protective in some aspects of cardiovascular disease (see below).

- Dyslipidaemia. Detection and management of hyperlipidaemias is important because of the huge increase in cardiovascular disease in those with nephropathy. The idea, however, that reducing lipidaemia slows the progression of the renal disease is unproven.
- Restricting protein intake has a small beneficial effect on the decline in glomerular filtration rate but unless the intake is very high (greater than 1 g/kg/day) restriction is not normally advised.
- Oral hypoglycaemic treatment in Type 2 diabetes must be reviewed: metformin should not be used when renal function is impaired because of the danger of lactic acidosis; also long acting, renally excreted sulphonylureas, notably glibenclamide, should not be used because of the risk of accumulation and hypoglycaemia. Drugs such as gliclazide which are mainly metabolised are preferable (see page 15).
- Anaemia often occurs relatively early in the course of the disease before renal failure is established, and much sooner than in non-diabetic renal disease, as a result of diminished erythropoietin production, which can be corrected by injections of erythropoietin, sometimes with considerable clinical benefit.
- Smoking should be strongly discouraged.
- Regular reassessment and management of all the other diabetic complications to which diabetic nephropathy patients are especially prone is extremely important in those who develop this disease.

Choice of antihypertensive agent

ACE inhibitors or angiotensin receptor blockers are the agents of choice for diabetic nephropathy patients at any stage. They probably provide benefits over and above their blood pressure lowering effects in comparison with other agents. However, the overriding need is to maintain good blood pressure control in all those with nephropathy using any hypotensive agent to suit the individual patient, and indeed for Type 2 diabetes, United Kingdom Prospective Diabetes Study (UKPDS) demonstrated no drug preferential benefit. Combinations of drugs are almost always required, especially in overweight Type 2 diabetic individuals when more than two drugs are often needed: the ideal blood pressure of <130/80 mm Hg may be difficult to achieve and some compromise following informed discussion with patients may be necessary. Tight blood pressure control may induce or exacerbate postural hypotension, which should be avoided.

For microalbuminuria

Even in normotensive patients, aim to titrate medication to reduce or eliminate microalbuminuria. Doses often needed are:

- ACE inhibitors*: enalapril 10 mg twice daily
lisinopril 20 mg daily
ramipril 2.5 mg daily.
- Angiotensin 2 receptor antagonists*†: irbesartan 300 mg daily
losartan 50 mg daily.

*Only some of the longest established and therefore most studied agents are mentioned here by name. Many others are available and can be found in the BNF.

†Angiotensin 2 antagonists do not cause the cough often induced by ACE inhibitors, but are more expensive than the latter.

Treatment of nephropathy

- Optimal diabetic control
- Antihypertensive treatment and diuretics
- Reduce hyperlipidaemia
- Stop smoking

Antihypertensive treatment reduces the decline of glomerular filtration rate (GFR) in patients with Type 1 diabetes

ABC of Diabetes

For hypertension

ACE inhibitors (or angiotensin 2 antagonists) to which may be added:

- calcium channel blockers (amlodipine)
- diuretics
- β blockers
- others.

For African-Caribbeans a calcium channel blocker such as verapamil may be a first choice hypotensive agent.

Creatinine should always be checked within one to two weeks of starting treatment with a ACE inhibitor or angiotensin 2 antagonist in case a rapid rise occurs in patients with renal artery stenosis. In this case, the patient should be changed to another agent, and appropriate investigations undertaken as well. For further information on treatment of hypertension, specific indications and contraindications to individual drugs, see chapter 17.

Patient counselling

Considerable fear is generated when patients are told that they have “kidney damage”, with visions of dialysis and transplantation. This is needlessly and carelessly damaging to patient well being; the proper context of the disease must be presented by physicians and nurse educators.

Renal failure

Patients with end-stage renal failure need much time and consideration. Renal support therapy is now available for most of these patients, who should be assessed by a nephrologist once the serum creatinine exceeds $150 \mu\text{mol/l}$. Transplantation or dialysis is often necessary at a lower serum creatinine concentration than in non-diabetic people, often around 450 to $550 \mu\text{mol/l}$. Kidney transplantation is the treatment of choice if the patient has good cardiac function, and cardiac and peripheral vascular assessments are essential before treatment becomes necessary. Results of renal transplantation are shown in the table. If cardiac function is severely compromised then continuous ambulatory peritoneal dialysis (CAPD) is preferable as long-term treatment. Long-term haemodialysis is used chiefly for those who cannot cope with CAPD for reasons of blindness, lack of manual dexterity or intellectual decline. One year after starting CAPD more than 70% of patients are alive, and even after five years approximately 40% survive.

Pancreas transplantation

Combined kidney and pancreas transplantation is undertaken at some major centres and aims to eliminate diabetes and with it the need for insulin injections. Patients who are liberated from decades of restrictions and self discipline imposed by diabetes experience a joy and happiness rarely witnessed in medical practice. This is the prime reason for offering combined transplantation. Other benefits derive from slowing the redevelopment of glomerulosclerosis in the transplanted kidney, and halting the progression of neuropathy. Retinopathy which by this stage has almost always been laser treated is unaffected. The future potential for islet cell transplantation is briefly described on page 22.

Management of diabetes during transplantation and dialysis

At transplantation

Continuous intravenous insulin infusion is always used; soluble insulin diluted in physiological saline at 1 unit/ml. Infusion

Counselling for patients with nephropathy

Physicians and nurse educators should explain that:

- Not all of those (approximately 20%) with microalbuminuria will go on to develop established nephropathy
- Many of those with microalbuminuria or even established nephropathy will not progress to end-stage renal failure
- Modern treatment properly taken is highly effective in retarding disease progression

Approximate expected survival after cadaver renal transplantation

	1 year	5 years
Patient survival (diabetic/non-diabetic)	90/95%	80/88%
Graft survival* (diabetic/non-diabetic)	75/85%	55/75%

*Graft survival includes death with a functioning graft

Approximate expected survival rates after pancreas and renal transplantation

	1 year	5 years
Patient survival (diabetic)	95%	80%
Functioning pancreas graft survival	85%	60%
Functioning kidney graft survival	90%	70%

Glomerulus showing changes of diabetic glomerulosclerosis (left) followed by illustrations at five years (middle) and 10 years (right) after pancreatic transplant, showing considerable resolution after 10 years

rates vary considerably, usually in the range 2 to 20 units/h; during high dose steroid treatment the higher infusion rates are often needed. Intravenous insulin infusion is continued until drips have been taken down and the patient can eat: the insulin regimen to be followed thereafter is described in chapter 9. The daily dose is started about 20% above the pre-transplant dose and adjustments thereafter are made by trial and error.

During peritoneal dialysis

With solutions of low glucose content (1.36% glucose) no adjustment to the normal insulin regimen is needed. Dialysates of high glucose content can however severely disrupt diabetes and additional insulin is needed. During CAPD insulin can be administered entirely from the dialysis bags: soluble insulin is added to each bag, initially using the existing total daily dose in divided amounts, often giving less at night. The dose may eventually be quite different from that given subcutaneously. The technique is often satisfactory and excellent control can be achieved without hypoglycaemia. Patients whose technique is poor, and who are thus liable to peritonitis, should not be given intra-peritoneal insulin. The use of dialysis fluids with high glucose content (3.86%), needed to alleviate fluid overload, causes havoc with diabetes control; additional soluble insulin (in a dose appropriately titrated) must be given before administration of the strong glucose concentrations, or possibly more effectively, additional insulin given intra-peritoneally.

Rejection

High doses of steroids always upset diabetes within a few hours. This problem may be anticipated by increasing the first insulin dose after steroids have been given. Intravenous insulin infusion (about 4 units/h) for a few hours as a supplement to the normal subcutaneous insulin is almost always needed until the administration of methylprednisolone has been completed.

Non-diabetic renal disease

Some patients, especially those with Type 2 diabetes, develop unrelated non-diabetic renal disorders. Clues to their presence have been presented above, but renal artery stenosis should be particularly mentioned. This is most common in Type 2 diabetic patients with hypertension and peripheral vascular disease. Full renal assessment including ultrasound examination is essential, although renal arteriography is often required to confirm or exclude the diagnosis. The distinction is vital as ACE inhibitors may provoke considerable deterioration in renal function or even precipitate renal failure.

Urinary tract infections

Urinary tract infections occur in diabetic people with the same frequency as in those without diabetes, but they are sometimes exceptionally severe and may cause the renal papillae to slough, causing necrotising papillitis, or rarely emphysematous cystitis with air in the bladder wall. Infection is particularly troublesome in the rare patient with urinary retention from neurogenic bladder. Diabetic control is easily disturbed by urinary infection, as with any infection, and must be regained quickly, with insulin if necessary, while the infection is treated with antibiotics.

Pyelonephritis with septicaemia is not uncommon in diabetes, with occasional formation of a perinephric abscess. The source of the infection may not be immediately apparent and sometimes patients present in profound shock without an obvious site of infection.

Renal protection during arteriography

The intravenous dye used during angiography can precipitate acute oliguric renal failure in patients with early renal impairment. The following preventive measures should be taken:

- Avoid dehydration
- Give intravenous fluids starting four hours before the procedure
- Intravenous insulin sliding scale should be used
- Monitor urine output
- Check creatinine before and on the day after the procedure

Note: Metformin should be stopped 48 hours before an angiographic procedure and resumed 48 hours after the procedure has been completed

Glomerulonephritis and other renal disorders can occur in diabetic patients and require renal biopsy for diagnosis and treatment in their own right

17 Cardiovascular disease, hypertension, lipids, and myocardial infarction

Diabetic patients, particularly those with Type 2 diabetes and those with proteinuria, are at very considerable risk of excessive morbidity and mortality from cardiovascular, cerebrovascular and peripheral vascular disease leading to myocardial infarction (MI), strokes and amputations. Much effort must be given to reducing as far as possible the risk factors which are known to predispose to major atheromatous arterial disease. Many effective measures can now be taken, adding considerably to the complexity of treating diabetic patients, especially those with Type 2 diabetes. The difficulties and dangers of polypharmacy are discussed on page 14.

The glycaemic disturbance (of Type 2 diabetes) may be mild, but the rest of the disease is not
George Alberti, 1988

Coronary artery disease

Cardiovascular disease is substantially increased in diabetes, hyperglycaemia representing an independent risk factor. It is the chief cause of death and this observation strongly influences the management of diabetes by the important focus on reducing the risk factors responsible.

Diabetes more than doubles the risk of cardiovascular disease. In the United Kingdom, 35% of deaths are attributable to cardiovascular causes, compared with about 60% in those with Type 2 diabetes, and 67% of Type 1 diabetic patients alive after 40 years of age. The relative risk is greater for women than for men, so that the sex ratio is equal in those with diabetes, with a loss of the usual male predominance. The development of MI over a period of seven years in middle-aged diabetic patients without known pre-existing coronary heart disease (CHD) is the same as that in non-diabetics with existing CHD. The presence of proteinuria and even microalbuminuria is associated with a particularly large risk of CHD and a high mortality from MI (see page 65).

- Those at especially high risk of developing CHD include**
- Smokers
 - Hypertensives
 - Those with insulin resistance associated with obesity
 - Patients of Asian origin
 - Those with microalbuminuria
 - Those with diabetic nephropathy (macroalbuminuria)
 - Those with poor glycaemic control (16% increased risk of MI for every 1% increase in HbA_{1c})
 - Those with hyperlipidaemic states

Prevention of cardiovascular disease: effects of lowering blood pressure

Those with a high risk of cardiovascular disease stand to gain proportionately greater benefit by reduction of risk factors. Two recently published major trials demonstrated exactly what can be achieved.

The United Kingdom Prospective Diabetes Study (UKPDS; published in 1998, see page 42): tight *v* less tight blood pressure control (mean 144/82 mm Hg *v* 154/87 mm Hg). Benefits:

- heart failure reduced by 56%
- strokes reduced by 44%
- combined MI, sudden death, stroke, peripheral vascular disease reduced by 34% (MI alone was reduced non-significantly by 16%).

There were also considerable benefits on the development of retinopathy and proteinuria (see page 43).

Heart Outcomes Prevention Evaluation (HOPE) and MicroHOPE study: this study over 4.5 years comprised 9297 patients overall and included 3577 diabetic patients (98% with Type 2 diabetes). Patients with diabetes and one other risk factor for cardiovascular disease were randomly treated with the

Rates of serious cardiovascular events according to target diastolic blood pressure in 1500 patients with hypertension and Type 2 diabetes

angiotensin converting enzyme (ACE) inhibitor ramipril 10 mg daily or placebo. Systolic blood pressure decreased by approximately 2 to 3 mm Hg and yielded a reduction of combined MI, strokes, and deaths from cardiovascular diseases of 25%.

The demonstrated benefits included:

- MI relative risk reduced by 22%
- stroke relative risk reduced by 33%
- cardiovascular death relative risk reduced by 37%.

It was concluded that ACE inhibitors were the first line treatment for blood pressure control in diabetes. Despite some caveats relating to the handling of the study, this treatment should probably be extended to normotensive patients with high cardiovascular risks.

There have been several other published multicentre trials: the results of the HOPE and other studies are well summarised by Bilous R, HOPE and other recent trials of antihypertensive therapy in Type 2 diabetes; in Amiel S ed. *Horizons in Medicine*, Royal College of Physicians of London, 2002.

Kaplan-Meier estimates of the composite outcome of myocardial infarction, stroke, or death from cardiovascular causes in the ramipril group and the placebo group in the HOPE study

Blood pressure management

Blood pressure should be checked annually or more frequently as indicated. Borderline readings should be re-checked several times before the decision to use medication is taken. Before using pharmacological agents, the measures shown in the box all have some effect on reducing blood pressure:

Blood pressure > 160/100 mm Hg should always be treated in those with and without diabetes aiming for a level of <140/80 mm Hg (audit standard <140/90 mm Hg).

Blood pressure 140-159/90-99 mm Hg should be treated in diabetic patients, most aggressively in those with cardiovascular risk factors, especially if there is evidence of end organ damage; aim for <140/80 mm Hg.

Blood pressure > 140/80 mm Hg should be treated if there is evidence of target organ damage or if the 10-year CHD risk exceeds 15%, aiming for a level <140/80 mm Hg. Blood pressure >130/80 mm Hg should be treated in those with microalbuminuria or macroalbuminuria (see page 68).

Choice of antihypertensive drugs

The key objective is to lower blood pressure by any means because most of the benefits relate to the blood pressure achieved rather than the drug used. There are however additional advantages using ACE inhibitors or angiotensin 2 receptor antagonists (see page 68). Indeed, results of the recent losartan intervention for end point reduction (LIFE) study showed additional benefits resulting from the use of the angiotensin 2 receptor antagonist losartan when compared with β blocker atenolol, despite comparable blood pressure reduction. Many, probably most, patients will need more or than one drug to achieve the intended goal. A pragmatic approach to treatment it is often needed.

ACE inhibitors or angiotensin 2 receptor blockers are the first choice in those with microalbuminuria. ACE inhibitors, angiotensin 2 receptor blockers, cardioselective β blockers or thiazide diuretics are reasonable first line treatment in those without microalbuminuria. Long acting dihydropyridine calcium channel antagonists (for example, amlodipine) have an important role in treating hypertension and are second line agents.

Factors that affect blood pressure

- Salt restriction
- Weight reduction or exercise programmes
- Reduction of excessive alcohol intake

First and foremost, the key objective when choosing antihypertensive drugs is to lower blood pressure by any means because most of the benefits relate to the blood pressure achieved rather than the drug used

Guidelines for choice of antihypertensive drugs

- Those with heart failure should have an ACE inhibitor whenever possible, which can be combined with a diuretic
- Conversion to an angiotensin 2 receptor blocker is helpful if a patient develops cough on an ACE inhibitor
- Addition of an angiotensin 2 receptor blocker to an ACE inhibitor will have an additive benefits on blood pressure but not on microalbuminuria
- Blood pressure in some African and Caribbean patients may respond better to calcium channel antagonists and diuretics than to other agents

Lipids and diabetes

Hyperlipidaemias also commonly exist in those with diabetes and increase still further the risk of ischaemic heart disease, especially in Type 2 diabetes. Detection and control of hyperlipidaemia can effectively reduce MI, coronary deaths and overall mortality. Indeed, even when low density lipoprotein (LDL) cholesterol is normal or even slightly raised in Type 2 diabetes (the major abnormalities being low HDL cholesterol and high triglyceride) the LDL particles may be qualitatively different and more atherogenic.

Screening for dyslipidaemia

This is an essential aspect of the annual review. If the lipid profile is entirely normal, further screening could be postponed for three to five years unless circumstances change. An elevated triglyceride needs confirmation when fasting.

Diabetic control

Optimising diabetic control often improves an abnormal lipid profile in Type 1 diabetes and sometimes in Type 2 diabetes.

Other medications and alcohol

Some drugs and also a high alcohol intake disturb plasma lipids (see table) and this aspect of treatment must be examined and if necessary modified.

Lifestyle measures

The importance of stopping smoking, weight reduction and exercise are described in chapter 3. Advice on low fat diets is also needed. Hypertension must be treated.

Lipid modifying drugs

Statins are the first line of drugs for treating hypercholesterolaemia; and fibrates for treating hypertriglyceridaemia. Statins and fibrates can be used alone or together for treating mixed hyperlipidaemia. Specialist advice should be taken on resistant or complex hyperlipidaemic states.

Targets for treatment

The current targets for cholesterol and other lipid fractions are now the same for primary prevention in diabetes as for secondary prevention in people without diabetes. They are as follows:

- total cholesterol <5.0 mmol/l
- fasting triglyceride <2.0 mmol/l
- LDL cholesterol <3.0 mmol/l
- high density lipoprotein (HDL) cholesterol >1.1 mmol/l.

It is desirable that the ratio (HDL cholesterol)/(total cholesterol – HDL cholesterol) should be >0.25. Alternatively, the total cholesterol/HDL cholesterol should be <3.0.

There is much debate as to whether lipid lowering agents are of any value if started over the age of 75 years.

Heart Protection Study

This huge double blind trial of 20 000 people at increased risk of vascular disease examined the benefits of treatment with simvastatin 40 mg daily, and reported its results in March 2002 (see further reading list). The vascular event rate curves began to separate by the end of the first year, and the absolute benefits of treatment were seen to increase over time, becoming very obvious after five to six years. The major results are shown overleaf.

Some causes of secondary hyperlipidaemia

	Main lipid abnormalities
Alcohol abuse	↑ Triglyceride, ↑ HDL
Therapeutic drugs (diuretics, oral contraceptives, retinoids, corticosteroids, anabolic steroids, progestogens related to testosterone)	↑ Triglyceride or cholesterol or both, ↓ HDL
Hypothyroidism	↑ Cholesterol
Chronic renal failure	↑ Triglyceride
Nephrotic syndrome	↑ Cholesterol, ± ↑ triglyceride
Cholestasis	↑ Cholesterol
Bulimia	↑ Triglyceride
Anorexia nervosa	↑ Cholesterol
Pregnancy	↑ Triglyceride

Targets for blood lipids control suggested by the European Diabetes Policy Group

	Low risk	At risk	High risk
<i>Serum total cholesterol</i>			
mmol/l	<4.8	4.8-6.0	>6.0
mg/dl	<185	184-230	>230
<i>Serum LDL cholesterol</i>			
mmol/l	<3.0	3.0-4.0	>4.0
mg/dl	<115	115-155	>155
<i>Serum HDL cholesterol</i>			
mmol/l	>1.2	1.0-1.2	<1.0
mg/dl	>46	39-46	<39
<i>Serum triglycerides</i>			
mmol/l	<1.7	1.7-2.2	>2.2
mg/dl	<150	150-200	>200

Simvastatin: vascular event by follow up duration

- reduction in vascular deaths 17%
- reduction in major vascular events 24%
- reduction in strokes 27%.

Treatment benefits were not only obvious among patients who had previously had an MI but also in those with prior cerebrovascular or peripheral vascular disease. Benefits were also demonstrated for diabetic patients without previous CHD. Both sexes benefited equally, and elderly patients over 75 years of age were seen to benefit to the same extent as younger patients.

The implications of the results of this study for diabetic patients are obvious, and serious consideration with regard to offering treatment with a statin drug must be given.

Severe hyperlipidaemic states

Extreme mixed hyperlipidaemias are, on rare occasions, associated with uncontrolled diabetes. The plasma has a milky appearance, and xanthomata appear in the skin as bright yellow papules particularly at the elbows, knees and buttocks. Even the retina assumes the pallor of lipaemia retinalis described as the “peaches and cream” appearance. The condition normally resolves when glycaemic control is achieved, lipid levels often return to normal, and the xanthomata disappear. Most but not all patients have Type 2 diabetes. The condition needs to be carefully monitored, and it is often wise to administer lipid lowering drugs until resolution. Sometimes they need to be continued indefinitely.

Milky plasma of severe hyperlipidaemia

Myocardial infarction (MI)

The greater risk of CHD in diabetic patients is accompanied by a greater risk of MI: approximately 10% of all MIs occur in diabetic patients. Unfortunately, mortality rates are also about twofold higher. The increased mortality is attributable to left ventricular dysfunction leading to left ventricular failure and cardiogenic shock.

Presentation of MI in those with diabetes is the same as in those without, although a greater proportion lack chest pain. Absence of cardiac pain has been attributed to the cardiac denervation although this concept lacks conviction.

Treatment

Thrombolysis

This should be used in diabetic patients for the same indications as for non-diabetics. The risk of vitreous haemorrhage in those with proliferative retinopathy is negligible. The benefits to diabetic patients with MI appears even greater than to those without diabetes.

Aspirin 300 mg

Given at the onset of a MI, enteric coated aspirin 75-150 mg daily should be continued indefinitely thereafter.

Insulin treatment

Commenced at the onset of an MI, insulin treatment leading to optimal glycaemic control confers benefits on reducing mortality after discharge from hospital. The DIGAMI (Diabetes, Insulin, Glucose infusion in Acute Myocardial Infarction) study examined 620 patients with established or newly diagnosed diabetes (plasma glucose exceeding 11.1 mmol/l): an insulin and glucose infusion was started at presentation, followed by a multiple insulin injection regimen for at least three months. Twelve-month mortality was reduced by 30%. Confirmation of these results is required, but at present this study presents the best evidence available for the management of diabetes after MI.

Xanthomata on the knee from severe hyperlipidaemia

ABC of Diabetes

All diabetic patients, newly diagnosed and with established disease should be treated with insulin, and in many, this should be continued indefinitely. Some discretion needs to be used among elderly patients, or others who cannot easily or comfortably use insulin, in whom other simple measures can also achieve very good diabetic control.

Coronary artery bypass grafts and angioplasty

Decisions advising on the need for invasive coronary artery treatments are made in the same way as for non-diabetics. Coronary artery bypass grafts may offer an improved prognosis to those with diabetes after spontaneous Q wave infarction compared with angioplasty, and further investigations of this apparent benefit are in progress.

After MI

Half the patients after their first MI die during the following twelve months, and half of those die before they reach hospital. Continuing optimal management of all risk factors is strongly recommended.

Management of risk factors after MI

- Cessation of smoking
- Optimal blood pressure management
- Optimal diabetic control normally with insulin
- Optimal lipid control
- Use of aspirin, β blockers, ACE inhibitors as indicated

The table showing some causes of secondary hyperlipaemia is adapted from International Task Force for Prevention of Coronary Heart Disease. *Nutr Metab Cardiovasc Dis* 1992;2:113-56.

18 Pregnancy

Fifty years ago, more than one quarter of diabetic pregnancies ended in fetal death. Now, due to major developments in obstetrics, diabetes, and paediatrics, most are successful, although perinatal mortality at 2 to 5% is still higher than normal (<1%). Major congenital malformations, some of which could be prevented by good preconception diabetes control, are still excessive.

Good results in diabetic pregnancy can only be achieved in centres where appropriate expertise exists. Joint clinics where care is shared between diabetes physicians and specialist nurses working alongside obstetricians with their team of midwives should be the norm. Attendance at separate clinics is a second-rate option: it is inconvenient and often confusing for patients and leads to inconsistent care and advice.

Management

Pre-pregnancy counselling

Education of diabetic women of childbearing age is important: they should be advised that if they plan a pregnancy they should attend a pre-pregnancy counselling clinic (ideally linked to the antenatal clinic), start taking folic acid and aim for optimal diabetic control before conception in order to reduce the incidence of congenital malformations. The goal is a HbA_{1c} < 6.5% although this is sometimes difficult to achieve even after several months of intense effort, and pragmatic decisions are often needed.

Pregnant diabetic women should report to their doctor or clinic as early as possible in pregnancy and be referred without delay to a joint diabetic antenatal clinic. The midwife should encourage them to attend their local antenatal classes for social contacts.

Congenital malformations

Pregnancy in Type 1 diabetes is associated with an increased risk of congenital malformations. There is a clear relationship between poor diabetic control in the first trimester, and it is equally established that optimal control before conception reduces the rate of congenital malformations to near normal. Thus an HbA_{1c} more than 50% above the upper limit is associated with a two to fourfold increase in the abnormality rate. While in a non-diabetic population congenital malformations occur in 1 to 1.5% of pregnancies, this may be as high as 4 to 6% in those with diabetes, or even higher in those with exceptionally poor control during the first trimester.

The abnormalities are essentially the same as those occurring in the general population and include skeletal abnormalities such as spina bifida or hemivertebra, congenital heart disease, and neurological defects such as microcephaly or anencephaly. Sacral agenesis is greatly increased in diabetes but is still very rare.

Tight control of diabetes before and during pregnancy

Diabetic control should be optimal throughout pregnancy; if it is not, admission to hospital, even for short spells, should be arranged without delay. Home blood glucose monitoring is performed at least four times daily to determine preprandial readings, and about one and a half hours after the main meals perhaps twice weekly to determine postprandial levels,

Diabetic pregnancies: perinatal mortality—King's College Hospital

Management of pregnancy and diabetes

- Pre-pregnancy counselling: understanding the need for tight diabetic control before conception, the need to take folic acid and of the commitment required for a good outcome
- Tight control of diabetes through pregnancy
- Management of diabetic complications during pregnancy
- Obstetric requirements and monitoring during pregnancy
- Management of diabetes in labour
- Management of the neonate

The incidence and relative risk of congenital malformations* in infants of diabetic mothers

Malformation	Incidence/1000 births	Relative risk compared with infants of non-diabetic mothers
Cardiac	10	4
Anencephaly	3	5
Arthrogryphosis	0.3	28
Ureteral duplication	0.7	23
Cystic kidney	0.6	4
Renal agenesis	0.3	5
Anorectal atresia	0.3	4
Caudal regression	1.3	212
Pseudohermaphroditism	0.6	11

*Thought to be of greater incidence in infants of diabetic mothers than in infants of non-diabetic mothers

especially when optimal HbA_{1c} levels have not been achieved. Insulin injections are usually needed three or four times daily and patients should be taught how to adjust their own insulin doses. The dose of insulin needed often increases substantially during pregnancy, sometimes to twice or three times the usual amount and this needs to be anticipated. Good blood glucose control can be difficult to attain during the first trimester and attempts to do so are often complicated by severe hypoglycaemic episodes; thereafter most patients find that they can reach the standards of tight control without difficulty and without untoward hypoglycaemia. Suitable insulin regimens for tight control are described on page 21. Where serious difficulties (including severe hypoglycaemia) in achieving optimal control are encountered, continuous subcutaneous insulin infusion should be considered (see page 28-9). These patients and their families should be equipped with all the essential materials needed to cope with hypoglycaemia (see pages 34-5).

Type 2 diabetic pregnant women are increasingly seen especially among ethnic minorities. Treatment is by diet or diet and insulin only. Those who are on oral hypoglycaemic drugs should be changed to insulin, preferably before conception. There is however no evidence that tablet treatment is teratogenic, and where circumstances demand (for example, in countries where insulin is not readily available, or for patients who absolutely refuse insulin) they can be used. Indeed the use of glyburide has been examined and from a single large study in gestational diabetes appears safe, effective and, unlike some other sulphonylureas, does not cross the placenta, thus not provoking neonatal hypoglycaemia.

Management of diabetic complications during pregnancy

Retinopathy

Fundi should be examined routinely at the beginning, middle and end of pregnancy. If retinopathy is present early in pregnancy, more frequent examination is needed because occasionally progression is rapid during the course of pregnancy. If proliferative changes are present photocoagulation should be performed urgently.

Nephropathy

Patients with established proteinuria from nephropathy can expect problems during pregnancy, with an increased risk of fetal loss. When this is considered, together with the knowledge that the mother may need dialysis or transplantation within a few years, many of these patients should be advised to avoid pregnancy. However, with skilful management, most such patients whose renal function is still normal or near normal can expect a live infant. If however the serum creatinine exceeds 200 $\mu\text{mol/l}$ the outlook for the fetus is bleak and patients should be strongly advised not to get pregnant.

Nephropathy and antihypertensive treatment

Patients with nephropathy who become pregnant can expect to become hypertensive and later often develop severe oedema. Fetal growth may be retarded, and because the problems can be severe, very early delivery of exceptionally small infants becomes necessary. With modern intensive neonatal care, most babies now survive, though a significant proportion develop mild or occasionally severe disabilities. Hypertension is treated with methyldopa, hydralazine, or occasionally labetalol or amlodipine. Frusemide can be given if a diuretic is needed, but

Preprandial blood glucose values should be maintained as near normal as possible and should preferably be kept below 4.0 to 5.5 mmol/l, though postprandial levels, which should be checked especially when HbA_{1c} is suboptimal, may be up to 7.0 mmol/l. The target for HbA_{1c} should ideally be within the normal range—that is, <6% if possible, although on occasions levels up to 7% represent the best that can be achieved

A typically large baby born to a diabetic mother

Diabetic women with established nephropathy should normally be advised against pregnancy. If the serum creatinine exceeds 200 $\mu\text{mol/l}$, the outlook for the fetus is very poor indeed

thiazides are contraindicated. Patients taking angiotensin converting enzyme inhibitors should be changed to other antihypertensive agents before pregnancy because of very serious later adverse effects on the fetus during pregnancy, though congenital malformations are not increased. Any patient with proteinuria from nephropathy may need protracted inpatient care, which should be undertaken in a specialist unit.

Obstetric requirements through pregnancy

An early ultrasound scan establishes the exact gestational age and detects major fetal abnormalities. A specific congenital abnormality ultrasound scan is required before 20 weeks. Thereafter a monthly scan documents the rate of fetal growth. There is considerable acceleration of growth after 28 weeks in the majority of diabetic pregnancies, even in the presence of good diabetic control. Retarded growth may be serious and requires specialist investigation. Assessment of fetal size and weight is important in determining the timing and mode of delivery.

Management in labour

Most patients should be admitted for a short period before planned delivery or for a longer period if there are either obstetric or diabetic problems. Fetal heart rate and its beat-to-beat variations are monitored regularly by an instantaneous heart rate meter and in cases of fetal distress other investigations are needed. Delivery is planned to take place as near to term as possible, unless there are medical or obstetric indications for earlier induction. The aim is for a vaginal delivery whenever possible. However, delivery is still on average at 37 weeks and about two-thirds of deliveries are still by caesarean section.

Glucose and insulin in labour

Glucose and insulin are given by intravenous infusion for all vaginal deliveries as follows:

Intravenous dextrose (10%): one litre every eight hours delivered at a steady rate.

Intravenous insulin: soluble insulin diluted in physiological saline (1 unit insulin/ml saline) and administered by infusion pump at about 1 unit/h (usual range 0.5-2 units/h). If very low infusion rates are used the insulin concentration can be halved.

Blood glucose concentrations should be maintained in the range 4.0-7.0 mmol/l. Insulin infusion is continued until the patient can restart her normal meals. The pre-pregnancy insulin dose is then restarted, otherwise severe hypoglycaemia will occur; if the patient was not previously on insulin, the insulin dose is halved.

Premature labour

Because of the hazards of premature labour, attempts may be made to promote fetal lung maturity by giving dexamethasone. This causes severe hyperglycaemia unless an intravenous insulin infusion is started at the same time as the administration of dexamethasone. Large doses of insulin may be needed.

Caesarean section

Insulin infusion is always used, as described in the section on management during surgery (see page 40).

Ultrasound measurement of fetal growth showing excessive increase of abdominal girth, indicating delivery of a large baby

Blood glucose regimen in labour

Blood glucose	Infusion rate
<4.0 mmol/l*	0.5 U/h
4.0-7.0 mmol/l	1 U/h
>7.0 mmol/l	2 U/h

*If the blood glucose concentration decreases to <3.0 mmol/l, insulin infusion can be stopped for up to 30 minutes.

If dexamethasone is used in premature labour, insulin must be infused at the same time to avoid severe hyperglycaemia

The neonate

The babies of diabetic mothers are larger than normal and nearly one-third of those with Type 1 diabetes exceed the 97.5% centile. However they no longer need care routinely in special care baby units unless there are specific reasons. Respiratory distress syndrome is now rarely seen in these infants unless they are very premature. Blood glucose concentrations should be checked regularly, especially in jittery babies, because hypoglycaemia is still commoner than in the infants of non-diabetic mothers. Polycythaemia, hyperbilirubinaemia, and hypocalcaemia are also commoner among these infants.

Breast feeding

This is encouraged in diabetic mothers as in non-diabetic mothers. The mother's diet should be increased by about 50 g of carbohydrate daily and ample fluids taken. The insulin dose is not usually affected when these measures are followed. Breast feeding mothers should not use oral hypoglycaemic agents.

Gestational diabetes (diabetes discovered during pregnancy)

The detection of gestational diabetes is undertaken by screening procedures in antenatal clinics. Babies born to women with gestational diabetes are frequently macrosomic and although both the effects on mortality and the benefits of intensive treatment are still uncertain, best practice requires optimal diabetic care for these patients.

Diagnosis

Routine blood glucose measurements are made in every pregnant woman between 26 and 28 weeks.

All women who have previously had gestational diabetes should have a glucose tolerance test between 26 and 30 weeks unless there are indications to perform it sooner.

Those from ethnic minorities carry a particularly high risk of gestational diabetes and at King's College Hospital those of African-Caribbean origin accounted for about 80% of them.

Treatment

Gestational diabetes is initially treated by diet alone. If control deteriorates using the criteria described above, insulin should be used, and stopped immediately on delivery of the infant. Oral hypoglycaemics are not advised, though there is no evidence that they are harmful.

Postpartum

A glucose tolerance test should be repeated six weeks after delivery. More than half of the patients return to normal; these women however have an approximately 50% risk of developing Type 2 diabetes later in life, sometimes within one year. An annual check of fasting blood glucose concentration is desirable, and they should be advised to avoid excessive weight gain by a regular programme of healthy eating and exercise (see chapter 3). Those patients who remain diabetic after pregnancy should be treated in the usual way.

The neonate. "... they convey the distinct impression of having had such a surfeit of food and fluid pressed on them by an insistent hostess that they desire only peace so that they can recover from their excesses" (J. Farquhar)

Diagnosis of gestational diabetes

- A random plasma glucose concentration ≥ 11.1 mmol/l; fasting plasma glucose ≥ 7.0 mmol/l; whole blood glucose ≥ 6.1 mmol/l; are diagnostic of diabetes
- If a random blood glucose measurement is greater than 5.8 mmol/l perform a glucose tolerance test
- A 2 hour blood glucose ≥ 7.8 mmol/l during a glucose tolerance test in pregnancy is diagnostic of gestational diabetes

Contraception and diabetes

Good contraceptive advice for diabetic patients is vital to ensure that pregnancies are planned and conception takes place when diabetic control is optimal. All methods of contraception are available to diabetic women; the combined oral contraceptive pill is suitable in the absence of macrovascular disease or microvascular disease especially proteinuria, while progestogen-only methods provide a range of options including highly reliable long term methods, such as Depoprovera and implantable methods such as Implanon.

There is no evidence of any clinically significant effect on diabetic control from either combined oestrogen-progestogen pills or progestogen-only methods, nor is there any influence on the progression of diabetic complications. In the case of women with a history of gestational diabetes, the use of combined pills does not influence the subsequent development of Type 2 diabetes, but there is at present some doubt regarding the use of progestogen-only pills during lactation in women with recent gestational diabetes in whom there may be an increase in the subsequent incidence of Type 2 diabetes.

Intrauterine methods of contraception are suitable for women in stable relationships who have had at least one

pregnancy, and may be ideal for diabetic women in whom hormonal (oestrogen containing) methods are contraindicated for either diabetic specific conditions or those unrelated to diabetes including cardiovascular or cerebrovascular disorders, venous thrombosis, pulmonary embolism or liver disease. Barrier methods of contraception have no metabolic consequences but are often insufficiently reliable, particularly if diabetic control is poor, when pregnancy should be rigorously avoided.

Sterilisation may be considered the ideal option when the family is complete, but it should be borne in mind that both Implanon and the progestogen delivering intrauterine system Mirena, provide more reliable contraception than laparoscopic sterilisation and are of course both reversible should circumstances change.

The table showing the incidence and relative risk of congenital malformations in infants of diabetic mothers is adapted from Combs CA, et al. *Clin Obstet Gynecol* 1991;5:315-31. The photograph of a typically large baby born to a diabetic mother is from Chamberlain G, Morgan M. *ABC of Antenatal Care*, 4th ed. London: BMJ Publishing Group, 2002.

The story of Mrs B-J continued: pregnancy

I had heard many tales about the trauma of diabetics who had babies, and I made up my mind I would never have any, even if I did get married. Once, when I was at the clinic, I was asked by the Sister if I would go up the maternity ward and have a chat with the two diabetic expectant mothers. They had been in hospital for nearly three months, which was normal in those days. The poor dears were bored stiff and glad to see a different face. I hope I cheered them up a bit. They convinced me that I would never want to follow their example and I never did. Dr Pyke told me a few years ago that things had changed now and expectant mothers no longer have to serve such a long sentence.

19 Organisation of diabetic care: primary-secondary care interface

Care of people with diabetes requires enthusiasm, commitment and organisation. There are various ways of undertaking it, but without interest and motivation, none will succeed.

It is best to bring diabetic patients together into properly organised clinics, whether in general practice or hospital, so that they can benefit from the wide range of services needed for their long-term care. A close liaison is needed between general practice and hospital specialists, and there are substantial new developments at the interface with Primary Care Groups and Primary Care Trusts. Patients can then have access to all members of the large team now involved in delivering the treatment and advice which they need. Diabetes shared care schemes are very advanced in many parts of the United Kingdom and set a model for other specialties, as they represent at the same time both efficient treatment and ideal links between hospitals and communities.

Any scheme aims to deliver the best care to patients. In order to do so there must be an efficient flow of information about patients, and the shared experience of a dedicated staff. Dissemination of expertise among all those concerned is essential. Schemes require nurturing, and an audit of outcome measures is needed for feedback to assess progress and identify courses of action. Local demographic trends must be understood, including an awareness of the needs of different ethnic groups. Education of the public is becoming increasingly important, and information is needed in schools as well. Research, innovation, and renewal are constantly needed. Increasingly, information regarding local diabetes services are provided on websites.

Requirements for diabetes care

A complex range of services for comprehensive diabetes care is needed as follows:

- to establish diagnosis and initiate treatment
- for patient education leading to independence
- to achieve optimal or appropriate diabetic control
- for screening and detection of diabetic complications
- to enable treatment of diabetic complications
- for care of those who are acutely or chronically ill
- for education of all medical and nursing staff involved in diabetes care.

The facilities needed to achieve these goals are provided by diabetes centres, which offer a common base for an integrated specialist and primary care diabetes service, and by the general practitioner.

Services provided by the general practitioner

- A diabetes register
- Dedicated time for care of people with diabetes
- Preferably one doctor with a special interest in diabetes
- A practice nurse who has received some specific training
- Access to all necessary laboratory services
- Facilities for complications screening and access to an eye screening programme
- Provision of access to the diabetes team to provide appropriate education, dietetic advice, and podiatry

St Vincent Declaration, 1989

A joint European initiative between the World Health Organization and the International Diabetes Federation resulted in the publication of the St Vincent Declaration in 1989, which calls for targets for improving the outlook for diabetic patients. The recommendations include:

- Reducing new blindness due to diabetes by a third or more
- Reducing numbers of people entering end stage diabetic renal failure by at least a third
- Reducing by a half the rate of limb amputations for diabetic gangrene
- Cutting morbidity and mortality from coronary heart disease in diabetic patients by vigorous programmes of risk reduction
- Achieving pregnancy outcome in diabetic women that approximates that of non-diabetic women

Services provided by diabetes centres

- Provide expertise, literature, and teaching aids based at the hospital department, and take the lead role in organisation of district diabetes services to co-ordinate hospital and general practitioner activities
- Provide mutually agreed guidelines on management
- Provide emergency access for patient and doctors (a direct, dedicated telephone line is essential)
- Establish a register of diabetic patients (and where possible also identify those at risk)
- The team should provide a clinical service for all new and established diabetic patients requiring specialist hospital attention
- Provide services jointly (ideally in joint clinics) with relevant specialists for the treatment of:
 - Retinopathy with an ophthalmologist
 - Pregnancy with obstetricians
 - Children and adolescents with a paediatrician
 - Foot problems (including peripheral vascular disease) with a vascular surgeon
 - Renal problems with a nephrologist
 - Neuropathy with a neurologist
 - Erectile dysfunction
 - Family and psychological problems
- Provide a screening service for detection of diabetic complications (see page 45)
- Oversee the care of all diabetic hospital inpatients by training ward-based "link" nurses
- Provide interpreters and patient advocates where necessary

The medical consultation

Every patient presenting for the first time should undergo a full clinical appraisal and physical examination. Subsequent consultations should not only include an assessment of the diabetes and its complications, but also specifically enquire regarding episodes of hypoglycaemia, supplementing this enquiry with reminders of how episodes should be managed and avoided. Inspection of insulin injection sites is often neglected. Assessment of other medical conditions and medication is also important because of potential interactions, and the need to offer each individual patient clinically appropriate advice.

The Physician's Visit by Jan Steen, 1663

Indications for referral to the hospital diabetes centre

Good communications between community and hospital are crucial. While referral patterns will depend on local expertise, the following guidelines are offered:

Group 1 These patients should normally attend hospital diabetic clinics:

- Type 1 diabetic patients
- all children and adolescents with diabetes
- those with problems from hypoglycaemia
- patients who need pre-pregnancy counselling and all those who are pregnant
- patients with significant complications
- those with active foot lesions or sepsis, or both.

Group 2 Referral to hospital desirable, depending on local practice expertise:

- decision to commence insulin
- patients in whom adequate control is not achieved (for criteria see page 10)
- newly diagnosed patients for assessment, education, and initiation of treatment.

Urgent expert assistance (usually at the hospital diabetes centre is needed):

- If an active foot lesion develops
- If there is a rapid decline of vision
- For reappraisal after a serious hypoglycaemic event
- If renal function deteriorates unexpectedly

The diabetes team

Because patient numbers are large, the disease lifelong, and its complications complex and diverse, a wide range of practitioners and specialists are involved in delivering a comprehensive service of high quality. The team needs a base, normally the diabetes centre in the local hospital, in order to maintain close communication with patients and professionals both in the hospital and in the community, as well as promoting innovation and research. Fragmented teams are likely to fail.

Diabetes specialist nurses and consultant nurses

The most important single innovation in diabetic care during the past three decades has been the increasing involvement of highly trained diabetes specialist nurses who can transform the standard of diabetic care, achieving liaison between hospital, general practitioner and patients at home, and offering a wide range of clinical and educational expertise. The Royal College of Nursing recommends that there should be one specialist nurse for a population of 50 000, and one for every 50 families with a diabetic child.

The training of nurses for diabetic care is of central importance and undertaken on specifically designed diploma and degree courses as well as at the diabetes centres themselves.

ABC of Diabetes

The many important roles of the diabetes specialist nurse are closely linked to those of consultants, and can be summarised as follows:

- treatment of individual patients, linked with advice and counselling, establishing the right techniques and motivation needed to achieve proper diabetic management and control
- care of patients in hospital wards
- education of patients and professionals (see below)
- involvement in community care
- research, audit, and setting standards.

Consultant nurses have been established recently, with the aim both of enhancing clinical care and stimulating research and service innovations as well.

The role of the consultant in the community

The specialist diabetic consultant has a major role to play not only in the management of diabetes itself but also in the delivery of services across the community. Experience in the community surrounding King's College Hospital suggests the potential benefits of the following model seen in the box.

Education

Education of patients

An integral aspect of diabetes care is to inform all patients of the nature of the disorder and its treatment, and to place the potential threat of complications in their true perspective. Educational facilities are offered by the whole of the diabetes team both to individuals and to groups.

Instructions to new patients are always given initially on an individual basis. Most centres also organise courses for groups, ranging from a single half-day to comprehensive weekly series. There should be separate education groups for Type 1 and Type 2 diabetic patients, and the courses should provide scope for discussion and questions as well as direct instruction. Ongoing education is also needed to refresh memories over the several decades following diagnosis.

Education of patients has become very sophisticated in the field of diabetes; it has reduced admissions and to some extent complication rates, notably amputations. It is a concept which could be applied much more extensively to other areas of medicine.

Education of health professionals

In order to maintain standards, all those involved in diabetes care require regular updating, and every locality must take responsibility for educational programmes. These should include practice nurses, specialist nurses, hospital nurses, as well as junior and senior medical staff in both hospitals and general practice. Organisation of educational programmes requires a considerable resource.

Records

Computers are essential for the maintenance of good records on diabetes, though no single system is clearly superior. Maintenance of a register of diabetic patients is an essential operation and becomes increasingly important for recalling patients for review and assessment. Records of varying complexity can be held on the computer and the presentation can be structured so as to present the necessary information described below.

Diabetic kitchen, King's College Hospital, 1935 (Diabetes UK)

Role of the consultant

- The hospital team regularly visits general practices to see selected patients attending consultation
- The hospital team comprises a consultant and a diabetes specialist nurse, accompanied by a specialist registrar and a medical student
- The practice team includes the host general practitioners, practice nurses, and others such as local district nurses, health visitors, podiatrists, and dieticians

Aims of an education programme

- To explain the nature of the disease and its complications
- To explain the treatment, starting with the simplest ground rules and eventually provide comprehensive instructions on both treatment and monitoring, enabling patients to take control of their own condition
- To explain dietary and other lifestyle requirements
- To provide printed literature. "Starter" packs should contain:
 - A booklet about diabetes
 - Dietary instructions
 - Home monitoring booklet with full instructions
 - Information on driving
 - Essential telephone numbers
 - Leaflets on Diabetes UK

Patient history record

ABC of Diabetes

Special records are needed for proper care of diabetic patients both in hospital and in general practice—however this is organised, records must be immediately available when required. In hospital there are huge advantages in maintaining a separate set of records for diabetic patients and this system is used by major departments. Many general practices also keep special records supplementary to the basic “Lloyd George” card. Such records must be designed for serial recording of factual data, including weight, blood glucose, urine tests, HbA_{1c}, visual acuity, complications (results of eye examination in particular), and treatment. There must always be space for recording the outcome of the medical consultation itself and for treatment recommendations. There should be a system to alert the staff to the presence of particular problems, for example, sight-threatening retinopathy, and to the date when the next examination is required (for example, blood pressure measurement or eye examination). Many also incorporate an education checklist which records when patients have attended sessions and ensure that essential advice has been given, for example on driving.

Early diabetic record in the hand of Dr R D Lawrence

Other facilities

Local diabetes service advisory groups (LDSAGs)

Coordination of services by LDSAGs is crucial to their success. Local committees can achieve this very effectively. They should comprise representatives of local purchasing authorities (for example health authorities or primary care trusts), providers (hospital consultants and general practitioners), diabetes specialist nurses, and consumers (diabetic patients). Effective discussions in this group can substantially enhance local services which might otherwise become seriously fragmented.

Diabetes facilitators

Support for general practices establishing diabetes services is crucial and a team for this purpose, comprising specialist nurses, facilitators, and a dietician, greatly enhances this process, assisting them with the development of optimal facilities and providing them with useful guidelines. The National Diabetes Facilitator's Group runs training courses.

Diabetes UK

The central resources of Diabetes UK provide direct advice for both patients and health professionals by printed literature, and access to scientific and epidemiological information. Diabetes UK also funds research, and provides scientific and educational meetings, children's camps, family weekends, and many other activities.

Local branches of Diabetes UK, organised by people with diabetes, serve as self help and fundraising groups, as well as helping to maintain high quality local services.

Juvenile Diabetes Research Foundation (JDRF)

This organisation was founded in the United States and is now established in the United Kingdom as well. Its chief aims are fund raising to support research, particularly in diabetes prevention and treatment, together with promotion of understanding of this condition by the public.

National Service Framework (NSF) for Diabetes: standards

The NSF for diabetes was published in 2002 and full details can be found on the website <www.doh.gov.uk/nsf/diabetes>

The standards have been divided into 12 sections relating to the following nine categories:

- 1 Prevention of Type 2 diabetes
- 2 Identification of people with Type 2 diabetes
- 3 Empowering people with diabetes
- 4 Clinical care of adults with diabetes
- 5 Clinical care of children and young people with diabetes
- 6 Management of diabetic emergencies
- 7 Care of people with diabetes during admission to hospital
- 8 Diabetes and pregnancy
- 9 Detection and management of long-term diabetic complications

Diabetes UK is at 10 Parkway, London NW1 7AA; telephone 020-7424-1000; <www.diabetes.org.uk>

The JDRF is at 19 Angel Gate, London EC1V 2PT; telephone 020-7713-2030 <www.jdrf.org.uk>

Conclusion

Obviously the requirements for diabetes care will vary from one geographical area to another, but anyone who undertakes the care of people with diabetes must heed the words of Dr Elliott P. Joslin: “To retain his patient for 20 years he must shun proprietary remedies as the devil does holy water, continually seek for new knowledge as eagerly as the diabetic grasps for life, but ever sift the wheat from the chaff remembering that faithful treatment in season and out of season is rewarded.”

Elliott P Joslin, 1869-1962

The Physician's Visit by Jan Steen, 1663 is reproduced with permission from the V&A Picture Library. The photograph of EP Joslin is from Joslin EP. *Diabetic Manual*, Lea and Febiger, 1941.

The story of Mrs B-J continued: joining the Diabetic Association

I joined the Diabetic Association, as it was called then, when it was first formed (1934). Through them, I was sent to St Mary's Convalescent Home at Birchington to recuperate after the whooping cough attack. I was there for the Coronation of George VI in 1936, and can well remember the lovely party we had that day. My mother had sent me a parcel of patriotic items such as red, white and blue crepe paper, ribbons, and flowers made of red, white and blue feathers. With these I made myself an outfit for the fancy dress parade and won first prize, a china plate coronation souvenir.

The war brought problems for me and at the end of it, in 1945, I was quite run down. I think this was due to lack of fresh fruit, especially oranges and bananas. Diabetics were allowed to have three times the normal ration of meat, butter, margarine and cheese. To get this, the sugar ration had to be surrendered. Later in the war, when milk was rationed to two pints a week for each adult, diabetics were allowed one pint a day. Apart from the extra milk, I never had extra rations, as my mother witnessed an unpleasant scene one day in Sainsburys, and it put her off ever getting the extras; when a lady with three diabetics in her family was handed a large joint, there was almost a riot and the poor lady was manhandled and the meat torn away from her. The manager called the police to restore order. My mother was so upset that she firmly refused to apply to the Food Office for the permits and said that I would have her rations if necessary.

20 Practical problems

Employment and hobbies

Most of the problems of people with diabetes in society result from the ever present possibility of hypoglycaemia in insulin treated patients. Although this hazard is small in many individuals, it is an unacceptable risk in some circumstances. The guiding principles in making the difficult assessments for employment or hobbies relate to whether the risk of confusion during hypoglycaemia affects only the individual or whether it also places the safety of others at risk; the magnitude of the risk of diminished awareness of hypoglycaemia; and the magnitude of the hazard should a hypoglycaemia related accident occur.

Individual firms and industries have generally established their own regulations about the suitability of those with diabetes for particular jobs. If the candidates for employment are rejected unreasonably, solely on account of diabetes they may appeal. People with diabetes are not normally accepted by the armed forces, the police, or the merchant navy, and those already in these occupations may be diverted away from active service to office work. Shiftwork, especially nightshift work, should be avoided if possible by those taking insulin, but some patients can make appropriate adjustments and many may successfully cope with such work.

Diabetic people treated by diet alone or with oral hypoglycaemic tablets who are otherwise fit should be permitted to undertake any occupation or hobby. Their risk of hypoglycaemia is negligible.

Driving

All diabetic patients who are otherwise physically fit and not affected by blackouts, or other proscribed or relevant medical conditions, are normally allowed to hold ordinary Group 1 (category B) driving licences—that is, vehicles up to 3500 kg with up to nine seats and with a trailer up to 750 kg. The law demands that diabetic patients treated with tablets or insulin (but not those on diet alone) should inform the Driver and Vehicle Licensing Agency (DVLA) in Swansea. If applying for a licence for the first time, the appropriate declaration must be made on the application form. It is helpful to indicate whether insulin is being used. Driving licences are granted for three years and are reissued (at no extra fee) subject to a satisfactory medical report for those on insulin, and up to 70 years of age for those on diet or tablets, subject to any change of their health or treatment.

For any driving licence, visual acuity must be better than 6/12 in the better eye, and the visual field should exceed 120° horizontally and 20° above and below throughout 120°. Those who have had laser photocoagulation should report this to the DVLA so that appropriate visual field perimetry can be performed.

Healthy people with diabetes who are treated with diet or tablets are normally allowed to drive vehicles larger than those defined above (that is, Group 2), provided they pass a separate test to meet the higher Group 2 standards. Group 2 or vocational licences include those for large group vehicles and passenger carrying vehicles. Those taking insulin are not permitted to hold Group 2 licences, unless the license was granted before 1991 and subject to satisfactory medical reports, because of the serious potential consequences of hypoglycaemia, no matter how small the risk may be for any

Hypoglycaemia is the major hazard for any insulin treated diabetic patient

Reproducible profiles of blood glucose levels over five days in an individual patient, showing times when there is a risk of hypoglycaemia

"One Sunday morning I think it was, I set off motoring and before lunch began to see double, a sure warning of hypoglycaemia. Not a good thing when you are driving to see two cars or four ditches."

R D Lawrence

Hazards when driving

individual diabetic patient. However, exceptional cases, based on individual assessment of the risk of experiencing diminished awareness of hypoglycaemia, can be identified (see Appendix 1) and enable some people to hold C1 licences (vehicles between 3500 and 7500 kg), although D1 vehicles (minibuses) do not fall into this category.

All insulin-treated diabetic patients who drive should always keep a supply of sugar in their cars. They should normally check blood glucose before driving, and should not drive if they are late for a meal, when the danger of hypoglycaemia is very great, especially around noon. If they experience warning symptoms of hypoglycaemia they should stop, switch off the ignition, and preferably leave the car, since they may otherwise be open to the charge of driving under the influence of drugs (insulin). Those unfortunate patients who are prone to hypoglycaemia without warning must not drive, and their doctors should make this advice very clear.

Insurance and pension

Driving insurance with a normal premium will usually be issued, subject to a satisfactory medical report. Life assurance premiums are often raised by amounts which depend on the result of a medical examination. It is worth looking for the “best buy”. Sickness and holiday insurance premiums are often higher than normal. Diabetes UK offers helpful advice on insurance.

Travel

Diabetic control is easily upset by the rigours of travelling. People with diabetes should therefore undertake regular blood tests and adjust diet and insulin if necessary. Ideally those on insulin should travel with a companion if they are going to remote places. It is well worth carrying an identity disk which can be obtained from Diabetes UK, which also helps with appropriate foreign language leaflets. Some of the following circumstances present special problems.

Sea sickness and other stomach upsets causing vomiting

Diabetic patients may use the same anti-seasickness tablets as non-diabetics; these drugs do not change diabetic control. They do however tend to cause drowsiness, so it is best not to drive. If vomiting occurs insulin should be continued without fail and the situation dealt with as described on page 37.

Time changes on long-distance air travel

There are inevitably difficulties with diabetic control for a few days.

Flying west

The time between injections can, with little problem, be lengthened by two to three hours twice daily. Regular blood tests should be performed and if they are excessively high (around 15 mmol/l or more) extra soluble insulin (between 4 and 8 units) can be taken. If the time gap between injections is lengthened still further, a small supplementary injection of soluble insulin (between 4 and 8 units) is taken between the usual injections.

Flying east

The time between injections will need to be shortened by two to three hours each time, which could result in rather low blood glucose readings. Careful testing should be performed, and if required each dose can be reduced by a small amount

Hazards when travelling (sea sickness, time changes, burns on feet)

Other problems while abroad

- Vomiting either from motion sickness or stomach upsets (see page 37)
- Intercurrent illnesses affecting diabetic control, for example infections (see page 37)
- Hypoglycaemia (see page 34)
- Alterations of diabetic control due to major changes in diet or activity
- Burning feet on hot sand or stones, making foot protection with sandals or trainers extremely important

ABC of Diabetes

(4 to 8 units on average). Regular meals should be taken as normal. Many airlines will make special provision for those with diabetes if notified in advance; it is nevertheless strongly advisable to carry a food pack in case of delays or other emergencies.

Physical activity

More insulin may be needed if those with diabetes decide to be much less active when on holiday, or vice versa. Dietary indiscretions may also play havoc with control.

Breakage or loss of equipment

People with diabetes should carry ample supplies of syringes, insulin, needles, and testing equipment, and it is wise for a travelling companion to have a second set. The equipment in current use and that for emergency use is best kept in separate places. Soluble and isophane insulins are obtainable in most countries.

Storage of insulin

In a temperate climate insulin will keep for some months at room temperature (and furthermore injections sting less if the insulin is not chilled). Refrigeration is wise for prolonged visits to a tropical climate, and is also recommended for stocks kept at home for long periods, although exposed insulin actually deteriorates very little. Insulin should never be deep frozen and should not be left in the luggage hold of an aircraft, where it may freeze. Insulin is not damaged when passing through scanners.

Vaccination and inoculation

These are quite suitable for diabetic people and should be given for the same indications as for non-diabetics.

Dental treatment

Diabetic people may receive dental treatment in the normal way and without any special arrangements, except in the case of insulin treated patients needing a general anaesthetic, when a short admission to hospital is the wisest course. Dental infections and abscesses can of course upset diabetic control as is the case with any other source of infection.

Dental treatment

The story of Mrs B-J concluded

I had started insulin only ten years after its discovery, but I remember meeting an elderly man in the upstairs waiting room by the path lab telling us that he had become diabetic before insulin, and how he thanked God for it every day. I know how he felt, but sadly his prophecy, that diabetes would be treated only like a cold in a further ten years, was not fulfilled.

During her early years Mrs B-J was treated with a variety of twice daily insulin regimens changing with the fashions of time and the whims of both herself and her physicians. The insulin dose in 1960 was around 26 units daily and in 2001 it is still approximately 24 units daily. Her HbA_{1c} has ranged between 9% and 10% between 1995 and 2001-2.

At the time of writing early in 2002, Mrs B-J, now nearly 80 years old and with diabetes of nearly 70-years duration, still regularly attends the diabetic clinic at King's College Hospital and has done so without a break since 1932. Her medical records from 1932 are complete, and correspondence dates back to 1966.

Apart from the recent development of infection in one great toe, it is remarkable to observe that after all these years, she has no retinopathy (1999) and only mild lens opacities; there has never been any proteinuria and an absence of microalbuminuria was noted in 1999.

We must congratulate Mrs B-J for her courage and perseverance over so many years. We are grateful now for the privilege of being able to read the very personal account of her own diabetes which must give so much encouragement to others.

Appendix 1

Questionnaire to assess diminished awareness of hypoglycaemia

This questionnaire is recommended by the Driver and Vehicle Licensing Agency for applicants for certain driving licences as indicated on page 88 and is also of value in assessing patients involved in other hazardous activities or occupations. The applicant should be assessed by a consultant specialising in diabetes.

- 1 Please give details of medical supervision for diabetes.
 - Date of interview
 - Date of previous attendance
 - Date of diagnosis of diabetes
 - Date insulin treatment commenced
- 2 Are you satisfied that the applicant:
 - (a) knows what symptoms can occur as a consequence of hypoglycaemia?
 - (b) can recognise these symptoms if they occur?
 - (c) can take appropriate action?
- 3 Has the applicant, to your knowledge, experienced hypoglycaemia while driving within the last 12 months, which required assistance from another person?
If yes please give details/date(s):
- 4 Is there evidence of impaired awareness of hypoglycaemia in the past 12 months, during waking hours?
If yes please give details/date(s):
- 5 Is there a history of hypoglycaemia during waking hours in the last 12 months requiring assistance from a third party?
If yes please give details/date(s):
- 6 Does the applicant have a very clear understanding of diabetes and the necessary precautions for safe driving?
- 7 Does the applicant always carry an accessible supply of carbohydrate in the vehicle?
- 8 Does the applicant undertake blood glucose monitoring at least TWICE daily and at times relevant to driving on their current entitlement?
- 9 Have you examined the applicant's blood glucose records for the past three months?
If no please explain why this was not done:
- 10 Are you satisfied with the accuracy of the results?
If no, please explain why not:
- 11 Is there evidence of biochemical hypoglycaemia without symptoms (blood glucose below 3.0 mmol/l) on routine testing?
If yes please give details:
- 12 Is there any diabetic complication or other medical condition that could affect safe driving?

Contributors

Peter Cantillon

Senior lecturer in medical informatics and medical education, National University of Ireland, Galway, Republic of Ireland

Richard Farrow

Director of problem based learning at the Peninsula Medical School at the Universities of Exeter and Plymouth

Jill Gordon

Associate professor in the department of medical education at the University of Sydney, Australia

Linda Hutchinson

Director of education and workforce development and consultant paediatrician, University Hospital Lewisham, London

David Jaques

Independent consultant in learning and teaching in higher education

Carol Jollie

Project officer in the skills enhancement project for the Camden Primary Care Trust at St Pancras Hospital, London

David M Kaufman

Director of the Learning and Instructional Development Centre at Simon Fraser University, Burnaby, British Columbia, Canada

Judy McKimm

Head of curriculum development at Imperial College School of Medicine, London and an educational consultant

Jill Morrison

Professor of general practice and deputy associate dean for education at Glasgow University

John J Norcini

President and chief executive officer of the Foundation for Advancement of International Medical Education and Research, Philadelphia, Pennsylvania

David Prideaux

Professor and head of the Office of Medical Education in the School of Medicine at Flinders University, Adelaide, Australia

Lambert W T Schuwirth

Assistant professor in the department of educational development and research at the University of Maastricht in the Netherlands

Sydney Smee

Manager of the Medical Council of Canada's qualifying examination part II, in Ottawa, Canada

John Spencer

General practitioner and professor of medical education in primary health care at the University of Newcastle upon Tyne

Cees P M van der Vleuten

Professor and chair in the department of educational development and research at the University of Maastricht in the Netherlands

Diana Wood

Director of medical education, University of Cambridge School of Clinical Medicine, Addenbrookes Hospital, Cambridge

Preface

Although we would never allow a patient to be treated by an untrained doctor or nurse, we often tolerate professional training being delivered by untrained teachers. Traditionally students were expected to absorb most of their medical education by attending timetabled lectures and ward-rounds, moving rapidly from one subject to the next in a crowded curriculum. Our junior doctors learnt by watching their seniors in between endless menial tasks. In recent years the importance of active, self directed learning in higher education has been recognised. Outcome led structured programmes for trainees are being developed in the face of reduced working hours for both the learners and teachers. These all present new challenges for teachers in medicine of all levels of seniority.

Throughout the world there is great interest in developing a set of qualifications for medical teachers, both at the elementary “teaching the teacher” level and as part of progressive modular programmes leading to formal certification. In addition to acquiring new qualifications and standards, teachers also need access to literature resources that describe essential components in medical education and supply tips and ideas for teaching.

This ABC began as an expressed wish of the BMJ to publish an introductory and accessible text on medical education. It grew into a book covering the more generic topics of learning and teaching in medicine with the aim of illustrating how educational theory and research underpins the practicalities of teaching and learning. The editors invited an international group of authors on the basis of their acknowledged expertise in the particular topics assigned to them. Each chapter was edited and illustrated to ensure maximum accessibility for readers and subsequently peer reviewed by two educational experts. Their suggestions have been incorporated into the finished book.

The *ABC of Learning and Teaching in Medicine* would not have been possible without the tireless support of BMJ editorial staff, Julia Thompson, Eleanor Lines, Sally Carter, and Naomi Wilkinson. We would also like to thank Professor Paul O’Neill and Dr Ed Peile for their excellent and timely peer reviews for each of the chapters. Finally we would very much welcome comments and suggestions about this ABC from its most important reviewers, you the readers.

PC, DW, LH

1 Applying educational theory in practice

David M Kaufman

How many times have we as teachers been confronted with situations in which we really were not sure what to do? We “flew by the seat of our pants,” usually doing with our learners what had been done with us. It would be useful to be able to turn to a set of guiding principles based on evidence, or at least on long term successful experience.

Fortunately, a body of theory exists that can inform practice. An unfortunate gap between academics and practitioners, however, has led to a perception of theory as belonging to an “ivory tower” and not relevant to practice. Yet the old adage that “there is nothing more practical than a good theory” still rings true today. This chapter describes several educational theories and guiding principles and then shows how these could be applied to three case studies relating to the “real world.”

Adult learning theory

Malcolm Knowles introduced the term “andragogy” to North America, defining it as “the art and science of helping adults learn.” Andragogy is based on five assumptions—about how adults learn and their attitude towards and motivation for learning.

Knowles later derived seven principles of andragogy. Most theorists agree that andragogy is not really a theory of adult learning, but they regard Knowles’ principles as guidelines on how to teach learners who tend to be at least somewhat independent and self directed. His principles can be summarised as follows:

- Establish an effective learning climate, where learners feel safe and comfortable expressing themselves
- Involve learners in mutual planning of relevant methods and curricular content
- Involve learners in diagnosing their own needs—this will help to trigger internal motivation
- Encourage learners to formulate their own learning objectives—this gives them more control of their learning
- Encourage learners to identify resources and devise strategies for using the resources to achieve their objectives
- Support learners in carrying out their learning plans
- Involve learners in evaluating their own learning—this can develop their skills of critical reflection.

Self directed learning

Self directed learning can be viewed as a method of organising teaching and learning in which the learning tasks are largely within the learners’ control (as with the adult learning principles described above).

It can also be viewed as a goal towards which learners strive so that they become empowered to accept personal responsibility for their own learning, personal autonomy, and individual choice. Success in the first view would lead to attaining the second.

Philip Candy identified in the literature about 100 traits associated with self direction, which he synthesised as the ability to be methodical and disciplined; logical and analytical; collaborative and interdependent; curious, open, creative, and motivated; persistent and responsible; confident and competent at learning; and reflective and self aware.

Andragogy—five assumptions about adult learning

- Adults are independent and self directing
 - They have accumulated a great deal of experience, which is a rich resource for learning
 - They value learning that integrates with the demands of their everyday life
 - They are more interested in immediate, problem centred approaches than in subject centred ones
 - They are more motivated to learn by internal drives than by external ones
-

Learners need to feel safe and comfortable expressing themselves

Self directed learning

- Organising teaching and learning so that learning is within the learners’ control
 - A goal towards which learners strive so that they become able to accept responsibility for their own learning
-

ABC of Learning and Teaching in Medicine

How do we develop these traits in our learners? Most importantly, learners must have the opportunity to develop and practise skills that directly improve self directed learning. These skills include asking questions, critically appraising new information, identifying their own knowledge and skill gaps, and reflecting critically on their learning process and outcomes.

Self efficacy

According to Albert Bandura, people's judgments of their own ability to deal with different situations is central to their actions. These actions include what they choose to do, how much effort they invest in activities, how long they persist in the face of adversity, and whether they approach the tasks anxiously or assuredly.

These judgments, called "self efficacy," may or may not be accurate, but they arise from four main information sources. In decreasing order of their strength, these sources are: performance attainments, observations of other people, verbal persuasion, and physiological state. Successes raise our self efficacy, while failures lower it. Failures are particularly likely to lower our self efficacy if they occur early in the learning process and are not due to lack of effort or difficult situations.

Observing other people similar to us performing successfully can strengthen our beliefs that we can perform similar tasks, especially when the tasks are unfamiliar. Verbal persuasion from a credible source also can help.

Finally, we (both teachers and learners) need to re-interpret our anxiety or nervousness in difficult situations as excitement or anticipation, rather than as an ominous sign of vulnerability.

Constructivism

Constructivism has important implications for teaching and learning. Firstly, the teacher is viewed not as a transmitter of knowledge but as a guide who facilitates learning. Secondly, as learning is based on prior knowledge, teachers should provide learning experiences that expose inconsistencies between students' current understandings and their new experiences. Thirdly, teachers should engage students in their learning in an active way, using relevant problems and group interaction. Fourthly, if new knowledge is to be actively acquired, sufficient time must be provided for in-depth examination of new experiences.

Reflective practice

The theory of reflective practice is attributed primarily to Donald Schön, whose work is based on the study of a range of professions. He argues that formal theory acquired through professional preparation is often not useful to the solution of the real life "messy, indeterminate" problems of practice.

Schön labels professionals' automatic ways of practising as professional "zones of mastery"—that is, areas of competence. Unexpected events or surprises trigger two kinds of reflection.

The first, "reflection in action," occurs immediately. It is the ability to learn and develop continually by creatively applying current and past experiences and reasoning to unfamiliar events while they are occurring. The second, "reflection on action," occurs later. It is a process of thinking back on what happened in a past situation, what may have contributed to the unexpected event, whether the actions taken were appropriate, and how this situation may affect future practice.

Learners should identify their own knowledge gaps and critically appraise new information

Teachers and learners need to view any anxiety or nervousness in difficult situations as excitement or anticipation

Self efficacy—roles for the teacher

- Modelling or demonstration
- Setting a clear goal or image of the desired outcome
- Providing basic knowledge and skills needed as the foundation for the task
- Providing guided practice with corrective feedback
- Giving students the opportunity to reflect on their learning

The primary idea of constructivism is that learners "construct" their own knowledge on the basis of what they already know. This theory posits that learning is active, rather than passive, with learners making judgments about when and how to modify their knowledge

"Reflection in action"

Through the process of reflecting both “in practice” and “on practice,” practitioners continually reshape their approaches and develop “wisdom” or “artistry” in their practice. Activities such as debriefing with peers or learners, seeking feedback from learners on a regular basis, and keeping a journal can provide vehicles for reflective practice.

Converting theory into practice

Each of the educational theories presented here can guide our teaching practices. Some theories will be more helpful than others in particular contexts. However, several principles also emerge from these theories, and these can provide helpful guidance for medical educators.

Three cases studies

The boxes (right) describe three “real world” case studies representing situations encountered in medical education settings. The educational theories described above, and the principles which emerge from them, can guide us in solving the problems posed in these three cases.

Case 1 solution

You could present an interactive lecture on the autonomic nervous system. You could distribute a notetaking guide. This would contain key points, space for written notes, and two key multiple choice or “short answer” questions requiring higher level thinking (principle 1, see box above). You could stop twice during the lecture and ask the students to discuss their response to each question with their neighbours (principles 1, 3, and 5). A show of hands would determine the class responses to the question (checking for understanding) and you could then give the correct answer (principle 5). Finally, you could assign a learning issue for the students to research in their own time (principle 4).

Case 2 solution

You could assign the students to small groups of four to six, and ask each group to submit two case studies describing clinical ethics issues in their local hospitals (principles 1 and 2). The ethics theory and approach needed to analyse these cases could be prepared by experts and presented on a website in advance of the sessions (principles 4, 5). The first of the six blocks of two hours could be used to discuss the material on the website and clarify any misunderstandings (principle 5). You could then show the students how to work through a case, with participation by the class (principle 7). The other five blocks could then be used for each small group to work through some of the cases prepared earlier, followed by a debriefing session with the whole class (principles 5 and 6).

Case 3 solution

You could first invite the registrar to observe you with patients, and do a quick debrief at the end of the day (principles 2, 6, and 7). With help from you, she could then develop her own learning goals, based on the certification requirements and perceived areas of weakness (principles 1, 3, and 4). These goals would provide the framework for assessing the registrar’s performance with patients (principles 5, 6). You could observe and provide feedback (principle 5). Finally, the registrar could begin to see patients alone and keep a journal (written or electronic) in which she records the results of “reflection on practice” (principle 6). She could also record in her journal the personal learning issues arising from her patients, could conduct self directed learning on these, and could document

Seven principles to guide teaching practice

- 1 The learner should be an active contributor to the educational process
 - 2 Learning should closely relate to understanding and solving real life problems
 - 3 Learners’ current knowledge and experience are critical in new learning situations and need to be taken into account
 - 4 Learners should be given the opportunity and support to use self direction in their learning
 - 5 Learners should be given opportunities and support for practice, accompanied by self assessment and constructive feedback from teachers and peers
 - 6 Learners should be given opportunities to reflect on their practice; this involves analysing and assessing their own performance and developing new perspectives and options
 - 7 Use of role models by medical educators has a major impact on learners. As people often teach the way they were taught, medical educators should model these educational principles with their students and junior doctors. This will help the next generation of teachers and learners to become more effective and should lead to better care for patients
-

Case 1: Teaching basic science

You have been asked to give a lecture on the autonomic nervous system to a first year medical class of 120 students. This has traditionally been a difficult subject for the class, particularly as it has not been explicitly covered by faculty in the problem based anatomy course. You wonder how you can make this topic understandable to the class in a 50-minute lecture.

Case 2: Ethics education

You are a member of a course committee in the department of internal medicine, which is charged with the task of integrating the topic of ethics into the third year medicine rotation. Your committee has been given six blocks of two hours over a 12 week period. You wonder how to make the material engaging, understandable, and useful to the students.

Case 3: General practice training

You are the trainer for a first year registrar in her first year of a general practice training programme. Your practice is so busy that you have very little time to spend with her. You wonder how you can contribute to providing a valuable learning experience for your trainee.

ABC of Learning and Teaching in Medicine

her findings in the journal (principles 1, 4, and 6). You could provide feedback on the journal (principle 5). If practical, the cohort of registrars could communicate via the internet to discuss their insights and experiences (principle 6).

Conclusions

This article has attempted to show how the gap between educational theory and practice can be bridged. By using teaching and learning methods based on educational theories and derived principles, medical educators will become more effective teachers. This will enhance the development of knowledge, skills, and positive attitudes in their learners, and improve the next generation of teachers. Ultimately, this should result in better trained doctors who provide an even higher level of patient care and improved patient outcomes.

2 Curriculum design

David Prideaux

The curriculum represents the expression of educational ideas in practice. The word curriculum has its roots in the Latin word for track or race course. From there it came to mean course of study or syllabus. Today the definition is much wider and includes all the planned learning experiences of a school or educational institution.

The curriculum must be in a form that can be communicated to those associated with the learning institution, should be open to critique, and should be able to be readily transformed into practice. The curriculum exists at three levels: what is planned for the students, what is delivered to the students, and what the students experience.

A curriculum is the result of human agency. It is underpinned by a set of values and beliefs about what students should know and how they come to know it. The curriculum of any institution is often contested and problematic. Some people may support a set of underlying values that are no longer relevant. This is the so called sabretoothed curriculum, which is based on the fable of the cave dwellers who continued to teach about hunting the sabretoothed tiger long after it became extinct. In contemporary medical education it is argued that the curriculum should achieve a “symbiosis” with the health services and communities in which the students will serve. The values that underlie the curriculum should enhance health service provision. The curriculum must be responsive to changing values and expectations in education if it is to remain useful.

Elements of a curriculum

If curriculum is defined more broadly than syllabus or course of study then it needs to contain more than mere statements of content to be studied. A curriculum has at least four important elements: content; teaching and learning strategies; assessment processes; and evaluation processes.

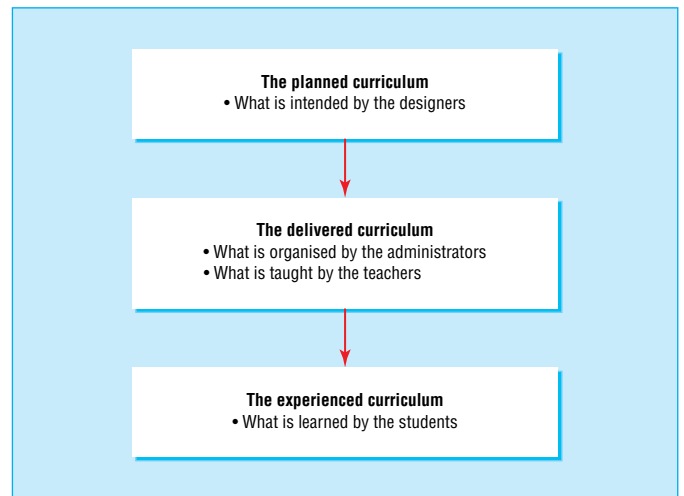

The process of defining and organising these elements into a logical pattern is known as curriculum design. Curriculum writers have tried to place some order or rationality on the process of designing a curriculum by advocating models.

There are two main types: prescriptive models, which indicate what curriculum designers should do; and descriptive models, which purport to describe what curriculum designers actually do. A consideration of these models assists in understanding two additional key elements in curriculum design: statements of intent and context.

Prescriptive models

Prescriptive models are concerned with the ends rather than the means of a curriculum. One of the more well known examples is the “objectives model,” which arose from the initial work of Ralph Tyler in 1949. According to this model, four important questions are used in curriculum design.

The first question, about the “purposes” to be obtained, is the most important one. The statements of purpose have become known as “objectives,” which should be written in terms of changed behaviour among learners that can be easily measured. This was interpreted very narrowly by some people and led to the specification of verbs that are acceptable and those that are unacceptable when writing the so called

Three levels of a curriculum

“Symbiosis” necessary for a curriculum. From Bligh J et al (see “Further reading” box)

Curriculum models

Prescriptive models

- What curriculum designers should do
- How to create a curriculum

Descriptive models

- What curriculum designers actually do
 - What a curriculum covers
-

Objectives model—four important questions*

- What educational purposes should the institution seek to attain?
- What educational experiences are likely to attain the purposes?
- How can these educational experiences be organised effectively?
- How can we determine whether these purposes are being attained?

*Based on Tyler R. *Basic principles of curriculum and instruction*. Chicago: Chicago University Press, 1949

ABC of Learning and Teaching in Medicine

“behavioural objectives.” Once defined, the objectives are then used to determine the other elements of the curriculum (content; teaching and learning strategies; assessment; and evaluation).

This model has attracted some criticism—for example, that it is difficult and time consuming to construct behavioural objectives. A more serious criticism is that the model restricts the curriculum to a narrow range of student skills and knowledge that can be readily expressed in behavioural terms. Higher order thinking, problem solving, and processes for acquiring values may be excluded because they cannot be simply stated in behavioural terms. As a result of such criticism the objectives model has waned in popularity. The importance of being clear about the purpose of the curriculum is well accepted.

More recently, another prescriptive model of curriculum design has emerged. “Outcomes based education” is similar in many respects to the objectives model and again starts from a simple premise—the curriculum should be defined by the outcomes to be obtained by students. Curriculum design proceeds by working “backwards” from outcomes to the other elements (content; teaching and learning experiences; assessment; and evaluation).

The use of outcomes is becoming more popular in medical education, and this has the important effect of focusing curriculum designers on what the students will do rather than what the staff do. Care should be taken, however, to focus only on “significant and enduring” outcomes. An exclusive concern with specific competencies or precisely defined knowledge and skills to be acquired may result in the exclusion of higher order content that is important in preparing medical professionals.

Although debate may continue about the precise form of these statements of intent (as they are known), they constitute an important element of curriculum design. It is now well accepted that curriculum designers will include statements of intent in the form of both broad curriculum aims and more specific objectives in their plans. Alternatively, intent may be expressed in terms of broad and specific curriculum outcomes. The essential function of these statements is to require curriculum designers to consider clearly the purposes of what they do in terms of the effects and impact on students.

Descriptive models

An enduring example of a descriptive model is the situational model advocated by Malcolm Skilbeck, which emphasises the importance of situation or context in curriculum design. In this model, curriculum designers thoroughly and systematically analyse the situation in which they work for its effect on what they do in the curriculum. The impact of both external and internal factors is assessed and the implications for the curriculum are determined.

Although all steps in the situational model (including situational analysis) need to be completed, they do not need to be followed in any particular order. Curriculum design could begin with a thorough analysis of the situation of the curriculum or the aims, objectives, or outcomes to be achieved, but it could also start from, or be motivated by, a review of content, a revision of assessment, or a thorough consideration of evaluation data. What is possible in curriculum design depends heavily on the context in which the process takes place.

All the elements in curriculum design are linked. They are not separate steps. Content should follow from clear statements of intent and must be derived from considering external and internal context. But equally, content must be delivered by

Behavioural objectives*

Acceptable verbs

- To write
- To recite
- To identify
- To differentiate
- To solve
- To construct
- To list
- To compare
- To contrast

Unacceptable verbs

- To know
- To understand
- To really understand
- To appreciate
- To fully appreciate
- To grasp the significance of
- To enjoy
- To believe
- To have faith in

*From Davies I. *Objectives in curriculum design*. London: McGraw Hill, 1976

Clearly stated objectives provide a good starting point, but behavioural objectives are no longer accepted as the “gold standard” in curriculum design

Outcomes based curriculum (defining a curriculum “backwards”—that is, from the starting point of desired outcomes)

Example of statements of intent

Aim

- To produce graduates with knowledge and skills for treating common medical conditions

Objectives

- To identify the mechanisms underlying common diseases of the circulatory system
- To develop skills in history taking for diseases of the circulatory system

Broad outcome

- Graduates will attain knowledge and skills for treating common medical conditions
- Students will identify the mechanisms underlying common diseases of the circulatory system
- Students will acquire skills in history taking for diseases of the circulatory system

Situational analysis*

External factors

- Societal expectations and changes
- Expectations of employers
- Community assumptions and values
- Nature of subject disciplines
- Nature of support systems
- Expected flow of resources

Internal factors

- Students
- Teachers
- Institutional ethos and structure
- Existing resources
- Problems and shortcomings in existing curriculum

*From Reynolds J, Skilbeck M. *Culture and the classroom*. London: Open Books, 1976

appropriate teaching and learning methods and assessed by relevant tools. No one element—for example, assessment—should be decided without considering the other elements.

Curriculum maps

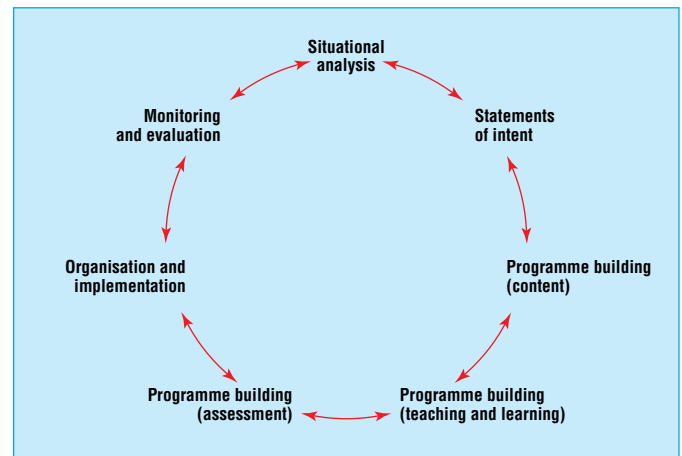

Curriculum maps provide a means of showing the links between the elements of the curriculum. They also display the essential features of the curriculum in a clear and succinct manner. They provide a structure for the systematic organisation of the curriculum, which can be represented diagrammatically and can provide the basis for organising the curriculum into computer databases.

The starting point for the maps may differ depending on the audience. A map for students will place them at the centre and will have a different focus from a map prepared for teachers, administrators, or accrediting authorities. They all have a common purpose, however, in showing the scope, complexity, and cohesion of the curriculum.

Curriculum maps with computer based graphics with “click-on” links are an excellent format. The maps provide one way of tracing the links between the curriculum as planned, as delivered, and as experienced. But like all maps, a balance must be achieved between detail and overall clarity of representation.

Example of a curriculum map from the students' perspective. Each of the boxes representing the elements of design can be broken down into further units and each new unit can be related to the others to illustrate the interlinking of all the components of the curriculum

3 Problem based learning

Diana Wood

Problem based learning is used in many medical schools in the United Kingdom and worldwide. This article describes this method of learning and teaching in small groups and explains why it has had an important impact on medical education.

What is problem based learning?

In problem based learning (PBL) students use “triggers” from the problem case or scenario to define their own learning objectives. Subsequently they do independent, self directed study before returning to the group to discuss and refine their acquired knowledge. Thus, PBL is not about problem solving per se, but rather it uses appropriate problems to increase knowledge and understanding. The process is clearly defined, and the several variations that exist all follow a similar series of steps.

Group learning facilitates not only the acquisition of knowledge but also several other desirable attributes, such as communication skills, teamwork, problem solving, independent responsibility for learning, sharing information, and respect for others. PBL can therefore be thought of as a small group teaching method that combines the acquisition of knowledge with the development of generic skills and attitudes. Presentation of clinical material as the stimulus for learning enables students to understand the relevance of underlying scientific knowledge and principles in clinical practice.

However, when PBL is introduced into a curriculum, several other issues for curriculum design and implementation need to be tackled. PBL is generally introduced in the context of a defined core curriculum and integration of basic and clinical sciences. It has implications for staffing and learning resources and demands a different approach to timetabling, workload, and assessment. PBL is often used to deliver core material in non-clinical parts of the curriculum. Paper based PBL scenarios form the basis of the core curriculum and ensure that all students are exposed to the same problems. Recently, modified PBL techniques have been introduced into clinical education, with “real” patients being used as the stimulus for learning. Despite the essential ad hoc nature of learning clinical medicine, a “key cases” approach can enable PBL to be used to deliver the core clinical curriculum.

What happens in a PBL tutorial?

PBL tutorials are conducted in several ways. In this article, the examples are modelled on the Maastricht “seven jump” process, but its format of seven steps may be shortened.

A typical PBL tutorial consists of a group of students (usually eight to 10) and a tutor, who facilitates the session. The length of time (number of sessions) that a group stays together with each other and with individual tutors varies between institutions. A group needs to be together long enough to allow good group dynamics to develop but may need to be changed occasionally if personality clashes or other dysfunctional behaviour emerges.

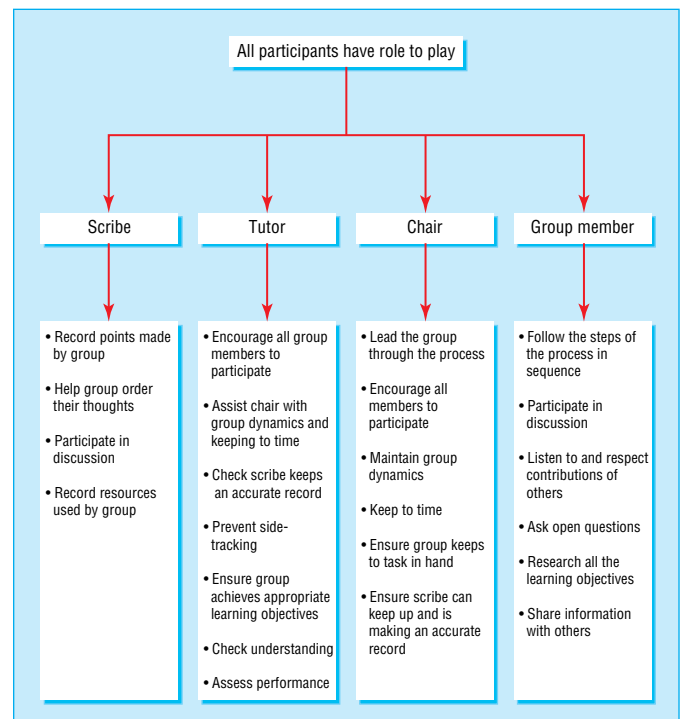

Students elect a chair for each PBL scenario and a “scribe” to record the discussion. The roles are rotated for each scenario. Suitable flip charts or a whiteboard should be used for recording the proceedings. At the start of the session,

The group learning process: acquiring desirable learning skills

Generic skills and attitudes

- Teamwork
- Chairing a group
- Listening
- Recording
- Cooperation
- Respect for colleagues' views
- Critical evaluation of literature
- Self directed learning and use of resources
- Presentation skills

Roles of participants in a PBL tutorial

depending on the trigger material, either the student chair reads out the scenario or all students study the material. If the trigger is a real patient in a ward, clinic, or surgery then a student may be asked to take a clinical history or identify an abnormal physical sign before the group moves to a tutorial room. For each module, students may be given a handbook containing the problem scenarios, and suggested learning resources or learning materials may be handed out at appropriate times as the tutorials progress.

The role of the tutor is to facilitate the proceedings (helping the chair to maintain group dynamics and moving the group through the task) and to ensure that the group achieves appropriate learning objectives in line with those set by the curriculum design team. The tutor may need to take a more active role in step 7 of the process to ensure that all the students have done the appropriate work and to help the chair to suggest a suitable format for group members to use to present the results of their private study. The tutor should encourage students to check their understanding of the material. He or she can do this by encouraging the students to ask open questions and ask each other to explain topics in their own words or by the use of drawings and diagrams.

PBL in curriculum design

PBL may be used either as the mainstay of an entire curriculum or for the delivery of individual courses. In practice, PBL is usually part of an integrated curriculum using a systems based approach, with non-clinical material delivered in the context of clinical practice. A module or short course can be designed to include mixed teaching methods (including PBL) to achieve the learning outcomes in knowledge, skills, and attitudes. A small number of lectures may be desirable to introduce topics or provide an overview of difficult subject material in conjunction with the PBL scenarios. Sufficient time should be allowed each week for students to do the self directed learning required for PBL.

Writing PBL scenarios

PBL is successful only if the scenarios are of high quality. In most undergraduate PBL curriculums the faculty identifies learning objectives in advance. The scenario should lead students to a particular area of study to achieve those learning objectives (see box on page 11).

How to create effective PBL scenarios*

- Learning objectives likely to be defined by the students after studying the scenario should be consistent with the faculty learning objectives
- Problems should be appropriate to the stage of the curriculum and the level of the students' understanding
- Scenarios should have sufficient intrinsic interest for the students or relevance to future practice
- Basic science should be presented in the context of a clinical scenario to encourage integration of knowledge
- Scenarios should contain cues to stimulate discussion and encourage students to seek explanations for the issues presented
- The problem should be sufficiently open, so that discussion is not curtailed too early in the process
- Scenarios should promote participation by the students in seeking information from various learning resources

*Adapted from Dolmans et al. *Med Teacher* 1997;19:185-9

Examples of trigger material for PBL scenarios

- Paper based clinical scenarios
- Experimental or clinical laboratory data
- Photographs
- Video clips
- Newspaper articles
- All or part of an article from a scientific journal
- A real or simulated patient
- A family tree showing an inherited disorder

PBL tutorial process

- Step 1*—Identify and clarify unfamiliar terms presented in the scenario; scribe lists those that remain unexplained after discussion
- Step 2*—Define the problem or problems to be discussed; students may have different views on the issues, but all should be considered; scribe records a list of agreed problems
- Step 3*—“Brainstorming” session to discuss the problem(s), suggesting possible explanations on basis of prior knowledge; students draw on each other’s knowledge and identify areas of incomplete knowledge; scribe records all discussion
- Step 4*—Review steps 2 and 3 and arrange explanations into tentative solutions; scribe organises the explanations and restructures if necessary
- Step 5*—Formulate learning objectives; group reaches consensus on the learning objectives; tutor ensures learning objectives are focused, achievable, comprehensive, and appropriate
- Step 6*—Private study (all students gather information related to each learning objective)
- Step 7*—Group shares results of private study (students identify their learning resources and share their results); tutor checks learning and may assess the group

Designing and implementing a curriculum module using PBL supported by other teaching methods

Staff development

Introducing PBL into a course makes new demands on tutors, requiring them to function as facilitators for small group learning rather than acting as providers of information. Staff development is essential and should focus on enabling the PBL tutors to acquire skills in facilitation and in management of group dynamics (including dysfunctional groups).

Tutors should be also given information about the institution's educational strategy and curriculum programme so that they can help students to understand the learning objectives of individual modules in the context of the curriculum as a whole. Methods of assessment and evaluation should be described, and time should be available to discuss anxieties.

Staff may feel uncertain about facilitating a PBL tutorial for a subject in which they do not themselves specialise. Subject specialists may, however, be poor PBL facilitators as they are more likely to interrupt the process and revert to lecturing. None the less, students value expertise, and the best tutors are subject specialists who understand the curriculum and have excellent facilitation skills. However, enthusiastic non-specialist tutors who are trained in facilitation, know the curriculum, and have adequate tutor notes, are good PBL tutors.

Assessment of PBL

Student learning is influenced greatly by the assessment methods used. If assessment methods rely solely on factual recall then PBL is unlikely to succeed in the curriculum. All assessment schedules should follow the basic principles of testing the student in relation to the curriculum outcomes and should use an appropriate range of assessment methods.

Assessment of students' activities in their PBL groups is advisable. Tutors should give feedback or use formative or summative assessment procedures as dictated by the faculty assessment schedule. It is also helpful to consider assessment of the group as a whole. The group should be encouraged to reflect on its PBL performance including its adherence to the process, communication skills, respect for others, and individual contributions. Peer pressure in the group reduces the likelihood of students failing to keep up with workload, and the award of a group mark—added to each individual's assessment schedule—encourages students to achieve the generic goals associated with PBL.

Conclusion

PBL is an effective way of delivering medical education in a coherent, integrated programme and offers several advantages over traditional teaching methods. It is based on principles of adult learning theory, including motivating the students, encouraging them to set their own learning goals, and giving them a role in decisions that affect their own learning.

Predictably, however, PBL does not offer a universal panacea for teaching and learning in medicine, and it has several well recognised disadvantages. Traditional knowledge based assessments of curriculum outcomes have shown little or no difference in students graduating from PBL or traditional curriculums. Importantly, though, students from PBL curriculums seem to have better knowledge retention. PBL also generates a more stimulating and challenging educational environment, and the beneficial effects from the generic attributes acquired through PBL should not be underestimated.

A dysfunctional group: a dominant character may make it difficult for other students to be heard

Advantages and disadvantages of PBL

Advantages of PBL

Student centred PBL—It fosters

active learning, improved understanding, and retention and development of lifelong learning skills

Generic competencies—PBL allows students to develop generic skills and attitudes desirable in their future practice

Integration—PBL facilitates an integrated core curriculum

Motivation—PBL is fun for students and tutors, and the process requires all students to be engaged in the learning process

“Deep” learning—PBL fosters deep learning (students interact with learning materials, relate concepts to everyday activities, and improve their understanding)

Constructivist approach—Students activate prior knowledge and build on existing conceptual knowledge frameworks

Disadvantages of PBL

Tutors who can't “teach”—Tutors enjoy passing on their own knowledge and understanding so may find PBL facilitation difficult and frustrating

Human resources—More staff have to take part in the tutoring process

Other resources—Large numbers of students need access to the same library and computer resources simultaneously

Role models—Students may be deprived access to a particular inspirational teacher who in a traditional curriculum would deliver lectures to a large group

Information overload—Students may be unsure how much self directed study to do and what information is relevant and useful

PBL scenarios: the importance of linking to faculty learning objectives**PBL scenario 1**

A 35 year old part time nurse, presented to her general practitioner, Dr Smith, with a six month history of weight loss (12.7 kg). When questioned, she said she was eating well but had diarrhoea. She also felt exhausted and had developed insomnia. On further questioning she admitted to feeling increasingly hot and shaky and to having muscle weakness in her legs, particularly when climbing stairs. She was normally well and had not seen the doctor since her last pregnancy eight years ago.

A blood test showed the following results:

Free thyroxine 49.7 pmol/l (normal range 11 to 24.5)

Total thyroxine 225 nmol/l (normal range 60 to 150)

Thyroid stimulating hormone < 0.01 mU/l (0.4 to 4.0)

Dr Smith referred her to an endocrinologist at the local hospital where initial investigations confirmed a diagnosis of Graves' disease. She was treated with carbimazole and propranolol for the first month of treatment followed by carbimazole alone. After discussing the therapeutic options, she opted to have iodine-131 treatment.

Faculty learning objectives

- Describe the clinical features of thyrotoxicosis and diagnostic signs of Graves' disease
- Interpret basic thyroid function tests in the light of the pituitary thyroid axis and feedback mechanisms
- List the types of treatment for thyrotoxicosis including their indications, mode of action, and potential side effects

Notes

This scenario is part of a core endocrinology and metabolism module for third year undergraduate medical students. The faculty learning objectives relate to the scenario; the problem is relevant to the level of study and integrates basic science with clinical medicine. The combination of basic science, clinical medicine, and therapeutics should lead to extensive discussion and broadly based self directed learning

PBL scenario 2

Mr JB, a 58 year old car mechanic with a history of chronic obstructive pulmonary disease, was at work when he complained of pain in his chest. The pain steadily got worse and he described an aching in his jaw and left arm. One hour after the pain started he collapsed and his colleagues called an ambulance. When he arrived at the local accident and emergency department, Mr JB was pale, sweaty, and in severe pain.

Examination showed:

Blood pressure 80/60 mm Hg

Heart rate 64 beats/min

Electrocardiography showed anterolateral myocardial infarction

He was treated with diamorphine, metoclopramide, and aspirin. As the accident and emergency staff were preparing to give him streptokinase, he had a cardiac arrest. Electrocardiography showed asystolic cardiac arrest. Despite all efforts, resuscitation failed.

Faculty learning objectives

- List the risk factors for myocardial infarction
- Describe a rehabilitation programme for patients who have had a myocardial infarction

Notes

This scenario is part of a core module in the cardiorespiratory system for first year undergraduate medical students. The scenario is complex for students with limited clinical experience. The faculty learning objectives relate to public health and epidemiological aspects of ischaemic heart disease. For increased impact, the faculty illustrated the case with a dramatic scenario. Students would be unlikely to arrive at the same objectives, probably concentrating on clinical aspects of acute myocardial infarction and its management

4 Evaluation

Jill Morrison

Evaluation is an essential part of the educational process. The focus of evaluation is on local quality improvement and is analogous to clinical audit. Medical schools require evaluation as part of their quality assurance procedures, but the value of evaluation is much greater than the provision of simple audit information. It provides evidence of how well students' learning objectives are being achieved and whether teaching standards are being maintained. Importantly, it also enables the curriculum to evolve. A medical curriculum should constantly develop in response to the needs of students, institutions, and society. Evaluation can check that the curriculum is evolving in the desired way. It should be viewed positively as contributing to the academic development of an institution and its members.

Evaluation versus research

Evaluation and educational research are similar activities but with important differences. Research is usually aimed at producing generalisable results that can be published in peer reviewed literature, and it requires ethical and other safeguards. Evaluation is generally carried out for local use and does not usually require ethics committee approval. Evaluation has to be carefully considered by curriculum committees, however, to ensure that it is being carried out ethically. Finally, evaluation is a continuous process, whereas research may not become continuous if the answer to the question is found.

What should be evaluated

Evaluation may cover the process and/or outcome of any aspect of education, including the delivery and content of teaching. Questions about delivery may relate to organisation—for example, administrative arrangements, physical environment, and teaching methods. Information may also be sought about the aptitude of the teacher(s) involved. The content may be evaluated for its level (it should not be too easy or too difficult), its relevance to curriculum objectives, and integration with previous learning.

Outcome measures may show the impact of the curriculum on the knowledge, skills, attitudes, and behaviour of students. Kirkpatrick described four levels on which to focus evaluation; these have recently been adapted for use in health education evaluation by Barr and colleagues. Some indication of these attributes may be obtained by specific methods of inquiry—for example, by analysing data from student assessments.

Evaluation in curriculum planning

Evaluation should be designed at the start of developing a curriculum, not added as an afterthought. When an educational need has been identified, the first stage is to define the learning outcomes for the curriculum. The goals of the evaluation should be clearly articulated and linked to the outcomes.

Clarifying the goals of evaluation will help to specify the evidence needed to determine success or failure of the training. A protocol should then be prepared so that individual responsibilities are clearly outlined.

Purpose of evaluation

- To ensure teaching is meeting students' learning needs
 - To identify areas where teaching can be improved
 - To inform the allocation of faculty resources
 - To provide feedback and encouragement for teachers
 - To support applications for promotion by teachers
 - To identify and articulate what is valued by medical schools
 - To facilitate development of the curriculum
-

Evaluation cycle. From Wilkes et al (see “Further reading” box)

Kirkpatrick’s four levels on which to focus evaluation*

- Level 1—Learner’s reactions
- Level 2a—Modification of attitudes and perceptions
- Level 2b—Acquisition of knowledge and skills
- Level 3—Change in behaviour
- Level 4a—Change in organisational practice
- Level 4b—Benefits to patients or clients

*Adapted by Barr et al (see “Further reading” box)

The full impact of the curriculum may not be known until some time after the student has graduated

Questions to ask when planning an evaluation

- What are the goals of the evaluation?
 - From whom and in what form will data be collected?
 - Who will collect and analyse data?
 - What type of analysis, interpretation, and decision rules will be used and by whom?
 - Who will see the results of the evaluation?
-

Designing evaluation

An ideal evaluation method would be reliable, valid, acceptable, and inexpensive. Unfortunately, ideal methods for evaluating teaching in medical schools are scarce.

Establishing the reliability and validity of instruments and methods of evaluation can take many years and be costly. Testing and retesting of instruments to establish their psychometric properties without any additional benefit for students or teachers is unlikely to be popular with them. There is a need for robust “off the shelf” instruments that can be used to evaluate curriculums reliably. The process of evaluation itself may produce a positive educational impact if it emphasises those elements that are considered valuable and important by medical schools.

Participation by students

Several issues should be considered before designing an evaluation that collects information from students.

Competence—Students can be a reliable and valid source of information. They are uniquely aware of what they can consume, and they observe teaching daily. They are also an inexpensive resource. Daily contact, however, does not mean that students are skilled in evaluation. Evaluation by students should be limited to areas in which they are competent to judge.

Ownership—Students who are not committed to an evaluation may provide poor information. They need to feel ownership for an evaluation by participating in its development. The importance of obtaining the information and the type of information needed must be explicit. Usually the results of an evaluation will affect only subsequent cohorts of students, so current students must be convinced of the value of providing data.

Sampling—Students need to feel that their time is respected. If they are asked to fill out endless forms they will resent the waste of their time. If they become bored by tedious repetition, the reliability of the data will deteriorate. One solution is to use different sampling strategies for evaluating different elements of a curriculum. If reliable information can be obtained from 100 students, why collect data from 300?

Anonymity is commonly advocated as a guard against bias when information is collected from students. However, those who support asking students to sign evaluation forms say that this helps to create a climate of responsible peer review. If students are identifiable from the information they provide, this must not affect their progress. Data should be collected centrally and students’ names removed so that they cannot be identified by teachers whom they have criticised.

Feedback—Students need to know that their opinions are valued, so they should be told of the results of the evaluation and given details of the resulting action.

Methods of evaluation

Evaluation may involve subjective and objective measures and qualitative and quantitative approaches. The resources devoted to evaluation should reflect its importance, but excessive data collection should be avoided. A good system should be easy to administer and use information that is readily available.

Interviews—Individual interviews with students are useful if the information is sensitive—for example, when a teacher has received poor ratings from students, and the reasons are not clear. A group interview can provide detailed views from students or teachers. A teaching session can end with reflection by the group.

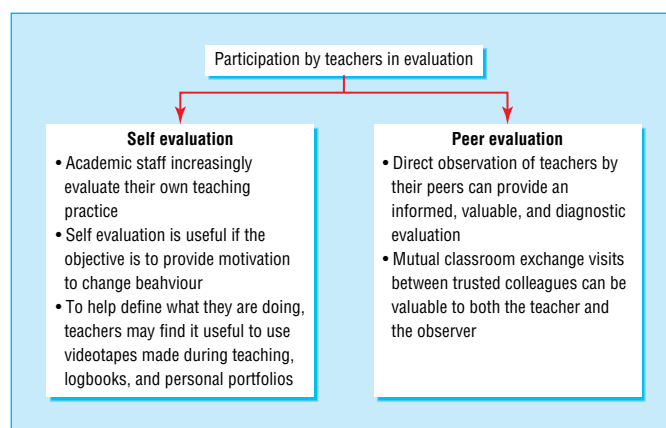

Characteristics of an ideal evaluation

- Reliability
- Validity
- Acceptability—to evaluator and to person being evaluated
- Inexpensiveness

To reduce possible bias in evaluation, collect views from more than one group of people—for example, students, teachers, other clinicians, and patients

Areas of competence of students to evaluate teaching and curriculum

- Design: whether the curriculum enables students to reach their learning objectives; whether it fits well with other parts of the curriculum
- Delivery: attributes of teacher and methods used
- Administrative arrangements

Issues relating to students’ participation in evaluation may also apply to teachers, but self evaluation and peer evaluation are also relevant

ABC of Learning and Teaching in Medicine

Surveys—Questionnaires are useful for obtaining information from large numbers of students or teachers about the teaching process. Electronic methods for administering questionnaires may improve response rates. The quality of the data, however, is only as good as the questions asked, and the data may not provide the reasons for a poorly rated session.

Information from student assessment—Data from assessment are useful for finding out if students have achieved the learning outcomes of a curriculum. A downward trend in examination results over several cohorts of students may indicate a deficiency in the curriculum. Caution is needed when interpreting this source of information, as students' examination performance depends as much on their application, ability, and motivation as on the teaching.

Completing the evaluation cycle

The main purpose of evaluation is to inform curriculum development. No curriculum is perfect in design and delivery. If the results of an evaluation show that no further development is needed, doubt is cast on the methods of evaluation or the interpretation of the results.

This does not mean that curriculums should be in a constant state of change, but that the results of evaluation to correct deficiencies are acted on, that methods continue to improve, and that content is updated. Then the process starts all over again.

Worked example

Background

Clinical teaching staff think that students are becoming weaker at examining cranial nerves. The examination scores for that part of the objective structured clinical examination (OSCE) carried out at the end of year three show a decline over several years. Three focus groups are held with students in year four, and several clinical teachers are interviewed. The results suggest that the decline is due to fewer appropriate patients presenting at outpatient sessions where cranial nerve examination is taught and to a lack of opportunities for practising examination skills.

Intervention

A teaching session is designed for delivery in the clinical skills centre. After that, students should be able to do a systematic examination of cranial nerves. They should also recognise normal signs and know which common abnormalities to look for. Sessions are timetabled for practising skills learnt during the teaching session.

Evaluation

A questionnaire is developed for completion by a third of students. It seeks their views on the teaching process, including the teaching skills of the tutor, physical aspects of the teaching environment, appropriateness of the teaching material, and opportunities for practising examination skills. Outcome measures include comparison of examination scores for students in the previous cohort with those participating in the teaching session, plus a questionnaire for all clinical supervisors for neurology in the following year to get their views about students' examination skills. A tenth of students with a range of scores in the relevant part of the OSCE are interviewed to find out the reasons for their varied scores. The evaluation results are disseminated widely to staff and students.

Questionnaire surveys are the most common evaluation tool

Examples of methods of evaluation

Key points

Evaluation should:

- Enable strategic development of a curriculum
- Be a positive process that contributes to the academic development of a medical school

The goals of an evaluation should:

- Be clearly articulated
- Be linked to the outcomes of the teaching

When carrying out an evaluation:

- More than one source and type of information should be sought
- The results should be fed back to participants and details of the resulting action given

Learners need:

- To be involved in developing an evaluation
- To feel their time is respected
- To know their opinions are valued and acted on

Evaluators must:

- Act on the results of the evaluation to correct deficiencies, improve methods, and update content
- Repeat the process

5 Teaching large groups

Peter Cantillon

Lecturing or large group teaching is one of the oldest forms of teaching. Whatever their reputation, lectures are an efficient means of transferring knowledge and concepts to large groups. They can be used to stimulate interest, explain concepts, provide core knowledge, and direct student learning.

However, they should not be regarded as an effective way of teaching skills, changing attitudes, or encouraging higher order thinking. Large group formats tend to encourage passive learning. Students receive information but have little opportunity to process or critically appraise the new knowledge offered.

How can lectures be used to maximise learning and provide opportunities for student interaction? This article will supply some of the answers and should help you to deliver better, more interactive lectures.

Getting your bearings

It is important to find out as much as possible about the context of the lecture—that is, where it fits into the course of which it is part.

An understanding of the context will allow you to prepare a lecture that is both appropriate and designed to move students on from where they are.

Helping students to learn in lectures

An important question for any lecturer to consider when planning a teaching session is, “how can I help my students to learn during my lecture?” There are several different techniques you can use to aid student learning in a large group setting.

Helping your students to learn

- Use concrete examples to illustrate abstract principles
- Give handouts of the lecture slides, with space to write notes
- Give handouts with partially completed diagrams and lists for the students to complete during or after the lecture
- Allow for pauses in the delivery to give students time to write notes
- Check for understanding by asking questions or by running a mini quiz

Planning your lecture

It is important to distinguish between the knowledge and concepts that are essential (need to know) and those which, though interesting, are not part of the core message (nice to know).

The aims of the lecture should be clearly defined (“what do I hope to achieve with this lecture?”). These will help to define the teaching methods and the structure. If, for example, the purpose of the lecture is to introduce new knowledge and concepts, then a classic lecture structure might be most appropriate.

On the other hand, if the purpose is to make the students aware of different approaches to a particular clinical problem, a problem oriented design in which alternative approaches are presented and discussed might be a more appropriate format.

A lecturer holds forth ...

What you need to know before planning a lecture

- How your lecture fits into the students’ course or curriculum
- The students’ knowledge of your subject—try to get a copy of the lecture and tutorial list for the course
- How the course (and your lecture) will be assessed
- The teaching methods that the students are accustomed to

The successful teacher is no longer on a height, pumping knowledge at high pressure into passive receptacles ... he is a senior student anxious to help his juniors.

William Osler (1849-1919)

Example of a lecture plan with a classic structure

Choosing teaching media

When you have selected the content of the lecture and placed it into a working structure, the next consideration is how to deliver the message. Which teaching media should be used (for example, slides, overheads, handouts, quizzes)? The most appropriate media will differ depending on the venue, class size, and topic.

Choosing the medium for delivering the lecture

- Which teaching media are available at the teaching venue?
- Which teaching media are you familiar with? (It is not always appropriate to experiment with new media)
- Which medium will best illustrate the concepts and themes that you want to teach the students?
- Which medium would encourage students to learn through interaction during your lecture?

Getting started

In the first moments of a lecture it is important that the students are given some sense of place and direction. Thus a brief summary of the previous lecture and an indication of the major themes and learning objectives for the current session provide both you and the students with a relatively easy start. If you are working with a new group it may be useful to indicate the ground rules for the session—for example, “switch off mobile phones,” or “ask questions at any time.”

Encouraging students to interact

Students learn well by “doing.” Yet there is an understandable tendency for students to regard lectures as an opportunity to sit back, be entertained, and “soak up” the learning. However, you can use various methods to encourage students to take a more active part in the learning process.

Students’ attention (and recall) is best at the beginning and end of a lecture. Recall can be improved by changing the format of your lecture part way through. It is also important when planning a lecture to think about activities and exercises that will break up the presentation.

Ask questions

It is useful to ask questions of the group at various stages in the lecture, to check comprehension and promote discussion. Many lecturers are intimidated by the silence following a question and fall into the trap of answering it themselves. Wait for the answers to come. It takes time for students to move from listening to thinking mode. A simple tip is to count slowly to 10 in your head—a question is almost certain to arrive.

Get students to ask you questions

An alternative to getting students to answer questions is to ask them to direct questions at you. A good way of overcoming students’ normal fear of embarrassment is to ask them to prepare questions in groups of two or three. Questions can then be invited from groups at random. When asked a question, you should repeat it out loud to ensure that the whole group is aware of what was asked. Seeking answers to the question from other students, before adding your own views, can increase the level of interaction further.

Example of a lecture plan with a problem oriented structure

Handouts

- Handouts can encourage better learning if they allow students more time to listen and think
- Handouts should provide a scaffold on which students can build their understanding of a topic
- Handouts should provide a summary of the major themes while avoiding an exhaustive explanation of each
- Handouts can be used to direct further learning, by including exercises and questions with suggested reading lists

Graph showing effect of students’ interaction on their ability to recall what they have heard in a lecture. Adapted from Bligh, 2000 (see “Recommended reading” box)

“Tell me, and I forget. Show me, and I remember. Involve me, and I understand”

Chinese proverb

Brainstorming

Brainstorming is a technique for activating the students' knowledge or current understanding of an issue or theme. The lecturer invites answers to a question or problem from the audience and writes them, without comment, on a board or overhead. After a short period, usually about two or three minutes, the lecturer reviews the list of "answers" with the class. The answers can be used to provide material for the next part of the lecture or to give students an idea of where they are before they move on. By writing answers in a way that can be seen by everyone in the audience, you allow the students to learn from each other.

Buzz groups

Buzz groups also encourage interaction. They consist of groups of two to five students working for a few minutes on a question, problem, or exercise set by the lecturer. Buzz group activity is a useful means of getting students to process and use new information to solve problems. At the end of the buzz group session, the teacher can either continue with the lecture or check the results of the exercise by asking one or two groups to present their views. Remember that in an amphitheatre lecture hall, students can sit on their own desks to interact with the students behind them.

Mini-assessments

Mini-assessments and exercises are used in lectures to help students to recognise gaps in their learning and to encourage them to use new material in practice. Brief assessments can also allow the lecturer to measure how well the messages are being understood. Students could be asked, for example, to complete a brief, multiple choice questionnaire or a "one-minute" paper. The timing of quizzes and exercises will depend on what is required. An assessment of prior learning would be best at the start of a lecture, whereas an estimate of learning from the current session might be best carried out towards the end of the lecture.

How to end your lecture

At the end of a lecture it is important to summarise the key points and direct students toward further learning. You may present the key points on a slide or overhead. Alternatively, you may go through the main headings on a handout. Students are encouraged to learn more about a subject if they are set tasks or exercises that will require them to look further than the lecture notes for answers and ideas. The end of a lecture is also a common time for questions. Students may find the use of a one-minute paper a useful tool to help them to identify concepts and impressions that need clarification.

Evaluating your lecture

Practice does not make perfect, but the process of developing as a lecturer is greatly helped if some effort is made to evaluate performance. Evaluation involves answering questions such as "how did I do?" or "what did the students learn?"

A lecture can be evaluated in different ways. If the students are to be used as a source of feedback, the following methods are useful:

- Ask a sample of the students if you can read their lecture notes—this exercise gives some insight into what students have learned and understood
- Ask for verbal feedback from individual students
- Ask the students to complete a one-minute paper

"One-minute" paper worksheet

Name: _____

Date: _____

Lecture title: _____

Directions: Take a moment to think about the lecture you have just attended, and then answer the following questions.

1. What was the most important thing you learned in today's lecture?

2. What question remains uppermost in your mind at the end of today's lecture?

3. What was the "muddiest point" in today's lecture?

Example of a one-minute paper

Please rate the lecture on the following items

	Strongly agree	Slightly agree	Slightly disagree	Strongly disagree
Clear				
Interesting				
Easy to take notes from				
Well organised				
Relevant to the course				

Example of an evaluation form focusing on the lecture. Adapted from Brown et al, 2001 (see "Recommended reading" box)

- Ask the students to complete an evaluation questionnaire.

If you want to evaluate your teaching style and delivery, peers can be a useful source of feedback:

- Ask a colleague to observe part or all of a lecture and provide feedback afterwards. It is important to inform the observer what aspects of the lecturing process you want evaluated—for example, clarity, logical flow, effectiveness of the media used
- Videotape the lecture for private viewing, and arrange a joint viewing with a colleague later.

Lectures are still a common teaching method in both undergraduate and postgraduate medical education. Their continued popularity is due to the fact that they represent an effective and efficient means of teaching new concepts and knowledge. This article has emphasised the importance of good lecture planning and of the inclusion of student interaction to ensure effective learning.

6 Teaching small groups

David Jaques

Group discussion plays a valuable role in the all-round education of students, whether in problem based learning and team projects or in the more traditional academic scenario of the tutorial or seminar. When it works well, discussion can allow students to negotiate meanings, express themselves in the language of the subject, and establish closer contact with academic staff than more formal methods permit. Discussion can also develop the more instrumental skills of listening, presenting ideas, persuading, and working as part of a team. But perhaps most importantly, discussion in small groups can or should give students the chance to monitor their own learning and thus gain a degree of self direction and independence in their studies.

All these worthy aims require active participation and the ready expression of ideas. Yet it frequently doesn't work out this way. Indeed many tutors too readily fall back on their reserve positions of authority, expert, and prime talker. Many of the problems associated with leading small groups effectively are likely to be exacerbated with larger groups. So how can we avoid the common traps?

If you are leading a group discussion you will need to consider both the configuration of the group and your own behaviour. Groups often communicate poorly because the physical conditions make it difficult to communicate. For example, in a group of 10 students seated round a rectangular table, at least four students on either side of the table have no eye contact with each other, thus reducing participation. If you ask and answer questions all the time, even less interaction is likely.

If a group sits in a circle without a table, communication is likely to be easier. When the discussion has started, it is your responsibility as discussion leader to listen to and respond to the whole group. Listening becomes a problem when the students regard you as an expert or you engage with one or two of the more vocal students rather than the whole group.

More structure, less intervention

Being a democratic discussion leader involves making the right sort of nudges and interventions. The role can be made a lot less demanding by using more structure and less intervention in the group process. The rest of this article shows how clear and purposeful group structures can help to bypass many of the problems outlined above, by delegating responsibility for group interaction (and therefore for learning) to the students.

Group structures and processes

You can minimise your internal involvement in the group process by organising or structuring groups into smaller units, especially when the group process is likely to be problematical. This is particularly so when you wish to mobilise a sense of coherence and full participation among a largish group of students. A sequence of tasks might then be set. For example:

- Students work individually for five minutes drawing up a list
- They share their ideas in pairs for 10 minutes
- In groups of four to six, students write up categories on a large sheet of paper
- This is followed by 25 minutes of open discussion among the groups.

“By separating teaching from learning, we have teachers who do not listen and students who do not talk”

Based on Palmer P (*The Courage to Teach*, Jossey Bass, 1998)

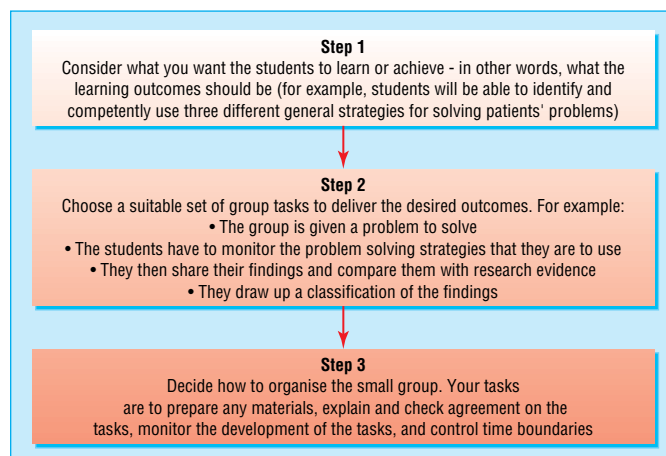

Problems associated with leading effective small groups

- The teacher gives a lecture rather than conducting a dialogue
- The teacher talks too much
- Students cannot be encouraged to talk except with difficulty; they will not talk to each other, but will only respond to questions from the tutor
- Students do not prepare for the sessions
- One student dominates or blocks the discussion
- The students want to be given the solutions to problems rather than discuss them

Your own behaviour can have an enormous effect on how the group functions

Techniques for effective facilitation in group discussion

- Ensure that group members have an agreed set of ground rules—for example, not talking at the same time as another group member
- Ensure that the students are clear about the tasks to be carried out
- When you present a question don't answer it yourself or try to reformulate it—count to 10 silently before speaking again
- When you have something you *could* say (which could be most of the time), count to 10 again
- Look round the group both when you are speaking and when a student is speaking. That way the students will quickly recognise that they are addressing the group rather than just you. It will allow you to pick up cues from those who want to speak but are either a bit slow or inhibited

Planning the structure of a small discussion group

ABC of Learning and Teaching in Medicine

Your role in this kind of situation may be to move round checking that everyone understands and accepts the task and is doing it in an appropriate way and to encourage completion as the end point approaches. You could leave the room for a while and let the groups work without supervision.

The following group structures require some assertive leadership to set up but allow you to take a back seat as the process itself takes over the direction of events.

Group round

Each person has a brief time—say, 20 seconds or one minute—to say something in turn round the group. The direction round the group can be decided by the first contributor, or members can speak in a random order. More interest and energy is usually generated, however, if the first person chooses who should go second, the second who should go third, and so on.

Buzz groups

With larger groups a break is often needed:

- To provide a stimulating change in the locus of attention
- For you to gain some idea of what the students know
- For the students to check their own understanding.

During a discussion students could be asked to turn to their neighbour to discuss for a few minutes any difficulties in understanding, to answer a prepared question, or to speculate on what they think will happen next in the proceedings. This will bring a sense of participation and some lively feedback. Buzz groups enable students to express difficulties they would have been unwilling to reveal to the whole class. (A variation is to allocate three or five minutes each way to the pairs—each phase is for one-way communication.)

Snowball groups

Snowball groups (or pyramids) are an extension of buzz groups. Pairs join up to form fours, then fours to eights. These groups of eight report back to the whole group. This developing pattern of group interaction can ensure comprehensive participation, especially when it starts with individuals writing down their ideas before sharing them. To avoid students becoming bored with repeated discussion of the same points, it is a good idea to use increasingly sophisticated tasks as the groups gets larger.

Fishbowls

The usual fishbowl configuration has an inner group discussing an issue or topic while the outer group listens, looking for themes, patterns, or soundness of argument or uses a group behaviour checklist to give feedback to the group on its functioning. The roles may then be reversed.

Crossover groups

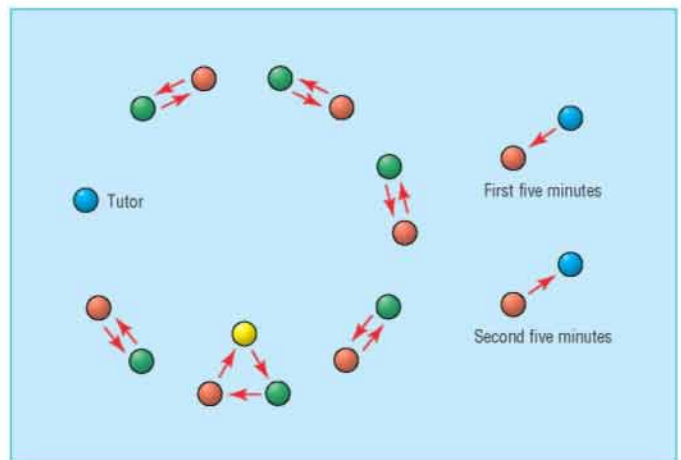

Students are divided into subgroups that are subsequently split up to form new groups in such a way as to maximise the crossing over of information. A colour or number coding in the first groupings enables a simple relocation—from, for example, three groups of four students to four groups of three, with each group in the second configuration having one from each of the first.

Circular questioning

In circular questioning each member of the group asks a question in turn. In its simplest version, one group member formulates a question relevant to the theme or problem and puts it to the person opposite, who has a specified time (say, one

To encourage group interaction consider breaking a larger group into smaller groups of five or six students; organise membership on a heterogeneous or random basis to prevent cliques forming

Group rounds are particularly useful at the beginning of any meeting so that everyone is involved from the start and, depending on what the group is asked to speak about, as a way of checking on learning issues

Buzz groups, with pairs for one-way, five-minute communication

Fishbowl structure—inside group discusses, outside group listens in

Crossover groups—redistribution of 12 students (each allocated one of four colours) for second period of session

or two minutes) to answer it. Follow up questions can be asked if time permits. The questioning and answering continues clockwise round the group until everyone has contributed, at which time a review of questions and answers can take place. This could also include answers that others would like to have given. Alternatively, you or the students could prepare the questions on cards. You could also mix the best of the students' questions with some of your own.

Horseshoe groups

This method allows you to alternate between the lecture and discussion formats, a common practice in workshops. Groups are arranged around tables, with each group in a horseshoe formation with the open end facing the front. You can thus talk formally from the board for a time before switching to presenting a group task. Subsequent reporting from each group can induce boredom. To avoid this danger, the tutor can circulate written reports for comment; get groups to interview each other publicly or get one member of each group to circulate; ask groups to produce and display posters; ask the reporters from each group to form an inner group in a fishbowl formation; or use the crossover method to move students around.

The group structures described require an explicit task and topic, and they are possible only if the furniture is movable. Tutors could also consider experimenting with furniture to see if other group structures work. The physical configuration is a strong determinant of social (and hence learning) processes, as is the sequence of activities

Conclusion

This article has emphasised the choices available to you in working with groups. Some of these involve more skilled and sensitive handling of group process from within the group; others require imaginative management in the setting of tasks and the organising of purposeful activities for subgroups. Well organised and purposeful group discussion can create a firm foundation for qualities such as openness, networking, and proactive communication—important ingredients in the process of personal and organisational change. The value of effective group management in professional development and lifelong learning cannot be underestimated.

Circular questioning

Horseshoe groups

7 One to one teaching and feedback

Jill Gordon

“My method (is) to lead my students by hand to the practice of medicine, taking them every day to see patients in the public hospital, that they may hear the patients’ symptoms and see their physical findings. Then I question the students as to what they have noted in the patients and about their thoughts and perceptions regarding the cause of the illness and the principles of treatment”

Dr Franciscus de la Boe Sylvius, 17th century professor of medicine at the University of Leyden, Netherlands

Dr Franciscus de la Boe Sylvius

Although it is not clear whether Dr Sylvius (above) was describing his teaching method in relation to a group of students or to a succession of individual students, he understood the essential features of clinical education. He understood, for example, the need for active learning in an authentic clinical setting.

Dr Sylvius also understood another important feature of one to one teaching—close behavioural observation (of each other, teacher and learner). No other setting provides the same opportunity for this. Dr Sylvius led his students “by [the] hand.” He cared about his role as a teacher. In the closely observed one to one relationship your unguarded statements, your reactions under pressure, and your opinions about other people and the world at large are all magnified.

Just as you cannot hide from the learner, so the learner’s knowledge, skills, and attitudes will become apparent to you. Provided that you have created a trusting relationship, you can discuss his or her personal and professional attitudes and values in a way that is seldom possible in a larger group. This is perhaps one of the key benefits of one to one teaching.

Another feature of one to one teaching is the opportunity to adjust what you teach to the learner’s needs—“customise” your teaching. In 1978 Ausubel and colleagues suggested that the secret of education is to find out what the learner already knows and teach accordingly. In a lecture, tutorial, or seminar you cannot hope to diagnose and respond to every individual’s learning needs, but a one to one relationship provides an opportunity to match the learning experience to the learner.

One to one teaching is perhaps one of the most powerful ways of “influencing students.” You can create opportunities for active learning in authentic clinical settings while modelling desirable personal and professional attributes.

Stott and Davis in 1979 promoted the idea that one to one primary care consultations offer exceptional but often unrealised potential. The principles used in primary care consultations can be applied to one to one teaching, and the secret is forethought and planning.

Exceptional potential of one to one teaching

- It tackles current learning needs
- It promotes autonomy and self directed learning
- It links prior knowledge with new clinical experiences
- It enables opportunistic teaching

Wards, operating theatres, general practice, and community clinics provide a context for active learning

As a teacher, you are an important role model whether you wish it or not

What’s different about one to one teaching?

	Lecture	Seminar	PBL group	Clinical tutorial	One to one clinical attachment
Efficiency*	High	Medium	Low	Low	Very low
Active learning	Low (usually)	Variable	High	Medium to high	Very high
Mutual feedback	Low	Medium	High	Medium to high	Very high
Modelling behaviour in real life setting	Low	Low	Medium	High	Very high

PBL = problem based learning.
*Based on student numbers.

Plan ahead—ask yourself some important questions

- What is the main purpose of the one to one attachment?
- Do you know why it is part of the learning programme?
- What are the learner’s needs?
- How will you gauge how effectively you have met the learner’s needs?
- How would you like this learner to describe the experience to a peer?

Provide an orientation

Most of us recall clinical teachers whose social skills amounted to a brief glance and a grunt. Times have changed, or should have. Find out and remember the learner's name—a simple but important courtesy. Outline the special opportunities and benefits that the attachment can provide. Ask the learner to prepare a learning plan and then compare the learner's plan to your own expectations. Once the plan has been agreed, don't shelve it—refer to it during the attachment and modify as necessary.

Agree on the ground rules

Ground rules are both practical (punctuality, dress, access to patient records) and philosophical (respect for patients and colleagues, confidentiality, consent, openness to different points of view). If these have been spelled out on day 1, you won't be caught out later. Make sure that the learner knows how much time you will be able to spend in observing, teaching, and giving feedback and what you expect in return.

Ask helpful questions

Open ended questions are generally better than closed questions at the beginning of the exchange. A small number of closed questions later in the conversation help you to “diagnose” just how much the learner knows and understands. Avoid questions that require nothing but recall. Try to formulate questions that assume an appropriate amount of knowledge, but build in higher order thinking and/or higher order skills. You might ask the learner, for example, to explain to you (as if you were the patient) the mechanisms behind a condition such as asthma or hypertension. This simulates clinical interface with a patient—testing recall, understanding, and communications skills all at once.

Give feedback

Learners value feedback highly, and valid feedback is based on observation. Deal with observable behaviours and be practical, timely, and concrete. The one to one relationship enables you to give feedback with sensitivity and in private. Begin by asking the learner to tell you what he or she feels confident of having done well and what he or she would like to improve. Follow up with your own observations of what was done well (be specific), and then outline one or two points that could help the student to improve.

Encourage reflection

Just as many learning opportunities are wasted if they are not accompanied by feedback from an observer, so too are they wasted if the learner cannot reflect honestly on his or her performance. One to one teaching is ideally suited to encouraging reflective practice, because you can model the way a reflective practitioner behaves. Two key skills are (a) “unpacking” your clinical reasoning and decision making processes and (b) describing and discussing the ethical values and beliefs that guide you in patient care.

Use other one to one teachers

Senior medical students, junior doctors, registrars, nurses, and allied health professionals are all potential teachers. When

Find out and remember the learner's name—a simple but important courtesy

Skilful teaching is not unlike skilful history taking

“If musicians learned to play their instruments as physicians learn to interview patients, the procedure would consist of presenting in lectures or maybe in a demonstration or two the theory and mechanisms of the music-producing ability of the instrument and telling him to produce a melody. The instructor of course, would not be present to observe or listen to the student's efforts, but would be satisfied with the student's subsequent verbal report of what came out of the instrument.”

George Engel, after visiting 70 medical schools in North America

Monitor progress

- Identify deficiencies
 - Ask the learner, half way through the attachment, to do a self assessment of how things are going. If both you and the learner can identify deficiencies within a safe learning environment, you can work together to tackle them well before the attachment ends
 - If you have serious concerns, you have an obligation to make them known to the learner and to the medical school or training authority
 - It is not appropriate to diagnose serious problems and hand the learner on to the next stage of training in the hope that the problems will somehow be correct themselves
-

ABC of Learning and Teaching in Medicine

junior colleagues interact with a learner, you can encourage them with positive feedback on their teaching.

Every patient interview and every physical examination places the learner in a privileged relationship with a patient. We all have patients whom we especially admire—particularly people who have coped bravely with a chronic illness or a major disability, a disaster such as war, or other misfortunes. Such patients activate an emotional response in the learner, imprinting an enriched memory of the patient and the patient's illness.

Promote active learning

- Time is limited in most clinical settings, and it can be tempting to revert to a passive observational teaching model
- Think about strategies to promote active learning
- Brief students to observe specific features of a consultation or procedure
- Ask patients for permission for the learner to carry out all or part of the physical examination or a procedure while you observe
- If space is available, allow students to interview patients in a separate room or cubicle before presenting them to you
- If possible videotape consultations for a debriefing session at a more convenient time
- Arrange for the learner to see the same patient over time, or in another context, such as a home visit

Reap the rewards

The role of the teacher is frequently undervalued, and yet teaching is potentially rewarding and enjoyable. It is also one of the defining features of a profession. Without teaching to ensure the transmission of knowledge, medicine becomes just another “job.”

One to one teaching inevitably exposes you to evaluation by the learner. If the learner trusts you, he or she will be able to tell you what has worked well, and what could be improved. Respond to feedback by reflecting rather than by explaining, excusing, or offering counter arguments to defend your particular style. Openness to feedback is another professional attribute that is best modelled one to one.

Learners for whom you have been a role model and mentor are likely to repay you many times over. Sometimes you have the opportunity to observe their personal and professional development long after the one to one attachment has finished. Dr Sylvius knew how to do it, and Cicero understood its rejuvenating qualities.

“Cultivate the society of the young, remain interested and never stop learning” (Cicero)

Points to remember

Do

- Welcome
- Set shared achievable goals
- Put yourself in the learner's shoes
- Ask interesting questions
- Monitor progress and give feedback
- Encourage

Don't

- Appear unprepared
- Be vague about your expectations
- Confine the learner to passive roles
- Be “nit-picking”
- Leave feedback to the final assessment
- Humiliate

8 Learning and teaching in the clinical environment

John Spencer

Clinical teaching—that is, teaching and learning focused on, and usually directly involving, patients and their problems—lies at the heart of medical education. At undergraduate level, medical schools strive to give students as much clinical exposure as possible; they are also increasingly giving students contact with patients earlier in the course. For postgraduates, “on the job” clinical teaching is the core of their professional development. How can a clinical teacher optimise the teaching and learning opportunities that arise in daily practice?

Strengths, problems, and challenges

Learning in the clinical environment has many strengths. It is focused on real problems in the context of professional practice. Learners are motivated by its relevance and through active participation. Professional thinking, behaviour, and attitudes are “modelled” by teachers. It is the only setting in which the skills of history taking, physical examination, clinical reasoning, decision making, empathy, and professionalism can be taught and learnt as an integrated whole. Despite these potential strengths, clinical teaching has been much criticised for its variability, lack of intellectual challenge, and haphazard nature. In other words, clinical teaching is an educationally sound approach, all too frequently undermined by problems of implementation.

Challenges of clinical teaching

- Time pressures
 - Competing demands—clinical (especially when needs of patients and students conflict); administrative; research
 - Often opportunistic—makes planning more difficult
 - Increasing numbers of students
 - Fewer patients (shorter hospital stays; patients too ill or frail; more patients refusing consent)
 - Often under-resourced
 - Clinical environment not “teaching friendly” (for example, hospital ward)
 - Rewards and recognition for teachers poor
-

The importance of planning

Many principles of good teaching, however, can (and should) be incorporated into clinical teaching. One of the most important is the need for planning. Far from compromising spontaneity, planning provides structure and context for both teacher and students, as well as a framework for reflection and evaluation. Preparation is recognised by students as evidence of a good clinical teacher.

How doctors teach

Almost all doctors are involved in clinical teaching at some point in their careers, and most undertake the job conscientiously and enthusiastically.

However, few receive any formal training in teaching skills, and in the past there has been an assumption that if a person simply knows a lot about their subject, they will be able to teach it. In reality, of course, although subject expertise is important, it

Clinical teaching in general practice

Common problems with clinical teaching

- Lack of clear objectives and expectations
 - Focus on factual recall rather than on development of problem solving skills and attitudes
 - Teaching pitched at the wrong level (usually too high)
 - Passive observation rather than active participation of learners
 - Inadequate supervision and provision of feedback
 - Little opportunity for reflection and discussion
 - “Teaching by humiliation”
 - Informed consent not sought from patients
 - Lack of respect for privacy and dignity of patients
 - Lack of congruence or continuity with the rest of the curriculum
-

Questions to ask yourself when planning a clinical teaching session

ABC of Learning and Teaching in Medicine

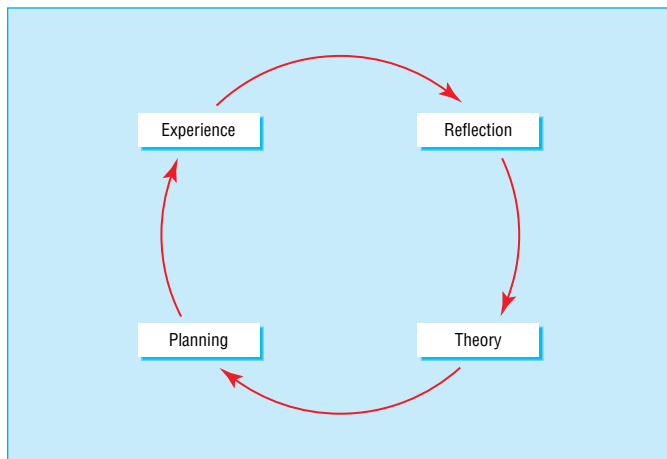

is not sufficient. Effective clinical teachers use several distinct, if overlapping, forms of knowledge.

How students learn

Understanding the learning process will help clinical teachers to be more effective. Several theories are relevant (see first article in the series, 25 January). All start with the premise that learning is an active process (and, by inference, that the teacher's role is to act as facilitator). Cognitive theories argue that learning involves processing information through interplay between existing knowledge and new knowledge. An important influencing factor is what the learner knows already. The quality of the resulting new knowledge depends not only on "activating" this prior knowledge but also on the degree of elaboration that takes place. The more elaborate the resulting knowledge, the more easily it will be retrieved, particularly when learning takes place in the context in which the knowledge will be used.

Experiential learning

Experiential learning theory holds that learning is often most effective when based on experience. Several models have been described, the common feature being a cyclical process linking concrete experience with abstract conceptualisation through reflection and planning. Reflection is standing back and thinking about experience (What did it mean? How does it relate to previous experience? How did I feel?). Planning involves anticipating the application of new theories and skills (What will I do next time?). The experiential learning cycle, which can be entered at any stage, provides a useful framework for planning teaching sessions.

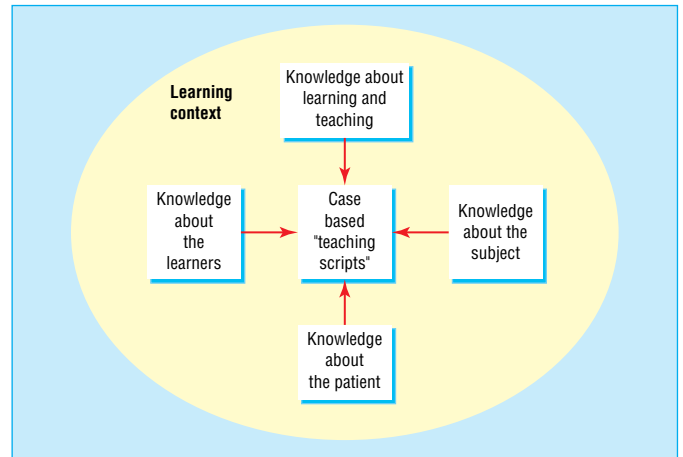

Experiential learning cycle: the role of the teacher is to help students to move round, and complete, the cycle

Questions

Questions may fulfil many purposes, such as to clarify understanding, to promote curiosity, and to emphasise key points. They can be classified as "closed," "open," and "clarifying" (or "probing") questions.

Closed questions invoke relatively low order thinking, often simple recall. Indeed, a closed question may elicit no response at all (for example, because the learner is worried about being wrong), and the teacher may end up answering their own question.

Various domains of knowledge contribute to the idiosyncratic teaching strategies ("teaching scripts") that tutors use in clinical settings

How to use cognitive learning theory in clinical teaching

Help students to identify what they already know

- "Activate" prior knowledge through brainstorming and briefing

Help students elaborate their knowledge

- Provide a bridge between existing and new information—for example, use of clinical examples, comparisons, analogies
- Debrief the students afterwards
- Promote discussion and reflection
- Provide relevant but variable contexts for the learning

Example of clinical teaching session based on experiential learning cycle

Setting—Six third year medical students doing introductory clinical skills course based in general practice

Topic—History taking and physical examination of patients with musculoskeletal problems (with specific focus on rheumatoid arthritis); three patients with good stories and signs recruited from the community

The session

Planning—Brainstorm for relevant symptoms and signs: this activates prior knowledge and orientates and provides framework and structure for the task

Experience—Students interview patients in pairs and do focused physical examination under supervision: this provides opportunities to implement and practise skills

Reflection—Case presentations and discussion: feedback and discussion provides opportunities for elaboration of knowledge

Theory—Didactic input from teacher (basic clinical information about rheumatoid arthritis): this links practice with theory

Planning— "What have I learned?" and "How will I approach such a patient next time?" Such questions prepare students for the next encounter and enable evaluation of the session

Effective teaching depends crucially on the teacher's communication skills. Two important areas of communication for effective teaching are questioning and giving explanations. Both are underpinned by attentive listening (including sensitivity to learners' verbal and non-verbal cues). It is important to allow learners to articulate areas in which they are having difficulties or which they wish to know more about

In theory, open questions are more likely to promote deeper thinking, but if they are too broad they may be equally ineffective. The purpose of clarifying and probing questions is self evident.

Questions can be sequenced to draw out contributions or be built on to promote thinking at higher cognitive levels and to develop new understanding

Explanation

Teaching usually involves a lot of explanation, ranging from the (all too common) short lecture to “thinking aloud.” The latter is a powerful way of “modelling” professional thinking, giving the novice insight into experts’ clinical reasoning and decision making (not easily articulated in a didactic way). There are close analogies between teacher-student and doctor-patient communication, and the principles for giving clear explanations apply. If in doubt, pitch things at a low level and work upwards. As the late Sydney Jacobson, a journalist, said, “Never underestimate the person’s intelligence, but don’t overestimate their knowledge.” Not only does a good teacher avoid answering questions, but he or she also questions answers.

Exploiting teaching opportunities

Most clinical teaching takes place in the context of busy practice, with time at a premium. Many studies have shown that a disproportionate amount of time in teaching sessions may be spent on regurgitation of facts, with relatively little on checking, probing, and developing understanding. Models for using time more effectively and efficiently and integrating teaching into day to day routines have been described. One such, the “one-minute preceptor,” comprises a series of steps, each of which involves an easily performed task, which when combined form an integrated teaching strategy.

Teaching on the wards

Despite a long and worthy tradition, the hospital ward is not an ideal teaching venue. None the less, with preparation and forethought, learning opportunities can be maximised with minimal disruption to staff, patients, and their relatives.

Approaches include teaching on ward rounds (either dedicated teaching rounds or during “business” rounds); students seeing patients on their own (or in pairs—students can learn a lot from each other) then reporting back, with or without a follow up visit to the bedside for further discussion; and shadowing, when learning will inevitably be more opportunistic.

Key issues are careful selection of patients; ensuring ward staff know what’s happening; briefing patients as well as students; using a side room (rather than the bedside) for discussions about patients; and ensuring that all relevant information (such as records and x ray films) is available.

Teaching in the clinic

Although teaching during consultations is organisationally appealing and minimally disruptive, it is limited in what it can achieve if students remain passive observers.

With relatively little impact on the running of a clinic, students can participate more actively. For example, they can be

How to use questions

- Restrict use of closed questions to establishing facts or baseline knowledge (What? When? How many?)
- Use open or clarifying/probing questions in all other circumstances (What are the options? What if?)
- Allow adequate time for students to give a response—don’t speak too soon
- Follow a poor answer with another question
- Resist the temptation to answer learners’ questions—use counter questions instead
- Statements make good questions—for example, “students sometimes find this difficult to understand” instead of “Do you understand?” (which may be intimidating)
- Be non-confrontational—you don’t need to be threatening to be challenging

How to give effective explanations

- Check understanding before you start, as you proceed, and at the end—non-verbal cues may tell you all you need to know about someone’s grasp of the topic
- Give information in “bite size” chunks
- Put things in a broader context when appropriate
- Summarise periodically (“so far, we’ve covered . . .”) and at the end; asking learners to summarise is a powerful way of checking their understanding
- Reiterate the take home messages; again, asking students will give you feedback on what has been learnt (but be prepared for some surprises)

“One-minute preceptor” model

Teaching during consultations has been much criticised for not actively involving learners

ABC of Learning and Teaching in Medicine

asked to make specific observations, write down thoughts about differential diagnosis or further tests, or note any questions—for discussion between patients. A more active approach is “hot seating.” Here, the student leads the consultation, or part of it. His or her findings can be checked with the patient, and discussion and feedback can take place during or after the encounter. Students, although daunted, find this rewarding. A third model is when a student sees a patient alone in a separate room, and is then joined by the tutor. The student then presents their findings, and discussion follows. A limitation is that the teacher does not see the student in action. It also inevitably slows the clinic down, although not as much as might be expected. In an ideal world it would always be sensible to block out time in a clinic to accommodate teaching.

The patient’s role

Sir William Osler’s dictum that “it is a safe rule to have no teaching without a patient for a text, and the best teaching is that taught by the patient himself” is well known. The importance of learning from the patient has been repeatedly emphasised. For example, generations of students have been exhorted to “listen to the patient—he is telling you the diagnosis.” Traditionally, however, a patient’s role has been essentially passive, the patient acting as interesting teaching material, often no more than a medium through which the teacher teaches. As well as being potentially disrespectful, this is a wasted opportunity. Not only can patients tell their stories and show physical signs, but they can also give deeper and broader insights into their problems. Finally, they can give feedback to both learners and teacher. Through their interactions with patients, clinical teachers—knowingly or unknowingly—have a powerful influence on learners as role models.

Drs Gabrielle Greveson and Gail Young gave helpful feedback on early drafts.

Seating arrangements for teaching in clinic or surgery

Working effectively and ethically with patients

- Think carefully about which parts of the teaching session require direct patient contact—is it necessary to have a discussion at the bedside?
 - Always obtain consent from patients before the students arrive
 - Ensure that students respect the confidentiality of all information relating to the patient, verbal or written
 - Brief the patient before the session—purpose of the teaching session, level of students’ experience, how the patient is expected to participate
 - If appropriate, involve the patient in the teaching as much as possible
 - Ask the patient for feedback—about communication and clinical skills, attitudes, and bedside manner
 - Debrief the patient after the session—they may have questions, or sensitive issues may have been raised
-

9 Written assessment

Lambert W T Schuwirth, Cees P M van der Vleuten

Some misconceptions about written assessment may still exist, despite being disproved repeatedly by many scientific studies. Probably the most important misconception is the belief that the format of the question determines what the question actually tests. Multiple choice questions, for example, are often believed to be unsuitable for testing the ability to solve medical problems. The reasoning behind this assumption is that all a student has to do in a multiple choice question is recognise the correct answer, whereas in an open ended question he or she has to generate the answer spontaneously. Research has repeatedly shown, however, that the question's format is of limited importance and that it is the content of the question that determines almost totally what the question tests.

This does not imply that question formats are always interchangeable—some knowledge cannot be tested with multiple choice questions, and some knowledge is best not tested with open ended questions.

Five criteria can be used to evaluate the advantages and disadvantages of question types: reliability, validity, educational impact, cost effectiveness, and acceptability. Reliability pertains to the accuracy with which a score on a test is determined. Validity refers to whether the question actually tests what it is purported to test.

Educational impact is important because students tend to focus strongly on what they believe will be in the examinations. Therefore they will prepare strategically depending on the question types used. Whether different preparation leads to different types of knowledge is not fully clear, however. When teachers are forced to use a particular question type, they will tend to ask about the themes that can be easily assessed with that question type, and they will neglect the topics for which the question type is less well suited. Therefore, it is wise to vary the question types in different examinations.

Cost effectiveness and acceptability are important as the costs of different examinations have to be taken into account, and even the best designed examination will not survive if it is not accepted by teachers and students.

“True or false” questions

The main advantage of “true or false” questions is their conciseness. A question can be answered quickly by the student, so the test can cover a broad domain. Such questions, however, have two major disadvantages. Firstly, they are quite difficult to construct flawlessly—the statements have to be defensibly true or absolutely false. Teachers must be taught thoroughly how to construct these question types. Secondly, when a student answers a “false” question correctly, we can conclude only that the student knew the statement was false, not that he or she knew the correct fact.

“Single, best option” multiple choice questions

Multiple choice questions are well known, and there is extensive experience worldwide in constructing them. Their main advantage is the high reliability per hour of testing—mainly

Choosing the most appropriate type of written examination for a certain purpose is often difficult. This article discusses some general issues of written assessment then gives an overview of the most commonly used types, together with their major advantages and disadvantages

Reliability

- A score that a student obtains on a test should indicate the score that this student would obtain in any other given (equally difficult) test in the same field (“parallel test”)
- A test represents at best a sample—selected from a range of possible questions. So if a student passes a particular test one has to be sure that he or she would not have failed a parallel test, and vice versa
- Two factors influence reliability negatively:

Sample error—The number of items may be too small to provide a reproducible result

Sample too narrow—If the questions focus only on a certain element, the scores cannot generalise to the whole discipline

Validity

- The validity of a test is the extent to which it measures what it purports to measure
 - Most competencies cannot be observed directly (body length, for example, can be observed directly; intelligence has to be derived from observations). Therefore, in examinations it is important to collect evidence to ensure validity:
 - One simple piece* of evidence could be, for example, that experts score higher than students on the test
 - Alternative approaches* include (a) an analysis of the distribution of course topics within test elements (a so called blueprint) and (b) an assessment of the soundness of individual test items.
 - Good validation of tests should use several different pieces of evidence
-

True or false questions are most suitable when the purpose of the question is to test whether students are able to evaluate the correctness of an assumption; in other cases they are best avoided

Multiple choice questions can be used in any form of testing, except when spontaneous generation of the answer is essential, such as in creativity, hypothesising, and writing skills

ABC of Learning and Teaching in Medicine

because they are quick to answer—so a broad domain can be covered. They are often easier to construct than true or false questions and are more versatile. If constructed well, multiple choice questions can test more than simple facts. Unfortunately though, they are often used to test only facts, as teachers often think this is all they are fit for.

Multiple true or false questions

These questions enable the teacher to ask a question to which there is more than one correct answer. Although they take somewhat longer to answer than the previous two types, their reliability per hour of testing time is not much lower.

Construction, however, is not easy. It is important to have sufficient distracters (incorrect options) and to find a good balance between the number of correct options and distracters. In addition, it is essential to construct the question so that correct options are defensibly correct and distracters are defensibly incorrect. A further disadvantage is the rather complicated scoring procedure for these questions.

“Short answer” open ended questions

Open ended questions are more flexible—in that they can test issues that require, for example, creativity, spontaneity—but they have lower reliability. Because answering open ended questions is much more time consuming than answering multiple choice questions, they are less suitable for broad sampling. They are also expensive to produce and to score. When writing open ended questions it is important to describe clearly how detailed the answer should be—without giving away the answer. A good open ended question should include a detailed answer key for the person marking the paper. Short answer, open ended questions are not suitable for assessing factual knowledge; use multiple choice questions instead.

Short answer, open ended questions should be aimed at the aspects of competence that cannot be tested in any other way.

Essays

Essays are ideal for assessing how well students can summarise, hypothesise, find relations, and apply known procedures to new situations. They can also provide an insight into different aspects of writing ability and the ability to process information. Unfortunately, answering them is time consuming, so their reliability is limited.

When constructing essay questions, it is essential to define the criteria on which the answers will be judged. A common pitfall is to “over-structure” these criteria in the pursuit of objectivity, and this often leads to trivialising the questions. Some structure and criteria are necessary, but too detailed a structure provides little gain in reliability and a considerable loss of validity. Essays involve high costs, so they should be used sparsely and only in cases where short answer, open ended questions or multiple choice questions are not appropriate.

“Key feature” questions

In such a question, a description of a realistic case is followed by a small number of questions that require only essential decisions; these questions may be either multiple choice or open ended, depending on the content of the question. Key feature questions seem to measure problem solving ability

Teachers need to be taught well how to write good multiple choice questions

Which of the following drugs belong to the ACE inhibitor group?

- | | |
|----------------------------|-----------------|
| (a) atenolol | (h) metoprolol |
| (b) pindolol | (i) propranolol |
| (c) amiloride | (j) triamterene |
| (d) furosemide (frusemide) | (k) captopril |
| (e) enalapril | (l) verapamil |
| (f) clopamide | (m) digoxin |
| (g) epoprostenol | |

Example of a multiple, true or false question

Open ended questions are perhaps the most widely accepted question type. Their format is commonly believed to be intrinsically superior to a multiple choice format. Much evidence shows, however, that this assumed superiority is limited

“Key feature” questions aim to measure problem solving ability validly without losing too much reliability

validly and have good reliability. In addition, most people involved consider them to be a suitable approach, which makes them more acceptable.

However, the key feature approach is rather new and therefore less well known than the other approaches. Also, construction of the questions is time consuming; inexperienced teachers may need up to three hours to produce a single key feature case with questions. Experienced writers, though, may produce up to four an hour. Nevertheless, these questions are expensive to produce, and large numbers of cases are normally needed to prevent students from memorising cases. Key feature questions are best used for testing the application of knowledge and problem solving in “high stakes” examinations.

Extended matching questions

The key elements of extended matching questions are a list of options, a “lead-in” question, and some case descriptions or vignettes. Students should understand that an option may be correct for more than one vignette, and some options may not apply to any of the vignettes. The idea is to minimise the recognition effect that occurs in standard multiple choice questions because of the many possible combinations between vignettes and options. Also, by using cases instead of facts, the items can be used to test application of knowledge or problem solving ability. They are easier to construct than key feature questions, as many cases can be derived from one set of options. Their reliability has been shown to be good. Scoring of the answers is easy and could be done with a computer.

The format of extended matching questions is still relatively unknown, so teachers need training and practice before they can write these questions. There is a risk of an under-representation of certain themes simply because they do not fit the format. Extended matching questions are best used when large numbers of similar sorts of decisions (for example, relating to diagnosis or ordering of laboratory tests) need testing for different situations.

Conclusion

Choosing the best question type for a particular examination is not simple. A careful balancing of costs and benefits is required. A well designed assessment programme will use different types of question appropriate for the content being tested.

Example of a key feature question

Case

You are a general practitioner. Yesterday you made a house call on Mr Downing. From your history taking and physical examination you diagnosed nephrolithiasis. You gave an intramuscular injection of 100 mg diclofenac, and you left him some diclofenac suppositories. You advised him to take one when in pain but not more than two a day. Today he rings you at 9 am. He still has pain attacks, which respond well to the diclofenac, but since 5 am he has also had a continuous pain in his right side and a fever (38.9°C).

Which of the following is the best next step?

- Ask him to wait another day to see how the disease progresses
- Prescribe broad spectrum antibiotics
- Refer him to hospital for an intravenous pyelogram
- Refer him urgently to a urologist

Example of an extended matching question

- (a) *Campylobacter jejuni*, (b) *Candida albicans*, (c) *Giardia lamblia*, (d) *Rotavirus*, (e) *Salmonella typhi*, (f) *Yersinia enterocolitica*, (g) *Pseudomonas aeruginosa*, (h) *Escherichia coli*, (i) *Helicobacter pylori*, (j) *Clostridium perfringens*, (k) *Mycobacterium tuberculosis*, (l) *Shigella flexneri*, (m) *Vibrio cholerae*, (n) *Clostridium difficile*, (o) *Proteus mirabilis*, (p) *Tropheryma whippelii*

For each of the following cases, select (from the list above) the micro-organism most likely to be responsible:

- A 48 year old man with a chronic complaint of dyspepsia suddenly develops severe abdominal pain. On physical examination there is general tenderness to palpation with rigidity and rebound tenderness. Abdominal radiography shows free air under the diaphragm
- A 45 year old woman is treated with antibiotics for recurring respiratory tract infections. She develops a severe abdominal pain with haemorrhagic diarrhoea. Endoscopically a pseudomembranous colitis is seen

Using only one type of question throughout the whole curriculum is not a valid approach

10 Skill based assessment

Sydney Smee

Skill based assessments are designed to measure the knowledge, skills, and judgment required for competency in a given domain. Assessment of clinical skills has formed a key part of medical education for hundreds of years. However, the basic requirements for reliability and validity have not always been achieved in traditional “long case” and “short case” assessments. Skill based assessments have to contend with case specificity, which is the variance in performance that occurs over different cases or problems. In other words, case specificity means that performance with one patient related problem does not reliably predict performance with subsequent problems.

For a reliable measure of clinical skills, performance has to be sampled across a range of patient problems. This is the basic principle underlying the development of objective structured clinical examinations (OSCEs). Several other structured clinical examinations have been developed in recent years, including modified OSCEs—such as the Royal College of Physicians’ Practical Assessment of Clinical Examination Skills (PACES) and the objective structured long case (OSLER). This article focuses mainly on OSCEs to illustrate the principles of skill based assessment.

OSCEs

The objective structured clinical examination (OSCE) was introduced over 30 years ago as a reliable approach to assessing basic clinical skills. It is a flexible test format based on a circuit of patient based “stations.”

At each station, trainees interact with a patient or a “standardised patient” to demonstrate specified skills. Standardised patients are lay people trained to present patient problems realistically. The validity of interactions with real patients, however, may be higher than that with standardised patients, but standardised patients are particularly valuable when communication skills are being tested.

OSCE stations may be short (for example, five minutes) or long (15-30 minutes). There may be as few as eight stations or more than 20. Scoring is done with a task specific checklist or a combination of checklist and rating scale. The scoring of the students or trainees may be done by observers (for example, faculty members) or patients and standardised patients.

Design

The design of an OSCE is usually the result of a compromise between the assessment objectives and logistical constraints; however, the content should always be linked to the curriculum, as this link is essential for validity.

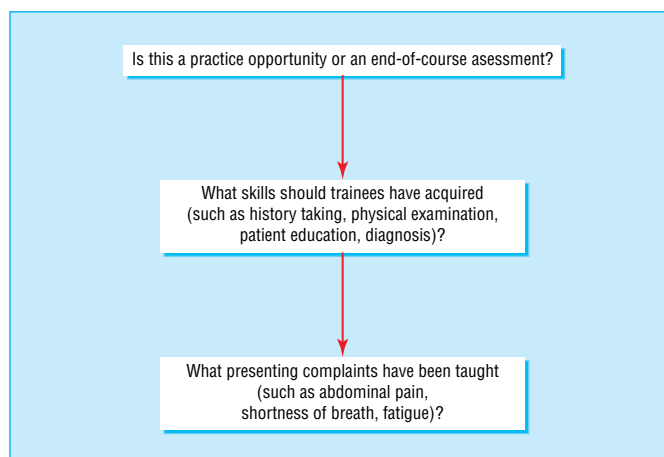

Using many short stations should generate scores that are sufficiently reliable for making pass-fail decisions within a reasonable testing time. (Whether any OSCE is sufficiently reliable for grading decisions is debatable.) Fewer but longer stations maximise learning relative to the selected patient problems, especially when students or trainees receive feedback on their performance. The number of students, time factors, and the availability of appropriate space must also be considered.

Written tests can assess knowledge acquisition and reasoning ability, but they cannot so easily measure skills

Patient-doctor interaction for assessing clinical performance

Questions to answer when designing an OSCE

Planning

Planning is critical. Patients and standardised patients can be recruited only after stations are written. Checklists must be reviewed before being printed, and their format must be compatible with the marking method, ideally computerised. OSCEs generate a lot of data—for 120 students in a 20 station OSCE there will be 2400 mark sheets!)

Stations are the backbone of an OSCE, and yet the single most common problem is that station materials are incomplete and subject to last minute changes. The result is increased cost and wasted time.

If OSCE scores are being used for making pass-fail decisions, then it is also necessary to set standards. Several methods for setting standards have been used, with the Angoff method described below being the most commonly used.

Plans should allow sufficient time to process and analyse the scores carefully.

Costs

OSCE costs vary greatly because the number of stations determines the number of standardised patients, examiners, and staff required. Whether or not faculty members volunteer to write cases, set standards, and examine is also a significant factor.

Developing the stations

OSCE stations have three components.

Stem

A standardised format for the “stem” (task) is helpful—for example, providing the patient’s name, age, presenting complaint, and the setting (such as clinic, emergency, or ward) for all stations. The stem must clearly state the task—for example, “in the next eight minutes, conduct a relevant physical examination.”

Checklist

The checklist items are the actions that should be taken in response to the information in the stem. These items should be reviewed and edited to ensure that (a) they are appropriate for the level of training being assessed, (b) they are task based, and (c) they are observable (so the observer can score them).

The length of the checklist depends on the clinical task, the time allowed, and who is scoring. A checklist for a five minute station that is testing history taking may have up to 25 items if a faculty observer is doing the scoring. If a patient or standardised patient is doing the scoring, then fewer items should be used. Use of detailed items will guide scorers: for example, “examines the abdomen” is a general item that might better be separated into a series of items such as “inspects the abdomen,” “auscultates the abdomen,” “lightly palpates all four quadrants,” and so on.

A score must be assigned to every item. Items may be scored 1 or 0, or relative weights may be assigned, with more critical items being worth more. Weights may not change the overall pass-fail rate of an OSCE, but they may improve the validity of a checklist and can affect which trainees pass or fail.

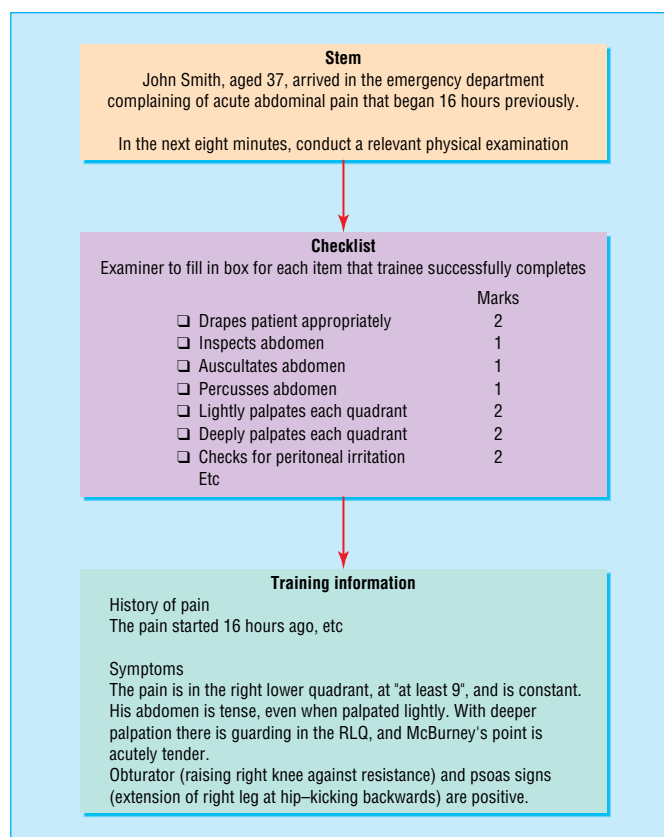

Training information

For standardised patients, directions should use patient based language, specify the patient’s perception of the problem (for example, serious, not serious), provide only relevant information, and specify pertinent negatives. Responses to all checklist items should be included. The patient’s behaviour and affect should be described in terms of body language, verbal

Tasks to do ahead

- Create blueprint
- Set timeline (how long do we need?)
- Get authors for a case-writing workshop
- Review and finalise cases
- Arrange workshop on setting standards
- Recruit standardised patients; recruit faculty members as examiners
- Train standardised patients
- Print marking sheets, make signs
- List all supplies for set-up of OSCE stations
- Remind everyone of date
- Make sure students have all the information
- Plans for the examination day: diagram of station layout; directions for examiners, standardised patients, and staff; possible registration table for students; timing and signals (for example, stopwatch and whistles); procedures for ending the examination
- Anything else?

The fixed costs of running an OSCE remain much the same regardless of the number of examination candidates. Administering an OSCE twice in one day only slightly increases the fixed costs, although the examiners’ time is an important cost

Components of OSCE station

ABC of Learning and Teaching in Medicine

tone, and pace. Symptoms to be simulated need to be described.

Limitations

Skill based assessments are based on tasks that approximate performance in the area of interest. The assumption is that the closer the tasks are to “real world” tasks, the more valid the assessment.

Three aspects of an OSCE limit how closely the stations approximate clinical practice. Firstly, time limited stations often require trainees to perform isolated aspects of the clinical encounter. This deconstructs the doctor-patient encounter and may be unacceptable for formative assessments. The trade-off is that limiting the time allows for more stations, which can provide performance snapshots that allow for reliable, summative decision making.

Secondly, OSCEs rely on task specific checklists, which assume that the doctor-patient interaction can be described as a list of actions. As a result, checklists tend to emphasise thoroughness, and this may become a less relevant criterion as the clinical experience of candidates increases. Thirdly, there are limits to what can be simulated, and this constrains the nature of the patient problems that can be sampled. Again, this becomes more of an issue as candidates’ level of training and clinical experience increases.

Other approaches to skill based assessment

Traditional approaches

The oral examination (also known as the “viva”) and the “long case” have long been used for assessing clinical competence. The oral examination is traditionally an unstructured face to face session with the examiners. This allows them to explore the trainee’s understanding of topics deemed relevant to clinical practice. The long case is patient based, but the interaction with the patient is usually not observed. Instead, trainees summarise the patient problem for the examiners and respond to examiners’ questions about findings, diagnosis or management, and other topics deemed relevant by examiners. The strength of the long case is the validity that comes from the complexities of a complete encounter with a real patient. However, the difficulty and relevance of these assessments varies greatly as the content is limited to one or two patient problems (selected from the available patients), and decisions are made according to unknown criteria, as examiners make holistic judgments. For this reason traditional unstructured orals and long cases have largely been discontinued in North America.

Alternative formats

Alternative formats tackle the problems associated with traditional orals and long cases by (a) having examiners observe the candidate’s complete interaction with the patient, (b) training examiners to a structured assessment process, and/or (c) increasing the number of patient problems. For a short case assessment, for example, one or two examiners may direct a trainee through a series of five or six encounters with real patients. They observe, ask questions, and make a judgment based on the candidate’s performance with all the patients. Similarly, a structured oral examination is still a face to face session with examiners, but guidelines for the topics to be covered are provided. Alternatively, a series of patient scenarios and agreed questions may be used so that the content and difficulty of the assessment is standardised across the trainees. Each of these adaptations is aimed at improving reliability, but

Limitations of OSCEs

- Stations often require trainees to perform isolated aspects of the clinical encounter, which “deconstructs” the doctor-patient encounter
- OSCEs rely on task specific checklists, which tend to emphasise thoroughness. But with increasing experience, thoroughness becomes less relevant
- The limitations on what can be simulated constrain the type of patient problems that can be used

None of these limitations is prohibitive, but they should be considered when selecting an OSCE as an assessment tool and when making inferences from OSCE scores

An alternative way to assess skills is to observe candidates’ interaction with patients

the most important improvement comes from greatly increasing the number of patient problems, which may well cause an impractical increased testing time.

Reliability and validity

The reliability of a test describes the degree to which the test consistently measures what it is supposed to measure. The more reliable a test, the more likely it is that a similar result will be obtained if the test is readministered. Reliability is sensitive to the length of the test, the station or item discrimination, and the heterogeneity of the cohort of candidates. Standardised patients' portrayals, patients' behaviour, examiners' behaviour, and administrative variables also affect reliability.

The validity of a test is a measure of the degree to which the test actually measures what it is supposed to measure. Validity is a property of test scores and justifies their interpretation for a specific purpose. The most basic evidence of validity comes from documenting the links between the content of the assessment and the curriculum's objectives and from the qualifications of those who develop the assessment.

Setting standards

Checklists generate scores; judges set standards. The validity of a standard depends on the judges' qualifications and the reasonableness of the procedure they use to set it. When pass-fail decisions are being made, a skill based assessment should be "criterion referenced" (that is, trainees should be assessed relative to performance standards rather than to each other or to a reference group). An Angoff approach is commonly used to set the standard for an OSCE.

Skill based assessments do not replace knowledge based tests, but they do assess aspects of competence that knowledge based tests cannot assess. Although the use of OSCEs for skill based assessment is increasingly widespread, modifying more traditional formats may be appropriate when they are combined with other forms of assessment or are used to screen trainees. The success of any skill based assessment depends on finding a suitable balance between validity and reliability and between the ideal and the practical.

Factors leading to lower reliability

- Too few stations or too little testing time
- Checklists or items that don't discriminate (that is, are too easy or too hard)
- Unreliable patients or inconsistent portrayals by standardised patients
- Examiners who score idiosyncratically
- Administrative problems (such as disorganised staff or noisy rooms)

Questions to ensure validity

- Are the patient problems relevant and important to the curriculum?
- Will the stations assess skills that have been taught?
- Have content experts (generalists and specialists) reviewed the stations?

A modified Angoff procedure for an OSCE

The second picture and the picture showing an oral examination are from Microsoft Clipart.

11 Work based assessment

John J Norcini

In 1990 psychologist George Miller proposed a framework for assessing clinical competence. At the lowest level of the pyramid is knowledge (knows), followed by competence (knows how), performance (shows how), and action (does). In this framework, Miller distinguished between “action” and the lower levels. “Action” focuses on what occurs in practice rather than what happens in an artificial testing situation. Work based methods of assessment target this highest level of the pyramid and collect information about doctors’ performance in their normal practice. Other common methods of assessment, such as multiple choice questions, simulation tests, and objective structured clinical examinations (OSCEs) target the lower levels of the pyramid. Underlying this distinction is the sensible but still unproved assumption that assessments of actual practice are a much better reflection of routine performance than assessments done under test conditions.

Methods

Although the focus of this article is on practising doctors, work based assessment methods apply to medical students and trainees as well. These methods can be classified in many ways, but this article classifies them in two dimensions. The first dimension describes the basis for making judgments about the quality of performance. The second dimension is concerned with how data are collected.

Basis for judgment

Outcomes

In judgments about the outcomes of their patients, the quality of a cardiologist, for example, might be judged by the mortality of his or her patients within 30 days of acute myocardial infarction. Historically, outcomes have been limited to mortality and morbidity, but in recent years the number of clinical end points has been expanded. Patients’ satisfaction, functional status, cost effectiveness, and intermediate outcomes—for example, HbA_{1c} and lipid concentrations for diabetic patients—have gained acceptance.

Patients’ outcomes are the best measures of the quality of doctors for the public, the patients, and doctors themselves. For the public, outcomes assessment is a measure of accountability that provides reassurance that the doctor is performing well in practice. For individual patients, it supplies a basis for deciding which doctor to see. For doctors, it offers reassurance that their assessment is tailored to their unique practice and based on real work performance.

Despite the fact that an assessment of outcomes is highly desirable, at least four substantial problems remain. These are attribution, complexity, case mix, and numbers.

Firstly, for a good judgment to be made about a doctor’s performance, the patients’ outcomes must be attributable solely to that doctor’s actions. This is not realistic when care is delivered within systems and teams. Secondly, patients with the same condition will vary in complexity depending on the severity of their illness, the existence of comorbid conditions, and their ability to comply with the doctor’s recommendations. Although statistical adjustments may tackle these problems, they are not completely effective. So differences in complexity directly influence outcomes and make it difficult to compare

This article explains what is meant by work based assessment and presents a classification scheme for current methods

Miller’s pyramid for assessing clinical competence

Classification for work based assessment methods

Three aspects of doctors’ performance can be assessed—patients’ outcomes, process of care, and volume of practice

Care is delivered in teams, so judging a doctor’s performance through outcomes is not realistic

doctors or set standards for their performance. Thirdly, unevenness exists in the case mix of different doctors, again making it difficult to compare performance or to set standards. Finally, to estimate well a doctor's routine performance, a sizeable number of patients are needed. This limits outcomes assessment to the most frequently occurring conditions.

Process of care

In judgments about the process of care that doctors provide, a general practitioner, for example, might be assessed on the basis of how many of his or her patients aged over 50 years have been screened for colorectal cancer. General process measures include screening, preventive services, diagnosis, management, prescribing, education of patients, and counselling. In addition, condition specific processes might also serve as the basis for making judgments about doctors—for example, whether diabetic patients have their HbA_{1c} monitored regularly and receive routine foot examinations.

Measures of process of care have substantial advantages over outcomes. Firstly, the process of care is more directly in the control of the doctor, so problems of attribution are greatly reduced. Secondly, the measures are less influenced by the complexity of patients' problems—for example, doctors continue to monitor HbA_{1c} regardless of the severity of the diabetes. Thirdly, some of the process measures, such as immunisation, should be offered to all patients of a particular type, reducing the problems of case mix.

The major disadvantage of process measures is that simply doing the right thing does not ensure the best outcomes for patients. That a physician regularly monitors HbA_{1c}, for example, does not guarantee that he or she will make the necessary changes in management. Furthermore, although process measures are less susceptible to the difficulties of attribution, complexity, and case mix, these factors still have an adverse influence.

Volume

Judgments about the number of times that doctors have engaged in a particular activity might include, for example, the number of times a surgeon performed a certain surgical procedure. The premise for this type of assessment is the large body of research showing that quality of care is associated with higher volume.

Data collection

Clinical practice records

One of the best sources of information about outcomes, process, and volume is the clinical practice record. The external audit of these records is a valid and credible source of data. Two major problems exist, however, with clinical practice records.

Firstly, judgment can be made only on what is recorded—this may not be an accurate assessment of what was actually done in practice.

Secondly, abstracting records is expensive and time consuming and is made cumbersome by the fact that they are often incomplete or illegible.

Widespread adoption of the electronic medical record may be the ultimate solution, although this is some years away. Meanwhile, some groups rely on doctors to abstract their own records and submit them for evaluation. Coupled with an external audit of a sample of the participating doctors, this is a credible and feasible alternative.

Unevenness in case mix can reduce usefulness of using patients' outcomes as a measure of doctors' competence

Judgments on process of care might include foot examinations for diabetic patients

For a sound assessment of an individual doctor's process of care, a sizeable number of patients need to be included

Advantages of volume based assessment over assessment of outcomes and process

- Problems of attribution are reduced substantially
- Complexity is eliminated
- Case mix is not relevant

However, such assessment alone offers no assurance that the activity was conducted properly

Traditional medical records may give way to widespread use of electronic records, making data collection easier and quicker

Administrative databases

In some healthcare systems large computerised databases are often developed as part of the process of administering and reimbursing for health care. Data from these sources are accessible, inexpensive, and widely available. They can be used in the evaluation of some aspects of practice performance—such as cost effectiveness—and of medical errors. However, the lack of clinical information and the fact that the data are often collected for invoicing purposes makes them unsuitable as the only source of information.

Diaries

Doctors, especially trainees, may use diaries or logs to record the procedures they perform. Depending on the purpose of the diary, entries can be accompanied by a description of the doctor's role, the name of an observer, an indication of whether it was done properly, and a list of complications. This is a reasonable way to collect data on volume and an acceptable alternative to the abstraction of clinical practice records until medical records are kept electronically.

Observation

Data can be collected in many ways through practice observation, but to be consistent with Miller's definition of work based assessment, the observations need to be routine or covert to avoid an artificial test situation. They can be made in any number of ways and by any number of different observers. The most common forms of observation based assessment are ratings by supervisors, peers, and patients. Other examples of observation include visits by standardised patients (lay people trained to present patient problems realistically) to doctors in their surgeries and audiotapes or videotapes of consultations such as those used by the General Medical Council.

Portfolios

Doctors typically collect from various sources the practice data they think pertinent to their evaluation. A doctor's portfolio might contain data on outcomes, process, or volume, collected through clinical record audit, diaries, or assessments by patients and peers. It is important to specify what to include in portfolios as doctors will naturally present their best work, and the evaluation of it will not be useful for continuing quality improvement or quality assurance. In addition, if there is a desire to compare doctors or to provide them with feedback about their relative performance, then all portfolios must contain the same data collected in a similar fashion. Otherwise, there is no basis for legitimate comparison or benchmarking.

Databases for clinical audit are becoming more available and may provide more useful information relating to clinical practice

Peer evaluation rating forms

Below are the aspects of competence assessed with the peer rating form developed by Ramsey and colleagues.* The form, given to 10 peers, provides reliable estimates of two overall dimensions of performance: cognitive and clinical skills, and professionalism.

Cognitive and clinical skills

- Medical knowledge
- Ambulatory care
- Management of complex problems
- Management of hospital inpatients
- Problem solving
- Overall clinical competence

Professionalism

- Respect
- Integrity
- Psychosocial aspects of illness
- Compassion
- Responsibility

*Ramsey PG et al. Use of peer ratings to evaluate physician performance. *JAMA* 1993;269:1655-60

Patient rating form*

The form is given to 25 patients and gives a reliable estimate of a doctor's communication skills. Scores are on a five point scale—poor to excellent—and are related to validity measures. The patients must be balanced in terms of age, sex, and health status. Typical questions are:

- Tells you everything?
- Greets you warmly?
- Treats you as if you're on the same level?
- Lets you tell your story?
- Shows interest in you as a person?
- Warns you what is coming during the physical examination?
- Discusses options?
- Explains what you need to know?
- Uses words you can understand?

12 Educational environment

Linda Hutchinson

A student might find a particular question threatening and intimidating in one context yet stimulating and challenging in a different context. What makes one learning context unpleasant and another pleasant?

Learning depends on several factors, but a crucial step is the engagement of the learner. This is affected by their motivation and perception of relevance. These, in turn, can be affected by learners' previous experiences and preferred learning styles and by the context and environment in which the learning is taking place. In adult learning theories, teaching is as much about setting the context or climate for learning as it is about imparting knowledge or sharing expertise.

Motivation

Motivation can be intrinsic (from the student) and extrinsic (from external factors). Assessments are usually a strong extrinsic motivator for learners. Individual learners' intrinsic motivation can be affected by previous experiences, by their desire to achieve, and the relevance of the learning to their future.

A teacher's role in motivation should not be underestimated. Enthusiasm for the subject, interest in the students' experiences, and clear direction (among other things) all help to keep students' attention and improve assimilation of information and understanding.

Even with good intrinsic motivation, however, external factors can demotivate and disillusion. Distractions, unhelpful attitudes of teachers, and physical discomfort will prompt learners to disengage. Maslow described a model to illustrate the building blocks of motivation. Each layer needs to be in place before the pinnacle of "self actualisation" is reached.

Physiological needs

Although the need to be fed, watered, and comfortable seems trite, many teachers will have experienced, for example, the difficulties of running sessions in cold or overheated rooms, in long sessions without refreshments, in noisy rooms, in facilities with uncomfortable seating.

Physical factors can make it difficult for learners and teachers to relax and pay attention. Ensuring adequate breaks and being mindful of the physical environment are part of the teacher's role.

Safety

A teacher should aim to provide an environment in which learners feel safe to experiment, voice their concerns, identify their lack of knowledge, and stretch their limits. Safety can be compromised, for example, through humiliation, harassment, and threat of forced disclosure of personal details.

Teachers can create an atmosphere of respect by endorsing the learners' level of knowledge and gaps in knowledge as essential triggers to learning rather than reasons for ridicule.

Remembering names and involving the learners in setting ground rules are other examples of building mutual trust. Feedback on performance, a vital part of teaching, should be done constructively and with respect for the learner.

Many factors influence learning

Maslow's hierarchy of needs for motivating learning. Adapted from Maslow A H. *Motivation and Personality*, New York: Harper and Row, 1954

Case history: safe environment

Dr Holden claims to use interactive teaching techniques. She introduces the topic then points to a student in the audience and says, "tell me five causes of cyanosis." Each student will get asked questions in the session, and most spend their time worrying about when it is their turn to be "exposed."

After a course on teaching skills, she runs the same session. After the introduction, she tells the students to turn to their neighbour and together come up with some possible causes of cyanosis. After a couple of minutes of this "buzz group" activity, she asks for one suggestion from each group until no new suggestions are made. The suggestions are then discussed with reference to the aims of the session.

ABC of Learning and Teaching in Medicine

Belonging

Many factors help to give a student a sense of belonging in a group or team—for example, being a respected member, having one's voice heard and attended to, being given a useful role, and having colleagues with similar backgrounds, experiences, and goals.

Learners are motivated through inclusion and consultation. Their input to a course's objectives and structure should be sought, valued, and acted on. On clinical placements, staff should help to prevent medical students from feeling ignored, marginalised, or "in the way." Students should instead be valued as assets to a clinical unit or team.

Self esteem

Several of the points mentioned above feed directly into self esteem through making the learner feel valued. Praise, words of appreciation, and constructive rather than destructive criticism are important. It can take many positive moments to build self esteem, but just one unkind and thoughtless comment to destroy it.

Doctors are well used to their role in the doctor-patient relationship. Some find it hard to translate the same skills and attitudes to the teacher-student relationship. Their own experience of education or their own distractions, time pressures, and other stresses may be factors.

Self actualisation

If a teacher has attended to the above motivational factors, then they have sought to provide the ideal environment in which a learner can flourish.

An ethos that encourages intrinsic motivation without anxiety is conducive to a "deep" learning approach. However, there may be some who remain unable to respond to the education on offer. Teachers may need to consider whether the course (or that particular piece of study) is suitable for that student.

Relevance

The relevance of learning is closely linked to motivation: relevance for immediate needs, for future work, of getting a certificate or degree regardless of content. Learning for learning's sake is back in vogue in higher education after a move towards vocational or industrial preparation.

Certain courses in medical degrees have been notoriously poorly received by students. Faculty members need to explain to students why these courses are necessary and how they link to future practice. Allowing them to see for themselves, through early clinical exposure and experience, is likely to be helpful. Similarly, learning the basic medical sciences in the context of clinical situations is the basis for problem based learning.

A challenging problem is the trainee who is in a post because he or she needs to do it for certification, although it is of no perceived value to the trainee's future career direction. A balance needs to be negotiated between respect for the individual's needs and the expectation of a level of professional conduct.

Teacher as role model

The teacher or facilitator is one of the most powerful variables in the educational environment. The teacher's actions, attitudes (as evidenced by tone of voice, comments made), enthusiasm, and interest in the subject will affect learners indirectly. The capacity for subliminal messages is enormous. Inappropriate

Case history: sense of belonging

Five medical students arrive at a distant hospital for a four week attachment. They are met by a staff member, shown around the unit, canteen, library, and accommodation. They are given name badges in the style of the existing staff, and after a couple of days are given specific roles on the unit. These roles develop over the weeks. There is little set teaching time, but the students feel free to ask any staff member for more details at quieter times.

After the attachment, they meet up with friends who were placed elsewhere. Their experience was different. No one was expecting them when they arrived, and ward and clinic staff were unhelpful. There was a set teaching programme and an enthusiastic teacher, but the students were relieved that the hospital was near a town centre with good shops and nightlife.

Case history: self esteem

A senior house officer (SHO) is making slow but steady progress. His confidence is growing and the level of supervision he requires is lessening. On one occasion, however, his case management is less than ideal, although the patient is not harmed or inconvenienced. The consultant feels exasperated and tells the SHO that everyone is carrying him and it still isn't working. The SHO subsequently reverts to seeking advice and permission for all decision making.

Students' perception of the relevance of what they are being taught is a vital motivator for learning

If a teacher is asked to do a one-off session with learners they don't know, he or she should prepare—both before and at the start of the session—by determining what the learners know, want to know, and expect to learn. This involves and shows respect for the learners and encourages them to invest in the session

Case history: role models

Dr Jones is a well known "character" in the hospital. Medical students sitting in his clinic hear him talk disparagingly about nurses, patients, and the new fangled political correctness about getting informed consent that wastes doctors' time. Most students are appalled; but a few find him engaging—they view him as a "real" doctor, unlike the ethics or communication skills lecturers.

behaviour or expression by a staff member will be noticed; at worst the learners will want to emulate that behaviour, at best they will have been given tacit permission to do so.

Maximising educational environment

Classroom, tutorials, seminars, lectures

Room temperature, comfort of seating, background noise, and visual distractions are all factors of the environment that can affect concentration and motivation. Some are within the teacher's control, others not.

Respect for the learners and their needs, praise, encouragement of participation can all lead to a positive learning experience. Lack of threat to personal integrity and self esteem is essential, although challenges can be rewarding and enjoyable.

Small group teaching facilitates individual feedback, but the seating arrangement used will have an important effect on student participation. If, for example, students sit in traditional classroom rows, those on the edges will feel excluded. A circular format encourages interaction. It allows the teacher to sit alongside a talkative person, thus keeping them out of eye contact and reducing their input. A quiet student can be placed opposite to encourage participation through non-verbal means. Students can also work in unfacilitated groups on a topic, enabling them to work in teams and share the learning tasks.

Clinical settings

In real life settings, the dual role of teacher and clinician can be complicated. The students will be closely observing the clinician, picking up hidden messages about clinical practice. They need to feel that there is no danger that they will unnecessarily distress or harm patients or their families. They also need to feel safe from humiliation. Making them feel welcomed and of value when they arrive at a new placement or post will aid their learning throughout.

Course and curriculum design

The designers of short and long courses should consider the relevance of the learning environment to the potential learners. Student representation on curriculum committees is one means of ensuring a more student centred course.

The aims, objectives, and assessments should be signposted well in advance of a course and should be demonstrably fair. The teaching methods should build on learners' experience, creating a collaborative environment. Disseminating the findings of course evaluations, followed by staff training, helps to identify and correct undesirable behaviour among faculty members. Evaluations should also include a means for reviewing the course's aims and objectives with the students.

In longer courses, student support systems and informal activities that build collective identity must be considered. Students who are having difficulties need to be identified early and given additional support.

It is easy to “learn” attitudes—including poor attitudes. Attitudes are learnt through observation of those in relative power or seniority. Teachers must therefore be aware of providing good role modelling in the presence of students

Checklist to ensure good physical environment

- Is the room the right size?
- Is the temperature comfortable?
- Are there distractions (noise, visual distractions inside or outside)?
- Is the seating adequate, and how should it be arranged?
- Does the audiovisual equipment work?

Traditional teaching can leave some students excluded (that is, outside the “triangle of influence”)

Checklist for teaching in clinical settings

- Have patients and families given consent for students to be present?
- Do the staff know that teaching is planned and understand what their roles will be?
- Is there adequate space for all participants?
- How much time is available for teaching?
- How may the students be made to feel useful (for example, “pre-clerking” and presenting)?

13 Web based learning

Judy McKimm, Carol Jollie, Peter Cantillon

Many of us use the internet or the “web” (world wide web) as a source of information. In medical education, the web is increasingly used both as a learning tool to support formal programmes and as a means of delivering online learning programmes. What can educators do to ensure that the potential of the web is used effectively to support both their own learning and that of their students?

The technology

Much of the literature on web based learning shows that one of the main barriers to the effective use of teaching materials is the technology (for example, poor access, slow downloading) rather than the design of the learning materials themselves. Some of these issues are discussed later in the article, but it is vital that teachers take on expert help with technical issues in the planning, design, and delivery of web based learning programmes. Through programming and the use of “plug-ins” (programs that can be downloaded from the internet), designers can produce interactive course materials containing online activities (such as self assessments), animations, and simulations. These can improve learning and are often more enjoyable and meaningful for learners.

Distance learning

Two of the main developments in web based learning have been the adaptation of communication technology to support learning and the changes in distance learning strategies necessary for delivering online courses. Both aspects should be considered when designing or delivering web based learning programmes. Lessons can be learned by considering how distance education evolved.

Distance and open learning began with correspondence courses. The Open University in Britain is one of the best known examples of how university level education became accessible, through effective distance learning, to people who had neither the traditional qualifications nor the time to enter full time higher education.

The secret of the Open University’s success lies in clearly identifying students’ needs; providing effective, local support; and combining conventionally taught components with the use of up to date multimedia resources, including books, course guides, videotapes, audiotapes, television, e-conferencing, and discussion groups.

What is web based learning?

Web based learning is often called online learning or e-learning because it includes online course content. Discussion forums via email, videoconferencing, and live lectures (videostreaming) are all possible through the web. Web based courses may also provide static pages such as printed course materials.

One of the values of using the web to access course materials is that web pages may contain hyperlinks to other parts of the web, thus enabling access to a vast amount of web based information.

A “virtual” learning environment (VLE) or managed learning environment (MLE) is an all in one teaching and learning software package. A VLE typically combines functions such as

Glossary

E-conferencing—Use of online presentations and discussion forums (in real time or stored as downloadable files on a website) to avoid the need for participants to travel

E-learning—Learning through electronic means, such as via the web (see world wide web), an intranet, or other multimedia materials

HTML (hypertext markup language)—The language used to create web pages. HTML files can also contain links to other types of files including wordprocessed files, spreadsheets, presentation slides, and other web pages

Hyperlinks—Links in web pages that enable the user to access another web page (either on the same or a different site) with just one mouse click

Internet—A global network of computers divided into subsets (for example, the web or email systems). Computers are linked to the internet via host computers, which link to other computers via dial up (for example, via a modem) and network connections

Internet service provider (ISP)—Home users usually access the internet through an internet service provider (such as AOL), which maintains a network of PCs permanently connected to the internet

Intranet—A network of computers that share information, usually within an organisation. Access normally requires a password and is limited to a defined range of users

Managed learning environment (MLE)—Usually has an integrated function, providing administrative tools, such as student records, and linking with other management information systems (MLS)

Search engines (such as Lycos, Google)—Can be used to help to find information

Videostreaming—The process by which video images are able to be stored and downloaded on the web. These might be in real time (such as a conference) or used asynchronously

Virtual learning environment (VLE)—A set of electronic teaching and learning tools. Principal components include systems that can map a curriculum, track student activity, and provide online student support and electronic communication

World wide web (web)—Use of the internet to present various types of information. Websites or home pages may be accessed with the aid of a browser program (such as Netscape Communicator or Microsoft Explorer). All such programmes use HTML

For additional information see www.learnthenet.com/english/section/intbas.html

discussion boards, chat rooms, online assessment, tracking of students' use of the web, and course administration. VLEs act as any other learning environment in that they distribute information to learners. VLEs can, for example, enable learners to collaborate on projects and share information. However, the focus of web based courses must always be on the learner—technology is not the issue, nor necessarily the answer.

Models of web based learning

Several approaches can be used to develop and deliver web based learning. These can be viewed as a continuum. At one end is “pure” distance learning (in which course material, assessment, and support is all delivered online, with no face to face contact between students and teachers). At the other end is an organisational intranet, which replicates printed course materials online to support what is essentially a traditional face to face course. However, websites that are just repositories of knowledge, without links to learning, communication, and assessment activities, are not learner centred and cannot be considered true web based learning courses.

In reality, most web based learning courses are a mixture of static and interactive materials, and most ensure that some individual face to face teaching for students is a key feature of the programme.

The individual learner

The first step in designing a web based course is to identify the learners' needs and whether the learners are to be considered as part of a group or as individual learners. The web can be a useful tool for bringing isolated learners together in “virtual” groups—for example, through a discussion forum. There are several online resources on how to design web based learning programmes (for example, at www.ltsn.ac.uk).

Questions to ask before starting a web based learning project

- What is the educational purpose of the web based learning project?
- What added value will online learning bring to the course or to the students?
- What resources and expertise on web based learning exist in the institution?
- Are colleagues and the institution aware of the planned course? (You need to avoid duplication of effort and be sure that the institution's computer system can support the course)
- Has the project taken account of existing teaching resources and ongoing maintenance costs after initial development?
- Have you allowed enough time to develop or redevelop materials?
- Have the particular design and student support requirements of web based learning courses been taken into account? If not, the e-learning starter guides on the LTSN website are a good resource (www.ltsn.ac.uk/genericcentre)

Incorporating web based learning into conventional programmes

Web based learning in an institution is often integrated with conventional, face to face teaching. This is normally done via an intranet, which is usually “password protected” and accessible only to registered users. Thus it is possible to protect the intellectual property of online material and to support confidential exchange of communication between students.

Medicine has many examples of online learning, in both the basic sciences and clinical teaching. As students are usually in large groups for basic science teaching, web based learning can

“Newer technologies such as computers and video conferencing are not necessarily better (or worse) for teaching or learning than older technologies ... they are just different ... The choice of technology should be driven by the needs of the learners and the context in which we are working, not by its novelty.”

Bates AW. *Technology, open learning and distance education*. London: Routledge, 1995

Features of a typical web based course

- Course information, notice board, timetable
- Curriculum map
- Teaching materials such as slides, handouts, articles
- Communication via email and discussion boards
- Formative and summative assessments
- Student management tools (records, statistics, student tracking)
- Links to useful internal and external websites—for example, library, online databases, and journals

The learning cycle: useful to bear in mind when planning a web based course

Learning and teaching support network (www.ltsn.ac.uk)

- The learning and teaching support network (consisting of 24 subject centres) was set up to help staff in higher education to deliver programmes in their own subjects more effectively and to improve communication between teachers in different organisations and government agencies
- One subject centre covers medicine, dentistry, and veterinary science (LTSN 01)
- Although not strictly web based learning, LTSN 01 uses a combination of activities delivered via the web (such as an email discussion forum, copies of useful articles, research and funding programmes, and job vacancies) to support staff working in medical, dental, and veterinary education

ABC of Learning and Teaching in Medicine

be used to provide learning materials to complement conventional programmes and to enable self assessment—for example, access to anatomical sites and image banks for the teaching of pathology courses. Web based learning can be useful to support clinical teaching when learners are geographically dispersed—for example, to learn clinical skills through video demonstrations.

Assessment

With all types of learning, including web based learning, it is useful for students to receive constructive, timely, and relevant feedback on their progress. Online assessment is sometimes constrained by the medium in which it is operating. Computer marked assessments alone are not appropriate for marking or giving feedback on assignments such as essays or projects that require more than the mere reproduction of knowledge.

When planning online assessment it is important to determine what is to be assessed. If knowledge reproduction is being tested, objective questions (such as multiple choice or “true or false” questions) with instant or model answers can provide excellent feedback. Assessment of higher cognitive functions, such as analysis and synthesis, will require more complex tests. Automated marking may be difficult for such assessments, and the teacher is likely to have to do a substantial amount of work before he can add his or her comments to the student’s record. Further guidance on how to design web based assessments for online courses can be found at www.ltsn.ac.uk and www.ltss.bris.ac.uk

For and against web based learning

When designing web based programmes (as with any learning programme), the learners’ needs and experience must be taken into account. Appropriate technology and reasonable computer skills are needed to get the best out of web based or online learning. Programmes and web pages can be designed to accommodate different technical specifications and versions of software. It is frustrating for learners, however, if they are trying to work on the internet with slow access or cannot download images and videos they need. On the other hand, web based programmes may, for example, encourage more independent and active learning and are often an efficient means of delivering course materials.

Effective web teaching and learning

Course designers need to remember that younger students are more likely to be familiar with using the internet than older learners, who may feel less comfortable with a web based course. To get the best out of their learning experience, learners need basic computer skills, support, and guidance.

Teachers must design their courses to encourage effective web based learning rather than aimless “surfing.” Programme design should therefore filter out poor information as well as signpost key information sources.

Many clinicians are beginning to use electronic patient records. This change means that doctors are becoming more adept at using computers and online resources to support their daily work and continuing professional development. Electronic media can facilitate access to evidence based

With web based learning, the material can be linked to libraries (for example, for ordering books or journals), online databases, and electronic journals. These functions are particularly useful for research and clinical activities

Advantages and disadvantages of online assessment

Advantages

- Students can receive quick feedback on their performance
- Useful for self assessments—for example, multiple choice questions
- A convenient way for students to submit assessment from remote sites
- Computer marking is an efficient use of staff time

Disadvantages

- Most online assessment is limited to objective questions
- Security can be an issue
- Difficult to authenticate students’ work
- Computer marked assessments tend to be knowledge based and measure surface learning

Advantages and disadvantages of web based learning

Advantages

- Ability to link resources in many different formats
- Can be an efficient way of delivering course materials
- Resources can be made available from any location and at any time
- Potential for widening access—for example, to part time, mature, or work based students
- Can encourage more independent and active learning
- Can provide a useful source of supplementary materials to conventional programmes

Disadvantages

- Access to appropriate computer equipment can be a problem for students
- Learners find it frustrating if they cannot access graphics, images, and video clips because of poor equipment
- The necessary infrastructure must be available and affordable
- Information can vary in quality and accuracy, so guidance and signposting is needed
- Students can feel isolated

resources such as the Cochrane Library. These web based clinical support sites are excellent resources for postgraduate “on the job” learning.

Teachers should be encouraged, through training and support, to use the web and other information technologysystems in their teaching. They need examples and awareness of good practice, and standards should be set in relation to how teachers present information and manage the learning environment.

Conclusion

Web based learning offers huge opportunities for learning and access to a vast amount of knowledge and information. The role of teachers is to ensure that the learning environment provided takes account of learners’ needs and ensures that they are effectively prepared and supported. Online learning has advantages, but web based learning should not always be viewed as the method of choice because barriers (such as inadequate equipment) can easily detract from student learning. The technology must therefore be applied appropriately and not used simply because it is available and new or because students and teachers have particular expectations of this means of course delivery.

14 Creating teaching materials

Richard Farrow

The nature and qualities of the teaching materials that you use can have a substantial effect on the educational experience of your students. Teaching materials can often distract learners rather than help them to learn. Common avoidable problems include overcrowded or illegible slides, irrelevant or badly prepared handouts, and incompatible multimedia equipment. It is important therefore to know how to create effective teaching materials.

Ground rules

Five basic principles apply to preparing teaching materials, irrespective of the type of material you choose: links, intelligibility, general style, highlighting, and targeting (LIGHT). You may sometimes decide to ignore one or more of these principles, but if you do, think carefully about what you are trying to achieve.

Links

Your teaching materials should have obvious and direct links to your talk, discussion, or presentation. Handouts are the main offenders in this category, and it is not unusual for handouts to have little in common with the talk. It is quite acceptable for the teaching materials to give some additional information, but this should not be excessive.

Intelligibility

The teaching material should be easy to understand and learn from. How this is achieved will depend on the medium used and the venue of the talk or presentation. Use simple language and avoid overlong sentences or statements. Diagrams can help to clarify a complex message. If you are using slides or overhead transparencies, the size of the print needs to be large enough to be read from the back of the auditorium. The font selected should be sans serif (for example, Arial).

General style

You should aim to use a consistent style throughout your teaching materials, particularly if you are giving a series of talks. Although it is tempting to use a variety of novel styles, consistency will allow learners to concentrate on the meaning and relevance of what you are trying to communicate.

Highlighting

Highlighted information helps to emphasise important issues or pivotal points in a developing argument. Methods of highlighting include changing the colour of text or underlining words or phrases. This also applies to videotapes and audiotapes, where changing your tone of voice can be used to emphasise key points.

Targeting

It is important that both the type of educational event (for example, presentation, seminar, discussion) and the teaching materials that supplement it are targeted at what your students need to learn. Targeting therefore requires an awareness of what knowledge and skills your students already have. This can

Preparing overhead transparencies

Do

- Try to use typed rather than handwritten script
- Use a type size that is big enough to be read by the whole audience—for example, at least 20 points
- Make sure that the colour of your text works—for example, dark print on a pale background
- Limit each transparency to one idea or concept

Don't

- Use small print
- Use overhead transparencies packed with tables and figures
- Use light colours

Uniformity in the teaching materials will help learners to focus on content rather than style

It is easy to **overdo** highlighting by **emphasising** virtually every point that you make. This reduces the **usefulness** of the technique and **hides** the really pivotal shifts in a **morass** of *highlighted text*.

Target your talk at learners' needs—don't just pull out the slides or overheads from a previous talk

be difficult to judge, but it is worth spending time finding out about your expected audience. It becomes easier if you are doing a series of talks with the same group as you can get feedback from the learners to help you plan more effectively.

Types of teaching materials

Black, green, or white boards

These are ideal for brainstorming sessions and small group work. If you are doing the writing, try not to talk at the same time as it is difficult for your learners to hear you if you have your back to them. Remember the LIGHT principles, and try to put concepts, not an essay, on the board. Make sure that everyone has finished copying information before you rub the board clean. Using different colours can add emphasis and highlight your important messages.

Lecture notes

Ensure that any handouts are produced to a high quality. Photocopies of handwritten notes (and frequently photocopied elderly pages) look scrappy and tend not to be valued. Give handouts to the learners at the beginning of the talk as copying down information is not a good use of their limited “face to face” time. Use headings and diagrams to make the handouts intelligible.

Overhead projector

The technical equipment for displaying overhead transparencies is widely available and reliable. It is a good backup resource, and for critical presentations it is comforting to know that, if all else fails, you have transparencies in your bag. Presentations using an overhead projector have the advantage that they allow you to face your audience while pointing out features on the transparency.

Correct preparation following the LIGHT principles is vital. Ensure that the transparencies will fit the projector—most will display A4 size, but some are smaller, so check in advance. The absolute minimum height for text on transparencies is 5 mm, although using larger text and fewer words usually produces a more effective educational tool. A good rule of thumb is to use a type size of at least 20 points. Several simple transparencies are usually better than one complicated one.

It is fairly straightforward to design your transparency on a computer then print it using a colour printer. Avoid using yellow, orange, and red, as these colours are difficult to see. Instead, use dark text on a light background. You can write and draw directly on to the transparencies with felt tipped pens. Use permanent markers to avoid smudging, and place a sheet of ruled paper underneath so that the writing is evenly spaced. You can also use a photocopier to copy print on to a transparency, but remember that you may need to enlarge it to make the text readable.

If you are likely to use a transparency again it is worth storing it carefully in dust free covers. One commonly used method is to store transparencies in clear plastic sleeves that can be filed in a ring binder. When showing transparencies, do not overuse the technique of covering the transparency and revealing a little at a time—many learners find this irritating.

35 mm slides

The need for 35 mm slides has decreased substantially with the advent of computer programs such as Microsoft's PowerPoint. However, multimedia projectors and computers are expensive and not available in all locations, whereas most educational institutions have a slide projector. Making your own slides can be difficult, so get help from the local illustration department or

Types and uses of teaching materials

- Boards, flip charts*—Small groups, problem based learning tutorials, workshops
- Lecture notes*—Small and large groups; help to improve interactivity
- Overhead projector*—Small and large groups, workshops, and interactive sessions
- 35 mm slides and PowerPoint*—Generally large groups and lecture formats
- Videos*—Good for clinical teaching in larger groups (use film of patients); also for teaching communication skills and practical skills (students can keep films for self appraisal)
- Life and plastic models*—Anatomy teaching in small groups or for self directed learning
- Computer assisted learning packages*—Small groups with a tutor; large groups in computer laboratories; self directed learning
- Skills centres and simulators*—Small groups learning clinical skills

Leave spaces in the handout for your learners to record the results of interactive parts of your talk—this ensures that the handout the learners take away has more value than the one they were given. Also, leave spaces for exercises to be completed later, thus linking self directed learning with face to face learning

Paper copies of transparencies and slides can make useful handouts—your learners can then add clarifying statements or diagrams to their own copy of the presentation

Number your slides so that if a projectionist is loading them or the carousel is dropped they can be quickly reordered

ABC of Learning and Teaching in Medicine

a commercial company. Ensure that the text is large enough to see when projected and that the slides are marked so that they are loaded in the projector correctly. Dual projection is rarely done well and rarely necessary unless you are using visual images (for example, x ray films, clinical photographs) with accompanying text. If you use dual projection make sure that each of the slides is labelled for the correct projector.

Computer generated slides

The ability to make computer generated slides (for example, PowerPoint) has transformed the way that many people create teaching materials and has greatly reduced the use of 35 mm slides. Try not to get seduced by the technology, however, and remember that it is just another educational tool. Having tried all of the colours and slide layouts available, many experienced lecturers now prefer simple formats that are easy to read and in which the medium does not get in the way of the message.

However, the computer package has many useful tools—diagrams and “clip art” can help to conceptualise difficult problems. Video clips can be inserted into a presentation, but be certain that they are there to illustrate a point and not simply to show off your own technological skills. Use advanced formats for PowerPoint presentations only if you are well practised and comfortable with the medium.

Ensure that the computer you are planning to use is compatible with the multimedia projector. Similarly, if you have stored your presentation on a CD or floppy disk (or any one of the other portable storage formats), make sure that this is supported at the venue. The latest version of the presentation software can give you access to many features that may not work on the computer provided at the teaching venue, so a wise precaution is to save your presentation as an older version of the software.

-

Ground rules for slide preparation (35 mm or PowerPoint)

- Use a clear font that is easily readable
 - Use a type size of 20 points or greater
 - Use a light text on a dark background for slides (in contrast with OHP transparencies)
 - Use short sentences and small tables
 - Restrict the overall number of words on each slide to about 40 or fewer
 - Avoid patterned backgrounds—they are extremely distracting
 - Limit the number of colours on your slides to a maximum of three
 - Use highlighting to emphasise items in lists
 - Use animation and sound effects sparingly

Preface

Diseases of the Liver, Pancreas and biliary system affect a substantial proportion of the worlds population and involve doctors and health care workers across many disciplines. Many of these diseases produce great misery and distress and are economically important requiring much time off work. The aim of this series was to provide an overview of these diseases and enable the busy clinician to keep abreast of advances in diagnosis and management of not only the common but also the rarer, but none the less important, conditions.

ABC of Liver, Pancreas, and Gall Bladder

Hepatectomy in the organ recipient is the most difficult part of the operation as the patient is at risk of developing a serious haemorrhage due to a combination of portal hypertension, defective clotting, and fibrinolysis. Improvements in surgical technique and anaesthesia have resulted in large reductions in blood loss, and the average requirement for transfusion is now four units of blood. At reimplantation, the suprahepatic and infrahepatic inferior vena cava and the portal vein are anastomosed and the organ is reperfused with blood. This is followed by reconstruction of the hepatic artery and bile duct.

Postoperative management

Patients are usually managed in an intensive care unit for the first 12-24 hours after surgery. Enteral feeding is restarted as early as possible, and liver function tests are done daily. Immunosuppressive protocols usually include a combination of cyclosporin or tacrolimus together with azathioprine or mycophenolate mofetil and prednisolone. The dose of steroids is rapidly tapered off, and they can often be stopped after two to three months. The doses of cyclosporin or tacrolimus are reduced gradually during the first year (during which pregnancy should be avoided) and continued at much lower levels for life.

Acute rejection occurs in about half of patients, but this is easily treated in most cases with extra steroids or by altering the drug regimen. Despite routine use of prophylactic treatment against bacterial, viral, and fungal pathogens, infections remain a major cause of morbidity. The side effects of the drugs are usually well controlled before the patient leaves hospital about two weeks after surgery.

At discharge, patients need to be familiarised with the drug regimen and side effects and educated about the warning signs of rejection and infection. Patients are usually followed up weekly for the first three months and then at gradually increasing intervals thereafter.

Results

The five year survival is 60-90%, depending on the primary disease and the clinical state of the patient before transplantation. The newer antiviral drugs plus the preoperative and postoperative adjuvant therapies for malignancies should lead to further improvements in survival. Although alcoholic liver disease remains a controversial indication for transplantation, carefully selected patients do well.

After successful transplantation patients have a greatly improved lifestyle and are often able to return to work and normal social activities. However, some patients experience medical and social problems. Drug compliance is one of the biggest problems after all types of organ transplantation. Poor compliance leads to chronic rejection and loss of the graft.

An extensive network of support services is available to help liver transplant patients. These include the transplant team, referring physician, general practitioner, social services, and local liver patient support groups. Shared care protocols operate in most regions, with most patients cared for primarily by their general practitioner and a gastroenterologist at their local hospital. The mainstay of follow up is regular liver function tests to detect any dysfunction of the transplant. Regular discussion of concerns with the transplant team is essential, and many problems can be sorted out by telephone.

Paediatric liver transplantation

In children, the most common indication for liver transplantation is biliary atresia, often after failure to respond to a portoenterostomy. Most children who need a liver transplant are young (under 3 years) and small (< 20 kg). Size matched donors are in short supply, and reduced size ("cut down") and

Figure 14.2 Implantation of liver transplant after hepatectomy

Table 14.1 Side effects of immunosuppressive drugs

Drug	Side effect	Monitoring
Cyclosporin	Neurotoxicity, nephrotoxicity, hypertension, hirsutism, gum hyperplasia, diabetes	Drug concentrations
Tacrolimus	Nephrotoxicity, neurotoxicity, hair loss, hypertension, diabetes	Drug concentrations
Azathioprine	Leucopenia, hair loss	White blood cell count
Mycophenolate mofetil	Gastrointestinal upset, leucopenia	White blood cell count and gastrointestinal symptoms
Steroids	Osteoporosis, diabetes, cushingoid face, hypertension	Symptoms
General	Infections, malignancy	Liver and renal function tests, regular follow up, and high index of suspicion

Figure 14.3 One year survival after first liver transplant according to primary disease, United Kingdom 1985-94

split (where one liver is split between two recipients) liver techniques have been used to overcome this problem. Donation of the left lobe of the liver by a living relative is also possible.

Pancreatic transplantation

The goals of transplantation of the pancreas are to eliminate the morbidity associated with labile blood glucose concentrations, stabilise or improve secondary diabetic complications, and improve the quality of life of patients with diabetes mellitus by restoring normal glucose metabolism. The stabilisation of diabetic control, the avoidance of exogenous insulin, and the ability to return to a normal diet for the first time since childhood are indisputable benefits of this procedure.

The selection of recipients for pancreatic transplantation is crucial. The magnitude of the surgery and need for long term immunosuppression means that whole organ transplantation is currently reserved for patients with end stage disease. Recipients are typically young (<50 years) with type 1 diabetes and end stage renal disease but without untreatable peripheral vascular or coronary artery disease. Simultaneous transplantation of the pancreas and kidney is the commonest procedure. Separate transplantation of the pancreas after kidney transplantation increases the chances of getting a good HLA matching for the kidney and allows a kidney to be donated by a living relative. The presence of immunosuppression at the time of implantation of the pancreas is also advantageous. The transplanted pancreas is usually placed in the pelvis and anastomosed to the iliac vessels, with the pancreatic duct anastomosed to the bladder or a loop of small bowel.

First year mortality is 3-10% in large units, with most deaths due to overwhelming sepsis. Transplant survival is 86% for the kidney and 70% for the pancreas. Successful transplantation greatly improves quality of life, and most patients are fully rehabilitated. Glucose homeostasis seems to be excellent after pancreatic transplantation. Patients can stop exogenous insulin treatment and have normal glycated haemoglobin concentrations and glucose tolerance test results within three months of transplantation.

The long term effect on diabetic complications will not be known for several years, but recent results are encouraging. Evidence that diabetic nephropathy does not recur in the kidney transplant is accumulating, but there is no evidence for amelioration of established glomerular lesions in native kidneys. Improvements in autonomic and peripheral neuropathy have been documented. Further studies are needed to examine the potential for reducing the rate of progression of retinopathy and macrovascular disease.

Isolated pancreatic islet transplantation

A more logical approach is to attempt to prevent the development of the irreversible complications of diabetes by improving blood glucose metabolism at an early stage. Transplantation of pancreatic islet cells has been studied extensively as an alternative to whole organ grafting and has several theoretical and practical advantages. Pancreatic islets can be isolated by using collagenase digestion to separate the endocrine from the exocrine tissues and purified by density gradient separation. Some difficulties remain, particularly with the purification stage. The islets are injected into the recipient liver via the portal vein or by subcapsular injection into the kidney or spleen. Rejection of the islets remains a problem, and the success rates of this type of transplantation have been poor in the clinical setting.

The shortage of child liver donors has been partly resolved by using smaller sections of adult livers, usually the left lobe

Table 14.2 Types of pancreatic transplantation

Type	Indication
Simultaneous pancreas and kidney transplant (SPK)	Diabetic renal failure
Pancreas after kidney transplant (PAK)	After successful kidney transplant
Pancreas transplant alone (PTA)	Prerenal failure, unstable diabetic control, severe neuropathy
Segmental (transplantation of pancreatic tail)	Applicable to live donation
Multivisceral (pancreas transplanted with liver and sometimes small bowel)	For example, extensive abdominal tumour
Isolated pancreatic islets	The future solution?

Figure 14.4 Simultaneous transplantation of pancreas and kidney with bladder drainage

Summary points

- Hepatitis C cirrhosis is the commonest worldwide indication for liver transplantation
- Alcoholic liver disease remains a controversial indication for liver transplantation but carefully selected patients do well
- Patients with chronic liver disease and signs of decompensation should be assessed for transplantation before they become critically ill
- Drug compliance is an important problem, with poor compliance leading to chronic rejection and graft loss
- Paracetamol overdose is the commonest cause of acute liver failure in the United Kingdom and accounts for 5% of all liver transplants in Britain
- Pancreas transplantation is most commonly performed for patients with end stage diabetes mellitus and renal failure

The photo of donor liver was obtained from J L Martha/Science Photo Library.

Preface

Preface to 3rd edition

Nutrition is one of those subjects which comes up every day in general practice—or should do—yet in most undergraduate medical schools it is crowded out by the big clinical specialities and high technology procedures. It is for subjects like nutrition that the British Medical Journal's ABC series is extremely useful.

This book was started when Dr Stephen Lock, previous editor of the BMJ asked me to write a series of weekly articles for an imagined general practitioner, in an unfashionable provincial town who had been taught almost no nutrition at medical school. They now felt the need to use nutrition in the practice, but could spare only 15 to 20 minutes a week to read about it.

The brief was that the writing must be practical and relevant; about half the page was to be for tables, figures, photographs or boxes (that is, not text) and these have to tell part of the story. The writing was to “come down off the fence”, to make up its mind on the balance of evidence and state it plainly. The first edition had no references but some reviewers asked for them and now in the era of evidence-based medicine some well chosen references seem indispensable when writing about nutrition.

Nutritional concepts, of course, are not as tightly evidence-based as information about drugs because randomised controlled trials, so routine for drug therapy, are rare for nutrition.

This book does not deal with all aspects of human nutrition, only those that are useful in everyday medical practice. The latest fads and controversies are not here either. This is the ABC of Nutrition, not the XYZ.

A Stewart Truswell
1999

Preface to 4th edition

When the first edition of this ABC was written in 1985 there was no “evidence-based medicine”, no human genome, no BSE or nvCJD, no epidemic of obesity and associated type II diabetes; there were no statins to lower plasma cholesterol and no genetically modified foods. *Helicobacter pylori* had just been discovered. The role of folate in neural tube defects had not been established, or raised plasma homocysteine as a risk factor for heart disease. The Barker hypothesis had not been propounded. These recent discoveries and ideas affect nutritional practice and they appear or influence what is in this new edition.

A Stewart Truswell
2003

1 Reducing the risk of coronary heart disease

For some doctors in affluent countries the first question about prevention of coronary heart disease (CHD) nowadays is whether to write a prescription for one of the statins (simvastatin, pravastatin, fluvastatin, atorvastatin, etc) which inhibit an early step of cholesterol biosynthesis in the body (see p 7). Tables are available to show whether the 5- or 10-year risk justifies the cost of long term statin medication, but the relation of diet and CHD is still of primary importance for the majority of people. **What we eat is bound up with the aetiology of CHD.** Many people do not know their current plasma cholesterol, many coronary deaths occur before medical help and most countries cannot afford these expensive drugs.

Coronary heart disease is the largest single cause of death in Britain and the disease that causes most premature deaths, but it is only one-seventh as common in industrial Japan and rare in the masses in most developing countries. Its incidence must be environmentally determined because **immigrant groups** soon take on the incidence rate of their new country and there have been large changes in mortality over time. Coronary heart disease was uncommon everywhere before 1925 and then increased steadily in Western countries until the 1970s, except for a dip during the Second World War. Age-standardised mortality rates from coronary heart disease in the United States of America and Australia **started to decline** from 1966 and have reduced by more than 70%. In Britain rates are higher in Scotland and Ireland than in England, and higher in the north of England than the south. They have been declining since 1979 and have fallen by about 25%. Most EU countries have shown similar recent modest reductions of coronary mortality, but in the countries of eastern Europe coronary mortalities have risen. They have, however, recently fallen in Poland and the Czech Republic.

Coronary heart disease is a **multifactorial disease**, but diet is probably the fundamental environmental factor. The pathological basis is **atherosclerosis**, which takes years to develop. **Thrombosis** superimposed on an atherosclerotic plaque, which takes hours, usually precipitates a clinical event. Then whether the patient dies suddenly, has a classic **myocardial infarct**, develops **angina**, or has asymptomatic electrocardiographic changes depends on the state of the myocardium. Each of these three processes is affected by somewhat different components in the diet.

The characteristic material that accumulates in atherosclerosis is **cholesterol ester**. This and other lipids in the plaque, such as yellow carotenoid pigments, come from the blood where they are carried on low density lipoprotein (LDL). In animals, including primates, atheroma can be produced by raising plasma cholesterol concentrations with high animal fat diets. Much of this cholesterol is present in modified macrophages that have the histological appearance of foam cells. Experimental pathology studies indicate that these cells only take up large amounts of LDL if *it has been oxidised*.² This oxidation probably occurs within the artery wall.

People with genetically raised LDL-cholesterol (*familial hypercholesterolaemia*) tend to have premature coronary heart disease. This is accelerated even more in homozygotes who have plasma cholesterol four times normal and all develop clinical coronary heart disease before they are 20.

Thousands of papers have been written on diet and CHD. Since early in the century scientists have suggested links

Coronary heart disease death rates in six countries, for men aged 25-74, 1950-83. (Adapted from *Heart and Stroke Facts* published by the National Heart Foundation of Australia, from WHO data.) CHD mortality in USA and Australia started to fall 10 years before any decline in UK coronary deaths and fell more profoundly. Smoking rates and medical treatments cannot explain these phenomena. They may have been due to dietary changes (increased polyunsaturated and decreased saturated fatty acids)¹

Photomicrograph of coronary artery with atherosclerosis

Evidence linking diet and CHD

This comes from:

- animal experiments
- pathology studies
- genetic polymorphisms
- epidemiology: ecological and cohort/prospective studies
- randomised controlled trials with dietary changes.

The strongest body of evidence comes from cohort studies which demonstrate environmental factors that are either associated with increased subsequent risk of CHD events (risk factors) or decreased subsequent risk (protective factors).

ABC of Nutrition

between a series of dietary components and CHD. Some of these were subsequently found to be unconnected or of little importance, for example sucrose, soft water, milk. The latest component to be associated is in the news, but this does not mean that the older components have been disproved—just that well-established facts are not newsworthy.

Risk factors

Over 50 prospective (cohort) studies in more than 600 000 subjects in 21 countries have reported on risk factors associated with or protective against CHD. The three best established risk factors are: raised plasma total and LDL-cholesterol, cigarette smoking, and high blood pressure.³

Two step reasoning

High plasma LDL- (and total) cholesterol is firmly established as a major risk factor for CHD, both from cohort study epidemiology and from randomised controlled trials with statins. In turn, how diet affects LDL-cholesterol concentration can be—and has been—demonstrated in controlled human dietary experiments, in which one dietary component is changed in the experimental period, with control periods on either side or in parallel.

Plasma total and low density lipoprotein cholesterol (LDL-cholesterol)

About three quarters of plasma total cholesterol is normally in LDL-cholesterol and the higher the total cholesterol the higher the percentage of LDL-cholesterol because HDL-cholesterol rarely exceeds 2 mmol/l (and never exceeds 3). The **mean** plasma total cholesterol of healthy adults ranges widely in different communities, from 2.6 mmol/l (Papua New Guinea highlanders) to 7.2 mmol/l (in east Finland some years ago). Only in countries whose average total cholesterol exceeds 5.2 mmol/l (200 mg/dl)—as in Britain—is coronary heart disease common.

Dietary components that affect plasma LDL-cholesterol: type of fat

The major influence is the type of fat. Fats in the diet are mostly in the form of triglycerides (triacylglycerols): three fatty acids joined to glycerol. The most abundant fatty acid(s) determine(s) the effect. *Saturated fatty acids* raise LDL-cholesterol; these are mostly 12:0 (lauric), 14:0 (myristic), and 16:0 (palmitic). Palmitic may be less potent but is the most abundant of these saturated fatty acids in foods. 18:0 (stearic) has little or no cholesterol-raising effect.

Monounsaturated fatty acids—the main one is 18:1 (oleic)—in the natural *cis* configuration have an intermediate effect on LDL-cholesterol: lower than on saturated fatty acids, not as low as on linoleic.

Polyunsaturated fatty acids (PUFA), (with two or more double bonds) lower LDL-cholesterol. The most abundant of these in foods is 18:2 (linoleic) which belongs to the ω -6 (omega-6 or n minus 6, n-6) family of polyunsaturated fatty acids (first double bond, numbering from the non-carboxylic acid end is at 6th carbon). The omega-3 (ω -3) series of PUFAs are less abundant in most foods 18:3, ω -3, α -linolenic occurs in plants and some vegetable oils. 20:5, ω -3, eicosapentaenoic acid (EPA) and 22:6, ω -3, docosahexaenoic acid (DHA) are mostly obtained from fatty fish and fish oils. The cholesterol-lowering effect of ω -3 PUFAs is less important than their other properties (p 6).

In unsaturated fatty acids the double bond is normally in the *cis* configuration and the carbon chain bends at the double

Within-population relation between plasma cholesterol and CHD and total mortality based on 6-year follow up of 350 000 US men. (Adapted from Martin *et al.*⁴) The increased total mortality at (only) the lowest cholesterol concentration is thought to reflect acute and chronic illnesses (which often lower plasma cholesterol)

Percentage distribution of serum total cholesterol in British adults by sex (Adapted from Gregory *et al.*⁵)

Omega 3 and omega 6	Unsaturated fatty acids
1 3 C-C-C=C-C-C=C-C-C-C-C-C-C-C-C-C-C-COOH	18 α -LINOLENIC (ω -3)
1 6 C-C-C-C-C=C-C-C-C-C-C-C-C-C-C-C-C-COOH	18 LINOLENIC (ω -6)

bond. If the configuration is *trans*, straight at the double bond, the fatty acid behaves biologically like a saturated fatty acid. The usual *trans* fatty acid is 18:1 *trans* (elaidic) acid, found in foods produced by hydrogenation in making older-type hard margarines.

Dietary cholesterol and phytosterols

Cholesterol is only found in animal foods. Dietary cholesterol has less plasma cholesterol-raising effect than saturated fats. This is because about half the plasma cholesterol comes from the diet and half is biosynthesised in the liver from acetate. When more cholesterol is absorbed it tends to switch off this endogenous synthesis.

Plant oils also contain sterols, but these are **phytosterols**, for example, β -sitosterol, campesterol, brassicasterol. These typically have one or two more extra carbons on the side chain of the cholesterol molecule. They interfere competitively with cholesterol absorption and are poorly absorbed themselves. Phytosterols in vegetable oils (200-500 mg/100 g) add a little to their cholesterol-lowering effect. They are also present in nuts and seeds. Some premium PUFA margarines (introduced 1999) are enriched with concentrated natural phytosterols (or-stanols) to enhance cholesterol lowering.

Overweight and obesity

Overweight people tend to have raised plasma triglycerides and to a lesser extent total and LDL-cholesterol. Weight reduction by diet and/or exercise will usually reduce their cholesterol. Overweight, especially abdominal visceral adiposity, is itself a direct risk factor for CHD.

Dietary fibre

The effect of dietary fibre depends on the type. Wheat fibre (bran or wholemeal breads) does not lower plasma cholesterol but viscous ("soluble") types, pectin and guar and oat fibre, in large intakes, produce moderate cholesterol reductions. Although wheat fibre does not lower plasma cholesterol cohort studies consistently show less subsequent CHD in people who eat more wheat fibre and whole grain foods.⁷

Vegetable protein

Most vegetable foods are low in protein. Soya is an exception. When soya protein replaces animal protein in the diet there has usually been a reduction of plasma total and LDL-cholesterol. Although many human trials have been carried out, the mechanism has been elusive.

Coffee⁹

Coffee contains small amounts of diterpenes (lipids), cafestol and kahweol—not caffeine—that raise plasma total and LDL-cholesterol. Several cups a day of boiled, plunger or espresso coffee can raise the cholesterol but filtered or instant coffee does not—the diterpenes have been removed from the beverage.

Mechanisms for LDL-cholesterol lowering

Many complex experiments have been done to elucidate how different fatty acids affect LDL-cholesterol. The main mechanism appears to be by effect on the number and activity of the LDL-receptors in cell membranes. Saturated fatty acids downregulate these receptors, so less cholesterol is taken up from the plasma; unsaturated fatty acids have the opposite effect. In overweight people there is increased secretion of very low density lipoprotein (VLDL) from the liver.

Effect of dietary fatty acids on plasma LDL-cholesterol

- Up to 10:0 (MCTs) 0
- 12:0 (lauric) ↑↑
- 14:0 (myristic) ↑↑↑
- 16:0 (palmitic) ↑
- 18:0 (stearic) (↑)
- 18:1 *cis* (oleic) (↓)
- 18:1 *trans* ↑↑
- 18:2 6-*cis* (linoleic) ↓
- Other polyunsaturates (↓)

MCTs = medium chain triglycerides

Cis unsaturated fatty acids are bent at the double bond(s), *trans* fatty acids are not

The relation between body mass index (weight/height²) and total cholesterol, HDL-cholesterol and triglycerides (all in mmol/l). (Adapted from Thelle *et al.*⁶)

Plasma LDL and total cholesterol change over 3.5 weeks (double-blind, controlled trial) in 100 healthy human subjects who took in turn (randomised) butter, standard PUFA margarine or this enriched with different amounts of phytosterols. 20 g/day of the commercial product provides 1.6 g phytosterols⁸

Large amounts of viscous (soluble) dietary fibre increase viscosity in the lower small intestine and reduce reabsorption of bile acids, so producing negative sterol balance, hence increased cholesterol → bile acids (cholestyramine effect). The mechanism for the potent plasma cholesterol-raising effect of coffee lipids has not yet been worked out (plasma aminotransferase goes up too); no animal model has been found.

Plasma high density lipoprotein cholesterol (HDL-cholesterol)

HDL-cholesterol is a potent protective factor in communities with high LDL- and total cholesterol.² It appears to act by mobilising cholesterol from deposits in peripheral tissues, including arteries, and transporting it to the liver for disposal (“reverse cholesterol transport”). Levels of plasma HDL-cholesterol do not explain the big differences of coronary disease incidence between countries; its concentration is often lower in countries with little coronary heart disease. But in countries with a high incidence of CHD and high plasma-LDL-cholesterol, individuals with above average HDL-cholesterol have a lower risk of the disease. HDL-cholesterols are higher in women (related to oestrogen activity), a major reason why coronary disease usually affects women at older ages than men.

Low HDL-cholesterols are often associated with raised plasma triglycerides and the latter metabolic dysfunction may compound the risk of coronary disease. HDL-cholesterols tend to be lower in overweight people, in those with diabetes, and in those who smoke. They may be reduced by a high carbohydrate (that is, low fat) diet. They are raised by alcohol consumption, by moderate or heavy exercise, by reduction of body weight, and by high fat diets.

Increased HDL concentration is the clearest reason why moderate alcohol consumption is associated epidemiologically with reduced risk of CHD. Note that above two drinks per day, total mortality goes up because of other diseases and accidents associated with alcohol.

When someone changes from a typical Western diet to a low fat (therefore high carbohydrate) diet LDL-cholesterol goes down, (good!) because percentage saturated fat was reduced, but HDL-cholesterol goes down as well (may not be so good). If instead the fat intake is maintained but saturated fat is replaced by polyunsaturated and monounsaturated fats, LDL also goes down but with little or no reduction of HDL-cholesterol. Changing fat type like this should give a lower risk of coronary disease but reducing total fat intake is better for the management of overweight.

Plasma triglycerides

If a patient has raised plasma triglycerides the first question is whether they had been fasting when the blood was taken. The next question is whether the hypertriglyceridaemia is a pointer to other risk factors that tend to be associated with it: high plasma cholesterol, overweight, lack of exercise, glucose intolerance, low-HDL-cholesterol or other metabolic disease (renal disease, hypothyroidism). A common cause of increased plasma triglycerides is excessive alcohol indulgence the evening before blood was taken.

Risk factors for coronary heart disease

- High plasma total cholesterol
- High plasma LDL-cholesterol
- Low plasma HDL-cholesterol
- High plasma triglycerides
- High blood pressure
- (Cigarette smoking)
- Obesity; high intra-abdominal fat
- Diabetes mellitus
- (Lack of exercise)
- Increased plasma coagulation factors
- Increased platelet adhesiveness
- High plasma homocysteine
- Increased Lp(a)
- (Apo E4 genotype)

Factors in parentheses are not influenced by diet.

Relation of HDL-cholesterol to incidence of CHD. (Adapted from Knuiman and West¹⁰)

Alcohol intake, coronary heart disease (CHD), and total mortality*

Stated alcohol consumption	Mortality-relative risk		
	From CHD	From accidents	Total
Non-drinkers	1.00	1.00	1.00
1/day	0.79	0.98	0.84
2/day	0.80	0.95	0.93
3/day	0.83	1.32	1.02
4/day	0.74	1.22	1.08
5/day	0.85	1.22	1.22
6+ /day	0.92	1.73	1.38

* 12-year follow up of cohort of 276 802 US men by stated alcohol habits at entry. Reduced risk of CHD brought down total mortality at 1 and 2 drinks/day but not above
 Reproduced from Boffeta and Garfinkel¹¹

The management of hypertriglyceridaemia consists of looking for and dealing with any of the common associations. The non-pharmacological treatment is more exercise, fewer calories (weight reduction), and less alcohol. Reduced carbohydrate is not advised; it implies an increased fat intake which can only increase lipaemia during the day. People with exaggerated postprandial lipaemia appear to have an increased risk of coronary heart disease. Fish oil (for example, Maxepa) is a nutritional supplement with a powerful plasma triglyceride-lowering effect and regular consumption of fatty fish also lowers plasma triglycerides.

Other risk factors

High blood pressure is discussed in chapter 2; **overweight and inactivity** in chapter 11.

Increased levels of two of the **coagulation factors**, Factor VII and fibrinogen, have been clear in some prospective studies (they were not assayed in most studies).¹³ **Factor VII** activity is increased during alimentary lipaemia after a fatty meal and is persistent in people with hypertriglyceridaemia. Plasma **fibrinogen** is raised in people who smoke and in obesity; it is reduced by alcohol consumption.

Antioxidants

The LDL oxidation hypothesis of atherogenesis predicts that if LDL carries more lipid-soluble antioxidants they should provide some protection against CHD. The principal antioxidant in LDL is α -tocopherol, vitamin E (average 7 tocopherol molecules per LDL particle). Its concentration can be raised by intake of vitamin E supplements. *In vitro* (outside the body) extra vitamin E delays the oxidation of LDL (by copper). In two large prospective studies, one in US nurses, the other in health professionals, those with high intakes of vitamin E experienced less subsequent CHD. But these high intakes of vitamin E were achieved by taking supplements, and people who regularly take vitamin supplements are likely to have more health conscious lifestyles than the average citizen.

Five large randomised controlled prevention trials, in Western populations, with acronyms ATBC,¹⁴ GISSI,¹⁵ HOPE, PPP, and CHAOS involving 56 000 subjects have now been reported. There was no reduction of cardiovascular disease or mortality. LDL contains smaller amounts of carotenoids, which are also lipid-soluble antioxidants. But supplements of β -carotene have also not prevented CHD in large randomised controlled trials.¹⁴

Polyunsaturated fatty acids, 18:2, 20:5 and 22:6 are more susceptible to peroxidation *in vitro* than saturated or monounsaturated acids but in the whole body there is a lot of evidence that PUFA intake is **negatively** associated with CHD.¹⁶

Plasma homocysteine

In the inborn error of metabolism homocystinuria, plasma homocysteine is so high that it spills into the urine and vascular diseases are among the complications. Then during the 1990s evidence accumulated (many case-control studies and several prospective studies) that lesser degrees of elevated plasma homocysteine (above 16 $\mu\text{mol/l}$ total homocysteine, tHcy) are a largely independent risk factor for CHD. They also increase the risk of cerebral and peripheral arterial diseases and even venous thrombosis.¹⁸ Raised plasma homocysteine appears to both damage the endothelium and increase liability to thrombosis.

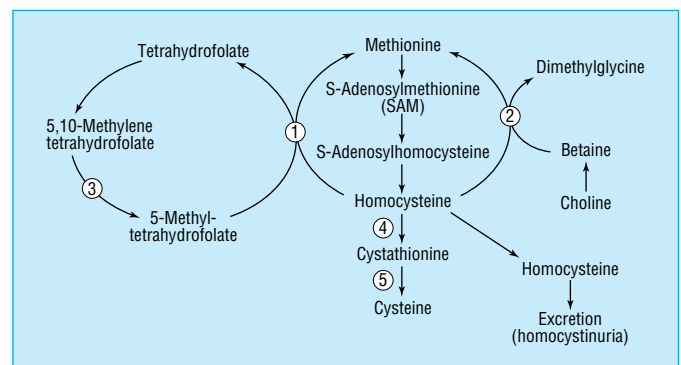

Homocysteine is an intermediary metabolite of the essential amino acid, methionine (it is methionine minus its terminal methyl group). Folic acid is co-factor for the enzyme in a pathway that re-methylates homocysteine back to methionine.

Plasma triglycerides

- Triglycerides in the blood after overnight fast are mainly in VLDL (very low density lipoprotein), synthesised in the liver, hence endogenous. Triglycerides in casual blood samples taken during the day may be mainly in chylomicrons, after a fatty meal, and hence exogenous.
- In prospective studies, raised fasting triglycerides have often shown up as a risk factor for coronary heart disease in single-factor analysis. But hypertriglyceridaemia is likely to be associated with raised plasma cholesterol, or overweight/obesity, or glucose intolerance, or lack of exercise or low HDL-cholesterol. When these are controlled, increased triglycerides is certainly not as strong a risk factor as hypercholesterolaemia but it has emerged in some studies as an independent coronary risk factor, more often in women.¹²

No significant benefit from vitamins C and E and β -carotene in MRC/BHF secondary prevention trial in over 20 000 subjects¹⁷

Homocysteine metabolism in humans. Enzymes [vitamins involved]: 1. N5-methyltetrahydrofolate:homocysteine methyltransferase (methionine synthase) [folate, vitamin B-12]; 2. betaine:homocysteine methyltransferase; 3. methylene-tetrahydrofolate reductase (MTHFR) [folate]; 4. cystathionine beta-synthase [vitamin B-6]; 5. gamma-cystathionase [vitamin B-6]

In apparently well-nourished people folic acid lowers elevated homocysteine by about a quarter.¹⁹ A dose of 0.5 mg or even 200 µg folic acid is effective. Plasma homocysteine is also increased in mild vitamin B-12 deficiency. Folic acid may be a safe, inexpensive way of reducing vascular disease. Randomised controlled trials are under way.

Dangerous arrhythmias

Dangerous arrhythmia is one of the two major causes of death in CHD. Over half the deaths occur before the arrival of paramedical or medical help. Then in the ambulance or coronary care unit the treatment of ventricular fibrillation saves lives. Developments in nutrition research are showing, with animal experiments, that electrical instability of ischaemic myocardium is influenced by the fatty acid pattern of the diet and hence of myocardial membranes. In rats or marmoset monkeys fed polyunsaturated oils, fewer animals had sustained ventricular arrhythmia when a coronary artery was tied, than in animals that had been fed on saturated fat or (monounsaturated) olive oil.²⁰ The fish oil group were more resistant to arrhythmia than the sunflower oil group (ω -6 linoleic acid). Canola oil containing linolenic acid (18:3, ω -3), the plant ω -3 fatty acid, also appears to reduce arrhythmias. Kang and Leaf have studied the mechanism of the fatty acid effect with cultured, neonatal, rat ventricular myocytes whose spontaneous contractions are recorded by a microscope and video camera. Eicosapentaenoic acid (20:5, ω -3) and the plant oil ω -3 acid, 18:3 (linolenic) as well as linoleic acid (18:2, ω -6) prevent tachyarrhythmia induced by a variety of chemicals known to produce fatal ventricular fibrillation in humans. It appears that polyunsaturated fatty acids act by binding to sodium channel proteins in the membrane and altering their electrical charge.²¹

The reduction of deaths outside hospital has been a striking feature in countries where coronary death rates have reduced. This may be explained, at least partly, by an anti-arrhythmic effect of increased ω -6 polyunsaturated fat intake (national fish intakes have not increased).

Platelet function and thrombosis

In patients with symptomatic CHD tests of platelet function have usually indicated activation. Available tests of platelet function are not on lists of risk factors predicting coronary disease; they are *in vitro* tests and are inevitably indirect. However platelet activation is of course a central phenomenon in myocardial infarction or recurrent angina, so that any diet that reduces platelet aggregation should reduce the risk of coronary disease.

Following up an observation that the rarity of coronary disease in Greenland Eskimos might be due to their heavy consumption of marine fat, it was discovered that eicosapentaenoic acid (20:5, ω -3) or EPA, a principal fatty acid of fish oil, displaces arachidonic acid (20:4, ω -6) in platelets, so that when stimulated they produce an inactive thromboxane TXA₃ instead of the active TXA₂ derived from arachidonic acid. EPA is only present in traces in the body fat of land animals and is absent from vegetable oils. In human experiments fish oil also reduced the levels of PAI-I, plasminogen activator inhibitor-1. Fish oil is therefore a pharmaceutical alternative (for example Maxepa) to aspirin to reduce the tendency to thrombosis. Results have been mixed in trials with fish oils to see if they delay restenosis after coronary angioplasty.

Total mortality from irreversible ventricular fibrillation during ischaemia or reperfusion in rats fed a saturated fat (SF), olive oil (OO), sunflower seed oil (SSO), or fish oil (FO) diet for 12 weeks from 18 weeks of age. *Significantly different from SF, *P* < 0.05. (Adapted from McLennan *et al.*²⁰)

Coronary deaths per 100 000 in men in three Australasian cities using standardised MONICA criteria

	1984	1993	Change
Coronary deaths before patient in hospital			
Auckland (NZ)	188	141	47
Newcastle (NSW)	186	102	84
Perth (WA)	128	78	50
Coronary deaths after patient in hospital			
Auckland (NZ)	57	24	33
Newcastle (NSW)	78	28	50
Perth (WA)	41	30	11

Effects of fish oil

- ↑ EPA and DHA in plasma and red cells
- ↓ Arrhythmias in ischaemic myocardium
- ↓ Platelet aggregation
- ↓ PAI-1, ↓ fibrinogen, ↓ TPA
- ↓ Fibrinolysis
- ↑ Bleeding time
- ↓ Fasting plasma VLDL and triglycerides
- ↓ Postprandial lipaemia

DHA = docosahexaenoic acid (22:6, ω -3), TPA = tissue plasminogen activator

More on diets and platelet function

- Several prospective studies (in countries with intermediate fish intake) and a secondary prevention trial in Cardiff²³ suggest that a modest intake of fatty fish (for example sardines, herring, mackerel, or salmon) two or three times a week may help to prevent coronary heart disease. The EPA in this amount of fish is less than that needed (at least 2 g of EPA per day) to inhibit platelet aggregation.
- ω -6 polyunsaturated oils also appear to have an inhibiting effect on platelet function. They are less active but people eat more plant seed oils than fish oil.
- Heavy alcohol ingestion exerts an inhibitory effect on platelet function, which is reversible on abstinence.

Dietary components associated directly with coronary disease in cohort epidemiological studies

Most of the many prospective studies involving coronary heart disease have not measured diet. It is much more complex and expensive to estimate all the different foods, and thence to compute all the nutrients, than to measure blood pressure or plasma lipids. Of all the parts of a total diet there have been most reports of **alcohol** intake. It is simpler to include in a questionnaire than to tackle the intricacies of type of fat intake.

In the minority of prospective studies that did report on foods or food components, most have used food frequency questionnaires (chapter 12), which are easier to handle than open-ended dietary records. Another method, occasionally used, is to measure objective biomarkers of food intake such as plasma fatty acid pattern. Interpretation of associations in the table must allow for uncertainties in assessing usual food intake, and confounding between different food components and with lifestyle. Vitamin E findings have not been confirmed in randomised controlled trials.

Adding a statin to the diet

Treatment with statins lowers raised plasma cholesterol by average 20% and LDL-cholesterol 25%, without lowering HDL-cholesterol, and reduces subsequent CHD events significantly. Statin treatment has also been shown to reduce CHD events by about 24% in people who had survived a myocardial infarction and had average plasma cholesterol of around 5.4 mmol/l.²⁶

Note that a statin is prescribed (as the manufacturers state) as an **adjunct to diet** and normally after a proper trial of a cholesterol lowering diet. The dietary principles described in this chapter lower plasma cholesterol by different mechanisms from the HMG COA reductase inhibition by statins. Parts of diets used to protect against CHD do not act by lowering LDL-cholesterol, for example, only by diet and exercise can overweight be treated.

Statin are very expensive at present, either for the patient or the health service, and we do not yet know if there might be long-term complications. Put very simply the indications for adding a statin to diet are for patients with:

- existing clinical CHD
- two or more coronary risk factors and high plasma cholesterol
- no or one coronary risk factor and very high plasma cholesterol.

In assessing the plasma cholesterol, LDL-cholesterol should be used or total cholesterol/HDL-cholesterol (after repeat measurements in a good laboratory). Risk factors are diabetes, hypertension, smoking, strong family history.

The dietary prescription (consistent with NCEP²⁷ and DOH²⁸)

Total fat

Reduction is not essential for improving plasma lipids but should reduce coagulation factors and daytime plasma triglycerides and contribute to weight reduction.

Saturated fatty acids

Principally 14:0, 16:0 and 12:0 should be substantially reduced from around 15% of dietary energy in many Western diets to 8-10%.

Polyunsaturated fatty acids

Mainly linoleic acid (18:2, ω -6): they should be about 7% of dietary energy (present British level), up to 10%. Omega-3

Dietary components directly related to CHD

Component	No. of studies
Alcohol ↓	29/38
Fruits and vegetables ↓	many
Cereal fibre ↓	several
Saturated fatty acids ↑	4/4
ω -6 PUFA ↓	6/12
<i>Trans</i> fatty acids ↑	2/3
α -linolenic (ω -3) ↓	2/3
Fish ↓	5/11
Coffee ↑ or 0	14
Nuts ↓	3/3
Vitamin E ↓	3/3
Folate ↓	3/3
And 0 for eggs (2/2) and iron intake (7/9)	
↑ Increased risk	↓ Protective

Randomised controlled trials (RCTs) with diet or nutrients

• **Reduced saturated, increased ω -6 PUFA diets**

8 RCTs in UK, USA, Finland and Norway, published 1965-1992. Total 17 529 subjects. In intervention groups plasma cholesterol fell. Combined result CHD events 81% of control ($P < 0.05$) and total mortality 95%.²⁴

• **Lyon “Mediterranean” diet²⁵**

Intervention group used a canola margarine, rich in linolenic acid (18:3, ω -3): they ate more bread, fruit, legumes, fish, less meat and butter but showed no fall in plasma cholesterol. CHD events were significantly reduced but the mechanism and dietary components responsible are not clear.

• **Fish and fish oil**

One secondary prevention RCT with fish (DART)²² and another with fish oil (GISSI)¹⁵ reduced CHD events significantly.

• **Vitamin E and β -carotene** have both been ineffective in several RCTs.

ABC of Nutrition

polyunsaturated fatty acids should be increased, both 20:5 and 22:6 from seafoods and 18:3 from canola (rapeseed) oil, etc.

Monounsaturated fatty acids

Ideal intake if total fat 30%, saturated 10% and polyunsaturated 8% would be 12% of total dietary energy.

Trans fatty acids

With the help of margarine manufacturers these have been reduced. The Department of Health recommends no more than 2% of dietary energy. Avoid older hard margarines.

Dietary cholesterol

This boils down to the question of egg yolks. Eggs are a nutritious, inexpensive and convenient food. The Department of Health recommends for the general population no rise in cholesterol intake.

Salt (NaCl)

Restriction to under 6 g/day is advised for the general population (100 mmol Na). It is more important for coronary patients.

Fish

The Department of Health recommends at least twice a week, preferably fatty fish. It should not be fried in saturated fat.

Fibre

Eat plenty of high fibre and whole grain cereal foods, including oatmeal.

Vegetables and fruit

These are low in fat, and contain pectin and other fibres, flavonoids and other antioxidants, and they contain folate. Expert Committees in Britain and the USA recommend five servings of different vegetables and fruit per day (400 g/day average weight).²⁸

Soy products

(Not salty soy sauce) recommended.

2 Diet and blood pressure

Essential hypertension is a multifactorial disease. It is common in older people not only in urban and industrialised areas but also in a quiet Hebridean island, in tropical Africa, where Albert Schweizer used to work, and in an isolated Solomon Islands' tribe minimally influenced by Western ways, which cooks in sea water.¹

Salt (sodium)

To what extent is essential hypertension related to an unnecessarily high intake of salt?

Hypertension is not an inevitable accompaniment of ageing. Evidence showed that hypertension did not occur in a few isolated communities, such as Yanomamo Indians (in the Amazon), Kalahari Bushmen (Botswana),² and remote Pacific islanders. These people typically had no access to salt and their urinary sodiums (reflecting salt intake) were under 30 mmol/day.

Salt and blood pressure history

Salt is the best known of the dietary factors affecting blood pressure. It has been hypothesised for the longest time, first by Ambard and Beaujard in 1904. Then in 1922 Allen first documented reduction of blood pressure by sodium restriction.

In the Intersalt study,³ 10 000 people were examined by standardised methods in 52 different communities in 30 countries around the world. The rise in blood pressure with age was significantly related to 24-hour urinary sodium.

Within communities correlation between individuals' blood pressure and sodium intake (or excretion) is difficult to see. This is partly because of large day-to-day swings in people's sodium intake,⁴ partly because people should only be compared in the same age group, and also because not all individuals are sensitive to salt—this can be demonstrated by a week of 12 g NaCl, followed by a very low salt diet.⁵ However, in the dietary and nutritional survey of British adults blood pressure was found to correlate with 24-hour urinary sodium, reflecting salt intake.⁶ A cohort study in 2436 Finnish men and women found that those who started with high 24-hour urine sodiums had more cardiovascular and total mortality over the following 8 years.⁷

The requirement for sodium in health is usually under 25 mmol Na/day (equivalent to 1.5 g NaCl).⁹ Normal kidneys can shut down sodium excretion almost to zero and sweat loss is reduced in people on low salt intakes or adapted to hot climates. Human milk contains only 7 mmol Na/litre, so young infants' sodium intake per megajoule is only about one-sixth that of their parents'!

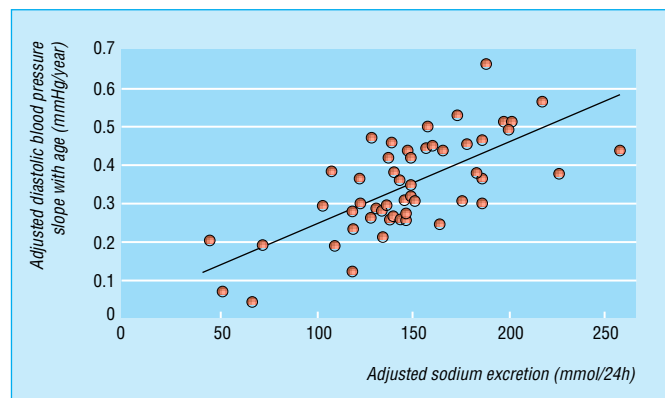

Salt intakes in Britain are around 9 g NaCl (150 mmol Na) per day and in parts of Asia considerably higher, over 250 mmol Na/day. To prove that our unnecessarily high intakes of salt contribute to the development of essential hypertension, blood pressures of a group of adults eating only their sodium requirement (25 mmol Na/day) would have to be compared over many years with another group, similar in all respects, eating the usual 150 mmol sodium/day. Such a human trial is probably impossible, so a trial in chimpanzees, who have 98% the same DNA as humans and half our life span, is important.

Causal factors in essential hypertension

- **Genetic**—several mechanisms
- **Tension from anxiety**—via increased sympathetic tone or circulating catecholamines
- **Dietary**—**positive correlation**—**negative correlation**
 - Overweight and obesity
 - Sodium (salt) intake
 - Alcohol
 - Potassium
 - ?Calcium

Blood pressure with age of 152 Bushmen, hunter gatherers (aged 15-83 years) in NW Botswana (continuous lines) compared with standard figures from London measured in 1954. (Adapted from Truswell *et al.*²)

Cross-centre plots of diastolic blood pressure slope with age and median sodium excretion; $P < 0.001$. (Adapted from Intersalt study³). For an additional 100 mmol Na/day, the increase of BP over 30 years (25 to 55) was 10 systolic/6 diastolic mmHg greater⁸

Distribution of normotensive and hypertensive respondents by urinary sodium excretion rate in the Dietary and Nutritional Survey of British Adults, 1986-87. (Adapted from Beard *et al.*⁶)

Chimpanzees, living on a natural (low sodium) vegetarian and fruit diet in Gabon (West Africa) were given a liquid infant formula with or without salt up to 15 g/day for 1.5 years.¹⁰ Blood pressures rose progressively in eight of the 10 animals given typical human salt intakes and in none of the controls.

Salt has been used since Neolithic times by most cultures as an important food preservative. Most of mankind has become used to the taste of more salt than we need now that canning, freezing, refrigeration, etc, are widely used to preserve our food.

For the general adult population, mainly as a measure to help prevent hypertension, Australia (from 1982), the USA (from 1989), WHO (1990) and the UK Department of Health (1994)¹¹ all recommend a target intake of 100 mmol sodium per day equivalent to 6.0 g NaCl or 2.3 g Na *or less*.

Sodium accumulation and arterioles

The mechanism of action of sodium is undoubtedly complex and involves kidney tubules and several hormones. One aspect is that if sodium tends to accumulate in cells it interferes with calcium transport, and elevated free calcium in the cytosol of arteriolar smooth muscle cells increases their tone and consequently the arterial blood pressure.

In people with hypertension, how much reduction of blood pressure can be achieved with a low salt diet and how difficult is this to organise (and persist with)?

Elevated blood pressure can usually be lowered by salt restriction.¹² Diuretic drugs work by increasing urinary sodium excretion. Alternatively a sufficient reduction of dietary sodium can achieve the same degree of negative sodium balance. In mild to moderate hypertension, a reduction of sodium intake (which can be monitored with 24-hour urinary sodium) by 50 mmol/day will usually give a useful reduction of blood pressure, so that the patient may be able to come off the hypotensive drugs (or not start them) or reduce the dose (and with this the probability of side effects). Salt restriction increases sensitivity to all hypertensive drugs except slow channel calcium blockers, like nifedipine. Some people are more responsive than others. Older people may be more responsive to salt reduction and they are particularly susceptible to the side effects of drugs.

When people change to a lower salt diet their taste adjusts after a few weeks. Other flavours are perceived and appreciated more. The major obstacle to eating low salt is that most of the salt in food is put in during processing and is outside the individual's control.

Sodium in foods

Most of the salt that we eat is not that added at the table or in cooking water (much of which goes down the sink). It is salt added in food processing, particularly of staple foods. Wheat flour contains 3 or 4 mg sodium/100 g but average breads have 520-550 mg/100 g. Oils like sunflower or olive oil contain only traces of sodium but butter averages 750 mg/100 g and margarines 800 mg/100 g. Many cereal products—biscuits, cakes and breakfast cereals (though not all)—are very high in sodium, which consumers cannot taste (being masked by the sugar content). Salted peanuts contain less sodium than breads; consumers can taste the salt because it is all on the surface. Anyone wanting to reduce salt intake must find low-salt breads and breakfast cereals and cheeses as well as cutting out the more obvious bacon and olives in brine which people eat less

Mean systolic and diastolic blood pressures of 10 salt-added (experimental) and 12 control chimpanzees over 2.5 years. Blood pressure rose in most of the experimental chimpanzees. It returned to normal when the salt was discontinued (post treatment). (Adapted from Denton *et al.*¹⁰)

Trial of low-salt diet in people with mild to moderate hypertension¹³

Average percentages of sodium from different sources¹⁴

• Discretionary	
Added at table	9.0
Used in cooking	6.0
• Food	
Naturally occurring	18.5
Added salt in processing	58.7
Non-salt additives	7.2
• Salt in water supply (average)	
	0.6
	100.0

often. Other sodium compounds in food, bicarbonate and glutamate, have less effect on blood pressure than sodium chloride.

Body weight

Obese people are likely to have a higher blood pressure than lean people. In a cohort of over 5000 people born in Britain in the same week, blood pressures at the age of 36 were progressively higher in those with a body mass index (weight (kg)/height (m²)) above 26. Typically a 3 mmHg higher diastolic pressure may be expected for every 10 kg increase in body weight.³ In a large Swedish study of 60-year-old men, a quarter of the fattest fifth were taking antihypertensive drugs compared with only 4% of the thinnest fifth.¹⁶ Raised blood pressure and hyperlipidaemia are both major risk factors for cardiovascular disease, and effective weight reduction will improve both.

Alcohol

Alcohol intake is emerging as one of the important environmental factors associated with raised blood pressure. Heavy drinkers have higher blood pressure than light drinkers and abstainers. The effect starts above about three (stated) drinks a day. Systolic pressure is more affected than diastolic.

The pressor effect of alcohol can be demonstrated directly. It was seen, for example, in men with essential hypertension who were moderate to heavy drinkers. They continued their habitual intake of beer and antihypertensive drugs; when low alcohol beer (0.9% alcohol) was substituted for the same intake of regular beer (5% alcohol), their blood pressure fell 5/3 mmHg.¹⁸ The mechanism(s) have not yet been established. Acute ingestion of alcohol causes peripheral vasodilatation, but there are features of a hyperadrenergic state in the withdrawal syndrome. Plasma cortisol concentrations are sometimes raised in alcoholics. Increased red cell volume, and hence increased blood viscosity, is a possible mechanism.

Components in the diet that may lower blood pressure

Potassium

In a placebo-controlled, crossover trial in mild to moderate hypertension, blood pressure fell by (average) 7/4 mmHg with a supplement of eight Slow-K tablets (64 mmol potassium) a day. But the same (London) clinic found little or no effect in similar hypertensive patients who had managed to reduce their sodium intake (and urinary sodium) to around 70 mmol a day—potassium acts as a sodium antagonist and has little effect when sodium intake has been halved.¹⁹

Calcium

Analyses of a diet and health study in the USA suggested that people with low calcium intakes had more hypertension, and in Britain less cardiovascular disease is reported in areas with hard water (which contains more calcium). Over 30 controlled trials with calcium supplements have been summarised in three meta-analyses,²¹ which showed that 1000 mg per day or more of calcium has only a trivial effect on systolic (not diastolic) blood pressure. Increased calcium, by diet or supplements, might be useful in a very small number of hypertensive patients who have a low calcium intake or increased plasma parathyroid levels.

Reduced food energy and falling blood pressure

- People who do not eat enough food energy and lose weight usually have a fall of (normal) blood pressure.
- If hypertensive obese patients reduce their weight they show falls of blood pressure like 10 mmHg systolic/5 mmHg diastolic for a 5-kg weight loss.
- Less food means less sodium eaten. Some weight loss occurs even if sodium intake is maintained, but the combination of weight loss and a low sodium intake is more effective.
- In a randomised placebo-controlled trial of first-line treatment of mild hypertension in overweight patients, the weight reduction group (mean loss 7.4 kg) had a 13 mmHg fall of systolic blood pressure while those treated with metoprolol (200 mg/day) had a 10 mmHg fall. Plasma lipids improved in the weight reduction group, but changed adversely in those on drug therapy.¹⁵

When alcoholic patients were admitted to hospital for detoxification their systolic blood pressure fell by about 20 mmHg; it stayed down if they continued to abstain, but rose again if drinking was resumed. The same pattern was seen with diastolic pressure.¹⁷

Potassium in foods

- **Moderate to high (mmol per usual serving):**
Potatoes (12-26), pulses (19), dried fruits (5-12), fresh meat and fish (8-10), All Bran (8), fresh fruit (2-10), vegetables (2-10), orange juice (6), oatmeal (5), cows' milk (5), nuts (2-6), wine (3-4), beer (3), coffee (2).
- **Low (1-3 mmol per usual serving):**
Rice, chocolate, egg, biscuits, bread, cheese, flour, cornflakes.
- **Very low or absent:**
Sugar, jam, honey, butter, margarine, cream, oils, spirits.

Potassium is the major intracellular cation; the more concentrated the cells in a food, the higher the potassium is likely to be.

In Britain potassium intakes are around 70 mmol/day in men and 60 mmol/day in women: 17% from potatoes (10% from fried potatoes), 14% from cereals, 14% from milk products, 13% from meat and products, 11% from other vegetables, 5% from fruit and 16% from beverages (coffee 6%, tea 4%, beer 3%, fruit 2%).²⁰

Magnesium

Magnesium can sometimes lower blood pressure. In patients who had received long term diuretics (mostly for hypertension) and potassium supplements, half were also given magnesium aspartate hydrochloride for six months. Their blood pressure fell significantly. The diuretics had presumably led to subclinical magnesium depletion.

Vegetarianism

Healthy (normotensive) hospital staff in Perth, Western Australia, were provided with all their meals as one of two diets—mixed omnivore or (lacto-ovo) vegetarian. Sodium intakes were kept the same. After six weeks the subjects were changed to the other diet. Blood pressures were significantly lower by about 6/3.5 mmHg while on the vegetarian diet.²³ The responsible ingredient(s) have not been clearly demonstrated.

DASH 1 and 2

Dietary Approaches to Stop Hypertension was a multicentre randomised controlled dietary trial in over 400 middle aged US adults with BP in the normal or mildly elevated range. In DASH 1 three diets were compared for eight weeks.²⁴ Blood pressures were lower with extra fruits and vegetables than on control diet and lower still with a combination of low fat dairy food and low saturated fat with the extra fruits and vegetables (cf control diet): $-7.2/-2.8$ on extra fruits plus vegetables and $-11.4/-5.5$ mmHg on the combination diet. Sodium and alcohol intakes and body mass index were held the same between groups.

In DASH 2 BPs were compared on control diet or DASH combination (extra fruits and vegetables, low fat dairy) at three different levels of salt intake (for one month in each subject in

Magnesium distribution in foods

Magnesium is distributed in foods somewhat similarly to potassium. Bran, wholegrain cereals, and legumes are the richest sources. Most vegetables contain similar moderate amounts to meat.

From management guidelines of the British Hypertension Society²²

Non-pharmacological measures... should be offered to all hypertensive patients whether taking drugs or not. This advice should also be offered to people with a strong family history of hypertension. In mild hypertension non-pharmacological measures may obviate the need for drugs.

- Reduce energy intake to achieve ideal weight.
- Alcohol <21 units/week in men and <14 units per week in women. One or two days/week no alcohol.
- Reduce salt intake.
- Regular physical exercise and improve level of fitness.

And to reduce the risk of cardiovascular disease stop smoking and reduce saturated fat intake.

random order).²⁵ As before BPs were lower on the DASH combination diet. Reduction from usual Na (143 mmol/day) to intermediate (105 mmol/day) they averaged 2.1 and 1.3 mm systolic on control and DASH diets. Between intermediate and low sodium (65 mmol/day) systolic BPs were -4.6 and -1.7 mmHg respectively. Black people with mild hypertension showed the largest falls of BP.

3 Nutritional advice for some other chronic diseases

Dental caries

Dental caries affects people predominantly in the first 25 years of life. Dental enamel is the hardest material in the body. Its weakness is that, because it is basically calcium phosphate, it is dissolved by acid. Three factors together contribute to caries.

Infection

A specific species of viridans streptococci, *Streptococcus mutans*, metabolises sugars to lactic acid and also polymerises sugars to a layer of covering polysaccharide in which the bacteria are shielded from saliva and the tongue. Some people harbour more of these bacteria than others.

Substrate

Most sugars serve as substrate—sucrose, glucose, fructose, and lactose (not sorbitol or xylitol). Starches too, if they stay in the mouth, are split to sugars by salivary amylase. Consumption of sugary foods between meals, especially if they are sticky and consumption is repeated, favours the development of caries. Brushing the teeth and flossing between them after meals reduces the likelihood of caries.

Resistance of the teeth

Caries is more likely in fissures. In older people the “mature” enamel is more resistant. An intake of 1-3 mg/day of fluoride—as occurs, for example, if drinking water is fluoridated at a concentration of 1 mg/l—increases the enamel’s resistance, especially if taken while enamel is being laid down before the tooth erupts.

The cariostatic effect of fluoride in natural water was noticed in Maldon, Essex in 1933, and confirmed by comparing children’s teeth and water fluoride across the United States in the early 1940s. Water fluoridation is widespread in the United States, Australia and New Zealand but still unusual in Scandinavia and The Netherlands. In Britain only about 10% of the population receive fluoridated water. Dental caries has nevertheless become less prevalent in most industrialised countries. Most toothpastes now contain fluoride and this, rather than any change in children’s sugar consumption, seems the main reason for the decline where water is not fluoridated. A controlled study in the north of England found 44% less caries in 5 year olds in 1991-94 in towns with a fluoridated water supply.²

Mottling of the (anterior permanent) teeth occurs if the fluoride intake is too high in the first eight years of life. Young children should either be persuaded not to swallow their toothpaste or be provided with a “junior” product with half-strength fluoride.

Gallstones

Most gallstones are composed mainly (about 85%) of crystallised cholesterol with small proportions of calcium carbonate, palmitate, and phosphate. Cholesterol, which is excreted by the liver into the bile, would be completely insoluble in an aqueous fluid like bile if it were not kept in micelle microemulsion by the combined detergent action of the bile salts and phospholipids (chiefly lecithin) in bile.

Non-dietary risk factors include female sex, pregnancy, oral contraceptives, age, ileal disease, clofibrate therapy, and certain

Dental caries

The shaded bars show what happened to the number of decayed temporary teeth in Kilmarnock after fluoridation of water, which started in 1956 and was discontinued in 1962. Unshaded bars are findings in Ayr, which never had fluoridated water.¹ Figures for children aged 5 years

Three major components of bile (bile salts, lecithin, and cholesterol) on triangular coordinates. Each component is expressed as percentage moles of total bile salt, lecithin, and cholesterol. The shaded area shows conditions required for cholesterol to be soluble in micellar form. If the concentration of cholesterol goes up or bile acids or lecithin go down then cholesterol is likely to precipitate out³

ABC of Nutrition

ethnic groups—for example, Pima Amerindians have a high incidence of gallstones.

In obesity and during dieting (with rapid weight loss) cholesterol secretion into bile tends to increase. During fasting and on total parenteral nutrition the gall bladder does not contract normally. In people on vegetarian and high cereal fibre diets the pattern of biliary bile acids change favourably, with less deoxycholate and more chenodeoxycholate.⁴ Moderate alcohol intake appears to be protective; decreased cholesterol saturation of bile has been reported. Regular exercise also appears to protect against gallstones.⁵ These associations do not apply to the less common pigment stones.

Urinary tract stones

Calcium stones

Dietary factors which tend to increase urinary calcium or have been associated with stones are high intakes of protein, sodium, refined carbohydrate, vitamin D, calcium (spread over the day), alcohol, curry, spicy foods, and Worcester sauce, and low intakes of cereal fibre and water. Since most patients with hypercalciuria have intestinal hyperabsorption of calcium it has been common to recommend a low calcium diet or phytic acid or a resin to reduce calcium absorption. Long term trials have been lacking. Now a diet providing usual calcium intake (1200 mg/day) but very low salt (50 mmol Na/day) and reduced animal protein (50 g/day) has reduced calcium stone recurrences significantly over five years compared with a low calcium diet (400 mg/day).⁶ The normal calcium, low protein, low salt diet reduced urinary excretion of both calcium and oxalate.

Oxalate stones

Associated dietary factors are high intakes of oxalate or vitamin C and low water intake.

Uric acid stones

Uric acid stones are associated with an acid urine, a high purine diet, and low water consumption.

The one common dietary association with all the common types of stone—and with the rare ones also—is a low water intake. Drinking plenty of water is an important habit for anyone liable to stones, especially if the weather is hot. Last thing at night is the important time to take water.

Diabetes mellitus

Insulin-dependent diabetes (Type 1) is usually caused by autoimmune damage to the β -cells in the pancreatic islets, which lose their ability to secrete enough insulin. This type of diabetes typically starts in adolescents or younger adults. Several epidemiological studies have reported that patients with type 1 diabetes were less often exclusively breast fed for the first 3-4 months of life than unaffected controls.

The prevalence of non-insulin dependent diabetes (Type 2) increases with age; overall it is about six times more common than Type 1. This type 2 diabetes is closely associated with overweight or obesity and with lack of exercise. Beyond Europe and Anglo-Celtic north Americans there is almost a pandemic of type 2 diabetes occurring in some communities that may have earlier experienced undernutrition but are now sedentary and eating refined, high energy “Western” foods. The thrifty genotype hypothesis attempts to explain this phenomenon, which is especially affecting people of south Asian descent in

Gallstone formation

Gallstones are more likely to form if:

- biliary cholesterol is increased, *or*
- biliary bile acids are reduced, *or*
- the gall bladder is less motile, *or*
- factors in the bile favour nucleation of cholesterol crystals.

Foods rich in oxalate

Spinach, rhubarb, beetroots, cocoa, chocolate, currants, dried figs, tea, swiss chard, blackberries, oranges, turnip greens.

Uric acid stones

- One dietary cause of acid urine is a high protein intake. The amino acids methionine and cystine are metabolised to urinary sulphuric acid.
- Foods traditionally rich in purines include liver, kidneys, sweetbreads, sardines, anchovies, fish roes, and yeast extracts, but there are no modern tables and dietary RNA may raise plasma urate more than DNA.

Relation of body weight to prevalence of diabetes (standardised criteria) between countries⁷

Britain and elsewhere, Pacific islanders, and north American and Australian aboriginals.⁸

Looked at another way, diabetes is the complication of **obesity** whose incidence goes up at the steepest gradient with degree of overweight. The risk of developing diabetes is greater in people whose obesity is mainly intra-abdominal rather than on the hips or buttocks (subcutaneous)—people with a high ratio of waist:hip circumferences.⁹

Diabetes is a multifactorial disease. There is a strong family influence, though this may be partly because eating habits and body weight are influenced by family behaviour. But a **genetic** factor is clear in some groups: the Pima Amerindians in North America and Micronesians in Nauru. When these people are obese (which most of them are these days) the incidence of diabetes (in older life) is over 50%.

The popular belief that eating a lot of sugar predisposes to diabetes is not confirmed by several epidemiological and prospective studies. High fat intake is more likely to lead to diabetes, a hypothesis first put forward in Britain in 1935 by Sir Harold Himsworth. High total carbohydrate (mostly starch) and high fibre intakes are characteristic of peasant communities, in which type 2 diabetes is uncommon.

In a **prospective study** of 7735 middle-aged men, drawn from group practices in 24 towns in England, Wales, and Scotland and followed for 12 years, the incidence was 2 per 1000 person years.¹¹ The risk of developing diabetes increased exponentially with increasing body mass index (BMI). It was 11 times higher in the upper fifth of BMI (>28 kg/m²). Men with moderate physical activity had less than half the risk. Moderate drinkers also developed less diabetes. On average those who developed diabetes had higher plasma triglycerides, higher blood pressures and higher casual blood glucose. Another finding in people who will later develop type 2 diabetes has been an increased fasting insulin and/or insulin response to standard glycaemic stimulus, due to insulin resistance.

Diets for managing established diabetes are discussed in chapter 13.

Relation of body weight to subsequent development of diabetes in 10 years¹⁰

Two large *randomised controlled trials*, one in 27 centres in the United States,¹² the other in five cities in Finland¹³ have both shown that **lifestyle intervention can halve the incidence of type 2 diabetes in middle-aged, overweight, sedentary people with impaired glucose tolerance. In the US trial lifestyle intervention was weight reduction averaging 6 kg and increased physical activity. This was more effective in preventing diabetes than metformin. In Finland the subjects were also asked to reduce saturated fat and increase whole grain foods.**

Alcoholic liver disease

Countries with high alcohol consumption per head have high mortalities from cirrhosis. These have fallen when there has been a reduction in the supply of alcohol—for example, during prohibition in the United States and during the two world wars in Europe. Correlation of alcohol consumption and deaths from cirrhosis between countries is close, but there are deviations. Britain has a lower incidence of cirrhosis than might be expected from the rate of alcohol consumption but mortality from cirrhosis has doubled here since 1970. Where alcohol consumption is high most cases of cirrhosis are due to alcohol. Other causes—for example, viral hepatitis B or C, account for important proportions of cases.

In heavy drinkers pre-cirrhotic liver disease—fatty liver or alcoholic hepatitis—is more common than cirrhosis. A fourth condition, primary liver cell cancer, is a complication of alcoholic cirrhosis.

Within countries the risk of developing cirrhosis is related to the dose and duration of alcohol intake. Daily heavy drinking for years is the typical pattern—80 g (eight drinks) a day in men, and usually well over this. In a large Italian study, cirrhosis appeared to be less likely in those who drank only with meals.¹⁵

Alcohol affordability and consumption and deaths from cirrhosis in the United Kingdom, 1965-87. As alcohol became more affordable, consumption of alcohol and harm related to alcohol increased¹⁴

The essential treatment of alcoholic liver disease is complete and permanent abstinence from alcohol. Although alcoholics may become deficient in nutrients, those who develop cirrhosis are often socially organised and well nourished. There is no evidence that a high protein diet or choline can prevent alcoholic cirrhosis in man. Even when cirrhosis is established, an improved clinical state and prognosis may be expected in those who manage to abstain completely.

Some types of cancer¹⁷

Differences in diets are thought to account for more variation in the incidence of all cancers than any other factor (with smoking in second order).¹⁸ The big questions are which dietary components are active, and how do they work? Our bodies have three routes of entry for foreign compounds: the skin, lungs, and intestines. As a function of surface area the chances of absorption are skin 1, lungs 1000, and intestines 1 000 000. There are countless natural non-nutrient substances in foods and several are mutagens. The fact that they can induce mutations in a standard bacterial culture does not, however, establish that they are dangerous to man: there are many available protective mechanisms.

Poor diet may have a more decisive effect by weakening defence mechanisms than by supplying potent carcinogens. Epidemiologists estimate that synthetic chemical additives in food account for under 1% of all cancers.¹⁸ The cancers most clearly related to habitual diet are oesophageal, gastric, and large intestinal cancers.

Oesophagus

In the Chinese focus of oesophageal cancer, nitrosamines have been found in mouldy food and there is a deficiency of molybdenum. Domestic fowl are affected too. In the Iranian focus there are some vitamin deficiencies and people may take opium by mouth. In the Transkei researchers think that fusarium mycotoxins, together with deficiencies of niacin, zinc, and other micronutrients, are responsible for the epidemic of oesophageal cancer. In Europe alcohol, especially that derived from apples, and tobacco are associated factors.

Stomach

From present epidemiological data protective factors are fruits and vegetables, refrigeration of foods and vitamin C intake. Apparent causative factors are intake of salt, pickled and salted foods, *Helicobacter pylori* infection, and smoking.

Large intestine

Cancer of the large intestine usually arises in a polyp. Different dietary factors may be involved in the successive stages: formation of polyps; malignant transformation; growth and spread of a cancer. Having a halfway stage of polyps should make study of causative factors easier. In some epidemiological studies animal fat and meat have emerged as risk factors. But in the majority of epidemiological studies meat has not been significantly associated.²⁰ One possible mechanism is the formation of heterocyclic amines (IQ, MeIQ, PhIP, etc.), which are potent mutagens, on the surface of well-cooked meat. Some types of beer have been associated with rectal cancer. Wheat fibre appears the best established protective factor. It dilutes and moves on potential carcinogens in the lumen and promotes fermentation. Brassicas and other vegetables also appear protective; they contain several anticancer substances and also folate, which may prevent hypomethylation of DNA, a characteristic change in this cancer. In a trial wheat bran plus low fat prevented polyp development. β -Carotene or vitamin E (α -tocopherol) have been ineffective; other prevention trials are underway.

No precise safe level of alcohol intake can be given—only a clinical impression—because people who drink heavily underestimate their consumption when asked about it, and no prospective epidemiological study has been done. Women are more susceptible to hepatic damage from alcohol because they have smaller livers (where most metabolism of alcohol occurs) and also lower rates of gastric (first pass) oxidation of alcohol than men.¹⁶ Only a minority of heavy drinkers get cirrhosis; there is presumably a synergy between alcohol and hepatitis viruses.

Oesophageal cancer

- 300× range in incidence
 - Highest rates: Linxian, People's Republic of China; East Mazandaran, Iran; and Transkei, South Africa.
 - In Europe there are moderately high rates in NW France and in Switzerland.
-

Gastric cancer

- Incidence in Britain has spontaneously fallen to half in the past 25 years.
 - There have been similar reductions in many developed countries.¹⁹
 - Highest rates, in Japan, are three times those in England and Wales, 10 times those in the United States of America, 20 times those in countries with the lowest rate, for example Gambia and Kuwait.
 - Chronic atrophic gastritis is a precancerous state.
-

Cancer of the large bowel

- Fourth largest cause of death from cancer in Britain (after lung cancer, breast cancer in women, and prostate cancer in men).
 - Ten times more common in developed Western countries such as Britain and USA than in the Third World.
 - Rates in Scotland have been among the highest in world
 - Epidemiology of rectal cancer shows some minor differences from the larger group of colon cancer.
 - Left side of the large bowel is usually affected.
-

Breast

Between-country comparisons and animal experiments suggest that high fat intake increases the risk of breast cancer but prospective and case-control epidemiological studies have not confirmed a role for fat, unless it operates in childhood or adolescence. Weight gain in adult life increases the risk of postmenopausal breast cancer. Adipose tissue is a major source of oestrogen after the menopause. Alcohol consumption also shows some association but this is not dose related. Plant foods appear protective. The two most promising of these are wheat fibre (which can bind oestrogens in the bowel, reducing reabsorption) and soya (which contains phytoestrogens, isoflavones).

Breast cancer

In countries with a high incidence the majority of cases are postmenopausal. Incidences are four times higher in western Europe and North America than in East Asia. Early menarche and/or late menopause increase the risk; bilateral oophorectomy protects, and endogenous plasma oestrogens are higher in patients with postmenopausal breast cancer.

4 Nutrition for pregnancy

Pregnancy is a time when appetite is altered and nutritional needs change. What the expectant mother eats or drinks can affect her baby's health and her own comfort. In pregnancy women develop a new interest in the consequences for health of what they eat. They are entitled to advice from their doctors.

The first advice should ideally be communicated before pregnancy, when a woman decides to try to have a baby. Pregnancies in women who are overweight, have anorexia nervosa, or whose growth is not completed are more difficult, and these women need extra nutritional care.

A good intake of folate is important in preventing neural tube defects and some other malformations in the fetus of a minority of women. The stage when this vitamin is most needed is the first 28 days after conception so supplementation or high folate diet has to be periconceptional. The supplement dose is 400 or 500 $\mu\text{g}/\text{day}$. Likewise, it is the early weeks when excess alcohol intake may lead to malformations.

During pregnancy extra nutrients are required, especially from 20 weeks, for the growing fetus and for the placenta. Tissue is also laid down in the uterus and breasts, blood volume is increased, and, in healthy women with adequate food, adipose tissue increases by around 2.7 kg. This fat is deposited more on the hips and thighs.

Folate and neural tube defects

- Folate is the most important nutrient for replication of DNA in cell division. Evidence for the role of folic acid in preventing neural tube defects (NTDs) has been accumulating for 50 years. The folate antagonist aminopterin, taken in pregnancy, led to NTDs.
- Lower biochemical folate levels in women who gave birth to babies with NTD were reported in 1975 and 1976. The first secondary prevention trials (reported in 1980) were encouraging but not randomised. So the MRC conducted a large randomised double-blind trial in seven countries and found that folic acid could prevent three-quarters of recurrences.² Other epidemiological studies are supportive and so is a primary prevention trial in Hungary.³ Evidently at the time of closure of the neural tube there is extra demand for folate for cell division and in some pregnancies on ordinary diets the level of folate at the site is inadequate.

Nutrition for pregnancy

The extra energy need for a pregnancy can be calculated as about 250 MJ (60 000 kcal).⁶ This includes energy stored in fetal fat and protein, and in maternal reproductive tissues and adipose tissue. It takes account of the mother's increased basal metabolic rate and the energy needed to move a heavier body. This corresponds to 1 MJ (240 kcal) a day (excluding the first month, for 250 days), and in Britain the recommended daily intake of energy during pregnancy (10 MJ, 2400 kcal) until 1991 was 1 MJ (240 kcal) above the non-pregnant amount (9 MJ or 2150 kcal). When actual food intakes are carefully measured, however, little indication exists of extra energy intake in Western women. This was found in careful intake measurements in London, Cambridge, Aberdeen, Glasgow,⁷ Wageningen, and Sydney. In all these centres women ate an average of almost 9 MJ (2150 kcal) per day. The extra energy need is probably balanced by decreased exercise and increased

BBC television survey of 6000 women, 1982¹

Alcohol in pregnancy⁴

- Heavy drinkers have a greatly increased risk of inducing the fetal alcohol syndrome—characteristic underdevelopment of the mid face, small size, and mental retardation.
- Women who intend to become pregnant should not sit drinking whatever the occasion: they could be two or three weeks pregnant.
- Once pregnancy is established the rule should be no more than one alcoholic drink a day to be sure of preventing minor effects, chiefly growth retardation.

Changes in skinfold thickness at different sites during pregnancy⁵

efficiency of metabolism. Pregnant women seem to reduce their exercise if they can. Postprandial cholecystokinin concentrations increase, which enhances nutrient absorption and the anabolic actions of insulin.⁸ So it is not true that a pregnant woman has to eat calories for two, but a few nutrients should be substantially increased. In 1991 the Department of Health revised the estimated average extra requirement of energy in pregnancy to 0.8 MJ (200 kcal) a day and this is only for the third trimester.⁹ However, in a developing country like rural Thailand,⁶ where pre-pregnant food intake may be marginally adequate and women are involved in agricultural labour, food intake may—and should—increase in pregnancy.

The amounts of different nutrients which the mother has to put into her fetus by the time of delivery have been worked out by chemical analysis of stillbirths. These can be estimated more accurately for stable inorganic elements than for the vitamins. From these figures for nutrients accumulated and from information on whether there is any change in their absorption and turnover, the extra requirements for pregnancy can be estimated.

The metabolism of protein is more efficient and so is the absorption of iron in pregnancy. For most nutrients like **protein** the small extra amounts required are covered adequately by a normal diet. But intakes are more critical for the other five nutrients in the table showing recommended daily intakes.

Recommended daily intakes* for six critical nutrients in pregnancy¹⁰

	Addition for pregnancy	Non-pregnant women	Total
Protein (g)	+10	50	60
Folate (μg total folate)	+220	180	400
Calcium (mg)	+400	800	1200
Iron (mg)	+15	15	30
Zinc (mg)	+3	12	15
Iodine (μg)	+25	150	175

*United States recommended dietary allowances, 1989

Folate is the only vitamin, and iron the only nutrient element whose requirements double in pregnancy. Extra folate is needed for the first month and again for the last trimester. Serum and red cell folate concentrations decline in pregnancy and, if looked for, some degree of megaloblastic change can be found in substantial minorities of women in late pregnancy. Such changes have been reported in 6-25% of women not taking supplements in Britain. The word folate comes from the Latin *folia* (leaf) because it was first found in spinach, but food sources are not the same as for vitamin C. Whole grain cereals, nuts, and legumes are good sources of folate. The folate content of vegetables varies from about 10 $\mu\text{g}/100\text{g}$ in potatoes and carrots up to 155 μg in asparagus, averaging round 50 μg per 100 g. Fruits average round 5 μg per 100, citrus and blackberries higher. The vitamin is largely destroyed by prolonged boiling.

The **iron** content of the fetus (about 300 mg), placenta (50 mg), and average postpartum blood loss (200 mg) add up to some 550 mg. The red cell mass also increases after 12 weeks by an amount which corresponds to about another 500 mg of iron, but this is a temporary internal borrowing from stores and causes no extra demand provided the stores are sufficient. Against these extra needs there is the saving from no menstruation (some 200 mg) and improved intestinal absorption. Maternal haemoglobin concentration declines by about 10% because of physiological haemodilution; and serum

Contributions to weight gain in average pregnancy

Energy intake increments (and confidence limits) for 71 Glasgow women throughout pregnancy⁷

Contribution of food groups to total folate content per head, Great Britain 1998³

- Vegetables 32%, of which potatoes 10%
- Cereals 32%, of which bread 11%*, breakfast cereals 14%*
- Milk and products 10%
- Fruit 7%
- Meat 5%
- Tea 4%
- Eggs 2%

*A significant proportion of the folate from cereals comes from fortification. In general the folic acid used for food fortification is more biologically available than naturally occurring folate.

Iron in pregnancy

There is no universal policy. Some doctors are more interventionist than others. Iron tablets can cause indigestion or constipation. The following is generally agreed.

- Women should be advised to eat meat regularly (unless vegetarian). This is the best absorbed source of iron in the diet.
- A woman with a history of anaemia, menorrhagia, poor diet, or repeated pregnancies should be given iron supplements or an iron-folate preparation.
- Haemoglobin should be checked and iron given if it is below 110 g/l (with a low mean cell volume).
- For prophylactic purposes one iron tablet a day is adequate.
- With the smaller dose of iron, side effects are fewer and compliance should be better.

ABC of Nutrition

iron concentration, transferrin saturation, and ferritin concentration all go down. These changes can be partly—but only partly—prevented by iron supplementation.

With **calcium**, absorption becomes more efficient.¹¹ Without any change of vitamin D intake or exposure to the sun, plasma concentrations of calcitriol (the active form of the vitamin converted in the kidney) are increased. Some of this extra conversion takes place in the placenta. The easiest way of obtaining the extra calcium needed for pregnancy and lactation is from milk; 0.5 litre supplies about 600 mg calcium.

The increased need for **iodine** may be taken for granted in Britain, but in areas where goitre is endemic (see chapter 8) there is a risk of cretinism. In such areas expectant mothers should be given an injection of iodised oil, preferably before conception.

Weight gain

The amount of weight gained from before conception to shortly before delivery ranges considerably in normal women—from about 6 to 24 kg. A good average to try to achieve is 12 kg (26 lb). This might be made up of about 115 g (1/4 lb)/week for the first 10 weeks and 300 g (2/3 lb)/week for the remaining 30 weeks. A mother's height, her weight for height at the start of pregnancy, and her weight gain can all influence the size of the fetus. Birth weights are lower in babies of mothers who choose (against medical advice) to continue to smoke during pregnancy. In affluent countries the body fat gained during pregnancy can persist after childbirth. Pregnancy is one of the factors that can predispose to obesity.¹²

In Third World countries, where mothers often start small and thin and gain little weight because of restricted and bulky food, and heavy physical work, birth weights are lower than in affluent communities. They have been increased, in controlled trials, by providing food (energy) supplements during pregnancy. Average gains of birth weight in eight different trials have been from 40 to 300 g.

Obesity in pregnancy increases the chances of a heavier and fatter baby and also of hypertension and gestational diabetes. Since 3 to 4 kg of the usual 12 kg weight gain is fat, overweight women should try to put on only 7 to 8 kg overall during their pregnancy.

Hypertension and “toxaemia”

In pregnancy-induced hypertension (toxaemia) no excess of sodium is retained. It is proportional to the fluid retained. No evidence exists that either a high or a low salt diet predisposes to pregnancy-induced hypertension or that any other dietary component—energy, protein, or any micronutrient—is directly responsible, except perhaps calcium deficiency.¹⁴

Diet and discomforts of pregnancy

Nausea and vomiting of pregnancy (NVP) is not confined to the mornings (so “morning sickness” is a misleading name). It is probably due to rising levels of pregnancy-associated hormones and often accompanied by increased olfactory sensitivity and aversion to strongly flavoured food and drink. In developed countries normal NVP appears to be beneficial, not detrimental to the fetus.¹⁹ There has been no controlled trial of simple management. One opinion is that it is related to a low blood glucose concentration and that a dry biscuit or similar light snack before getting up may help. It now seems

Birth weight is related positively to amount of maternal weight gain and to pre-pregnancy weight of the mother¹³

The Barker hypothesis

- Professor David Barker (Southampton) found very good birth weight records in Hertfordshire for 1911-30 and was able to trace health records of most of this cohort in later life. Coronary heart disease (CHD) mortality was higher in those who had had low birth weights (at term).¹⁵
- The large US Nurses prospective study provides good supportive evidence (birth weights here were by recall).¹⁶ Low birth weight, reflecting subnormal intrauterine growth, can only influence CHD incidence if there are risk factors for CHD in adult life (chapter 1). Low birth weights have also been reported to be followed in middle age by hypertension and type 2 diabetes.
- All these discoveries emphasise the importance of good nutrition in young women before and during pregnancy. But this does **not** mean that women who enter pregnancy with a body mass index over 26 need to “eat for two”!¹⁷
- In Britain little or no relation has been found between nutrient intakes in pregnancy and birth weight.¹⁸

Diet and discomforts of pregnancy

possible that the increased cholecystokinin concentration could explain the symptoms. Unlike other conditions that cause nausea, women tend to put on weight during the phase of morning sickness.⁸ Severe, persistent NVP, hyperemesis gravidarum is uncommon. When it occurs, note that thiamin is the most critical micronutrient.²⁰

Constipation and its complication haemorrhoids are very common in pregnancy. All pregnant women should be advised to eat more wholemeal bread, bran, or bran cereals to loosen and increase the bulk of their faeces.

Heartburn should improve if the woman eats smaller meals and avoids foods which she finds indigestible. The common meal pattern of tiny breakfast, small lunch, and large dinner becomes unsuitable in late pregnancy. It is a good plan for her to have four, five, or even six small meals throughout the day. This also helps NVP.

Cravings and aversions—at some stage in pregnancy most women experience a distortion of their usual range of likes and dislikes of foods. Women may develop a nine-month aversion to foods they usually like—for example, fried foods, coffee, tea. Contrariwise and at the same time they may experience a craving for certain foods. These are often sweet foods, such as fruits and chocolate ice cream, and sometimes salty, but some remarkable non-foods—coal, soap, soil—have been recorded.

Vegetarians who are pregnant may need extra dietary advice. There are several types of vegetarian (chapter 7). Those most at risk are vegans. It is essential for them to take a supplement of vitamin B-12 for normal cerebral development of the fetus. Other lacto-ovo vegetarians, especially if they are prosperous and belong to a traditional vegetarian group, usually manage well enough but may want or need advice to optimise their protein and iron intakes. Legumes and nuts are an important part of a balanced vegetarian diet.

Food safety in pregnancy

- Avoid unpasteurised milk, soft cheeses and paté, raw eggs—danger of listeria and salmonella infection is more serious in pregnancy.
 - Pre-cooked foods (for example, pies) should be thoroughly re-heated before eating.
 - Avoid extra vitamin A, in the form of supplements or multivitamins containing vitamin A, or liver more than occasionally in early pregnancy. Retinoic acid is involved in normal morphogenesis and excess can be teratogenic.
-

What are pregnant women thinking about their food?

- “Eating the right foods”, for example plenty of meat, fish, eggs, milk and fresh vegetables
- “Watching weight”, taking care how much weight is gained
- “Eating for two”, a largely outmoded idea

Based on Baric and MacArthur, cited by Anderson²¹

5 Infant feeding

Infant feeding is the dominant nutritional interest in less affluent countries and it gets much attention in Western countries because infants depend on others to feed them. For their first few months babies are fed only one food, so its composition is much more critical than the compositions of the many different foods in a mixed diet. Babies cannot eat ordinary adult food or say how they feel after the feed. Though there are still many questions, scientific knowledge is perhaps fuller about nutrition for this age of man than any other.

Breast or bottle?

For the first 4-6 months of life the infant should be fed either by breast feeding or on a formula based on cows' milk modified to make its composition suitable for infants—that is, more like breast milk. The decision on which method to use should be made well before delivery, and it should be made by the mother. The doctor's role is to give advice to help her make up her mind and then, whichever method she wants to use, to provide support and arrange instruction.

Advantages of breast feeding

- Breast feeding is natural and may confer advantages that science has not yet discovered.
- Breast milk is microbiologically clean.
- Breast milk's nutrient composition is the standard against which infant formulas for bottle feeding must be judged. Many of the differences between cows' and human milk have been minimised in modern infant formulas, but by no means all and some nutrients such as iron and zinc are known to be better absorbed from human milk.
- Only breast milk provides a complex range of anti-infective components: macrophages, lymphocytes, immunoglobulins (especially IgA), lactoferrin, lysozyme, complement, interferon, oligosaccharides (for example, bifidus factor), sialic acid, xanthine oxidase, gangliosides, glycoconjugates, growth factors, and enzymes.
- Breast feeding reduces the risk of gastrointestinal, respiratory and other infections (otitis media, meningitis, urinary tract infections), SIDS, childhood lymphomas, early allergic diseases, and type 1 diabetes.
- For most women breast feeding is a satisfying, convenient and enjoyable experience that is beneficial to the mother-child relationship.
- Mothers' milk is always at the right temperature.
- A mother can always change from breast to bottle feeding but not the other way round.

Breast feeding is recommended by the UK Department of Health, the WHO, the American Academy of Pediatrics and all authorities. The organisation of maternity wards (encouraged by UNICEF's Baby Friendly Hospital Initiative), control of advertising watched by WHO's Code of Marketing Breast Milk Substitutes, and change of social attitudes all make it easier than it used to be. On the other hand, modern technology makes bottle feeding easy and safe in developed countries and the newer infant formulas are closer to breast milk in nutrient composition.

Breastfeeding from a woman who is in good health and nutritional status provides a complete food, which is unique to the species. There is no better nutrition for healthy infants at term and during the early months of life.... Breast feeding is preferable to feeding with infant formulas and should be encouraged.

DHSS⁵

Composition of cows' milk compared with human milk and a modified infant formula (breast milk substitute) (All per 100 ml)

	Human* (mature) ^{1,2}	Cows' (full cream) (unfortified)	A modified milk formula† (powder diluted as directed)

* The composition of breast milk varies considerably with stage of lactation, between individuals, and with maternal nutrition
 † Mean of Cow and Gate Premium and SMA Gold Cap

In Third World countries breast feeding unquestionably reduces infant mortality.

In affluent countries, however, epidemiologists have difficulty in showing an appreciable reduction in mortality when confounding factors are taken into account. Mothers who breast feed tend to have higher educational and income levels. A well designed study in Dundee seems to have corrected for all such confounding variables. It showed that breast feeding for the first three months of life confers a protection against gastrointestinal illness, which persists beyond the period of breast feeding itself.^{3,4}

Prevalence of breast feeding in Great Britain, 1995⁶

Two examples of ongoing research about human milk

Docosahexaenoic acid (DHA)

The brain grows rapidly in infancy, from 350 g at birth to 1000 g at 12 months. Sixty per cent of its solids are lipids and two very long chain polyunsaturated fatty acids are more abundant here and in the photoreceptors of the retina than elsewhere—DHA (22:6, ω -3) and AA (arachidonic, 20:4, ω -6). DHA is present in human, not cows' milk. It is synthesised in the body from α -linolenic (18:3, ω -3) but probably not fast enough for the brain's requirements especially in premature babies. Young infants fed on standard formulas had lower DHA concentration in red cells and brain (SIDS post-mortem) than breast fed infants.⁷

Oligosaccharides

Lactose is not the only sugar in human milk. The concentration of oligosaccharides is higher than the protein! Over 100 of these oligosaccharides have been chemically defined—all made up of five monosaccharides: fucose, galactose, glucose, *N*-acetylglucosamine, and sialic acid (NANA) and ranging from three to ten residues in length. Cows' milk, and infant formulas, contain only trace amounts. These human milk oligosaccharides (HMOs) are not digested in the small intestine. Small amounts are absorbed and found in the urinary tract. Most passes to the large intestine where it acts like dietary fibre.⁹ Oligosaccharides containing *N*-acetylglucosamine promote the growth of bifidobacteria, which are the dominant colonic bacteria in breast fed infants.

Micro-organisms and their toxins gain entry to cells by attaching to specific sugars on the cell surface. Oligosaccharides in mucus and in human milk include particular sugars that can act as decoys for many specific micro-organisms and so prevent their access to the body. HMOs have been shown to include receptors for *E. coli*, *E. coli* toxins, *Campylobacter*, *Candida*, Rotavirus and *Strep pneumoniae*.¹⁰

How to manage breast feeding

Knowing how to establish breast feeding is no longer instinctive in the women of our complex industrial societies. Some take to it naturally but others will not do well without guidance and a sympathetic environment.

- The mother should be adequately nourished during pregnancy.
- She should have watched others breast feeding and talked about it.
- She needs to involve and consider her partner. There can be sexual implications in breast feeding. His support (or opposition) is important.
- The National Childbirth Trust or La Lèche League or the Association of Breastfeeding Mothers can help to provide information and support (for addresses see end of this chapter).
- The baby should be put to the breast as soon as possible after delivery.
- The midwife can play an important part, giving advice on positioning the baby, and encouragement in the first few days.¹¹
- Frequent suckling stimulates prolactin secretion. Suckling more than six times a day maintains high basal prolactin as well as initiating prolactin surges with feeding.
- Feeding should be on demand or baby-led.
- After delivery the baby should be in a crib next to its mother all or most of the time and suckled whenever it seems to be hungry. Colostrum is a concentrated anti-infective fluid.
- Relaxation and privacy are needed.

Randomised controlled trials have found better eye function in pre-term infants who were breast fed or given formula enriched with DHA and AA than in babies fed on standard formulas. In full term infants a few (not all) trials have had similar results.⁸ It is not known whether there will be benefits beyond infancy. Socio-economic and psychological confounding factors will make interpretation of brain function tests difficult. Some manufacturers now add DHA and AA to premium infant formulas.

Eating for breastfeeding. Reproduced with kind permission from the Food Standards Agency

ABC of Nutrition

- The baby should not be given other complementary milk or juice—only water if necessary.
- The baby should feed from both breasts each time and start the feed with the breast used last.
- Advice may be needed about sore nipples or breasts, oversupply, or undersupply.
- In developed countries rates of breast feeding are lower in younger, less educated mothers in less skilled occupations, and in single mothers.

Obstacles to initiation and continuation of breast feeding are listed in the box alongside.

Contraindications to breast feeding are rare: galactosaemia in the infant; mother uses illegal drugs; mother has active untreated tuberculosis; mother has HIV infection (controversial); mother has to take therapeutic drugs that adversely affect her milk—radioisotopes, cancer chemotherapy, etc.

Nutrition for the lactating mother

Except in malnourished communities, there is little evidence that dietary calories, protein, fat, water, or anything else have a consistent effect on milk volume. Regular and fairly frequent suckling is the well established stimulus. Human lactation works more by pull than by push.

Some constituents in the milk are affected by the mother's intake.

- (1) Fatty acid pattern, vitamin A, thiamin, riboflavin, biotin, folate, vitamin B-12, and vitamin C are affected, especially downwards if the mother's diet is deficient.
- (2) Zinc, iron, fluoride, and vitamin D may be responsive in some circumstances, but more research is needed.
- (3) Protein, lactose, total fat content, calcium—that is, the major proximate constituents of milk—do not appear to be affected.
- (4) Specific proteins in the mother's diet might be excreted intact in small amounts and an allergic (IgE) reaction occasionally occurs in the baby.
- (5) The amount of caffeine in the milk after a cup of coffee is only about 2% of the maternal dose. Likewise, the alcohol concentration of breast milk is about the same as that of plasma so single drinks of coffee or alcohol, well spaced out, are harmless, but the babies of alcoholics can be affected. Beer stimulates prolactin secretion (at least in non-lactating women) and so might increase lactation. Milk production is reduced in heavy smokers.
- (6) The fat-soluble environmental contaminants, polychlorinated biphenyls, dry cleaning solvents, and organochlorine insecticides (DDT, etc), are stored in adipose tissue and excreted in the cream of breast milk (though the DDT group is fairly innocuous in man).

The mother's need for extra nutrients

A good average production of breast milk is 800 ml/day, and the mother's extra nutritional requirements are calculated from this and the average composition of milk, taking into account the available information about efficiency of absorption. The gross energy value of average human milk is 280 kJ/100 g and efficiency of conversion from maternal dietary energy to milk energy is assumed to be 80%. Hence the energy lost in exclusive breast feeding in the first three months is:

$$800 \text{ ml} \times 280 \text{ kJ} \times 100/80 = 2.8 \text{ MJ (675 kcal)}.^{13}$$

If, as is usual, the mother does not eat the full amount of this extra energy she will lose some of the body fat put on during

Obstacles to breast feeding¹²

- Doctor's apathy and misinformation
 - Insufficient prenatal education in breast feeding
 - Disruptive hospital policies
 - Inappropriate interruption of breast feeding
 - Early hospital discharge
 - Lack of regular home health visits, post-partum
 - Maternal employment (especially if no workplace facilities or support for breast feeding)
 - Lack of broad societal support
 - Portrayal by media of bottle feeding as normative
 - Commercial promotion of infant formula, for example distribution of hospital discharge packs
-

Drugs and lactation

- For most drugs the concentration in human milk is of the same order of magnitude as the plasma concentration or in some cases less. The infant would thus receive around 1% of the maternal dose. But the milk/plasma ratio is 12 for propylthiouracil and 25 for iodine-131.
 - Other drugs are contraindicated if they are radioactive, can cause allergy, agranulocytosis or bleeding disorders, or are poorly metabolised in the newborn, or can suppress lactation. These include chloramphenicol, indomethacin, diazepam, reserpine, anti-cancer drugs, lithium, and some others.
 - Tetrahydrocannabinol is concentrated in the milk of cannabis smokers, as are opiate narcotics in the milk of those taking them.
 - The *British National Formulary* has an appendix on prescribing during breast feeding.
-

Constituents of milk affected by mother's intake

- Fatty acid pattern, vitamin A, thiamin, riboflavin, biotin, folate, vitamin B-12 and vitamin C
 - Possibly zinc, iron, fluoride and vitamin D
 - Protein, lactose, total fat content, calcium
 - Some proteins in mother's diet
 - Caffeine in milk after coffee, alcohol after alcohol consumption (only in large doses)
 - Environmental contaminants
-

pregnancy. When the infant is getting other foods the energy expenditure on breast milk usually declines.

Most of the nutrients come along with the extra calories; lactating women usually have a good appetite and if this is satisfied by a mixed diet the nutrients that need watching (because there is little excess in the diets of non-lactating women) are calcium, iron, folate, and vitamin D. The extra **calcium** can come from a pint of milk or two cartons of yoghurt. Calcium metabolism changes during lactation. There is some loss of bone density, which is apparently not prevented by calcium supplements. These changes are reversed when lactation ceases.¹⁴ There is no evidence that women who have breast fed have increased incidence of osteoporosis. **Iron** supplements may be advisable, and **vitamin D** supplements are recommended for any mother whose vitamin D status is in doubt (such as Asian mothers eating a wholly vegetarian diet). **Folate** deficiency incurred during pregnancy may first show as anaemia in the puerperium. **Zinc** is secreted in the milk but staple isotope studies show increased zinc absorption during lactation.

Mothers return to pre-pregnant weight?

Mothers are more likely to lose the fat stores put on during pregnancy if they choose to breast feed. The energy lost in lactation is usually more than the mother's increased food intake over her non-pregnant, non-lactating level. DHSS estimated an average energy deficit of 0.5 MJ (120 kcal) per day, which corresponds to a fat loss of 0.5 kg per month (14.5 MJ).¹³ But in fact appetite and weight loss during lactation is highly variable.¹⁵ Obviously lactation cannot contribute to worthwhile weight loss if it is only brief. The question arises whether milk production will suffer if the mother deliberately restricts her food intake. Lovelady *et al.* tested this out in a randomised controlled trial in overweight (not obese) women. (BMI 25-30).¹⁶ They lost approximately 0.5 kg per week between 4 and 14 weeks post partum from moderate food restriction and exercise: their infants gained the same weight and length as the controls, but some of the control mothers put on weight.

Ending lactation

In an industrial population the prevalence of breast feeding goes down with infant's age in a curve reminiscent of first order elimination kinetics. A few mothers continue breast feeding towards or beyond 12 months. In a British national sample the major reasons for stopping in the first six weeks were insufficient milk (54%) and painful breasts or painful or inverted nipples (18%); the commonest reason for stopping between 6 and 16 weeks was also insufficient milk (66%). Those with insufficient milk early on never got lactation well established. Those with insufficient milk later may have had normal volume production but the baby's energy needs started to outgrow this.

Complementary and supplementary bottles of milk

Complementary bottle feeds are used to finish off a breast feed and supplementary bottle feeds replace a breast feed. The occasional bottle feed once a day or less is convenient if the mother has to leave the baby with a friend, but regular topping up of the baby's intake with bottle milk is likely to reduce sucking and breast milk production. Some mothers produce less milk than others, however, and if the baby is not gaining, and hungry on pure breast feeding with good technique, extra bottle feeding may be necessary.

Bottle feeding

Some mothers choose to bottle feed from the start and others will change over from breast to bottle feeding after weeks or months, so they need practical advice.

Mean consumption of different types of milk in normal Canadian infants¹⁷

Measured breast milk intakes of Cambridge infants. Mean and ranges against estimated requirements¹⁸

ABC of Nutrition

- A cows' milk formula specially modified for infants should be used in which the protein has been reduced, the casein partly replaced by whey protein, the fat made more unsaturated, the lactose increased, sodium and calcium reduced, and enough of all the essential micronutrients added.
- Bottles and teats should be washed in water and detergent (the bottle brush used only for this), rinsed and sterilised by boiling in water or by standing covered in sterilising solution (usually hypochlorite) in a plastic container. It saves time to prepare several bottles at once. Empty the water out of each bottle, without touching the inside, then fill to the mark with recently boiled water that has cooled some minutes, not too hot or it will destroy some vitamins and may produce clumping.
- Exactly the amount of powder in the manufacturer's instructions should be put into the (wide mouthed) bottle, using the scoop provided (levelled with a clean knife, not pressed down). "One for the pot" can lead to obesity. Mothers and even nurses are often found to prepare feeds inaccurately. Screw on the cap and shake the bottle well. Bottles may be kept in the refrigerator for up to 24 hours.
- If the hole in the teat is too small it can lead to aerophagia or underfeeding. Milk should drip from the inverted teat at about one drop per second. Teats need replacing every few weeks.
- Babies do not mind cold milk but usually prefer it warm. The bottle should be not warmed for too long and the milk's temperature should be checked by dropping some on the parent's skin. Infant feed should be not warmed in a microwave oven once it is in the feeding bottle. Very hot fluid at the centre of the bottle may be missed and may scald the baby.⁵ For about the first eight weeks of life babies need to be fed every three to four hours, including the small hours of the morning. (Fathers can bottle feed as well as mothers.) By the end of the first week most babies are taking 120-200 ml/kg per day (160 ml/kg corresponds to the old $2\frac{1}{2}$ fluid ounces per lb bodyweight).
- Cereals or rusks should not be added to milk in the bottle and babies should not be left to sleep with a bottle in their mouth.
- Vitamin drops, fruit juices, are not required as supplements to modern infant formulas.
- Uncles, grannies, and baby sitters can give a bottle feed but parents should feed their infant themselves as much as possible with the same sort of closeness, cuddling, and communication as in breast feeding.

Weaning¹⁹

In the first six months

Young infants cannot deal properly with solid foods (in reality semisolid foods at first) for the first four months. The natural time for starting solids (beikost) is when the energy provided by well established breast feeding starts to become insufficient. The Department of Health and other authorities advise that the introduction of any food to the baby, other than milk, should be unnecessary before the age of 4 months, but mothers may be tempted to jump the gun. Most babies should start a mixed diet not later than the age of 6 months.

Weight in the lower half of the standard percentiles without other symptoms is not an indication to augment breast feeding. Breast fed babies tend to put on weight (and length) a little more slowly than bottle fed infants. Indeed, the standard percentiles, derived mostly from bottle fed babies, may not be ideal. The time to start thinking about adding solids is when the infant still seems hungry after a good milk feed. But by

Fifteen month old child bottle feeding. (Courtesy of Mr PM Whitfield, reproduced with permission)

Babies cannot cope with solid food in the first few months because:

- the extrusion reflex prevents spoon feeding
- they cannot swallow solids
- pancreatic amylase is not produced for the first three months
- pancreatic lipase is absent for the first month (fat digestion in breast milk is facilitated by the bile salt-activated lipase it contains)
- there is an increased likelihood of absorption of intact foreign (food) proteins.

Mean consumption of energy from different foods in normal Canadian infants¹⁷

six months body stores of several nutrients, such as iron, zinc, and vitamin C, are often falling in exclusively milk fed infants, whether from breast or bottle.

When solids are introduced, single ingredient foods should be used and started one at a time at half weekly intervals so that there is time to recognise allergy or other intolerance to each food. A little of the food on the tip of a teaspoon is enough at first, given after a milk feed when the baby is wide awake.

Infant cereals (usually enriched with iron) are traditional foods to start with; rice is better before wheat. They can be thinned with baby's usual milk (mother's or formula) or water. Thereafter different soft foods can be added: mashed potato; soft porridges; puréed fruit and vegetables, meat, or chicken. Foods should be semisolid—sieved or blended or commercial baby food. It is nutritionally sensible to give a balance of foods from the four major food groups: cereals, vegetables/fruit, dairy products, and meats/fish. Combination foods should not be given until tolerance to their individual components is established. Egg should not be started before six months because of the chance of allergic reactions, and then it is best to begin with a small amount of cooked yolk. Spinach, turnip, and beets can contain enough nitrate to cause methaemoglobinaemia in young infants. Coffee and tea should not be given. Babies should not be left alone while they are eating.

In the second six months

In the second six months other liquids can be given from a cup, especially citrus fruit juices. Untreated cows' milk can sometimes cause gastrointestinal bleeding from irritation by the bovine serum albumin. This does not happen with boiled milk or infant formulas (which have been heat treated). Iron-fortified infant formula contributes to iron intake, which is critical in the second six months of life. It is wrong to add any salt to the foods given to infants. A fully breast fed infant receives only about one-twentieth of the sodium in a typical British adult diet. There has been a quiet revolution in commercial baby foods; most contain no added salt or colours and only up to 4% sugar (needed with sour fruits). Infants' sodium intakes have been found to shoot up after six months but more from home prepared rather than commercial baby foods.

An increasing range of foods is given in the second six months. Variety is likely to cover the needs for most nutrients and provide a basis for healthy food habits. Some fruits or vegetables should be given each day, but the most critical nutrients at this stage are protein and iron: finely minced beef and legumes should be given regularly and the protein in cereal foods should not usually be diluted by refining or by added fat or sugar. Foods should become progressively more chewy and fibrous and include rusks and other finger foods like bread or cheese. Babies do not usually like strongly flavoured foods like pickled onions. Nuts, popcorn, raw peas, and similar small hard foods should be avoided; they can be breathed in accidentally. Commercial baby food manufacturers offer a succession of "strained", "junior", and "toddler" foods for maturing babies, and similar meals are usually made at home. Some cookbooks for babies are more sensible than others.

Milk continues to be the main source of calories but a diminishing one. Sweetened fruit juices should be given by cup not bottle because the latter can promote dental caries. Infantile obesity is probably becoming less common in the United Kingdom now that people are aware of it. It is not usually caused by bottle feeding or early introduction of solids in themselves, but by more concentrated feeds, by pushing food at mealtimes, or by snacks in between. Between feeds, water for thirst and a minimum of snacks or sweets are good general rules.

A suggested timetable for the introduction of solid foods

- 1-4 months Breast milk only
 - 4-6 months Cereal(s) added
 - 6-7 months Vegetables (puréed) added
 - 8-9 months Start finger foods (rusk, banana) and chopped (junior) foods
 - 9 months Meat, citrus juice (from a cup)
 - 10 months Egg yolk (cooked), bite-sized cooked foods
 - 12 months Whole egg, most table foods
- No peanuts or hard particles of similar size

Feeding your baby (from breast feeding to solid foods). Reproduced with kind permission from the Food Standards Agency

In a survey for MAFF of food and nutrient intakes of British infants aged 6-12 months,²⁰ the percentage contribution of food types to energy intake were:

- *In infants 6-9 months old (median energy 792kcal), family foods 30%, infant formula 23%, infant foods 23%, cows' milk 18%, breast milk 6%*
- *In infants 9-12 months old (median energy 894kcal), family foods 53%, cows' milk 28%, infant foods 11%, infant formula 7%, breast milk 1%.*

ABC of Nutrition

Two other nutrients are not adequately supplied in all mixed diets. In communities where rickets occurs—for example, among Asian babies in northern cities—a supplement of vitamin D $10\ \mu\text{g}$ (400 IU) a day is good insurance. Bottle fed infants who are consuming 500 ml infant formula as follow on formula a day do not need vitamin supplementation because these manufactured products are fortified with vitamin D. In areas where the drinking water is not fluoridated, sodium fluoride prophylactic tablets or drops (0.25 mg/day) should be considered.

6 Children and adolescents

Pre-school children (1-5 years of age)

What children eat between being weaned and starting school is important. Food habits are established in this phase of life. They are less under parental control than they used to be. Mothers often go out to work, the toddler eats at a child care centre or pre-school. Food companies make some products specially for this age group and young children are targeted by advertisements on television. Young children have different taste perception from adults. They prefer sweeter foods, dislike bitter tastes, and often object to vegetables of the cabbage family.

Young children's eating is still mostly controlled by their mothers. Four simple principles should help them.

- (1) Eat from each of the **four basic groups** every day (the fifth will accompany the basic four). These four basic food groups contain all the essential nutrients between them.
- (2) Aim for **variety** within each food group—for example not always the same vegetable. The modern child should be prepared to eat food from other cultures. Food neophobia is a social handicap in later life. Young children should be able to eat most of the same food as the rest of the family.
- (3) To minimise **dental caries**, sweets and other sugary foods should be rationed and not eaten between meals as a rule.
- (4) The most likely **nutrient deficiency** in Britain is a low iron status with mild anaemia.² The easiest way to prevent this is for the child to be given meat, chicken or fish regularly, which provide haem iron.

Rickets in the northern winter, though now uncommon, is prevented by children getting out of doors regularly, eating plenty of the foods that contain some vitamin D and, in vulnerable groups, taking BNF vitamin capsules or children's vitamins drops (contains 7.5 µg vitamin D) during the winter. In a sample of Asian children, 1½-2½ years old in England, 20-34% had 25-OH vitamin D levels under 25 nmol/l.³ Low vitamin D status tended to be associated with low haemoglobin and serum iron.

Overweight increasing

Health visitors in the Wirral, NW England weigh and measure pre-school children regularly. Records from over 28 000 children show that the percentage overweight (>85% of the British growth reference BMI) rose from 14.7% in 1989 to 23.6% in 1998.⁴ What has changed since the 1980s? The *Lancet* asked:

Children's leisure activities have shifted from active outdoors play—often because of parents' perception that neighbourhoods are unsafe—to television watching and computer games. Cars are used even for short distance journeys. And children's diets including school meals, commonly consist of fast food with high fat and sugar contents. Many parents, especially when overweight themselves, do not recognise obesity in their children.⁵

Faddy toddlers

After having a reliable appetite for their first twelve months, some children aged 1-3 go through a phase of poor eating, which can make parents anxious or even exasperated. Children are less enthusiastic about eating and refuse foods that the rest of the family eat, especially vegetables.

Food groups for nutrition¹

- (1) Bread, other cereals and potatoes
- (2) Fruits and vegetables
- (3) Milk and dairy foods
- (4) Meat, fish, and alternatives
- (5) Foods containing fat
Foods containing sugar

1-4 are the basic four food groups. The fifth group includes foods low in nutrient density that should be used sparingly or enjoyed as treats.

Foods that contain some vitamin D

- Milk, eggs, cheese, butter, liver, all contain some.
 - Fatty fish (herring, mackerel, sardines, pilchards, tuna, and salmon) contain more.
 - Infant milks, infant cereals, margarines, some breakfast cereals, some yoghurts, and branded food drinks have vitamin D added during manufacture.
-

Favourite foods

- In the 1992-93 survey of British children aged 1½-4½ years² the foods or drinks most frequently recorded over 4 days were (in descending order): biscuits (88%); white bread (86%); non-diet soft drinks (86%); whole milk (83%); savoury snacks (potato crisps or cereal-based) (78%); boiled, mashed or jacket potatoes (77%); chocolate confectionery (75%); potato chips (71%); chicken (70%); breakfast cereals (66%); cheese (59%); sugar confectionery (58%); buns, cakes and pastries (55%); sausages (53%); beef dishes (47%); pasta (51%); carrots (54%); peas (53%); baked beans (49%); apples & pears (50%); bananas (46%); fruit juice (36%); eggs (46%); yoghurt (40%); coated and fried white fish (36%); leafy green vegetables (39%).
 - Many of the top half of items in this frequency list are high in fat, added sugar or salt. It would be preferable if the lower half of the list had been at the top.
-

One reason for this is that growth slows at around twelve months. This can be seen in the changes in gradient of normal weight for age, and height for age curves. It is even more obvious in weight and height velocity curves, which descend to about a quarter and a half, respectively, of the values in early infancy. Energy intake can be very variable from time to time in toddlers.

Other things are also happening. Children are discovering their independence and testing their choice in food selection. Once they have some control over what is offered, foods that they find unattractive are displaced by those they think delicious: cakes, biscuits, chocolate, crisps, ice cream, etc.

Schoolchildren

In developed countries undernutrition is exceptional nowadays—a big advance from Dickens' time. Children are growing taller than ever.⁸ Deficiency is limited to a few micronutrients and usually subclinical. Iron nutrition is low in a minority of older girls (their requirements increased by menstruation) and plasma 25-OH vitamin D is low in some susceptible children.

The main nutritional concerns in schoolchildren are:

- the increasing percentage who are overweight, even obese
- whether the most frequently consumed foods are healthiest in the long term? Vegetable, fruit and whole grain consumptions are often below dietary guideline recommendations (see chapter 7)
- the continuing opportunity to minimise dental caries by reducing the time that teeth are exposed to acid-producing carbohydrates in the mouth
- diets of socially deprived children can be of poorer quality.⁹

Overweight

It is now agreed that overweight can be diagnosed with body mass index (kg/m^2) using reference curves worked out for children's different ages. There are BMI reference curves for the United Kingdom (1995) and for the United States (2000). The cut offs shown on page 34¹¹ were calculated by Cole *et al.* for international use, based on data from Brazil, Great Britain, Hong Kong, the Netherlands, Singapore and the USA.

The role of high fat foods in the epidemic of overweight is generally known, and realised among schoolchildren themselves, though cheese or biscuits may not be recognised as high fat. Another contributor to overweight, more recently revealed, is the widespread consumption of sugar-sweetened soft drinks.¹² It is sometimes hard to visualise how much sugar and calories are in these liquids. In the NDNS survey⁸ 76% of 4-18 year olds consumed "carbonated soft drinks, not low calorie" over seven days while only 61% drank tap water!

Energy expenditure has fallen in young people. Many do not participate in sport, are driven to school and spend hours everyday looking at television or a personal computer. Children who watch more TV have higher BMIs¹³ and most of the food adverts they see are for fast foods, high in fat, sugar or salt.

How could schools help?

(Suppose a local doctor is on the school board.)

Much could be done (though nutrition is low priority at present for management, teachers, and pupils), including:

- there needs to be modernised food education across the years
- ALL pupils should get regular physical exercise; there is too much emphasis on competitive sport
- foods served in and around the school should help children eat a varied and nutritious diet

Advice for parents of faddy toddlers^{6,7}

- Most toddlers will eat some form of bread, cereals, meat, milk, and some fruits and fruit juices. The fibre foregone in vegetables can be replaced by breads and the vitamins by fruits and juices.
- Do not have battles over foods. Do not use bribes or force. Try to avoid tension at meal times.
- Keep meal preparation for toddlers easy and quick, so you can accept it without anger if they will not eat what you have made for them.
- Make eating fun—for example, cut sandwiches, pieces of fruit, cheese into patterns. Let toddlers eat at a small table, etc.
- When it is clear that they will not eat any more, let them leave the table. Do not insist on clean plates; serve a little less next time. With proper education, parents may be led to understand that a "good" eater is not a big eater but a moderate eater.
- Rejection of new foods is usually a transitory phenomenon which can be reduced by repeated exposure to small quantities without undue coercion (followed by praise if the child eats some). Parents should not interpret initial rejection to mean the child has an immutable distaste for the food.
- Children are more likely to try new foods offered in small amounts at the start of meals when they are hungry. If they help preparing (or even growing) vegetable foods (for example, shelling peas or making a salad) they may like to taste them.
- Do not give delicious (for them) high fat and sugar foods (cake or chocolate) before a meal or if they will not eat their main meals.
- Many toddlers cannot adjust to their parents' three meals but will eat nutritious foods as snacks.

Mean energy intakes of boys and girls studied in 1930-55 compared with more recent studies in relation to WHO/FAO (1973) recommendations¹⁰

National Diet & Nutrition Survey, Great Britain⁸

- Young people, aged 4-18 years from 1700 weighed dietary records.
- Most frequently consumed (% consuming over 7 days): White bread (95), milk (93), potato chips (89), biscuits (84), chocolate confectionery (82), other potato dishes (82), carbonated drinks (76), cakes (74), chicken (74).
- But consumption frequency was lower for: sausages (64), baked beans (60), apples, pears (54), beef, veal (51), peas (50), fruit juice (49), fried coated fish (46), pizza (45), green vegetables (39), bananas (38), citrus fruits (26).
- Average fat intake total 35.5% of energy, saturated 14.25% of energy, polyunsaturated 5% of energy.

ABC of Nutrition

- resist sponsorship by food companies and vending machines
- all children's weights and heights should be measured at school once a year.

James and McColl have written a paper for government departments setting out the justification for **schools that promote a healthy lifestyle** and how changes can be made.¹⁴

Adolescents

Teenagers are not fed; they eat. For the first time in their lives they assume responsibility for their own food intakes. At the same time they are intensely involved in day-to-day life with their peers, and preparation for their future lives as adults. Social pressures thrust choices at them: to drink or not to drink, to smoke or not to smoke, to develop their bodies to meet sometimes extreme ideals of slimness or athletic prowess. Few become interested in foods and nutrition except as part of a cult or fad such as vegetarianism or crash dieting.¹⁵

Several facets of eating behaviour are different or more pronounced in adolescents than in other people and each may cause concern in the older generation.

- **Missing meals**, especially breakfast. This does not usually affect classroom performance, partly because of—
- **Eating snacks** and confectionery. The major snack is usually in the afternoon, after school. Snacks tend to be high in “empty calories”—fat, sugar, and alcohol—but some provide calcium (for example milk) or vitamin C (fruit).
- **“Fast”, take-away, or carry-out foods**. These provide some nutritious portions, but adolescents may not choose balanced meals from what is offered. There is not enough accessible information about the nutrient composition of fast foods.
- **Unconventional meals** may be eaten in combinations and permutations that other members of the family do not approve of, but they often add up to an adequate nutritional mix.
- **Start of alcohol consumption**. This is the most dangerous of the new food habits. Alcohol-related accidents are the leading cause of death in the 15-24 year age group.
- **Soft drinks and other fun drinks**. If they are an alternative to alcoholic drinks should not be discouraged, but (unless sweetened with aspartame, etc) they provide only empty calories and by replacing milk can reduce the intake of calcium. Bottled pure water is a healthy trend.
- **High energy intakes**. Many adolescents go through a phase of eating much more than adults, sometimes up to 16.7 MJ per day (4000 kcal). This seems to occur near the age of peak height velocity in girls (around 12 years), but in boys may come later than the age of peak height velocity (usually 14 years). Presumably the larger, more muscular male adolescent is expending more energy at this stage.
- **Low levels of some nutrients**. Iron deficiency is quite common in adolescent girls who are menstruating, still growing, and often restricting their food intake. It may sometimes occur in boys too. Calcium accretion in the skeleton can be as much as 100 g/year at peak height velocity. Around 20% is absorbed so that about 500 grams per year are needed in the diet—that is, 1370 mg/day.
- **Adolescent dieters**. There are two aspects to this: overweight/obesity and social dieting. Obese adolescents are usually inactive and tend to have low socio-economic status. Dietary management should aim to hold the weight constant while the young person continues to grow and so thins out. Increased exercise should be emphasised and anorectic drugs should not be used.

Body Mass Index international cut off points for overweight ($\equiv 25 \text{ kg/m}^2$ in adults) and obesity ($\equiv 30 \text{ kg/m}^2$ in adults)¹¹

Age (years)	Overweight		Obese	
	Boys	Girls	Boys	Girls

Thiamin	28	22	28	20
Riboflavin	27	17	26	18
Vitamin C	14	19	27	27

As well as overweight youngsters there are adolescent girls of normal weight modifying their diet because they are not as thin as they or their peers think they should be. Some may fast and binge alternately. With a smaller energy intake they are more likely not to reach their requirements for iron and other essential nutrients. In a small minority this social dieting goes on to anorexia nervosa (incidence in some places as high as 1% of middle class girls aged 15-25) or bulimia. Treatment of anorexia nervosa is best handled by a specialised team of psychiatrist and dietitian. The general practitioner's main role is to recognise the early case. The longer the duration the worse the prognosis. A young woman whose weight goes below a body mass index (weight (kg)/height(m)²) of 17 should be warned, with her parents, that her thinness is unhealthy and referred for treatment if she cannot put on weight. (See page 56 for more on eating disorders.) By contrast, adolescent boys are more likely to worry that they are not growing tall enough or not developing enough muscles.

Does diet affect acne?

The popular belief is that chocolate, fatty foods, soft drinks, and beer can all aggravate acne vulgaris. This is not surprising since 85% of people have acne at some time during adolescence and most adolescents eat and enjoy these foods.

Controlled trials—for example, of chocolate—have proved negative but their design can be criticised. It is very difficult to produce double blind conditions. Individual cases appear to respond to cutting down confectionery, fatty foods, or alcoholic drinks and there are other reasons to recommend such a dietary change. Zinc, polyunsaturated fats, and vitamin A are reported to improve acne, and adolescents can be advised to eat foods that are good sources of each: meat and wholemeal bread (zinc), polyunsaturated margarine or cooking oil, and (for vitamin A) carrots or liver.

Perspective

Patience, and a sense of humour help in watching and advising on adolescent food habits. The serious concerns are drinking with driving, usually in boys, and excessive slimming, usually in girls.

No young person wants to lose their teeth and spoil their good looks. As in children, sticky sugary foods should not be eaten between meals, or if they are, the teeth should be thoroughly brushed afterwards.

Parents have more influence than they may think. They can choose which foods and drinks they buy and prepare and keep in the refrigerator. The adolescent's food habits are laid down in the family and the family remains one influence. The other three are the peer group, the need to develop an independent personality, and society in general.

Adolescence is a transitional stage when the structure of food habits is loosened. In a few years the young person will usually get married, work out a compromise set of food habits with the spouse or partner,¹⁷ and settle down to re-establish the eating behaviour of a new family. It is here, in preparing for and starting marriage that nutrition education should probably focus more.

Between the ages of 10 and 20 years:

- **lean body mass** goes from (average) 25 to 63 kg in boys, 22 to 42 kg in girls
- **body fat** goes from (average) 7 to 9 kg in boys, 5 to 14 kg in girls
- **triceps skinfolds (subcutaneous fat)** in boys stay at about 9 mm with a dip at year 15; in girls they climb steadily from 11 to 16 mm.

Too thin: entering anorexia nervosa range, BMI=17

7 Adults young and old

UK food guide plate¹

Most adults

Adults should eat enough of the essential nutrients by eating a healthy varied diet. This is more difficult to achieve if people have a low energy intake and if much of their diet consists of fats, alcohol, and sugar, which provide empty calories but little or no protein, or micronutrients.

Food guides

The food guide plate, with pictures of real foods, shows the four groups of foods that should between them provide enough of all the essential nutrients and the fifth group that provides mostly energy. (The plate picture makes a good poster for the waiting room.) The areas indicate relative amounts, so that people can see they should eat plenty of vegetables and fruit, plenty of cereal foods, and potatoes; moderate amounts of meat, fish and alternatives, and of dairy foods. The fifth group, “fatty and sugary foods”, are foods and drinks on which to go easy. Other countries have food guides rather like this but use different shapes. The United States and Australia use (different) pyramids. Canada has a quarter rainbow.

It becomes complicated to specify amounts (in grammes or servings) because there is a big range of energy intake from small old ladies to large male athletes. UK health authorities, however, do recommend that adults aim to eat five (or more) servings of vegetables or fruit each day.²

Fats and Sugars leaflets. Reproduced with kind permission from the Food Standards Agency

HEA/MAFF/DoH eight guidelines for a healthy diet³

- (1) *Enjoy your food*
No food needs to be excluded from the diet—except occasionally for special medical reasons. There is enough stress in life already without adding to it by worrying unnecessarily about food. It is good to be a little adventurous too with foods that have not previously been tried.
- (2) *Eat a variety of different foods*
The food plate guide shows the types and proportions. Under this heading is a note on **salt**: eating too much can contribute to high blood pressure. Most people eat more salt than they need.
- (3) *Eat the right amount to be a healthy weight*
Fat has more than twice as many calories as the same weight of starch or protein. Exercise does not have to be strenuous. Lots of small changes like walking ... and using the stairs ... can add up.
- (4) *Eat plenty of foods rich in starch and fibre*
Foods like bread, other cereals (rice and pasta) and potatoes and legumes. Cooking potatoes in oil or fat greatly increases their calorie content.
- (5) *Eat plenty of fruit and vegetables*
There are many biologically active substances in fruit and vegetables, as well as essential nutrients, that may help to reduce the risk of chronic diseases.
- (6) *Don't eat too many foods that contain a lot of fat*
It is best to cut down on saturates as much as possible.
- (7) *Don't have sugary foods and drinks too often*
Eating sugary foods frequently is the main cause of tooth decay. Children's teeth are the most susceptible.
- (8) *If you drink alcohol, drink sensibly*
Up to 3-4 units* a day for men; 2-3 units* for women (except in pregnancy) will not significantly increase the risk to health over time.

*British units are 8 g of alcohol; US units are approximately 12 g of alcohol

US National Research Council 1989⁴

Reduce total fat to 30% or less of calories and saturated fat to less than 10% of calories and dietary cholesterol to less than 300 mg/day. Polyunsaturated fatty acid optimal intake 7% to 8% of calories (not over 10%).

ω -3-polyunsaturates from regular fish consumption. (Concentrated fish oil supplements not recommended for general public).

Eat five or more servings of vegetables or fruits daily, especially green and yellow vegetables and citrus fruits, and six or more daily servings of bread, cereals, and legumes. Do not increase intake of added sugars.

Maintain a moderate protein intake, not more than twice the RDA.

Balance food intake and physical activity to maintain appropriate body weight.

If you drink alcohol limit it to no more than two standard drinks a day. Women who are pregnant or attempting to conceive should avoid alcoholic beverages.

Limit total salt intake to 6 g a day sodium chloride.

Maintain adequate calcium intake.

Avoid eating nutrient supplements with dose above the RDA (that is, avoid megavitamin supplements).

Maintain an optimal intake of fluoride, particularly during the years of primary and secondary tooth formation and growth.

RDA = recommended dietary allowance

Dietary guidelines for Americans⁵

- *Aim for a healthy weight.* If you are at a healthy weight aim to avoid weight gain. If you are already overweight (BMI > 25 kg/m²) first aim to prevent further weight gain, and then lose weight to improve your health.
- *Be physically active each day.* Choose activities that you enjoy and that you can do regularly. Be physically active for at least 30 minutes most days of the week. You can do it all at once or spread it over two or three times during the day.
- *Let the pyramid guide your food choices.* That is eat most bread, cereal, rice and pasta; next level (not so much) vegetable group (including potatoes) and fruit group; next level (less again) milk, yoghurt, cheese group and meat, poultry, fish, dry beans, eggs, nuts group. The smallest group (use sparingly) is fats, oils and sweets.
- *Choose a variety of grains daily, especially whole grains.*
- *Choose a variety of fruits and vegetables daily.*
- *Keep food safe to eat.* Safe means that the food poses little risk of foodborne illness from harmful bacteria, toxins, parasites, viruses or chemical contaminants.
- *Choose a diet that is low in saturated fat and moderate in total fat.* Use moderate amounts of food high in unsaturated fat, taking care to avoid excess calories.
- *Choose beverages and foods to moderate your intake of sugars.* In the United States the number one source of added sugar is non-diet soft drinks (soda or pop)... Drink water often.
- *Choose and prepare foods with less salt.* Many people can reduce their chance of developing high blood pressure by consuming less salt... Most of the salt you eat comes from foods that have salt added during food processing.
- *If you drink alcoholic beverages, do so in moderation.* Moderation here is defined as no more than one drink per day in women (that is, 12 g alcohol) and no more than two drinks per day in men (that is, 24 g alcohol).

Dietary guidelines

The box on page 38 shows three sets of dietary guidelines. These mostly give advice about how the part of the diet that provides energy—fats, carbohydrate, protein, etc.—should be made up. They are expressed in terms of averages. The average person, eating the average amount of (say) fat, should reduce this by or to a new national average. The advice has to be modified for individuals: Jack Spratt should not reduce fat intake as much as his wife. Recommendations from the US National Research Council use some numbers and technical terms. They need to be translated by health professionals for most consumers. The UK and US guidelines are written in non-technical language. The box shows the headings. There are more details in the booklets.³⁻⁵

Other aspects

Other aspects of a healthy diet, sometimes taken for granted, are that food should be wholesome and not contaminated with pathogenic micro-organisms or their toxins or with other toxins (chapter 14). Some of our foods are routinely enriched with micronutrients—for example, B vitamins and iron in white flour, vitamins A and D in margarine.

The municipal drinking water should likewise be nearly chemically pure. Calcium, magnesium, sodium, and fluoride concentrations in it vary from place to place. There is suggestive—but not conclusive—evidence that hard water (more calcium or magnesium, or both), is associated with lower cardiovascular mortality. Fluoridation at 1 ppm is recommended by all orthodox medical and dental authorities.

Vegetarianism

Are vegetarians more healthy or less? The answer depends first on the degree of vegetarianism.

Vegans, who eat no animal products, are at risk of vitamin B-12 deficiency. Supplements are essential during pregnancy and for infants of vegans. Vegans lack the best dietary sources of calcium—milk, yoghurt, and cheese.

Lacto-ovo-vegetarians have no absolute nutritional risk. They miss the best absorbed form of iron in the diet, haem iron, but may largely compensate because ascorbic acid enhances the absorption of non-haem iron.

The other determinant is the reason for the vegetarianism. People belonging to long traditions of vegetarianism have the necessary recipes to prepare vegetarian centres for their dishes, using legumes (including soya) and nuts, and so have a good protein intake. It is new vegetarians, some of whom simply remove meat from the centre of the plate, who may eat inadequately.

On the whole vegetarians appear to have lower risk of obesity, coronary heart disease,⁷ hypertension, and possibly some cancers. However, many of the figures come from well documented groups such as Seventh Day Adventists, who have a more healthy lifestyle than average in other ways—for example, they do not smoke or drink alcohol.

Nutrition and poverty in industrialised countries

In different countries of the EU between 4% and 25% of people live below the poverty line (50% of the national average household expenditure, adjusted for family size).⁸ In these subcultures of otherwise rich societies people are deprived of jobs, education, security, family support, adequate housing, transport, and/or language skills. The food and nutrients they eat and resulting nutritional status contribute to inequalities of health.⁹

Five grades of vegetarianism

- Do not eat meat of some animals (for example, horse) or some organs (for example, brain). *This is the norm for omnivorous humans except in a disaster.*
 - Do not eat meat but eat fish (and dairy produce). *Very little nutritional risk.*
 - Do not eat meat or fish but eat milk and eggs = lacto-ovo-vegetarian. *This is the most common degree of vegetarianism. The only nutritional risk is of iron deficiency.*
 - Do not eat any animal products = vegan. *Vitamin B-12 deficiency is likely and can be very serious in infants.⁶ Adequate protein can be ensured with regular legume products and nuts. Calcium, iron, and zinc nutrition should be watched.*
 - Do not eat anything but fruit = fruitarian. *Unlike some primates, people cannot usually manage on such a diet for long and seldom try to. It is inadequate in protein (unless nuts are included) and even in sodium as well as the nutrients above.*
-

Supplements

- Most people do not need nutritional supplements, but women with high menstrual losses may benefit from iron supplements.
 - Women who are, or who are planning to become, pregnant are advised to take 0.4 or 0.5 mg of folic acid each day and to eat folate-rich foods (chapter 4).
 - Older house-bound people, or people who wear enveloping clothes out of doors all year round, do not make enough vitamin D for their needs by the action of sunlight on their skin and should take 7-10 μg of vitamin D daily.
 - Vitamin drops are available for young children below the age of 5.
 - Before starting to take a dietary supplement it is advisable for people to consult a medical practitioner.
 - Someone drinking alcohol too heavily can at least prevent Wernicke's encephalopathy by taking thiamin (or vitamin B Co) tablets.
-

Sports nutrition¹⁰

- Dietary guidelines are the foundation of nutritional health, and competitive athletes are motivated to take their health seriously. There are no magic foods, no supplements which will improve sports performance on their own. Body weight and build differ for the various sports and events. Marathon runners are lightly built with little body fat. Champion weight lifters have a BMI in the "obese" range but this is due to an unusual amount of muscle, not fat. Athletes in regular training use and need more energy than sedentary folk. Compared with an average energy intake of around 10 MJ/day (2500 kcal), competitors during the Tour de France use a very high average of 33.7 MJ/day (8000 kcal).
 - Athletes take various regimes of high carbohydrate intakes before major events to maximise muscle glycogen content and hence extend the duration of top performance. During long events, drinks similar to oral rehydration fluid (chapter 8) (with glucose, NaCl, and potassium) may sustain performance and prevent dehydration. Different sports drinks and schedules have their devotees.
 - Two conditions are important in female athletes, including ballet dancers: mild iron deficiency anaemia, which limits performance, and osteopenia associated with amenorrhoea. For the latter, reduced training and/or increased body fat to restore menstruation, and calcium supplements are advised.
-

ABC of Nutrition

Low birth weight, lower rates of breast feeding, shorter children and overweight adults are more common in these people.

People in this group have to pay more for their food because they lack transport and funds to shop in large supermarkets. They consume less lean meat, fresh fruit and vegetables, and wholemeal bread than average. They suffer food insecurity at times. Their intake of micronutrients is lower, they are liable to anaemia, and their plasma lipids are higher than the average of the country. The Rome Declaration of World Food Security (1996) stated: "Governments will implement cost-effective public works, programmes for unemployed (and) develop social welfare and nutrition safety nets to meet the needs of the food insecure". In Britain the Low Income Project Team of the Nutrition Taskforce has published a report with far-ranging recommendations.¹¹ This problem of poor nutrition in deprived sections of prosperous countries is a failure of present capitalism and all who are trying to alleviate it deserve our support.

Older people

In developing countries children suffer most of the malnutrition. In developed countries it is the elderly who are most at risk of nutritional deficiency, though this is usually mild or subclinical and often associated with other disease(s). But it is very misleading to lump everyone over 65 together and expect them all to show the same problems and diseases. Healthy older people who are socially integrated are no more likely to get into nutritional trouble than anyone else.

For the majority people most of their life after 65 should be healthy and enjoyable. This "third age" is a time when people want to look after their health. They can now give more attention, time and money to getting and keeping healthy. They can take plenty of gentle exercise, have none of the stress of the workplace, few deadlines, and plenty of rest, and have time to choose food carefully and prepare it nicely. The dietary guidelines for younger adults all apply after retirement.

Dietary guidelines after retirement age

- A nutritious diet from a variety of foods is more important than when people are younger because the total energy intake is usually smaller than in young adults. The number of calories needed is less but not the requirements for most essential nutrients.
- To be light in weight eases the load on osteoarthritic joints and ageing heart and lungs and reduces the risk of accidents. Judicious regular exercise is much better than food restriction.
- Cut down on fat, especially saturated fat. Fat supplies more empty calories than any other dietary component. It predisposes to thrombosis, raised plasma cholesterol, and atherogenesis.
- Eat plenty of bread and cereals (preferably wholegrain) and vegetables and fruits; older people are liable to constipation, and a good intake of fibre will help to control this.
- Limit alcohol consumption. The smaller liver cannot metabolise as much alcohol as in young adults and the consequences of falls or accidents are more serious. No more than one or two drinks a day.
- Cut down on salt and salty foods. They tend to raise blood pressure; salt sensitivity increases with age and hypertension predisposes to strokes.
- Avoid too much sugar because of the empty calories, but dental caries is less troublesome in surviving mature teeth.

It is wrong, however, to use these guidelines for people who are declining in health (the "fourth age"); and some doubt even exists about whether low serum cholesterol concentration or body weight give any survival advantage to very old people.

Eating for the environment

People may rightly choose foods because the environment was considered in their production, for example more humane housing of hens and chickens (free-range eggs), fish nets that do not catch dolphins, or organic farming. The basis for preferring such produce has to be environmental rather than nutritional. Analysis of all the nutrients in foods adds up to be very expensive and no one can guarantee an overall nutritional advantage.¹²

Average daily intakes of 1275 free living older people in Britain (age 65-97)¹³

With ageing (from 20-30 to over 70 years):

- average body weight goes down after middle age (partly because of selective mortality of obese people)
- lean body mass declines from average 60 to 50 kg in men and 40 to 35 kg in women
- there is a loss of height and of mass of the skeleton
- muscle mass declines from about 450 g/kg to 300 g/kg
- body density goes down from 1.072 to 1.041 in men and from 1.040 to 1.016 in women
- body fat (as % of body weight) increases from about 20% to 30% in men and from 27% to 40% in women. It becomes more central and internal
- liver weight falls from about 25 g to 20 g/kg body weight
- basal metabolic rate goes down proportionally with lean body mass.

Diet and longevity 1¹⁴

- McCay in 1931, and others since, have found that rats and mice live longer if their diet is restricted to 60% of ad libitum intake long term. This is not because one type of food, fat or protein, is restricted and the effect still occurs after growth is completed. A favoured explanation is reduced exposure to reactive oxygen species from lower metabolic activity. Rats usually live about two years. Dietary restriction experiments have not yet been completed in larger animals. Whenever humans have been subjected to undernutrition they have usually been in an unhealthy environment with heavy exposure to infections but the diet-restricted rodents were kept away from pathogens. It is unlikely that a sufficiently long and controlled human experiment could ever be carried out.
- Humans are in any case an unusually long-lived species. We live twice as long as great apes. This may be because several antioxidant systems are unusually well developed in our species.¹⁵

Risk factors for impaired nutrition in older people**Social risk factors**

- Loneliness
- Isolation
- Immobility (no transport)
- Poverty
- Ignorance (the widower who cannot cook)
- Bereavement
- Alcoholism
- Dependence
- Regression

Medical risk factors

- Cancer and radiotherapy
- Depression
- Chronic bronchitis and emphysema
- Anorexia
- Cardiac failure
- Angina
- Insomnia
- Blindness
- Deafness

Some common drugs that can lead to malnutrition

- Aspirin and NSAIDs → blood loss, so iron deficiency
- Digoxin → lowers appetite
- Purgatives → potassium loss
- Cancer chemotherapy → anorexia
- Many diuretics → potassium loss
- Metformin → vitamin B-12 malabsorption
- Co-trimoxazole → can antagonise folate

NSAIDs = non-steroidal anti-inflammatory drugs

Some suggested extra dietary guidelines for older people

- Women especially should keep up a good intake of calcium from (low fat) milk or cheese, or both. This may help to delay osteoporosis.
- Those who are housebound or do not get out regularly should take small prophylactic doses of vitamin D (5-10 µg/day).
- Elderly people should avoid big meals, as Hippocrates, Galen, and Avicenna all advised. On the other hand, they should not miss any of the three main daily meals.

Old men have little warmth and they need little food which produces warmth; too much only extinguishes the warmth they have.

Hippocrates, *Aphorisms* 1, 14

- Coffee or tea in the evening may contribute to insomnia.
- There is a place for fatty fish or small amounts of fish oils containing fatty acids like eicosapentaenoic acid (20:5, ω-3), which can reduce the risk of thrombosis.

Assessment of nutritional status

There have been several studies of the nutrition of elderly people in Britain and similar countries. Findings have differed, partly because different sectors of the elderly population have been sampled, partly because different parts of the range of possible biochemical tests have been done. Nutritional deficiency is nearly always secondary to a social problem or to disease. The first step in diagnosing malnutrition is to recognise one or more **risk factors**. The chances of risk factors and of nutritional deficiencies in elderly people increase progressively from those at normal risk (the healthy and socially integrated), through those who have one or more chronic illnesses but are nevertheless socially organised, and the housebound, to those at high risk—the institutionalised.

Assessment of nutritional status can be difficult in old people. The history of food intake may be unreliable because of poor memory. We are not yet sure whether the recommended intakes of some nutrients should be adjusted downward or upward, or by how much. Height (stature) may be impossible to measure exactly because of deformities.

Nutrients most likely to be deficient in old people are (roughly in order of importance):

- total energy—thinness, wasting, undernutrition
- potassium—deficiency can present with confusion, constipation, cardiac arrhythmias, muscle weakness, etc
- folate—deficiency can present with anaemia or with confusion
- vitamin B-12—because of gastric atrophy. Serum methylmalonate may be elevated before vitamin B-12 is low
- vitamin D—deficiency can present with fractures or bone pains of osteomalacia
- water—frail old people may not drink enough, which can lead to urinary tract infection or dehydration
- dietary fibre—deficiency leads to constipation
- vitamin C—low plasma concentration, haemorrhages
- iron—anaemia, koilonychia
- protein—low plasma albumin, oedema
- calcium—low intake; decreased bone density
- zinc—low plasma concentration
- thiamin—biochemical features of deficiency (red cell transketolase)
- magnesium—low plasma concentration
- pyridoxine—biochemical features of deficiency.

Knee height (from heel to top of patella with the knee flexed) can be used to estimate stature in centimetres

- **for men** stature = 2.02 KH - (0.04 × age, y) + 64.2
- **for women** stature = 1.83 KH - (0.24 × age, y) + 84.9.

Weight-for-height standards (for younger adults) are not strictly applicable because of the decline in lean body mass. Some recent anthropometric data on 200 people over 75 living independently in two general practices are provided by Bannerman *et al.*¹⁶

Clinical examination is complicated by the presence of other diseases. Oedema is usually due to cardiovascular disease, loss of ankle jerks to ageing nerves rather than nutritional deficiency. For several biochemical tests we are not quite sure what the normal range is in old people.

Preventive measures

Only rarely are low intakes of nutrients and abnormal laboratory findings associated with a disturbance of function that would support the diagnosis of clinical malnutrition. The usual finding can best be called subclinical deficiency, and we are often not sure of its clinical importance. It is prudent to attempt to raise the level of nutrients to make people with subclinical deficiency more resistant to the effects of stress caused by non-nutritional diseases, which become increasingly common with advancing years.

General practitioners, with the younger family members or a friend, district nurse, or social worker can improve an old person's nutrition in several ways:

- suggest cooking lessons for retired men
- arrange help for partly disabled people to adapt cooking techniques
- organise delivery of heavy shopping
- suggest (where one is absent) buying a refrigerator or freezer
- ensure that every elderly person or couple has an emergency food store
- suggest that a younger relative helps with shopping and invites the elderly person for a regular good meal
- arrange for him or her to attend a lunch club
- arrange for meals on wheels
- possibly prescribe micronutrient supplements, but some multivitamin tablets do not contain them all (some miss folic acid) and there may be more need for potassium
- build on established eating patterns when advising about changing food consumption; drastic changes are likely to confuse
- warn that reduced sense of smell and sight make it hard to detect food that is no longer wholesome.

Nutrition in institutions

In nursing homes, practices that contribute to poor nutrition include:

- lack of communication between nursing and kitchen staff
- disregarding residents' suggestions about menus
- ignoring residents' requirements for special diets
- offering no choice of portion size or second helping
- monotonous menus
- not noting food left or residents not eating
- not weighing residents regularly
- little or no homestyle cooking
- inadequate help with feeding frail residents
- cooks that lack basic knowledge of nutrition
- meals rushed or served too early
- no facilities for residents to make hot drinks for themselves
- low fibre diets.

More details for those inspecting or advising on nutrition in nursing homes can be found in *Eating well for older people*.¹⁸

Diet and longevity: 2

- Claims that people live longer than usual in parts of Georgia (Europe), or in Vilcabamba in Ecuador have proved dubious on investigation. There were no birth certificates.
- The food that our centenarians ate when young they say was less processed and simpler than contemporary food patterns. Of course it was. That was what ordinary people ate in 1903.
- No special food emerged when a sample of centenarians recalled their lifestyles to the US House of Representatives Select Committee on Aging.

“Food, like sex, is one of the pleasures that stays with us all our lives” (as Alex Comfort put it).¹⁷ When life is limited because of disabilities and loss of social and environmental stimulation, it is very important for the morale and well being of elderly people in institutions that their food is what they like, and is served with courtesy, and that they have at least some control over it. We younger adults are always making compromises between ideal nutrition and a little of what we fancy, and we must allow and help elderly people in nursing homes to do the same—by offering them a glass of sherry or beer, a favourite dessert, or a piece of confectionery.

8 Malnutrition in developing countries

Some former “developing countries” really have been developing, and as a byproduct malnutrition has largely disappeared. Other countries have been static or lost ground. A country can become poorer from reduced income, reduced gross national product (GNP) per head (caused by bad climate, economic mismanagement, or war) or from population growth faster than economic growth, or both. Many of the poorest countries have suffered civil wars.

About two-thirds of the world’s six million people live in countries with low and lower middle incomes (on the current lists of the United Nations). In most of these countries people are very poor; the population is young and growing fast; there is no welfare state and little mechanisation. Food at an affordable price cannot be taken for granted; nor can clean drinking water. Tropical infections are an additional burden.

Public health indicators do not correlate closely with national income. Vietnam is an outstanding example of a poor country which nevertheless has enough food to go round, and health statistics better than that, for example, of South Africa, whose GNP/head is 10 times higher. Economic development is thus only one factor—an important one—that reduces malnutrition. But even if a country’s income stays low there are things that doctors, nurses, agriculturists, administrators, and politicians can do to combat malnutrition.

Diagnosis and management of malnutrition in developing countries have to be mostly a public health operation. Many of the malnourished live in slums, shanty towns, or remote rural areas. They cannot be brought to a central teaching hospital. There are fewer doctors—in some countries only 1 for 50 000 people—so they have to work through teams of community health workers, who should be trained to recognise and cope with the common diseases, including malnutrition and the closely related infections.

Protein-energy malnutrition^{3,4}

What is described here is malnutrition in young children. They are dependent on adults for their food and are therefore especially vulnerable where there is food insecurity. They have high food energy needs for their size (kg body weight) and because of higher protein requirements per calorie (or kJ) they are more at risk of protein deficiency than adults.

The prevalence of protein-energy malnutrition (PEM) in its various forms is high in South and South-East Asia, in Africa and the Middle East, in some Caribbean islands, and in Central and South America. Severe forms affect around 2% and mild to moderate PEM affects around 20% of young children (in many places more) in developing countries. WHO has estimated that about 200 million children in the world at any time have moderate or severe PEM. Although it affects only some children in each community, it is a larger and more intractable problem than famines.

Severe PEM

Nutritional marasmus is the commonest severe reform of protein-energy malnutrition, the childhood version of starvation. It usually occurs at a younger age than kwashiorkor. The cause is a diet very low in both calories and protein—caused, for example, by early weaning then feeding dilute food because of poverty or ignorance. Poor hygiene leads to

1998 Figures	39 Poorest countries	Vietnam	United Kingdom
GNP/head (US\$)	110 to 390	310	20 870
Population growth %	-0.7 to 4.7	1.9	0.2
Infant mortality Rate/1000	31 to 182	31	6
Under 5 mortality Rate/1000	42 to 316	42	6
Life expectancy at birth (years)	38 to 68	68	77

Data from *The State of the World’s Children 2000*¹

From the first three paragraphs of the World Declaration on Nutrition, 1992²

- We, the Ministers and Plenipotentiaries representing 159 states and the EEC ... declare our determination to eliminate hunger and to reduce all forms of malnutrition. Hunger and malnutrition are unacceptable in a world that has both the knowledge and the resources to end this human catastrophe ...
- ... We all view with the deepest concern the unacceptable fact that about 780 million people in developing countries—20% of their combined population—still do not have access to enough food to meet their basic daily needs for nutritional well-being.
- We are especially distressed by the high prevalence and increasing numbers of malnourished children under five years of age in parts of Africa, Asia and Latin America and the Caribbean. Moreover, more than 2000 million people, mostly women and children, are deficient in one or more micronutrients: babies continue to be born mentally retarded as a result of iodine deficiency; children go blind and die of vitamin A deficiency; and enormous numbers of women and children are adversely affected by iron deficiency...

Protein-energy malnutrition	Bodyweight as % of standard	Oedema	Deficit in weight for height
Marasmus	60	0	++
Marasmic kwashiorkor	60	+	++
Kwashiorkor	80-60*	+	+
Nutritional dwarf	60	0	minimal
Underweight child	80-60	0	+

*Occasional cases are not underweight at the oedematous stage

gastroenteritis and a vicious circle starts. Diarrhoea leads to poor appetite and more dilute foods. In turn further depletion leads to intestinal atrophy and more susceptibility to diarrhoea.

Kwashiorkor in its full blown form is less common than marasmus. It is most common in poor rural children, displaced from the breast by the next child and given a very low protein starchy porridge—for example, made with cassava or plantain. There have been several hypotheses about the antecedent diet because it is very difficult to reconstruct the exact dietary history of a malnourished child. But careful studies by Whitehead's group⁵ of pre-kwashiorkor in Uganda compared with pre-marasmus in the Gambia, and other information support the classical hypothesis of protein deficiency with relatively adequate carbohydrate intake. Pure cases of kwashiorkor can develop in a few weeks and the patients sometimes have normal weight for age.

The pathogenesis of kwashiorkor appears to be: very low protein intake with more dietary carbohydrate leads to insulin secretion being maintained (unlike marasmus). Insulin spares muscle protein when there is shortage of amino acids, but there is loss of liver protein. So synthesis is reduced of two proteins made in the liver: (a) plasma albumin, hence oedema (potassium depletion makes it more likely), and (b) low density lipoproteins, hence lipids accumulate in the liver. Some of the features of kwashiorkor may be due to associated zinc deficiency.

Marasmic kwashiorkor has some features of both conditions. Severe protein-energy malnutrition can be thought of as a spectrum from marasmus to kwashiorkor. Most affected children have some skin lesions, hair changes, and fatty liver (as in kwashiorkor) together with the wasting of marasmus.

Malnourished children are likely to be depleted in other nutrients (see box opposite).

Treatment

Management of severe protein-energy malnutrition is in three phases.⁶

- (1) **Resuscitation**
Correction of dehydration, electrolyte disturbances, acidosis, hypoglycaemia, hypothermia, and treatment of infections.
- (2) **Start of cure**
Refeeding, gradually working up the calories (from 100 to 150 kcal (420-630 kJ) per kg) and protein (to about 1.5 g per kg). There may be anorexia, and children often have to be hand fed, preferably in the lap of their mother or a nurse they know. Potassium, magnesium, zinc, and a multivitamin mixture are needed but iron should not be given for the first week.
- (3) **Nutritional rehabilitation**
After about three weeks if all goes well the child has lost oedema and the skin is healed. The child is no longer ill and has a good appetite but is still underweight for age. It takes many weeks of good feeding for catch up growth to be complete. During this stage the child should be looked after in a convalescent home or by its mother, who should if possible have been educated about nutrition and provided with extra food. Locally available foods are best.

Mild and moderate protein-energy malnutrition

This is much more common than the obvious severe forms. Outside observers, even the mothers themselves, do not notice most of these cases because the children are similar in size and vitality to some of the other children of the same age. The condition is like an iceberg. For every severe case there are likely to be seven to 10 in the community with lesser degrees of malnutrition. These latter children do not grow normally and

are at increased risk of infection. They may also have more difficulty learning motor and cognitive skills.

National statistics used to indicate nutrition¹

Underweight can be due to either wasting or stunting. **Wasting** is a fairly direct indication of undernutrition but the causes of **stunting** are complex. The NCHS anthropometric references used by WHO for international comparisons are based on large samples of US children measured in the 1960s and 1970s. A high percentage of stunted children means that they are short by US standards. The causes can be genetic, or intra-uterine growth retardation, or delayed growth from multiple infectious diseases, or insufficient nutrition. Small size is an adaptation. It cannot be equated with malnutrition.⁷

Most children with mild protein-energy malnutrition are thin and underweight. Because scales are difficult to carry children who are malnourished may be identified in the field by measuring the mid-upper arm circumference. From 12 to 60 months of age over 13.5 cm is a normal circumference; 12.5 to 13.5 cm suggests mild malnutrition and under 12.5 cm indicates definite malnutrition. The normal circumference stays the same for these four years.

Sometimes a child is seen who has adapted to chronic inadequate feeding by reduced linear growth but looks like a normal child a year or two younger—this is **nutritional stunting**.

Prevention of protein-energy malnutrition

Five measures to prevent protein-energy malnutrition are being actively promoted round the world.

Growth monitoring. The WHO has devised a simple growth chart—the Road to Health card. The mother (not the clinic) should keep the card in a cellophane envelope and bring the child (plus card) to the nearest clinic regularly for weighing and advice.

Oral rehydration. The UNICEF formula is saving many lives from gastroenteritis: NaCl 3.5 g, NaHCO₃ 2.5 g, KCl 1.5 g, glucose 20 g (or sucrose 40 g) and clean water to 1 litre.

Breast feeding is a matter of life and death in a poor community with no facilities for hygiene. Additional food, prepared from locally available products, is needed from four to six months of age.

Immunisation should be done against measles, tetanus, pertussis, diphtheria, polio, and tuberculosis.

Family planning advice and inexpensive or free contraception should be readily available.

Starvation and famine

When there is not enough food for an entire community children stop growing, and children and adults lose weight. The symptoms include craving for food, thirst, weakness, feeling cold, nocturia, amenorrhoea, and impotence.

The face at first looks younger but later becomes old and withered and expressionless; pupils react poorly to light. The skin is lax, pale, and dry and may show pigmented patches. Hair becomes thinned or lost except in adolescents. The extremities are cold and cyanosed. There may be pressure sores. Subcutaneous fat disappears, skin turgor is lost, and muscles waste. The arm circumference is subnormal. Oedema may be present; in adults this is famine oedema, which is not always associated with hypoalbuminaemia. Temperature is subnormal. The pulse is slow, blood pressure low, and the heart small with muffled sounds. The abdomen is distended.

Diarrhoea is common, often associated with blood. Muscles are weak and tendon jerks diminished. Psychologically, starving

Underweight, wasting and stunting, defined by WHO

- Underweight is moderate if 2 to 3 standard deviations below the median NCHS **weight for age** (see page 30) and severe if more than 3 SDs below the reference.
- Wasting is moderate if 2 to 3 standard deviations (79-70%) below the median NCHS **weight for height** and severe if more than 3 SDs (<70%) below the reference.
- Stunting is moderate if 2 to 3 standard deviations (89-85%) below the NCHS median **height for age** and severe if more than 3 SDs (<85%) below the reference.

The standard deviation score is also called the “z score”.

Percentage of children under 5 with moderate or severe underweight, wasting or stunting

	Under weight	Wasting	Stunting
Sub Saharan Africa	32	9	41
Middle East and North Africa	18	8	25
South Asia	51	18	52
Latin America and Caribbean	10	3	18
USA	1	1	2

people lose initiative; they are apathetic, depressed, and inverted but become aggressive if food is nearby.

Infections are to be expected, especially gastrointestinal infections, pneumonia, typhus, and tuberculosis. The usual signs of infection (pyrexia, leucocytosis) may not appear. Delayed skin sensitivity with recall antigens—for example, tuberculin—are falsely negative. But the erythrocyte sedimentation rate is normal unless there is infection. In advanced starvation patients become completely inactive and may assume a flexed, fetal position. Death comes quietly and often quite suddenly in the late stage of starvation. The very young and the very old are most vulnerable.

Inside the body plasma free fatty acids are increased; there is ketosis and may be a mild metabolic acidosis. Plasma glucose is low but albumin concentration is often normal. Insulin secretion is diminished, reverse triiodothyronine replaces normal T3, and glucagon and cortisol concentrations tend to increase. The resting metabolic rate goes down considerably; oxygen consumption per person goes down more than when expressed per kg body weight. The urine has a fixed specific gravity, and creatinine excretion becomes as low as 300 mg/day. There may be a mild anaemia, leucopenia, and thrombocytopenia. The electrocardiogram shows sinus bradycardia and low voltages. All the organs are atrophied and have subnormal weights at necropsy except the brain, which tends to maintain its weight.

Much the same clinical and metabolic features of starvation are seen in hunger strikers as in the much more common situation in a famine, but in the latter intercurrent infections usually compound the disorder. The problem in a famine is not so much loss of food availability as loss of food entitlement. People have to sell all their assets in the attempt to buy food. Practically all social and economic structures break down and there may as a last resort be mass migration of the sufferers. The worst famines of recent times have been in areas torn by civil war. This greatly hampers communication of early warning of food shortage and transport of relief food into the area.

Any doctor involved in relief operations should expect to have a mainly administrative and organisational role. It is impossible to give most time to treatment of a few very sick individuals. Therapeutic feeding is not an effective use of resources. Field workers have three options for distribution of food where supplies are insufficient to provide the minimum requirements of 1900 kcal (8MJ)/person/day:

- (1) where community and family structure is still intact and community representatives can be identified, let the community decide how the limited food should be distributed
or
- (2) where community structures have been disrupted field workers distribute food selectively to those at highest risk of mortality
or
- (3) the third alternative is equitable distribution of the same basic ration to all members of the affected population with selection of particularly vulnerable members.⁹

Each option has its unsatisfactory aspects and work is easier when and if enough food is shipped in for all. The standard rations usually consist of cereals, legumes, and some oil. If the cereal is wholegrain, milling equipment is needed. Milk powder is used for malnourished children. Care must be taken that the population is getting the critical micronutrients, for example, vitamin C, potassium.¹⁰

To assess the degree of undernutrition in individuals two measures are used: mid-upper arm circumference (MUAC) and

Famine is different from endemic undernutrition

Because present-day famines strike in developing countries where malnutrition is endemic, there is an unfortunate tendency to blur the differences between endemic malnutrition and famine-induced malnutrition, to treat the latter as if it were simply the former writ large ...

Famines are distinct ... They are different not only in severity, but in kind. This is because the famine year is neither characterised by poverty, nor even death, but by social disruption. Miserable though it is, chronic poverty in traditional societies is a situation to which considerable social, psychological and physiological adaptation has occurred. Only when these mechanisms of cultural homeostasis are unable to cope does the situation shift into famine ...

What distinguishes famine-induced malnutrition is not that it is *acute*, but that it is *extensive*.

*Standard weight = W/H² 22.5. 80% standard = BMI 18
70% standard = BMI 16

weight for height in children or BMI (kg/m²) in adults. MUAC is obviously quicker and a tape measure more portable, but in children low MUAC tends to select younger children as malnourished and miss older children with low weight for height.¹¹ In adults MUAC and BMI appear to correlate fairly well. A MUAC of 220 mm in men or 210 mm in women corresponds approximately to a critical BMI of 16 kg/m².¹² As a general rule **moderate starvation**=weight for height 80-71% of standard (BMI 18-16 kg/m²) and **severe starvation**=weight for height ≤70% of standard (BMI ≤15.7).

Circumstances and resources are different in every famine. The problems are mainly non-medical: organising transport and repair of trucks and shelters, coordinating relief from different organisations, reconciling international workers with local politicians and administrators, arranging security of food stores, seeing that food is distributed on the basis of need, trying to procure the right food and the appropriate medical supplies. Civil disturbances do not occur during severe famine. They may happen at an early stage (food riots) or afterwards (revolution). Meanwhile, the future has to be planned for; agricultural workers are going to be needed with enough strength to plough and plant the next crop when the rains return.

Vitamin A deficiency and xerophthalmia

In 1857 David Livingstone first suggested that eye lesions in some African natives were caused by nutritional deficiency: “The eyes became affected as in the case of animals fed pure gluten or starch.” The antixerophthalmia factor was the first of the vitamins to be isolated, in 1915 by McCollum in the USA. Xerophthalmia is a late manifestation of vitamin A deficiency. Its global incidence has been estimated at some 500 000 new cases a year, half of which lead to blindness. Because of its social consequences vitamin A deficiency is given priority by the WHO for prevention programmes. The highest incidence is in South and South-East Asia—for example, India, Bangladesh, and the Philippines. It also occurs in some underdeveloped parts of Africa and Central and South America.

Vitamin A is not only the antixerophthalmia vitamin. It has also been called the “**anti-infective vitamin**” because rats with experimental deficiency had multiple infections. Children with full-blown xerophthalmia have high mortality. The importance of vitamin A for humans broadened when a longitudinal survey in Java showed that even mild forms of xerophthalmia were associated with a four-fold risk of death, often from respiratory or intestinal infections. Sommer’s group¹³ went on to a large randomised controlled trial in an area where cases of xerophthalmia occur. Children of 1-5 years given vitamin A capsules (one single capsule of 200 000 IU, repeated after six months) had a 34% lower mortality than untreated children in adjacent villages.¹³ Subsequently similar prevention trials have been completed in several developing countries. Most reported significant benefits from vitamin A supplementation; the overall average reduction of death rate was 23%. By 1996, 40 developing countries had programmes for giving routine vitamin A supplements to young children.¹

There is a strong synergistic association of measles and vitamin A deficiency. Measles can precipitate xerophthalmia and leads to low plasma vitamin A even in developed countries. In Cape Town (where clinical xerophthalmia is rare) a controlled trial in black children hospitalised with measles showed a strikingly better outcome in those given vitamin A (200 000 IU once on admission and repeated the next day).

Child receiving vitamin A capsule. Reproduced with permission from *Sight and Life*

ABC of Nutrition

Vitamin A should be given to any child with severe measles or from a deprived background.¹⁴ With the new broader concepts of subclinical vitamin A deficiency, over 200 million young children have been estimated to be at risk and three million clinically affected.¹⁵

Stages of xerophthalmia

Severe xerophthalmia is virtually confined to infants and young children and usually associated with protein-energy malnutrition. The stages are classified by the WHO as follows.

- **Night blindness (XIN)** is the earliest symptom but not elicited in infants.
- In **conjunctival xerosis (XIA)** one or more patches of dry non-wettable conjunctiva emerge “like sand banks at receding tide” when the child ceases to cry. It is caused by keratinising squamous metaplasia of the conjunctiva.
- **Bitot’s spots (XIB)** are glistening white plaques formed of desquamated thickened epithelium, usually triangular and firmly adherent to the underlying conjunctiva.
- **Corneal xerosis (X2)** is a haziness or a granular pebbly dryness of the cornea on routine light examination, beginning in the inferior cornea.
- **Corneal ulceration (X3A) or keratomalacia (X3B)**.
A punched out ulcer may occur or, in a severe case, colliquative necrosis of the cornea (keratomalacia).
If promptly treated a small ulcer usually heals, leaving some vision. Large ulcers and keratomalacia usually result in an opaque cornea (X5) or perforation and phthisis bulbae.

Pathogenesis of xerophthalmia

In countries where xerophthalmia occurs, adults have much lower vitamin A stores in their livers than in well-fed people. Women start with low stores and throughout pregnancy have low intakes of vitamin A and carotene. Newborn babies have only one-fifth the liver vitamin A concentration of their mothers, even in well-fed communities, because vitamin A transport across the placenta is limited. Since the mother has low intakes and stores, her breast milk contains low concentrations of vitamin A and carotene. If the child has protein-energy malnutrition this impairs absorption and transport of vitamin A. Then a severe infection can precipitate clinical deficiency by increasing urinary loss of the vitamin and reducing hepatic synthesis of retinol binding protein.

The symptomatology of vitamin A deficiency can be explained by several functions of the vitamin. Retinaldehyde (retinal) is needed for the response of rods in the retina to light. Retinoic acid is needed to maintain differentiation of epithelia (for example, conjunctiva, respiratory), secretion of mucus, and tear production. In vitamin A deficiency cell-mediated immunity is impaired.

Diagnosis and treatment

Xerophthalmia is rare in Britain. It is seen occasionally in patients with chronic jaundice or small bowel resection or very restricted diets. A British doctor going to work in a developing country should familiarise themselves with the early features of xerophthalmia from colour photographs. (An excellent set is obtainable from American Foundation for Overseas Blind, 22 West 17th St, New York, NY 10011, USA. Or see a recent WHO publication on diagnosis and management of xerophthalmia.)

Treatment of xerophthalmia is urgent. The differential diagnosis includes smoke exposure, trauma, bacterial infections, measles, and trachoma. The child often has some other illness at the time like gastroenteritis, kwashiorkor, measles, or respiratory infection, which can distract attention from the eyes unless they are examined systematically. If in doubt a dose of vitamin A

Colliquative necrosis of lower 2/3 of the cornea (Keratomalacia).
Reproduced with permission from *Sight and Life*

In Britain conscientious objectors volunteered for a classic vitamin A depletion experiment in Sheffield during the Second World War. There were no features of deficiency until they were into the second year of a diet lacking vitamin A and carotene, and even then the symptoms were minor (night blindness and follicular hyperkeratosis). In well-nourished countries adults have enough vitamin A stored in their liver to last over a year of deprivation.

should be given. It can do no harm. The immediate treatment is 110 mg retinol palmitate or 66 mg retinol acetate (200 000 IU) orally or (if there is repeated vomiting or severe diarrhoea) 55 mg retinol palmitate (100 000 IU) **water soluble** preparation intramuscularly. For the next few days repeat the oral dose.

Prevention

There are four strategies for prevention. In some countries two or more are being used side by side.

(1) Nutrition education

This emphasises garden cultivation and regular consumption of locally grown plant sources of β -carotene (pro-vitamin A). The best sources include mango, papaya, pumpkin, yellow sweet potatoes, carrots and palm oil, as well as eggs and liver. Dark green leafy vegetables, formerly encouraged, contain useful amounts of β -carotene but this was found to be poorly absorbed (and converted to vitamin A) with traditional cooking methods. β -Carotene in plant leaves is mostly in the chloroplasts, which are not well digested. The carotene in fruits that contain it are more available¹⁶ and absorption of β -carotene is improved if there is oil or fat in the meal.

(2) Vitamin A for mothers

The vitamin may be given to pregnant women, but it must not exceed 3300 IU (1 mg retinol) per day (or 23 300 IU once a week) because more vitamin A can be teratogenic. After delivery large single oral doses (200 000 IU) can be given to them in the first month. It should not be given later in case they become pregnant again.

(3) Periodic dosing of young children

This should be done in areas of high incidence with capsules of 110 mg retinol palmitate or 66 mg retinol acetate (200 000 IU) at six monthly intervals. Doses must be smaller in infancy.

(4) Fortification of staple foods with vitamin A

In industrialised countries vitamin A is added to margarines to the level found in summer butter (2500 IU or 0.75 mg retinol per 100 g). In Central America sugar is fortified; the World Food Programme requires dried skim milk used in its aid schemes to be fortified with vitamin A.

Indian education poster (the plate contains green vegetables and orange-coloured fruits in additions to the staple, rice)

Iodine deficiency disorders (IDDs)¹⁷

Iodine deficiency disorders are also given priority by WHO for preventive efforts among nutritional diseases because of their extent—about 1500 million people live in iodine-deficient environments—and feasibility of prevention. Their social importance is greater than was formerly realised. In the major inland mountainous areas of the world, especially the Himalayas, the Alps, the Andes, inland mountainous areas of China and Africa, Indonesia and Papua New Guinea, the soil has had its original iodine leached out of it by heavy rainfall or glaciation, so that the human diet is lacking in iodine if people rely on locally grown foods. When the iodine intake is below the minimum (about 50-75 μ g/day) required to replace the turnover of thyroid hormones, pituitary thyrotrophin secretion increases and the thyroid takes up more than its usual 50% of absorbed iodine. Hypertrophy of the gland develops—a goitre. The prevalence of goitre was estimated at about 200 million people worldwide in the early 1990s.

When just visible goitres occur in at least 5% of adolescents this is defined as **endemic goitre**. It usually shows first at puberty, and women are more affected than men. In some areas the iodine intake, indicated by the 24-hourly urinary iodine, is not very low and endemic goitre is attributed partly to thyroid antagonists such as glucosinolates or thiocyanate in certain brassicas or in cassava or soya beans.

Areas of endemic goitre

ABC of Nutrition

When endemic goitre occurs in almost all the women a small percentage of babies, 1% up to 5%, are born with **cretinism**. There are two types. In nervous cretinism there is mental deficiency, deaf mutism, spasticity, and ataxia but features of hypothyroidism are hard to find. In myxoedematous cretinism there are dwarfism, signs of myxoedema, and no goitre. The nervous type predominates in Papua New Guinea and parts of the Andes, while the myxoedematous type is seen in Zaire.

Endemic goitre has by now almost disappeared from the low iodine regions of developed, industrial areas like Derbyshire, the North American middle west, Switzerland, New Zealand, and Tasmania because much or all the salt that people eat is iodised; foods come in to the area that were grown or reared on soils with normal iodine; iodophors used as disinfectants in dairies get into the milk; dairy cows' winter rations have added iodine; and iodate may be used as a bread additive.

But in many remote, inaccessible parts of developing countries, endemic goitre and cretinism persist. Iodine status can be surveyed in such places by collecting single urine samples. Where goitre is common iodine excretions are all low and average less than 25 µg/1 g creatinine; the whole community is deficient. Endemic goitre was thought to be unaccompanied by functional effects (except for occasional local retrosternal pressure).

But in the 1980s it was recognised that "normal" people in goitrous districts (not diagnosed as cretins) have among them higher prevalences of deafness, slower reflexes, features of hypothyroidism, poorer learning ability, more stillbirths and malformed babies, and subnormal plasma thyroxines compared with control communities.¹⁹ Any cretinism is thus the tip of the iceberg and the whole community on very low iodine intakes has a burden of miscellaneous impairments, iodine deficiency disorders (IDD), which reduce its capacity for productive work and development.

The collaboration of WHO, UNICEF, and ICCIDD (the International Council for Control of IDD) has achieved remarkable progress in reducing IDD during the 1990s. The major preventative measure is for governments of countries at risk to make iodisation of salt mandatory—and most of these countries have now done this, with particular success in South America. Where communities are isolated, away from the market economy the first line of prevention is to give all women of childbearing age 1 ml of iodised oil (rapeseed or poppy seed). In original trials this was injected but an oral capsule is nearly as effective and more convenient. UNICEF estimates that the number of children born with cretinism has been halved from the 1990 estimates of 120 000 worldwide. Doctors interested in activities towards IDD elimination can keep informed with the IDD Newsletter (obtainable free from the Editor, Dr J T Dunn, Box 800746, University of Virginia Medical Center, Charlottesville VA 22908, USA, email: jtd@virginia.edu).

Other types of malnutrition

Nutritional anaemia

The other WHO priority is nutritional anaemia. The commonest cause is iron deficiency, with folate deficiency second but well behind. Iron deficiency is probably the commonest of all nutritional deficiencies. WHO estimates more than 2 billion people—principally women and children—are iron deficient. It occurs in developed as well as developing countries and will be considered in the next chapter.

Iodine deficiency disorders (IDDs)

Endemic goitre—just visible goitre in at least 5% of adolescents
When nearly all mothers have endemic goitre 1%-5% of babies are born with one of two types of **cretinism**:

- *Nervous cretinism* mental deficiency
 deaf mutism
 spasticity
 ataxia, squint
 (features of hypothyroidism
 hard to find)
- *Myxoedematous cretinism* dwarfism
 signs of myxoedema
 mental deficiency
 (no goitre)

"Normal" people (not cretins) in goitrous districts, when compared with control communities have:

- higher incidence of deafness
 - slower reflexes
 - more pronounced features of hypothyroidism
 - poorer learning ability
-

Boys at an oasis in Egypt. Most have goitres¹⁸

Distribution of other types of malnutrition

- Anaemia—common world wide
 - Pellagra—seasonal in some developing countries in maize eaters
—florid form rare
 - Beriberi—occasional in infants in parts of South-East Asia
-

Pellagra

This is still seen in parts of Africa where people subsist on maize, in black people in rural areas of southern Africa, and in Egypt. Most of the niacin in maize is bound and not bioavailable. It is also poorer than other cereals in tryptophan, which can be partly converted to niacin in the liver. Clinical pellagra is seasonal and the florid form is no longer common anywhere in the world. Pellagra is also reported from Hyderabad, India, in people whose staple diet is sorghum. Sorghum eaters elsewhere in the world do not seem to be vulnerable. In Central America the staple food is maize (American corn), but pellagra is rare. This is because treating maize meal with lime ($\text{Ca}(\text{OH})_2$) water, a traditional preliminary step in making tortillas, makes the bound niacin in cereals bioavailable. In developed countries, maize meal is fortified with niacin (as in the United States) or maize has been largely replaced by wheat in the diet.

Beriberi

In adults beriberi has almost disappeared but infantile beriberi is still occasionally seen in some underdeveloped rural areas of South-East Asia.

9 Other nutritional deficiencies in affluent communities

Protein-energy malnutrition in Britain and other Western industrial countries is almost always secondary to disease—for example, it may be due to diseases of the gastrointestinal tract (persistent vomiting, dysphagia, upper intestinal obstruction, malabsorption) or wasting diseases (some cancers, HIV infection, metabolic disorders) or to radiotherapy. It is briefly described in chapter 17 (enteral and parenteral nutrition management to prevent or treat malnutrition in hospital). How to assess the degree of malnutrition is dealt with in chapter 12 (Measuring nutrition). For a background, famine and childhood protein malnutrition are described in chapter 8 (Malnutrition in developing countries).

In Britain vitamin D deficiency is still a public health issue, requiring preventive measures, though rickets is not common now. Its pathogenesis is discussed in chapter 10 (Vitamins). Among hospital patients in developed countries, however, the most common vitamin deficiency is probably folate deficiency, of which there is an account in chapter 10. The most serious nutritional deficiency in alcoholics is the complex of Wernicke's encephalopathy and Korsakoff's psychosis, which is summarised under thiamin in chapter 10. The following nutritional problems have not been discussed anywhere else in this book.

Iron deficiency

Iron deficiency is probably the commonest micronutrient deficiency in the world. Over 400 million women are estimated to have subnormal haemoglobins and over one billion people to have iron deficiency.¹ People in industrialised countries are affected as well as those in developing countries, especially women aged 15 to 50. In a survey in Vanuatu, however, most people with hypochromic anaemia were found to have normal plasma ferritin but, by DNA analysis, a unsuspectedly high prevalence of α -thalassaemias.² Hypochromic anaemias in other tropical countries cannot all be assumed to be due to iron deficiency unless biochemical studies of iron status are done. In Britain 33% of women had serum ferritin under $25 \mu\text{g/l}$, indicating low stores and 14% had very low ferritins (below $13 \mu\text{g/l}$). In the same survey only 4% of women had haemoglobins below 11g/dl .³ In British children serum ferritins are more likely to be low in youngest boys (13% were $<20 \mu\text{g/l}$) and in adolescent girls (27% were $15 \mu\text{g/l}$).⁴

Iron is the second most abundant metal in the earth's crust but it is virtually insoluble in the complexes of ferric iron usual in foods at neutral pH, and absorption is difficult. There is no physiological mechanism for secretion of iron so maintenance of iron homeostasis depends on its absorption. Normally in men, children, and postmenopausal women iron is lost only in desquamated surface cells from gut and skin at an estimated rate of 1 mg/day or less.

Blood is by far the richest tissue in iron; 1 ml contains 0.5 mg so that a regular loss of only 2 ml/day—for example, from epistaxis or haemorrhoids—doubles the iron requirements. Women of reproductive age lose an average of 30 ml blood per period, corresponding to 0.5 mg iron per day over the month, so they need more iron than men. An important minority of women lose considerably more.

Menstrual blood loss per period in 476 Swedish and 328 British women⁵

Iron content of some foods⁶ (mg/100 g) (in descending order of total iron per usual serving)

Food	Iron content
Cockles (boiled)	26.0*
Black pudding (blood sausage)	20.0*
Liver, cooked: ox – pig	7.8-17.0*
Beef, rump steak, grilled, lean	3.5*
Lamb, leg, roast, lean	2.7*
Oatmeal	3.8
Legumes, cooked: baked beans – tofu	1.4-3.5
Green leafy vegetables: lettuce – watercress	0.7-2.2
Wines, white or red	0.6-1.2*
Egg, boiled	1.9
Dried fruit: dates – figs	1.1-4.2
Fish: cod-anchovies	0.4-4.1*
Chicken, roast, meat	0.8*
Nuts: chestnuts – cashew	0.9-6.2
Chocolate, plain, dark	2.4
Potato, baked	0.7
Bread: white-wholemeal	1.6-2.7
Fresh fruit: apples – passion fruit	0.1-1.3
Milk, cows', whole	0.05

* Higher availability—haem and muscle iron or alcohol
Other foods with unusually high Fe content: curry powder (58 mg/100 g), All Bran (20 mg/100 g), wheat bran (13 mg/100 g), some other fortified breakfast cereals (13 mg/100 g), venison (8 mg/100 g), pigeon (15 mg/100 g), hare (11 mg/100 g), grouse (8 mg/100 g), hearts (5-8 mg/100 g), kidneys (5-8 mg/100 g)

These women, pregnant women, children growing fast, and anyone with chronic bleeding all need to absorb extra iron or they will use up what tissue stores they have.

Absorption of iron is inefficient. It averages roughly 10% from a mixed diet but is much less from many plant foods and from eggs and dairy foods. Haem iron is better absorbed than non-haem iron. Absorption of the latter is enhanced by animal flesh and by ascorbic and other organic acids (for example citric and lactic) and reduced by phytates and polyphenols (as in tea). Iron absorption is being studied by extrinsic labelling of foods with isotopes of iron (radio-iron was used earlier, but stable isotopes are now available and preferred). The different factors in foods combine algebraically to produce a high, medium, or low absorption from the meal. For example, tea reduces iron absorption from a meal but orange juice enhances it.

Iron is essential for haemoglobin formation. It is also part of myoglobin, of some enzymes required for neurotransmitter synthesis, and of an important enzyme in DNA synthesis. In deficiency, sometimes even before there is anaemia, adults have decreased capacity for heavy work, pregnant women have an increased risk of low birth weight or premature babies, and children do not concentrate or learn as well as they can after iron treatment.⁷

In people at risk of iron deficiency the haemoglobin (at least) should be checked, in:

- infants at the age of 1 year
- children and adolescents during phases of rapid growth
- through and after pregnancy
- after gastric surgery at least once a year
- women with heavy periods (direct questions may need to be asked)
- patients presenting with gastrointestinal symptoms or disease
- anyone with a history of recurrent bleeding, with a positive occult blood test, or a woman who is a frequent blood donor
- people (for example, with arthritis) taking aspirin or NSAIDs regularly.

Ferrous sulphate is standard **therapy** for iron deficiency. The traditional dose for anaemia has been three tablets per day (3 × 60 mg Fe) but gastrointestinal side effects are common, related to the dose of iron and can lead to poor compliance. Absorption of iron is enhanced when there is deficiency and it may be practical to prescribe a more modest dose of 60 mg iron (one tablet) per day (given between meals). Iron is as well absorbed from ferrous fumarate (60 mg/tablet) or gluconate, but the latter only contains 35 mg per tablet. There is no advantage to more complex and expensive tablets containing iron. In developing countries trials are underway in which iron tablets are given only weekly for mild to moderate chronic iron deficiency.

Prevention

A common cause of iron deficiency is that women, who require twice as much as men, consume only half as much. They often eat less liver, meat, and fish, the best sources of available iron. People who take no exercise or are on a weight reducing diet have such a low calorie intake that it is difficult for them to eat enough iron.⁸ Iron absorption is increased in deficient individuals but this may not be enough to compensate for low intake or increased losses. Staple foods are fortified with iron in some countries (for example, many breakfast cereals in Britain) and old fashioned iron cooking pots add some iron to the food.

Calcium and the bones

Calcium is the most obvious and persistent of the micronutrients, the fifth most abundant element (and the most

Too much iron?

- There is no homeostatic mechanism for disposing of excess iron; if too much is absorbed it accumulates in liver, heart and other organs. Chronic iron overload occurs in three situations. In **hereditary haemochromatosis** absorption is enhanced on an ordinary diet. One in 300 men of North West European descent are affected and fewer women, who have a mutation of the HFE gene, discovered in 1996. Patients with intractable anaemias, (for example, thalassaemia) **and repeated blood transfusions** receive excess iron parenterally, and people who regularly imbibe **alcohol beverages with high iron content** receive excess absorbable iron by mouth (for example, Bantu siderosis).
- Free iron can damage tissues by catalysing the conversion of hydrogen peroxide to the destructive hydroxyl free radical (OH[•]). This is why in the body iron (and copper) are almost always bound to carrier proteins or locked away in storage proteins.

	Normal	Iron depletion	Iron deficient erythropoiesis	Iron deficiency anaemia
Iron stores →	Full	Empty	Empty	Empty
Erythron iron →	High	Low	Low	Low
Reticuloendothelial marrow iron (0-6)	2-3	0-1	0	0
Transferrin iron building capacity (µg/dl)	330 ± 30	360	390	410
Plasma ferritin (µg/l)	100 ± 60	20	10	<10
Iron absorption	Normal	↑	↑	↑
Plasma iron (µg/dl)	115 ± 50	115	<60	<40
Transferrin saturation (%)	35 ± 15	30	<15	<10
Sideroblasts (%)	40-60	40-60	<10	<10
Red blood cell protoporphyrin (µg/dl/RBC)	30	30	100	200
Erythrocytes	Normal	Normal	Normal	Microcytic and hypochromic

Sequential changes in the development of iron deficiency⁵

ABC of Nutrition

abundant cation) in the body, yet it is more difficult to measure adequacy of intake for calcium than for other nutrients. There are two major questions about calcium.

- (1) Will a generous intake during childhood and adolescence contribute to taller adult height or heavier bones, or both? If so how much is needed?
- (2) Will a generous intake from about 45 years onwards delay the onset of osteoporosis, especially in women, who are more likely to be affected? If so how much is best and in what form?

Over 99% of body calcium is in the skeleton. Here it not only provides structural support but is a large reservoir for maintaining the plasma calcium concentration at very stable concentrations. Any reduction of absorbed calcium does not show in the plasma concentration, which is immediately reset by an increased parathyroid hormone concentration and the formation of active 1,25 dihydroxyvitamin D (in the kidney from 25 hydroxyvitamin D). Ionised calcium **in the plasma** has many vital functions—muscle contractility, neuromuscular irritability, blood coagulation, etc—which would be disturbed if its concentration fell. By different modulators the ionised calcium **inside cells** is also tightly controlled. An inadequate dietary calcium will therefore not normally be allowed to lower plasma or intracellular calcium concentrations and disturb their numerous important soft tissue functions; instead a little less will go into the bones in children or a little will be removed from the bones in adults.

Calcium in the bones amounts to 25 g at birth and builds up to about 1200 g in an adult. From the indices of growth and skeletal composition the amount of calcium which is being added to the bones each day in growing children can be calculated. It averages about 180 mg calcium per day but reaches 400 mg per day at the peak of adolescent linear growth. This amount is the required positive balance. Calcium absorption is inefficient—faecal calcium is about 70% of intake in adult calcium balances—and there is an obligatory loss of calcium in urine as well. The diet must therefore supply substantially more than the daily skeletal increment, and the recommended daily amount in Britain is 1000 mg in boys and 800 mg in girls aged 11-18 years. There is evidence that in some conditions a supplement of milk (the best source of calcium) has improved the growth rate of children. The great increase in the height of young Japanese adults from 1950 to 1970 coincided with a tripling of the national calcium intake from about the lowest in the world to 600 mg/day.

Yet it is hard to understand how poor children in developing countries on diets of cereals and vegetables and no milk obtain enough calcium to grow. Their final adult height is usually lower than in industrial countries, but osteoporosis in older people seems to be less of a problem. There are several possibilities to explain the more economical handling of calcium in people in countries where there is little or no milk.

- More skin synthesis of vitamin D from sunshine in the tropics.
- Regular weight-bearing exercise which promotes bone formation and muscle strength.
- Lower intake of animal protein (which is known to increase the obligatory urinary calcium).
- Lower intake of salt (which also increases urinary calcium loss).
- Genetic selection.

Osteoporosis

Osteoporosis is porosis of the bones. There are more holes in trabecular (inside) bone and thinning of cortical bone. The ratio of mineral (mostly CaPO_4) to organic matter (collagen

Estimated daily increment in skeletal calcium of children at various ages⁹

Age related changes in total skeletal weight of black and white people in the United States of America¹⁰

In 1927 a series of trials was carried out in Scotland in which about 1500 children in the ordinary elementary schools in the seven largest towns were given additional milk at school for a period of seven months. Periodic measurements of the children showed that the rate of growth in those getting the additional milk was about 20% greater than in those not getting additional milk. The increased rate of growth was accompanied by a noticeable improvement in health and vigour. This experiment was twice repeated by different observers who obtained substantially the same results on numbers up to 20 000 children.¹¹

and cells) is normal but the amount of total bone is reduced. In other words osteoporosis is atrophy of bones. It causes no symptoms unless/until there is the only complication—a fracture associated with inadequate trauma.

The commonest sites of osteoporotic fracture are:

- neck of femur (hip) fracture, the most serious
- vertebral collapse fracture(s)
- arm fracture—Colles' wrist fracture.

Osteoporosis cannot be recognised by clinical examination. It can be diagnosed with DEXA (dual x-ray absorptiometry) of a femoral neck and/or lumbar spine and/or a distal forearm. WHO defines osteoporosis as a bone mineral density less than 2.5 standard deviations below the mean for young adults (separate standards for women and men; for Caucasians and African Americans).

Osteoporosis is thus analogous to atherosclerosis. They are both important pathological states because they are precursors of common and serious clinical diseases, but they can only be recognised by special techniques (special imaging for osteoporosis, invasive for atherosclerosis). There are two main types of **primary** osteoporosis: postmenopausal and senile. **Secondary** osteoporosis is due to conditions such as long-term corticosteroid treatment. Bone density is also reduced by vitamin D deficiency (disproportionate loss of mineral) or infiltration by different types of cancer.

Dieting can be dangerous

Malnutrition can result from dietary regimens which happen to be very unbalanced nutritionally. Some of these were introduced by medical graduates, others are unscientific. The following are only a sample.

“Liquid protein” combined with fasting

In the United States of America in the late 1970s this diet led to at least 60 deaths from cardiac arrhythmias in people with no history of heart disease. The product “Prolinn”, an extract from beef hides, lacked several essential amino acids. It was withdrawn, but prolonged fasting with or without protein supplements (even those of good biological value) carries the risk of sudden fatal arrhythmias and has been criticised authoritatively.

Zen macrobiotic diets

These diets consist of 10 levels. The highest level is 100% cereals and prescribes a very low fluid intake. These diets have led to scurvy and/or impaired renal function, anaemia, hypocalcaemia, and emaciation. In some cases these have been fatal. These diets have been condemned by the American Medical Association.

Dr Atkins's diet revolution

This weight reducing diet in a popular paperback written in 1972 prescribed a minimal carbohydrate intake. Ketosis is inevitable; and the diet raises plasma lipid concentrations. It was condemned by the American Medical Association but the book can still be found on bookstalls, having sold millions of copies. It has been revived recently. This time it should be thoroughly tested for efficacy and safety.

Strict vegan diets for infants

Plant foods contain no vitamins B-12 or D. The latter can be synthesised in the skin if a child is exposed to sunlight, but the most serious nutritional complication of strict vegetarian diets is vitamin B-12 deficiency in infants. The milk of vegan mothers

Calcium and osteoporosis

- There have been several controlled trials of the effect in adolescent girls of extra milk or calcium tablets on bone density. Most reported small extra gains in the supplement group¹² but the trials were only of 1 or 1½ year's duration and it is not known whether the effects persist.
- In postmenopausal women 20 trials have been reported with calcium tablets or extra milk (usually 1000 mg Ca for two years) added to usual diet. In most of the trials bone density increased 1-3% (not always significantly) in the treated group.¹³ Presumably extra calcium has most benefit where the usual dietary calcium was low. The US Committee on Dietary Reference Intakes has set the dietary reference intake for people over 70 years at 1200 mg (30 mmol) Ca/day¹⁴ but in the UK a COMA subcommittee's re-examination did not consider there was evidence for increase of the dietary reference value of 700 mg/day.¹⁵
- A good calcium intake is part of preventing (delaying) osteoporosis, along with regular weight bearing exercise and vitamin D from sun or diet. For treating osteoporosis calcium is less effective than hormone replacement but should be prescribed alongside the latter.

Osteoporosis is only important because of these fractures. The most serious is hip fracture. Its pathogenesis is multifactorial. As well as low bone mineral density of the proximal femur, instability, muscle weakness and lack of adipose “padding” all contribute.¹⁶

Average bone density with age and fracture threshold

Articles which show the dangers of some diets

- *Zen macrobiotic diets*—AMA Council on Foods and Nutrition. *JAMA* 1971; **218**: 397-8.
- *Dr Atkins's diet revolution*—AMA Council on Foods and Nutrition. *JAMA* 1973; **224**: 1415-19.
- Vitamin B-12 deficiency in vegan infants—Wighton MC *et al.* *Med J Aust* 1979; **ii**: 1-3 (see next box).
- *Beverly Hills diet*—Mirkin GB, Shore RN. *JAMA* 1981; **246**: 2235-7.

contains insufficient vitamin B-12 unless she takes a supplement. This vitamin is required for normal myelin formation, and infants' nervous systems are specially susceptible to deficiency. They can show impaired mental development, involuntary movements, and even coma responsive to vitamin B-12, as well as megaloblastic anaemia.

The Beverley Hills diet

This weight reducing diet requires consumption of nothing but fruit (all in a certain order and only the designated fruits) for the first 10 days. Some bread, salad, and meat are added later. The theory behind this diet is unscientific, and it has been criticised in detail in the *Journal of the American Medical Association*.

Eating disorders¹⁷

Anorexia nervosa is an illness of our time, although it was first described and named in 1874. Many teenage girls and young women say they are dieting to stay or become slim but most are not very successful. They do not stick to their diets. The young woman with anorexia nervosa is unusual: without talking about dieting she succeeds in losing a lot of the weight that the others say they would like to. But then she cannot stop. By rigid control of her eating she avoids foods that she understands to be fattening (appetite is usually there, but suppressed). She has a phobia of being fat and a distorted body image, seeing herself fatter than she really is. Amenorrhoea is characteristic.

Up to one in 100 middle class women aged 15 to 25 may be affected. Before this loss of weight the young woman with anorexia nervosa was often a model of good behaviour, conformism, and achievement though this probably concealed a sense of ineffectiveness and self doubt.

Some women not only abstain: they have learnt to induce vomiting or purging and may have eating binges between. When habitual this behaviour is **bulimia nervosa**.

The physical effects of a young woman starving herself to 45 kg and below are similar to those described for famine in chapter 8. But there are differences. The anorectic patient usually eats adequate protein and micronutrients and is restless and overactive. There is skinniness or emaciation, cold extremities, lanugo hair, bradycardia, low blood pressure, and normal pubic and axillary hair. Plasma potassium concentrations may be low if there has been vomiting or purging, and plasma cholesterol or carotene values are sometimes raised. The amenorrhoea is similar to that which occurs in starvation.

Early diagnosis is important because a long illness, and severe weight loss are all bad prognostic features. The young woman denies she is too thin or that she is dieting. Amenorrhoea may appear to have preceded the weight loss. Other organic diseases that can lead to emaciation and amenorrhoea have to be excluded—for example, thyrotoxicosis, malabsorption, and hypopituitarism. But the bigger challenge for the family doctor is to detect the characteristic features of anorexia nervosa and to convince the young woman that she needs treatment.

Treatment is usually best managed by a specialised team, most often a psychiatrist with special experience in anorexia nervosa working with a dietitian. Moderate cases are treated as out patients. Admission to a special anorexia unit is indicated if weight loss is severe (BMI 16.5) or there is some medical or psychological complication. The two lines of treatment are to persuade her to increase food intake and to get her weight up to a target figure (usually a compromise) and at the same time

An exclusively breast fed infant of a vegan mother

“Neurological deterioration commenced between 3 and 6 months of age and progressed to a comatose premoribund state by the age of 9 months. Investigations revealed a mild nutritional vitamin B-12 deficiency in the mother and a very severe nutritional B-12 deficiency in the infant with severe megaloblastic anaemia. Treatment of the infant with vitamin B-12 resulted in a rapid clinical and haematological improvement but neurological recovery was incomplete ...”

By 17 months of age his general level of motor, social, and intellectual development was that of a child of 11 months.

Wighton *et al.*, 1979
(reference in previous box)

Criteria for diagnosis

Anorexia nervosa

- 1 Loss of weight to body mass index* under 17.5.
- 2 Disturbance of body image.
- 3 Refusal to maintain normal weight.
- 4 Intense fear of becoming fat.
- 5 Amenorrhoea.
- 6 No known medical illness leading to weight loss.

Bulimia

- 1 Recurrent episodes of binge eating, often secretive with rapid consumption of high calorie foods.
- 2 Binge followed by self-induced vomiting or purging.
- 3 Strict dieting between binges.
- 4 Body weight may be within the normal range.
- 5 Awareness of abnormal eating patterns and fear of not being able to stop voluntarily.
- 6 Not due to any physical disorder.

In practice intermediate and atypical forms are common

*Weight (kg)/height (m)²

Treatment in a special anorexia unit

to provide emotional support. Eating is tactfully supervised by nurses, and behavioural principles can be effective, more privileges for each step of weight gain, previously agreed by the patient. As she is refed and becomes physically stronger it becomes easier for the patient to tackle the changes needed so that she can adapt to society and develop a healthier body image.

Interactions of food, nutrition, and drugs

Particular drugs can affect the nutritional state, changing the results of biochemical tests or even leading on occasions to clinical undernutrition, overnutrition, or malnutrition.

Appetite may be decreased by anorectic drugs, bulking agents, dexamphetamine, metformin, cardiac glycosides, glucagon, morphine, phenylbutazone, indometacin, cyclophosphamide, fluorouracil, methylphenidate, salbutamol, levodopa, etc, and by drugs that alter taste (griseofulvin, penicillamine, and lincomycin).

Appetite may be increased by sulphonylureas, oral contraceptives, cyproheptadine, chlorpromazine, androgens, anabolic steroids, corticosteroids, insulin, lithium, amitriptyline, pizotifen, clomipramine, benzodiazepines, and metoclopramide.

Malabsorption for more than one nutrient may be induced by neomycin, kanamycin, paromomycin, colchicine, phenindione, chlortetracycline, cholestyramine, colestipol, cyclophosphamide, indometacin, liquid paraffin (fat soluble vitamins), methotrexate, and methyl dopa.

Energy metabolism may be stimulated by caffeine, smoking, and some sympathomimetic drugs.

Carbohydrates—Increased blood glucose concentrations may be produced by corticosteroids, thiazide diuretics, diazoxide, oral contraceptives, and phenytoin. Hypoglycaemia may be produced by propranolol and by alcohol (as well as by sulphonylureas, metformin and insulin).

Lipids—**Plasma total cholesterol** may be raised by thiazides (for example, chlorthalidone, hydrochlorothiazide), by phenobarbital, chlorpromazine, some oral contraceptives, and large intakes of boiled coffee. As well as specific cholesterol lowering drugs, aspirin, colchicine, prazosin, clonidine, neomycin, phenformin, and sulphapyrazone may lower total cholesterol. **Plasma high density lipoprotein cholesterol** may be raised by phenytoin, ethanol, cimetidine, valproate, carbamazepine, terbutaline, and prazosin. It may be lowered by danazol, propranolol, and oxprenolol.

Plasma triglycerides may be raised by propranolol, ethanol, and (oestrogenic) oral contraceptives. They may be lowered by norethisterone.

Protein—Nitrogen balance may be made negative by corticosteroids, vaccines, and tetracyclines. It may be made positive by insulin or anabolic steroids. **Plasma amino acids** may be increased by tranlycpromine and lowered by oral contraceptives. Plasma phenylalanine may be raised by trimethoprim and methotrexate.

Thiamin absorption can be reduced by ethanol.

Riboflavin status may be lowered by oral contraceptives and by chlorpromazine.

Niacin may be antagonised by isoniazid.

Vitamin B-6 may be antagonised by isoniazid, hydralazine, cycloserine, penicillamine, oral contraceptives, oestrogens, hydrocortisone, imipramine, levodopa, piperazine, and pyrazinamide.

In a 5-year follow up study Ben Tovim *et al.* found that 3/95 anorexia patients died and 20 had persistent anorexia nervosa. Prognosis was better for bulimia: none died and only 8% still had bulimia. Many patients made a good recovery without accessing specialised treatments. Those with lengthy admissions did not necessarily have better long term outcome.¹⁸

Nutrients, foods, and drugs can interact in several ways

- **Foods can affect drugs**, for example, by affecting absorption, an acute effect of single meals. Grapefruit juice inhibits one of the cytochrome P450s that metabolises drugs such as calcium-channel blockers, statins, carbamazepine, and terfenadine.¹⁹
 - **Nutrition can affect drugs**. The nutritional state can affect drug metabolism and hence dosage and toxicity, for example, in Kwashiorkor.
 - **Particular drugs can affect the nutritional state**. Appetite, absorption, metabolism, and concentration of nutrients can be affected, positively or negatively, by different drugs (see Left).
 - **Drugs can cause unpleasant reactions to minor components in some foods** whose metabolism we normally take for granted—for example, hypertension from tyramine in cheese in patients taking monoamine oxidase inhibitors.
 - **A few drugs are used as drinks**, as part of the usual diet: alcoholic drinks, coffee, tea, and carbonated cola beverages.
 - **Some nutrients are used as drugs**. The nutrients are all obtainable in pure form. They may, in doses above the nutrient requirement, sometimes have a useful pharmacological action—for example, nicotinic acid for hyperlipidaemia.
-

Should I take the medicine before or after meals, doctor?

- Most drugs are best taken with or just after meals, because this is the easiest way to remember to take any drug and some are gastric irritants. Absorption of several drugs is a little delayed but this is unimportant and a few are better absorbed when taken with meals—for example, griseofulvin, metoprolol, and labetalol.
 - Plenty of water should be taken with uricosurics (to prevent renal precipitation) and with cholestyramine and bulk formers like methyl cellulose.
 - A few drugs should be taken **half an hour before meals**: antibiotics which are labile in acid—ampicillin, benzylpenicillin, cloxacillin, erythromycin, lincomycin, tetracycline, rifampicin, and isoniazid. So should one of the antidiabetic agents—glipizide—and, of course, appetite suppressant drugs.
-

Folate may be antagonised by ethanol, phenytoin, oral contraceptives (uncommonly), cycloserine, triamterine, and cholestyramine. In addition several drugs owe their antibacterial action to antagonism of folate metabolism—more in microbial than mammalian cells—pyrimethamine, trimethoprim, and pentamidine. Methotrexate is a potent folate antagonist which has more effect on rapidly dividing cells—for example, cancer cells.

Vitamin B-12 absorption may be impaired by slow K, cimetidine, ranitidine, metformin, colchicine, trifluoperazine, and by high doses of vitamin C, cholestyramine, and methotrexate. Prolonged nitrous oxide anaesthesia oxidises vitamin B-12 *in vivo*. Smoking and oral contraceptives reduce the plasma concentration.

Vitamin C—Plasma concentrations are lowered by oral contraceptives, smoking, aspirin, and tetracycline. Ascorbate excretion is increased by corticosteroids, phenylbutazone and sulfinpyrazone.

Vitamin A plasma concentration is increased by oral contraceptives. Absorption may be reduced by liquid paraffin and cholestyramine.

Vitamin D status is lowered by anticonvulsants—for example, phenytoin, phenobarbitone, and when these are taken in high dose for long periods rickets can occur.

Vitamin E is antagonised by iron in premature newborns. Fish oils (refined) increase requirements.

Vitamin K—Coumarin drugs—for example warfarin—are antimetabolites. Purgatives and intestinal antibiotics, such as neomycin, tetracyclines, and sulphonamides, may remove the contribution from colonic bacteria. Salicylates and cholestyramine may reduce absorption, and some cephalosporin antibiotics antagonise the vitamin K-epoxide cycle.

Potassium—Drugs are important causes of potassium depletion: purgatives and laxatives increase faecal loss; thiazide diuretics and frusemide and ethacrynic acid increase renal loss. Other drugs that may increase urinary potassium are penicillin, glucocorticoids, liquorice, outdated tetracycline, gentamicin, and alcohol. Insulin can lower serum potassium. Drugs that raise serum potassium include ACE inhibitors, spironolactone, succinylcholine, triamterene, and potassium compounds.

Calcium—Absorption may be increased by aluminium hydroxide or by cholestyramine and decreased by phosphates and corticosteroids. Thiazide diuretics decrease urinary calcium excretion. Gentamicin, dactinomycin, frusemide, and ethacrynic acid increase it.

Iron—Gastrointestinal bleeding from aspirin and NSAIDs depletes the body's iron. Allopurinol, fructose, and ascorbic acid increase absorption. Antacids, phosphates, and tetracycline decrease it. Oral contraceptives tend to increase serum iron.

Iodine—Sulphonylureas, phenylbutazone, amiodorone, and lithium can cause goitre; they interfere with iodine uptake in the gland. Serum protein bound iodine is increased by oral contraceptives, x-ray contrast media, and potassium iodide, and decreased by phenytoin.

Phosphate absorption is decreased by aluminium or calcium compounds.

Zinc depletion from increased urinary excretion may be produced by thiazide diuretics and frusemide, by cisplatin, penicillamine, and alcohol.

Magnesium depletion from increased urinary loss may be produced by thiazides and frusemide, cisplatin, alcohol, aminoglycosides, amphotericin, ciclosporin, and gentamicin.

10 Vitamins and some minerals

No animal can live on a mixture of pure protein, fat and carbohydrate, and even when the necessary inorganic material is carefully supplied the animal still cannot flourish. The animal body is adjusted to live upon plant tissues or the tissues of other animals and these contain countless substances other than the proteins, carbohydrates and fats.

Sir Frederick Gowland Hopkins (1906)

Deficiencies of vitamins still occur in affluent countries: folate, thiamin, and vitamins D and C. Some of these deficiencies are induced by diseases or drugs. In developing countries deficiency diseases are more prevalent. Vitamin A deficiency (xerophthalmia), for example, is a major cause of blindness. Some vitamins may have useful actions above the dose that prevents classic deficiency disease—for example, vitamins A, C, and B-6; nicotinic acid has been used to treat hyperlipidaemia.

Vitamins have caught the popular imagination, and they are also big business. Many people take over the counter vitamins without medical advice and a few unorthodox practitioners prescribe “megavitamin therapy”. Doctors therefore need to know the symptoms of overdosage.

Definition

Vitamins are:

- (a) Organic substances or groups of related substances
- (b) found in some foods
- (c) substances with specific biochemical functions in the human body
- (d) not made in the body (or not in sufficient quantity)
- (e) required in **very small** amounts.

Many people seem to have lost sight of point (e), but it appears in all dictionary definitions and can be seen in the table of requirements. The daily requirement of most vitamins is around 1 mg, the weight of one grain of raw sugar. There are no exceptions to points (a), (b), and (e). On point (c), the biochemical action of most vitamins can now be visualised, but those of vitamins A and C are not yet explained fully, and the active metabolite of vitamin D acts as a hormone. Exceptions to point (d) are that certain carotenoids can replace vitamin A; proteins (through the amino acid, tryptophan) can replace niacin; and exposure to sunlight can replace vitamin D.

Vitamin A

Best understood of the actions of vitamin A is its role in night vision; 11-*cis* retinaldehyde is combined with a specific protein in the light-sensitive pigment, rhodopsin, in the rods of the retina. Night blindness occurs in children deficient in vitamin A in some developing countries, and in affluent countries it is seen rarely in patients with chronic biliary obstruction or malabsorption.

More recently discovered functions of vitamin A affect many different cell types. Retinol, carried in plasma on retinol binding protein, is taken up in cells by cellular retinol binding protein, oxidised to retinoic acid or 9-*cis* retinoic acid. These are transported to the nucleus where they are bound to specific receptors and initiate genetic transcription. In vitamin A deficiency there is metaplasia of conjunctival epithelium and

Daily requirements for healthy adults*

Vitamin A	1 mg
Thiamin	1 mg
Riboflavin	1.5 mg
Niacin	15-20 mg**
Vitamin B-6	1.5 mg
Pantothenic acid	5 mg
Biotin	30 µg
Folate	200 µg [†]
Vitamin B-12	1.5 µg
Vitamin C	40-60 mg
Vitamin D	5 µg [†]
Vitamin E	10 mg
Vitamin K	70 µg

*Based on DHSS 1991¹ and rounded

**Part replaceable by tryptophan in proteins

[†]Double this in pregnancy

‡More for growth: no dietary requirement if adequate exposure to sunlight

Recommended names for vitamins

Recommended name*	Alternative name	Usual pharmaceutical preparation
Vitamin A	Retinol	Retinol palmitate
Thiamin [†]	Vitamin B-1	Thiamine hydrochloride
Riboflavin	Vitamin B-2	Riboflavin
Niacin	Nicotinic acid and nicotinamide	Nicotinamide
Vitamin B-6	Pyridoxine	Pyridoxine hydrochloride
Pantothenic acid		Calcium pantothenate
Biotin		Biotin
Folate	Folacin	Folic acid
Vitamin B-12	Cobalamin	Hydroxocobalamin or Cyanocobalamin
Vitamin C	Ascorbic acid	Ascorbic acid
Vitamin D	Vitamins D ₂ and D ₃	(Ergo) calciferol
Vitamin E		α-Tocopheryl acetate
Vitamin K		Vitamin K ₁

Formation of retinol from β-carotene

ABC of Nutrition

loss of mucus production, leading to xerophthalmia (chapter 8). Other epithelia, for example, respiratory, are similarly affected and their resistance to infection is lowered.

Preformed vitamin A (retinol) is found in animal foods: liver is the richest source, but about a quarter of vitamin A intake in Britain comes from carotenes, yellow and orange pigments in the leaves of vegetables and in some fruits, chiefly β -carotene. One molecule of β -carotene can be cleaved by a specific intestinal enzyme into two molecules of vitamin A. But this conversion is not very efficient, 6 μg β -carotene is assumed to be equivalent to 1 μg retinol. Vitamin A is stored in the liver; stores are enough for one to two years in most British adults (see chapter 8). Retinol is transported from the liver to the rest of the body on retinol binding protein, part of the pre-albumin complex. Its concentration is normally held constant and does not reflect vitamin A intake except when this is very low or high.

[International units of vitamin A can be confusing if used for β -carotene and are best avoided, but some pharmaceuticals continue to use them. For retinol 1 IU = 0.3 μg retinol, so the UK reference nutrient intake for men is either 700 μg or 2333 IU.]

In supranutritional amounts vitamin A reduces both keratinisation of skin and sebum production. 13-*cis* retinoic acid (tretinoin) and its isomer isotretinoin, are used either topically in creams or orally in capsules, but oral retinoids are teratogenic and must not be prescribed for women in whom there is any possibility of pregnancy.

Because vitamin A is teratogenic there is no role for megadosage of this vitamin. Regular intakes should not exceed 3.3 mg in early pregnancy (4.5 times the UK reference nutrient intake of 0.7 mg). Liver contains 13–40 mg vitamin A per 100 g (depending on species), so women who are or might become pregnant are advised not to eat liver or products made from it. High doses of vitamin A are toxic to non-pregnant people and fatalities have occurred. Acute hypervitaminosis A causes raised intracranial pressure and skin desquamation. Chronic overdosage is more common and can occur after long term intakes of 10 times the nutritional requirement or more. Symptoms include headache, alopecia, dry itchy skin, hepatomegaly, bone and joint pains. A high plasma vitamin A confirms the diagnosis. High intakes of β -carotene, on the other hand, colour the plasma and skin (hypercarotenaemia) but are not dangerous.

Thiamin (vitamin B-1)

Thiamin plays a part in the metabolism of carbohydrates, alcohol, and branched chain amino acids. The body contains only 30 mg—30 times the daily nutrient requirement—and deficiency starts after about a month, on a thiamin free diet sooner than for any other vitamin. The requirements are proportional to the non-fat energy intake. The two principal deficiency diseases are beriberi and Wernicke–Korsakoff syndrome.

Beriberi is now rare in the countries where it was originally described—Japan, Indonesia, and Malaysia. In Western countries occasional cases are seen in alcoholics: clinical features are a high output cardiac failure with few electrocardiograph changes and a prompt response to thiamin treatment alone.

Wernicke–Korsakoff syndrome is usually seen in alcoholics: it can also occur in people who fast (such as hunger strikers) or who have persistent vomiting (as in hyperemesis gravidarum). Early recognition is important. The ophthalmoplegia and lowered consciousness respond to thiamin (50 mg intramuscularly) in two days, but if treatment is delayed the

Food sources of vitamin A

Preformed vitamin A (retinol)

Liver, fish, liver oils (very rich sources)
kidney, dairy produce
eggs, fortified margarine

β -carotene

Carrots, red palm oil
apricots, melon, pumpkin
dark green leafy vegetables
(spinach, broccoli, sprouts, etc)

In Britain the main sources in the diet are liver, margarine, butter and dairy products.

Carotenoids

600 colours of flowers, autumn leaves and birds, yellow to red, have chemically similar structure to β -carotene, with variations usually at the end rings. Of the three carotenoids in higher concentration in human plasma (reflecting dietary intake) only β -carotene is pro-vitamin A. The other two are lycopene, the red colour of tomatoes, which has antioxidant properties, and lutein/zeaxanthin (stereoisomers) which give the yellow colour to the macula lutea in the retina.

Food sources of thiamin

- whole wheat and wholemeal breads
- wheat germ (richest source) bran
- yeast, mycoprotein, nuts
- pork, bacon, Marmite
- fortified breakfast cereals
- oatmeal, potatoes, and peas

In Britain the main sources in the diet are bread and cereal products, potatoes, and meat.

memory may never recover. Red cell transketolase and the effect on it of thiamin pyrophosphate (TPP) *in vitro* are used to confirm thiamin deficiency, but fresh whole blood is needed and must, if it is to be meaningful, be taken before thiamin treatment is started. If thiamin deficiency is suspected treatment should be started without waiting for the laboratory result. Two days later there will either have been a clinical response and a positive laboratory report of high TPP effect (indicates deficiency) or the provisional diagnosis will not have been confirmed.

Patients on regular haemodialysis should routinely be given small supplements of thiamin and other water-soluble vitamins. Thiamin should also be given prophylactically to people with persistent vomiting or prolonged gastric aspiration and those who go on long fasts, as well as alcoholics. The toxicity of thiamin is very low, though occasional cases of anaphylaxis have been reported after intravenous injection.

Riboflavin (vitamin B-2)

Riboflavin, a yellow substance with green fluorescence in the coenzymes flavin mononucleotide (FMN) and flavin adenine dinucleotide (FAD), has vital roles in cellular oxidation. Its biochemical functions do not easily explain the clinical manifestations that have been recorded in volunteers on a riboflavin deficient diet: angular stomatitis, cheilosis, atrophic papillae on the tongue, nasolabial dyssebacea, and anaemia. There are no real body stores of riboflavin, but the liver contains enough (in coenzyme form) to withstand depletion for about three months.

Most of the features of riboflavin deficiency have more than one cause. Angular stomatitis, for example, may occur with deficiencies of niacin, pyridoxine, or iron; after herpes febrilis; or with ill fitting dentures. Clinical riboflavin deficiency is very uncommon in milk drinking countries like Britain. Pregnant women, people with thyrotoxicosis, and those taking chlorpromazine, imipramine, and amitriptyline have increased requirements. Riboflavin has to be included in total diets: infant formulas, fluids for total parenteral nutrition, and supplements for patients on dialysis.

Niacin

Niacin (nicotinamide and nicotinic acid) is the part of the coenzymes, nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP), that has to be supplied by the diet. In addition the amino acid, tryptophan has a minor metabolic pathway via kynurenine to nicotinamide; about $\frac{1}{60}$ of ingested tryptophan goes this way. Tryptophan makes up about 1% of dietary proteins, so 70 g protein a day provides about 12 mg niacin equivalents towards the total niacin requirement of 15-18 mg a day (for adults).

Pellagra, caused by niacin deficiency, is now rare except in areas, such as parts of Africa, where people subsist on maize and little else. In maize the niacin is in a bound form, biologically unavailable (except when cooked after pre-treatment with calcium hydroxide water, the traditional Central American way), and tryptophan is its limiting amino acid (unlike other cereals). Secondary pellagra may occur in patients with chronic renal failure on low protein diets or dialysis, if niacin is not included in the regimen. Another rare cause is Hartnup disease, a recessive inborn error of tryptophan absorption.

Above the nutrient dose nicotinic acid (not the amide) produces cutaneous flushing from histamine release at doses of 100 mg/day or more; it has been used for chilblains.

Wernicke–Korsakoff syndrome

In 1880 Wernicke first described an encephalopathy. Characteristic features are:

- stupor or apathy
- ophthalmoplegia (lateral or vertical)
- nystagmus
- ataxia.

With treatment most patients pass through a phase in which they show the memory disorder, first described by Korsakoff (1887), which consists of inability to retain new memories and confabulation.

The pathological findings in Wernicke's encephalopathy and Korsakoff's psychosis are similar: capillary haemorrhages in the mammillary bodies and round the aqueduct in the mid brain.

Wernicke's encephalopathy responds rapidly to thiamin but Korsakoff's psychosis responds slowly or not at all.

Food sources of riboflavin

- liver, kidney (richest sources)
- milk, yoghurt
- cheese, Marmite
- fortified cereals
- eggs, beef
- wheat bran
- mushrooms, wheat germ

In Britain the main sources in the diet are milk, meat, fortified breakfast cereals, and vegetables.

Food sources of niacin

- liver, kidneys (richest source)
- meat, poultry
- fish
- brewer's yeast, Marmite
- peanuts
- bran, pulses
- wholemeal wheat
- coffee

The above are foods with useful amounts of niacin. Protein-rich foods also provide niacin equivalents via their tryptophan content.

ABC of Nutrition

At doses of 3 g/day or more it inhibits lipolysis in adipose tissue and lowers plasma cholesterol and triglyceride concentrations. It has been one of the treatments for combined hyperlipidaemia—hypercholesterolaemia plus hypertriglyceridaemia. Patients often develop tolerance to the flushing. Its other side effects (in high dosage) include gastric irritation, hyperuricaemia, impaired glucose tolerance and liver function tests, and occasionally cholestatic jaundice.

Vitamin B-6

The term vitamin B-6 includes five closely related substances that all occur in foods and in the body: pyridoxal and pyridoxamine, their 5' phosphates, and pyridoxine, best known to doctors as the pharmaceutical form. Pyridoxal 5' phosphate is coenzyme for over 100 reactions in the body involving amino acids. Many foods contain moderate amounts. Primary dietary deficiency is rare. An outbreak of convulsions in infants in 1954 was traced to insufficient vitamin B-6 in milk formula because of a manufacturing error. Several drugs interfere with vitamin B-6: hydralazine, penicillamine, and possibly oestrogens. Peripheral neuropathy from high dose isoniazid is prevented with pyridoxine. There are several conditions for which pharmacological doses of 50 to 100 mg pyridoxine are probably beneficial. These include homocystinuria, hyperoxaluria, gyrate atrophy of the choroid, hypochromic sideroblastic anaemia, and radiation sickness. Some biochemical indices of vitamin B-6 state may be abnormal in women taking some oral contraceptives, but these are indirect indices. The more specific plasma pyridoxal phosphate concentration is usually normal. Premenstrual tension is a very variable condition: prescribed or self medication with pyridoxine has no physiological basis and has never been subjected to a convincing double-blind trial.

Above 100 mg/day pyridoxine in repeated dosage may cause severe sensory neuropathy.² All seven patients in the first report of this side effect were taking pyridoxine for an inadequate indication—mostly for premenstrual oedema—and most had increased the dosage on their own. Pyridoxine should not be available over the counter at tablet size above 50 mg (which is already 33 times the nutrient requirement).

Vitamin B-12

The red vitamin was the last to be isolated (1948). Humans eat it preformed in animal foods including fish and milk. It is synthesised by some micro-organisms—for example, in the rumen of cows and sheep (which require traces of cobalt in the pasture). No vegetable food has been shown to contain vitamin B-12 consistently unless it is contaminated—for example, by manure. Humans excrete in the faeces vitamin B-12 that has been synthesised by the colonic bacteria. Vitamin B-12 is the largest of the nutrients, with a molecular weight of about 1350. The physiological mechanism for its absorption requires intrinsic factor from the stomach, and the complex is absorbed only at a special site, in the terminal ileum. Deficiency occurs in several gastric, intestinal, and ileal diseases, including pernicious anaemia (gastric atrophy; no intrinsic factor), and in vegans (pure vegetarians). Adult body stores of vitamin B-12 in the liver last longer than those for any other vitamin, but deficiency occurs more quickly in infants. Vitamin B-12 cooperates with folate in DNA synthesis, so deficiency of either leads to megaloblastosis (anaemia and infertility). Vitamin B-12 has a separate biochemical role, unrelated to folate, in synthesising fatty acids in myelin,

Food sources of vitamin B-6

- wheat germ and bran
 - potatoes
 - nuts and seeds, peanut butter
 - meat, fatty fish, and offal
 - other fish
 - fortified breakfast cereals
 - banana, avocado, dried fruits
 - vegetables (especially raw), baked beans
 - milk
-

Food sources of vitamin B-12

- liver (richest source)
 - kidney
 - sardines, oysters
 - heart, rabbit
 - other meats, fish
 - eggs
 - cheese
 - milk
 - some fortified breakfast cereals
-

so deficiency can present with neurological symptoms. Deficiency is diagnosed by measuring the serum vitamin B-12 and/or the concentration of methylmalonate which requires vitamin B-12 for its metabolism.

Supplementation with hydroxocobalamin is desirable for adult vegans and essential for their young children. Several drugs, such as colchicine and metformin, and prolonged anaesthesia with nitrous oxide, can interfere with absorption of vitamin B-12. Hydroxocobalamin can improve some cases of optic neuritis, possibly by detoxifying accumulated cyanide. Apart from rare hypersensitivity reactions there are no known toxic effects from vitamin B-12. It thus makes an ideal placebo, which may still be the commonest reason for its prescription!

Folate

Folic acid (pteroylglutamic acid) is the primary vitamin from the chemical point of view, and this is the pharmaceutical form because of its stability. But it is rare in foods or in the body. Most folates are in the reduced form (tetrahydrofolate); they have one-carbon components attached to the pteroyl ring, and up to seven (instead of one) glutamic acid residues in a row at one end. Folate is the group name for all these compounds with vitamin activity. These folates have many essential roles in one-carbon transfers in the body, including one of the steps in DNA synthesis.

In folate deficiency there is first a reduction of serum folate below 3 ng/ml (7 nmol/l) and later megaloblastosis of blood cells and other cells with a rapid turnover because cells cannot double their DNA to enable nuclear division. As well as anaemia, diarrhoea is common when the deficiency results from antagonism (due to drugs) rather than dietary lack.

Folate deficiency may occur simply from a poor diet, but it is usually seen when there is malabsorption or increased requirements because of pregnancy (chapter 4) or increased cell proliferation (haemopoiesis, lymphoproliferative disorders) or antagonism from a number of drugs. Methotrexate, pyrimethamine, and co-trimoxazole act preferentially in cancer cells or micro-organisms by inhibiting the complete reduction of folate to the active form, tetrahydrofolate, preferentially in cancer cells or micro-organisms. Alcohol is the commonest antagonist.

Body stores of folate are not large and deficiency can develop quickly in patients on intensive therapy. In some cases this can be ascribed to intravenous alcohol or particular parenteral amino acid mixtures. Trauma, infection, uraemia, increased haemopoiesis, dialysis, vomiting, or diarrhoea may also be partly responsible. Folate deficiency appears to be the most common vitamin deficiency among adult hospital patients in countries such as Britain, so supplements should be prescribed whenever patients are fed intravenously for more than a few days.

The name comes from the Latin *folia* (= leaf), but liver, legumes, nuts, and even wholemeal bread are as good dietary sources as leafy vegetables. Prolonged boiling destroys much of the vitamin in hospital cabbage. No toxic effects are known from moderate doses up to 1000 µg/day; 200 µg folate/day is more than enough to prevent folate deficiency megaloblastic anaemia and had been accepted worldwide as the reference nutrient intake (or recommended dietary allowance). Two research developments in the late 1990s changed this concept. Firstly, maternal folate intakes at the start of pregnancy above this level have been shown to greatly reduce the risk of neural tube effects in the fetus (chapter 4). Secondly, extra folate can reduce raised plasma homocysteine levels which have been

Food sources of folate

- liver (especially chicken)
- fortified breakfast cereals
- wheat germ, bran, soya flour
- blackeye beans (boiled)
- Brussels sprouts, peanuts
- kidney, other nuts and seeds
- broccoli, lettuce, peas, etc
- wholemeal bread, eggs
- citrus fruits, blackberries, potatoes
- cheese
- beef

In Britain the foods that provide most folate are potatoes, fortified breakfast cereals, bread, and fresh vegetables and some from beer

This is folic acid with extra hydrogens at 5, 6, 7 and 8. Tetrahydrofolate (pteroyl glutamic acid) monoglutamate.

Folic acid (pteroyl glutamic acid) is the primary vitamin from the chemical point of view, and it is the pharmaceutical form because of its stability. But it is rare in foods and in the body. Most folates are in the reduced form, tetrahydrofolate (THF); they also have 1-carbon components (methyl or formyl) attached to nitrogen atom 5 or 10, or bridging between them (5,10-methylene-tetrahydrofolate). In addition, they have up to 7 glutamic acid residues in a row (at the right in the figure)

shown to be an independent risk factor for cardiovascular disease (chapter 1).

In the USA fortification of cereal foods with folic acid was made mandatory in 1998 and the recommended intake has been increased to 400 µg per day for men and women (600 µg in pregnancy).

Vitamin C

Ascorbic acid is the major dietary antioxidant in the aqueous phase of the body. The best established biochemical consequence of its deficiency is impaired reduction of the amino acid, proline to hydroxyproline. Hydroxyproline is an uncommon amino acid, except in collagen, of which it makes up an indispensable 12%. Impaired collagen formation is the biochemical basis of scurvy.

Small doses of vitamin C will cure scurvy. Lind achieved this with two oranges and a lemon in the first controlled trial on HMS *Salisbury* in 1747; 30 mg of vitamin C is more than enough to prevent scurvy. Desirable intakes of vitamin C can be thought of at three levels.

- (1) The official reference nutrient intake for adults—40 mg/day in Britain and 75 to 90 mg/day in the United States—is for healthy people. This is more than enough ascorbate to prevent scurvy.
- (2) In hospital patients this is not enough. Absorption of the vitamin may be reduced or its catabolism increased by disease. Trauma and surgery increase the need for vitamin C for collagen synthesis. Several drugs antagonise vitamin C: adrenal corticosteroids, aspirin, indometacin, phenylbutazone, and tetracycline, together with smoking. Hence it is advisable to give a supplement of up to 250 mg ascorbic acid a day to cover major surgery.
- (3) The third level is the great vitamin C debate: megadoses (up to 10 g/day) proposed by the late Linus Pauling for superhealth—or not? The best known claim for large intakes of vitamin C is that they prevent common colds. At least 31 controlled trials have been reported and in 23 of them (including the largest and best designed ones) there was no significant preventive effect. The eight supportive trials all had qualifications—for example, they were not double blind, had tiny groups, or showed an effect only in a subgroup.⁴

The present evolution of Pauling's hypothesis is that high intakes of ascorbate increase antioxidant capacity in the body and may help to prevent (or delay) degenerative diseases, such as cataract.⁵ High intakes of fruits and vegetables appear epidemiologically to reduce the risk of stomach cancer. The active protective factor might be vitamin C.

At megadosage the law of diminishing returns comes in. The small intestine has limited capacity to absorb ascorbate (so it should be eaten, or taken as tablets, tds). When blood levels increase, the vitamin is excreted in the urine. Careful pharmacokinetic experiments show that little further increase of plasma ascorbate can be achieved above intakes of 250 mg/day.⁶ At high intakes urinary excretion of oxalate (which is a metabolite of ascorbate) increases somewhat. Although oxalate is a common component of urinary tract stones, large epidemiological studies have not found more cases of stones in people who take vitamin C supplements.⁷ People with a history of nephrolithiasis should nevertheless avoid these supplements, so should patients with chronic renal failure whose plasma ascorbate can rise to levels above the normal range.

Vitamin C enhances the absorption of non-haem iron taken at the same time. This works with mixtures of foods or juices and is a benefit from generous intakes for 299/300 people.

Serum folate results 1994–1998 in a large clinical laboratory in California, USA

Year	Number of tests	Rate of serum folate testing*	Test results < 2.7 µg/l	Test results ≥ 20 µg/l	Median serum folate value µg/l
1994	14 493	7.3	183 (1.3)	3709 (25.6)	12.6
1995	14 750	6.7	186 (1.3)	3652 (24.8)	12.7
1996	17 642	7.5	223 (1.3)	4130 (23.4)	11.7
1997	22 805	8.9	134 (0.6)	7185 (34.3)	14.9
1998	26 662	10.2	89 (0.3)	12 990 (45.3)	18.7
Total	98 351	8.3	815 (0.8)	31 666 (32.9)	14.7

*Per 1000 members

Since mandatory fortification with folate in the USA (Jan 1998) and Canada (Nov 1998) serum folates have increased, homocysteines have declined and the incidence of neural tube defects is lower³

Food sources of vitamin C

- blackcurrants, guavas
- rosehip syrup, green peppers
- oranges, other citrus fruit, strawberries
- cauliflower, broccoli
- sprouts, cabbage, watercress
- potatoes
- (liver and milk)

In Britain the main sources of vitamin C are fruit juices, potatoes, and other vegetables.

But for the 1/300 people with homozygous haemochromatosis genes vitamin C supplements are contraindicated.

Vitamin C is easily destroyed by cooking (aggravated by alkaline conditions, for example, sodium bicarbonate), so fresh fruit and juices and salads should be encouraged and vegetables cooked lightly and quickly.

Vitamin D

Cholecalciferol is hydroxylated in the liver to 25-OHD₃, the plasma concentration of which is a good index of vitamin D status. In the kidney 25-OHD₃ is further hydroxylated either to 1,25(OH)₂D₃ (calcitriol) or to an inactive metabolite. Calcitriol functions as a hormone whose best known action is to stimulate the synthesis of a calcium transport protein in the epithelium of the small intestines.

The natural substance cholecalciferol was originally called vitamin D₃. Vitamin D₂ is the artificially produced ergocalciferol. The natural and usual source of cholecalciferol is by the action of short wavelength ultraviolet light from the sun on a companion of cholesterol in the skin, 7-dehydrocholesterol. Cholecalciferol also occurs in a small minority of our foods. When people live in high latitudes, wear clothes, and spend nearly all the time indoors and the sky is polluted with smoke they have insufficient exposure in the winter to ultraviolet light to make the required amount of this substance; under these conditions dietary intake becomes critical and cholecalciferol assumes the role of a vitamin.

In rickets and osteomalacia there is reduced calcification of growing and mature bones respectively. These diseases have been more prevalent in Britain than in other Western countries. They tend to affect adolescents and the elderly, especially Asians in northern cities. In Britons with normal levels plasma 25-OHD₃ concentrations show annual fluctuations, with their trough in late winter and their peak after the summer holidays. It is not clear whether the lower prevalence of rickets in Canada and Sweden is because milk is fortified with vitamin D or because people receive more ultraviolet radiation of their skin over the year in these other northern countries.

The small dietary contribution of vitamin D is lost in malabsorption and chronic biliary obstruction. Long term anticonvulsants, phenobarbitone, and phenytoin, increase metabolic losses. Vitamin D is indicated in these conditions. In chronic renal failure and hypoparathyroidism 1 α-hydroxylation to the active metabolite is impaired and renal bone disease responds only to 1,25(OH)₂D₃ (calcitriol) or 1α-OHD₃ (alfacalcidol), a synthetic derivative.

Irradiation of the skin may cause sunburn but does not lead to vitamin D toxicity. On the other hand, the margin of safety with oral vitamin D, between the nutrient requirements of up to 10 μg and toxic intakes, is narrow. Overdose with vitamin D causes hypercalcaemia, with thirst, anorexia, polyuria, and the risk of metastatic calcification. Some children have developed hypercalcaemia on vitamin D intakes only five times the recommended nutrient intake. More than this should not be taken except for rickets or osteomalacia. Here 25 to 100 μg vitamin D—for example, as ergocalciferol—is the usual therapeutic dose.

[One international unit (IU, obsolescent) of vitamin D = 0.025 μg of cholecalciferol or ergocalciferol—to convert IU to micrograms, divide by 40.]

Vitamin E

α-Tocopherol is the most active of eight very similar compounds with vitamin E activity. Being fat soluble, vitamin E

It may be difficult to remember which foods contain useful amounts of which vitamins but it's a good general rule that highly refined foods and drinks like fats, oils, sugar, cornflour, and alcoholic spirits contain little or no vitamins.

Food sources of vitamin D

- fish liver oils
- fatty fish (sardines, herring, mackerel, tuna, salmon, pilchards)
- margarine (fortified)
- infant milk formulas (fortified)
- eggs, liver

In Britain the main sources in the diet are margarines, fatty fish, dairy spreads, breakfast cereals, and eggs

ABC of Nutrition

is present in all cell membranes where, being an antioxidant, it is thought to reduce peroxidation of unsaturated fatty acids by free oxygen radicals.

The nutritional requirement for vitamin E is roughly proportional to the intake of polyunsaturated fat. Vitamin E is not easily transported across the placenta, and signs of deficiency, mild haemolytic anaemia, are sometimes found in premature infants.

The most severe cases of deficiency occur in patients with chronic fat malabsorption, especially fibrocystic disease of the pancreas and abetalipoproteinaemia. As well as mild anaemia, in these conditions ataxia, loss of tendon jerks, and pigmentary retinopathy have been reported, which respond to long term vitamin E treatment.

Many people take vitamin E supplements on their own initiative in large doses. Earlier it was rumoured to enhance virility (infertility had been the first reported effect of deficiency in rats) but double-blind trial did not confirm this. In the 1990s the focus is on whether vitamin E's antioxidant activity *in vitro* can reach sufficient concentrations inside the body to reduce atherogenesis. Two large cohort studies in the United States⁸ suggest that vitamin E supplements may reduce the risk of coronary heart disease, but a large 5-year randomised trial in Finland⁹ found no benefit from 50 mg α -tocopherol/day (about five times average dietary intake). Two other large preventive trials in Italy and another in Canada have likewise found no benefit with even larger doses. Although it is a fat-soluble vitamin, tocopherol has a low toxicity. Few adverse effects have been reported from doses up to 3200 mg/day and none were observed consistently.¹

Vitamin K

The Koagulations vitamin (Dam, 1935) comes in two chemical forms. Vitamin K₁ (phytylmenadione) is found mainly in vegetables. The K₂ vitamins (menaquinones) are a series produced by bacteria—for example, in the gut. Deficiency of vitamin K manifests itself as hypoprothrombinaemia and bleeding.

Cord blood levels of vitamin K are very low (evidently placental transfer is limited), and breast milk contains little of the vitamin unless the mother has been dosed with vitamin K. To prevent haemorrhagic disease of the newborn 1 mg of vitamin K₁ (by injection or by mouth) is given either to all infants or to those at increased risk (low birth weight or difficult delivery), depending on the hospital's policy. The single intramuscular injection of vitamin K₁ prevents both early and late vitamin K deficiency bleeding. In one British epidemiological study this injection at birth appeared to be associated with increased risk of childhood cancers. Subsequent studies in several countries have not confirmed this and in the United States there has been no increase of childhood cancer nationally since vitamin K injection at birth became common practice around 1961.¹⁰ Oral vitamin K prevents early but not late haemorrhagic disease. Doubts still linger¹¹ and doctors should follow locally agreed policy.

In adults vitamin K deficiency is to be expected in obstructive jaundice and can occur in malabsorption syndromes. Vitamin K₁ must be given before surgery for these conditions. Anticoagulants of the warfarin group owe their therapeutic action to antagonism of vitamin K, and vitamin K₁ is the antidote for overdose.

Vitamin K promotes the synthesis of an unusual amino acid, γ -carboxyglutamic (gla) a component of coagulation proteins II, VII, IX, and X. Another protein that contains gla and

Food sources of vitamin E

- vegetable oils—wheat germ oil the richest
- margarines, mayonnaise
- nuts and seeds

Small amounts in wholegrain cereals, eggs, butter, some vegetables, and some fruits.

-
- Four members of the vitamin E family are α -, β -, γ - and δ -tocopherol. These differ chemically in the number and position of methyl groups on the double ring at one end of the molecule. Biologically α -tocopherol is the most potent and β , γ , and δ are each in turn less active. The tocopherols are more active than the four *tocotrienols*, which have double bonds in the side chain; α -tocotrienol is the most biopotent, next β -tocotrienol.
 - The eight vitamin E compounds also show d- and l-stereoisomerism. Natural forms are d- (or RRR) and synthetic or dl- (or racemic). Both forms of α -tocopherol are available commercially. The most biologically active compound is the natural d- (or RRR) α -tocopherol, and vitamin E activity in foods or tissues is summed as d- (or RRR) α -tocopherol equivalents.
-

Food sources of vitamin K

- turnip greens
- broccoli
- cabbage, lettuce
- liver

These are all good sources, though there is no systematic list.

requires vitamin K for its synthesis is osteocalcin, involved in bone formation.

Vitamins that can usually be taken for granted (but are required in total parenteral nutrition)

Biotin is cofactor for several carboxylase enzymes concerned in fat synthesis and amino acid catabolism. It is widely distributed in foods, the requirement is small, and deficiency is rare.

Deficiency has occurred in people who eat large amounts of raw eggs (which contain a protein that binds biotin and prevents its absorption) and in patients receiving total parenteral nutrition with biotin omitted. They suffer scaly dermatitis, loss of hair, hypercholesterolaemia, and a characteristic combination of organic acids in the urine.

Panthenic acid is a constituent of coenzyme A which has many functions and is widespread in the body and in foods. The name means “available everywhere”. Spontaneous deficiency in man has never been proved. **Choline** is part of lecithin and of sphingomyelin, the two major phospholipids in the body, and it is also part of acetylcholine, the neurotransmitter. It is a dietary essential for the rat, but man seems to be able to synthesise it (partly from methionine) and does not have the active catabolising enzyme (choline oxidase) found in rat liver.

Multivitamins

The sensible purpose of multivitamin preparations is an insurance policy for people whose diet may be restricted or unbalanced but neither they nor their adviser is sure which vitamin may be lacking. There is a case for multivitamin supplements for people with low calorie intake because of poor appetite or a weight reducing diet or frailty, also for food faddists, the emotionally disturbed and socially disadvantaged people.¹² The dose of each vitamin should be near the nutritional requirement so a multivitamin cannot do harm, even if it does not do good. A doctor prescribing multivitamins or talking to patients who choose to take them should sometimes check the small print—as one should with an insurance policy. How many vitamins of the maximum 13, or the 11 described above are in the ingredient list? Do they contain folic acid? Multivitamin preparations have no lucrative patents, so drug companies are not very interested in keeping them up to date; reformulating is expensive. They are also rather neglected by medicine committees and by dietitians.

Some minerals

At least 13 inorganic elements *per se* are known to be essential for man (the same as the number of vitamins) while others are needed in compounds (P, S, Cl, Co). All must be provided for long term total parenteral nutrition and ensured in infant formulas. Of the nutritionally important inorganic elements, sodium and potassium are discussed in chapter 2, fluoride in chapter 3, iodine in chapter 8, calcium and iron in chapter 9. Zinc and selenium are sometimes taken as supplements and deserve mention here.

Zinc

This metal is cofactor for over 100 enzymes (including superoxide dismutase) and “zinc fingers” are part of a number

Not vitamins

The following compounds sold in “health food” shops and still included in some multivitamin pharmaceuticals are not vitamins. They are not required in infant formulas or in fluids for total parenteral nutrition:

- Bioflavonoids
 - Inositol
 - Orotic acid
 - Aminobenzoic acid (PABA)
 - Vitamin B-15 (“pangamic acid”)
 - Vitamin B-17 (laetrile)
 - Vitamin P
-

of important transcription factors for DNA. Tissue concentrations of zinc are highest in the choroid of the eye, the prostate and in semen.

The first recognised human deficiency disease (1963) was adolescent growth retardation and hypogonadism in rural Iran; absorption of the small zinc intake in their mainly vegetable diet was hindered by phytate in unleavened bread. The most florid clinical features of zinc deficiency—moist facial eczema, depression, hair loss and diarrhoea have been seen with total parenteral nutrition that omitted zinc and in acrodermatitis enteropathica, a rare inborn error of zinc absorption. Zinc is predominantly intracellular and serum zinc is not a reliable indicator of deficiency. Randomised controlled trials have demonstrated benefit from zinc supplements in children in developing countries with acute diarrhoea,¹³ pneumonia, and stunting.¹⁴ Universal zinc supplements will not, however, improve the growth of stunted children except where zinc is the primary growth-limiting nutrient. Reports of benefit in cases of the common cold in industrial countries were not confirmed. The best dietary sources of zinc are meat, fish, cheese, and whole grain cereals (though absorption is reduced by phytate).

Selenium

Selenium compounds have long been known to be toxic. The content of this trace element in foods varies greatly, depending on the amount in the soil. Since the 1950s selenium deficiency in animals has been known to cause muscular dystrophy in sheep and liver necrosis in rats. Human deficiency has caused juvenile cardiomyopathy in Keshan, China (1979). In the body selenium replaces sulphur in selenomethionine and selenocysteine. It is part of glutathione peroxidase (antioxidant) and an enzyme that converts thyroxine to triiodothyronine. Blood selenium reflects intake and nutritional status and so does the Se content of toenails. Intakes have been moderately low in Finland and in South Island, New Zealand. Finland corrected this by fortifying fertilisers used for wheat fields with selenium from 1994. In New Zealand extensive research has been done at Otago University on selenium nutrition and metabolism. No clear human condition has been attributable to the local selenium level. Meanwhile intakes there are rising a little with more foods coming in from Australia. But in Britain selenium intakes have been declining¹⁵ due to less wheat coming in from North America (high Se) and more from the continent of Europe (lower Se). Occasional cases of muscular disease have been reported in patients maintained long term on total parenteral nutrition if selenium was not included. A large randomised

controlled trial with selenium in people with early skin cancer for five years, in low selenium areas in the south east United States of America showed an unexpected significantly reduced incidence of prostate cancer.¹⁶

11 Overweight and obesity

Obesity is an increasing problem

Obesity is rising to alarming levels around the world.¹ In England during the 15 years 1980 to 1995 some important health statistics improved and life expectancy lengthened by three years. But the numbers of obese men (16-64 years) increased from 6% to 15% and obese women from 8% to 16.5%. Obesity is one of only four of the 25 targeted statistics in the Health of the Nation strategy that has moved in the wrong direction. Similar trends of increasing obesity have occurred in almost all industrialised countries and in the prosperous class in developing countries.

There have been recent advances in our understanding of genetics, endocrinology and metabolism related to adiposity. However treatment options have not kept pace; fenfluramine and dexfenfluramine, sadly, in 1997 joined the list of disappointing and/or potentially dangerous treatments for obesity.¹ Resources for the management of obesity—dietetic, pharmaceutical, and surgical—have been likened to treatment options for hypertension 40 years ago.³

Why is there an epidemic of increasing obesity?

Although the external influences and internal processes are both very complex the ultimate causes of obesity are under-exercising and/or over-eating: energy intake > energy expenditure. But the development of obesity, via overweight is usually so slow and insidious that people hardly notice it is happening. The body's homeostatic energy regulation is better able to defend against insufficient food than against a little more food, a little less energy expenditure (see box opposite).

Possible reasons for over-eating these days:

- cheaper foods (relative to incomes)
- more varied foods; supermarkets
- advertising and promotion of foods
- more eating outside the home (pubs, ethnic restaurants, fast food chains, etc)
- more fatty food; more snack foods
- over-eating because of anxiety (for example, work stress) or depression (for example, unemployment)
- grazing and irregular meal times
- fewer people now smoke (smoking suppresses appetite)

Possible reasons for under-exercising these days:

- more labour-saving machinery at work and at home (fork-lift trucks, power tools, washing machines, even automatic doors and lifts)
- television (couch potatoes)
- personal computers ("mouse potatoes") and email
- more cars; less walking and cycling
- less open space for recreation
- fear of violence in the streets
- central heating might also reduce energy expenditure

Prentice and Jebb⁴ considered the case for Britain. The continuing series of food consumption data in households shows a reduction in average total energy intake per head since 1980. But this is food disappearance data (not food actually eaten) and does not include food eaten outside the home. The National Food Surveys, year by year, also show that consumption of fat (the most concentrated food energy) has

Prevalence of obesity in the UK and the Netherlands 1987-1995²

Energy balance

1 kg body weight gained has energy of approx 7000 kcal

10 kg weight gain over 5 years = $\frac{70000}{5 \times 365} = 38$ kcal/day

This is a daily error of energy balance of +1.5%

ABC of Nutrition

declined slightly since 1980. The evidence for reduced energy expenditure is more persuasive, though based on indirect indices. Car ownership and television viewing were strikingly related to the prevalence of obesity whether plotted against year or against socioeconomic status.

Facing moderate obesity

It is easy to diagnose moderate and gross obesity before the patient undresses. The difficulty with these patients is to organise the time and summon up the enthusiasm to embark on management which will be lengthy and may be unsuccessful. While our profession can transplant a human heart, manage *in vitro* fertilisation, and eliminate smallpox, to manage obesity is a challenge for a conscientious practitioner. A health service, like the British NHS, which provides an annual fee per patient is a suitable framework.

Obesity is different from most other diseases. If the general practitioner feels they are not the best person to look after a patient's haemorrhoids or backache or poor vision there is usually a specialist at the nearest big hospital who has the skills and equipment and will be happy to manage this part of the patient. But there is unlikely to be a consultant with special skills or equipment for looking after obesity. Obesity is a continuum and all but the most complicated or severe cases would not be welcome in the district hospital.

Many obese patients are referred to dietitians but there are too many obese people for the number of dietitians in Britain, and hospital staff are not well placed for looking after obese "outpatients"—that is, people who live at home and have to go out to work each weekday.

To put in the hard work of treating the obese people on the practice's list reduces the likelihood of having to treat them later for complications of obesity. The best conditions for managing obesity are:

- regular visits, at least once a fortnight
- weighing the patient under the same conditions on the same scale
- about quarter of an hour's talk with the same practitioner each visit
- opportunity to bring wife, or husband
- the therapist is not obese.

Complications of obesity

Most of the medical complications of obesity are well known. Risks of cardiovascular complications and diabetes are greater in people with abdominal obesity. This can be assessed clinically by measuring waist circumference. In men the normal measurement is up to 94 cm and metabolic complications are substantially increased at above 102 cm. The corresponding waist circumferences in women are: healthy <80 cm, increased risk 80-88 cm, substantially increased risk 88 cm.⁵ Considerable weight gain in a short time carries greater risks than reaching the same weight slowly.⁶

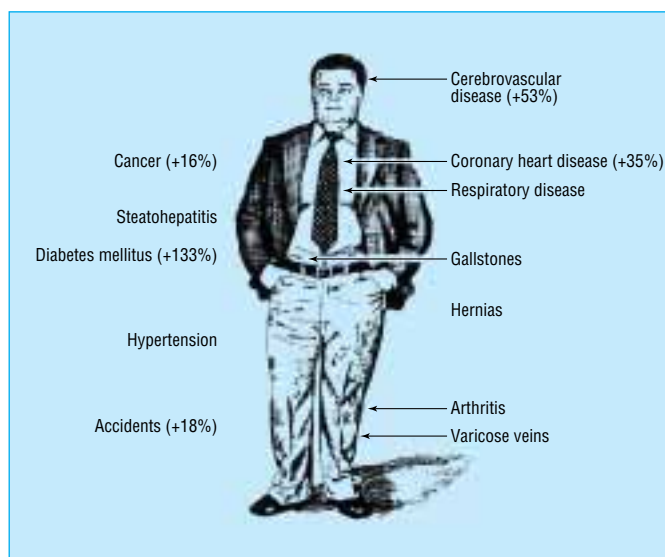

The social complications are more immediate and may be very painful. Religious, racial, and gender prejudice are now unacceptable in mainstream Western societies, as is prejudice against the disabled. But prejudice against fat people is undisguised. It starts at school, affects the job opportunities and social status of obese people—and it is so pervasive that it probably colours many doctors' attitudes towards their obviously obese patients.

Make less thy body hence, and more thy grace;
Leave gormandising; know the grave doth gape
For thee thrice wider than for other men.

Shakespeare, *King Henry IV* Part II, V, v.

Secular trends in diet (left) and activity (right) in relation to obesity in Britain. (Adapted from Prentice and Jebb⁴)

Obesity increases the risk of mortality from some of these diseases (notably diabetes) more than others

Substances secreted by adipose tissue⁷

Adipose tissue liberates free fatty acids and glycerol under the stimulus of catecholamines on lipase. When it loses fat in this way some of the stored cholesterol and accumulated non-polar foreign substances, for example DDT, also go into the circulation.

Since the discovery (1994) of **leptin**—the chemical signal to the brain of the amount of adipose tissue—it is realised that adipocytes are more than simple fat stores. They also secrete:

- tumour necrosis factor α , TNF α
- interleukin 6, IL6
- resistin
- angiotensinogen
- adipsin (complement factor D)
- tissue factor (initiator of coagulation)
- adiponectin
- aromatase, etc

TNF α , IL6 and resistin appear to increase insulin resistance,⁸ the extra angiotensinogen makes hypertension more likely and aromatase converts androstenedione to the oestrogen estrone.

Recognising mild obesity/overweight

By contrast, for overweight or mild obesity diagnosis and recognition are where the management goes wrong. Yet there are several people with mild obesity for every case of obvious obesity in a practice. Mild obesity is much easier to treat, and prevention of gross obesity is much easier than cure.

People with mild obesity do not usually come to their practitioner complaining that they are too fat. The adiposity has been slowly creeping up on them and does not cause pain, distress, or fear. They come to the doctor with any other symptom and disease.

Patients may become mildly obese under their doctor's eyes, during the course of an illness which the practitioner is following and concentrating on: bed rest after myocardial infarction; giving up smoking; pregnancy and lactation; anxiety or depression from stress at work or at home. Recognition of overweight can be more difficult too in a patient in bed.

Measuring obesity

It is part of good practice to have a system so that all patients on the list are weighed at regular intervals by the receptionist or nurse. The weight is entered on the record. Knowing the patient's height (without shoes) the doctor can then decide whether he or she is: underweight, in the normal range, overweight, or obese. Comparison with previous weights shows if the patient is putting on weight.

Weight measurements are objective. To show the patient his or her weight against the standards for his or her height is impressive and, if outside the normal range, the basis for action. Obesity is an excess of adipose tissue. There are two methods for deciding whether someone is too fat. One is **social** or according to fashion. The doctor's role here is to advise patients not to make themselves too thin, not to take unphysiological diets or drugs to lose weight unnecessarily, and not to start on the road to anorexia nervosa.

The other method for deciding whether someone is too fat (or too thin) is **actuarial**. Above (or below) a range of weights for a given height the risk of developing illness or of mortality increases. Weight/height^2 (in kg/m^2) is a convenient index of relative weight. It gives a single number and is almost independent of height. This is the body mass index (BMI) or Quetelet's index. Note that smoking carries a higher risk of mortality than overweight or the milder degrees of obesity.

The lower and upper ends of the acceptable range here are close to, respectively, the lowest weight for small frame and highest weight for large frame for men in the earlier "desirable weights" of the Metropolitan Life Insurance Company of New York (1959).

The unisex table on page 72 was introduced in the early 1980s. It is simpler than older standards. They had somewhat lower cut off points for women than men, but the numbers of women taking out life insurance were probably inadequate. Modern prospective data show no significant differences between men and women.

BMI cut offs in different ethnic groups

The range 18.5 to 24.9 may not be optimal for the whole world. Somewhat higher ranges probably suit Polynesians who tend to have more muscle, less fat. Somewhat lower ranges are probably optimal for south Asians who have insulin resistance at lower BMIs than Caucasians.¹⁰

Have you got a minute doctor to sign this for me?

Measuring the patient

- Beam and lever scales are more reliable but take more space and are slower to use.
- For screening it is a good idea to have a lever scale in the reception area and for the receptionist or nurse to weigh the patient with shoes and coat removed.
- Obese patients being treated can be weighed (ideally in their underclothes) at each visit by the doctor in his consulting room on the same platform scale with a quick reading dial.
- The patient's height can be measured with a rule or tape measure attached to a flat wall and recorded in the notes. Heights are lower in the evening than in the morning. If the patient has any weakness or deformity an assistant is needed to get them as straight as possible for the measurement.

Variations in mortality by weight among 750 000 men and women.⁹ Cut off for obesity starts at BMI of 30

Obesity is taken in this table as generally starting at a BMI of 30 kg/m², which is 20% above the upper end of the acceptable range of weights for height. Between the top of acceptable weight and start of obesity is “overweight”, which is the BMI range 25-29.9. The column at the far right shows weights for BMI of 40 kg/m², the start of “gross obesity”. Adiposity is thus graded; this grading is needed for deciding management, and reflects prognosis.

The cut off values in the table have to be read from the viewpoint of the individual patient, like normal ranges for laboratory tests. People with gracile bones should weigh less than heavy boned people. Unusual muscle development (as in weight lifters) and oedema increase body weight. The waist circumference or waist/hip ratio should also be included in the assessment.

In children there are no actuarial data on which to base cut off weights for obesity. However, the upper percentiles of BMI references for British boys and girls by Cole *et al.*¹¹ can be used. These are based on a total sample of 30 500 children and adolescents (also see chapter 6, page 24).

Causes

Obesity **secondary** to hypothalamic conditions that increase appetite is rare, and to endocrine disorders uncommon.

Obesity may follow (a) enforced inactivity such as bed rest, arthritis, stroke, change to a less active job, sports injury, or (b) over-eating associated with psychological disturbances, for example, depression or anxiety, or some drugs that increase the appetite. Pregnancy and stopping smoking contribute to overweight.

Drugs that can increase appetite and promote weight gain

Corticosteroids, anabolic agents, some oral contraceptives, sulphonylureas, cyproheptidine, amitriptyline, clomipramine, lithium, pizotifen, metoclopramide, clozapine, olanzapine, some benzodiazepines

The genetic influence on obesity was clearly shown in a study using the Danish Adoption Register. A strong relation existed between the weight class of the adoptees (thin, acceptable, overweight, or obese) and the body mass index of their **biological**, but not their adoptive, parents. In twins body mass index is more strongly correlated between monozygotic than dizygotic twins, even when they are reared apart.¹²

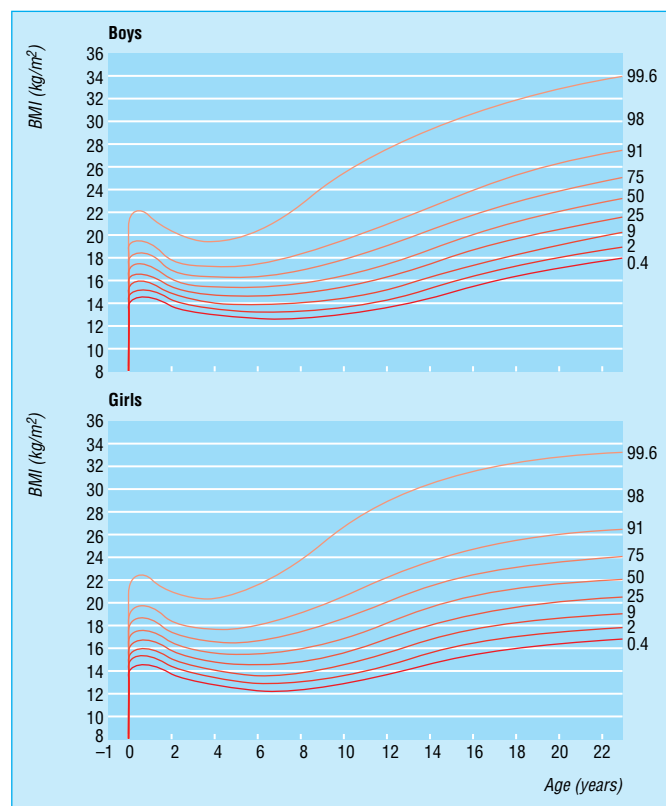

Wide searches are going on to see if mutations of candidate genes for peptides and receptors involved in energy regulation are associated with obesity. Mutations of MC4R the melanocortin receptor, of β_1 , β_2 and β_3 adrenoreceptors, of the leptin receptor and of leptin have been found associated with obesity. All are very rare except the MC4R mutation which is uncommon. In the great majority of obese people the weight gain is polygenic.

In most people obesity is **primary**. There is no obvious predisposing condition. If the patient says (s)he eats little: (1) the weight gain may have been in the past (2) some people undoubtedly need less food than others apparently comparable; they are efficient metabolisers with a low basal metabolic rate (but normal thyroid) and may feel the cold sooner than others, (3) repeated periods on low calorie diets, weight cycling, may lead to further adaptive lowering of the basal metabolic rate.

In surveys, obese people have often reported that they do not eat more than thin people. But the doubly labelled water technique (that measures rates of disappearance of the stable

Guidelines for body weight in adults

Height (without shoes) ft, in (m)	Weight (kg) (minimal clothes)

BMI reference curves for boys and girls: 1990. Figures on right indicate percentiles (Adapted from Cole *et al.*¹¹)

isotopes, ^2H and ^{18}O) showed that the energy expenditure of a group of obese people was higher than their self-recorded food energy intakes. In other words, obese people tend to **under-report** their food intake.¹³

Regulation of energy balance

Many outside influences and numerous complex biological mechanisms inside the body affect energy balance. No diagram or model can adequately describe how most people's energy metabolism and fat stores are unconsciously regulated with little or no cumulative error. The system can be visualised at four levels: cerebral cortex, satiety, control centres in the hypothalamus, and thermogenesis.

Cerebral cortex

Eating behaviour is initiated by cultural and psychological influences: meal times, habitual diet, olfactory and visual stimuli, perception of appetite, social norms, foods available, personal relationships, etc.

*Satiety*¹⁴

Signals to stop eating come from distension and from chemical stimuli in the stomach and upper small intestine. These send afferent impulses via the vagus and cause secretion of gut hormones, for example cholecystokinin (CCK) is the most potent. Satiety signals go to the tractus solitarius nucleus in the brain stem, which has connections to the hypothalamus. Serotonergic receptors are involved in the brain.

*Thermogenesis*¹⁷

Animals that hibernate or adapt to cold have brown fat in which (unlike white fat) noradrenaline stimulates uncoupling of energy flow in the mitochondria, with production of heat instead of ATP. After infancy humans possess little or no distinct area of brown fat but are capable of some thermogenesis (increased metabolic rate)—on exposure to cold and with overfeeding. There appear to be varying numbers of brown adipose cells dispersed in white fat depots. The agent that catalyses the proton leak in these cells is Uncoupling Protein 1 (UCP1) which is triggered by β_3 adrenergic receptors and influenced by thyroid hormone. Two other uncoupling proteins UCP2 and UCP3 have been recently discovered in humans.

It is not possible to conjure a unifying theory which will explain why some people become fat while others remain lean. This is too much to expect; economists have no simple explanation for the commercial success or failure of businesses or nations, and the energy economy of a human being is subject to as many influences as any financial economic model.¹⁸

Management

There are three phases in the management.

- First is for the obese patient to reach an agreement with the health professional about what they believe they can achieve.
- Second is the difficult phase of the patient modifying eating and exercise habits to lose this much weight.
- Third is the longer and sometimes more difficult phase of the patient maintaining the new lower weight.

First: agreeing on the objective

To reduce weight to the acceptable range is a reasonable aim that should be achievable for someone who is in the overweight category (BMI 25-30, or grade 1 obesity). With this grade of adiposity the weight loss required is only about 10 kg (22 lb).

Control centres in the hypothalamus¹⁵

Circulating leptin conveys information about the size and fluctuation of the adipose tissue stores to receptors in the hypothalamus. There are also receptors there for insulin. If leptin or insulin is injected directly into the brain it reduces food intake: deficiency of either hormone increases intake. Decreased leptin (reduced energy stores) activates neurones in the arcuate nucleus that express two neuropeptides that increase appetite: **neuropeptide Y (NPY)** and **agouti-related protein (AGRP)**. Increased leptin inhibits these neurones and instead activates neurones that express **melanocortin**, which suppresses appetite. These different neuropeptides act on specific receptors in the paraventricular nucleus, notably Y1 and Y5 for NPY and MC4 for melanocortin. (Drugs that could block NPY receptors are already being studied.)

Ghrelin is a newly discovered peptide secreted by the stomach during fasting.¹⁶ It acts on the hypothalamus to stimulate the neurones that express NPY and AGRP.

“Obesity cannot be prevented or managed solely at the individual level. Communities, governments, the media and the food industry need to work together to modify the environment so that it is less conducive to weight gain. Such partnerships are required to ensure that effective and sustainable changes in diet and everyday levels of physical activity can be achieved throughout the community.”¹⁹

Three phases in management of obesity

- Agreement on what can be achieved
 - Modification of eating and exercise habits
 - Maintenance of new lower weight
-

But for someone considerably obese, BMI 35 or more, we know that most people cannot manage, with present resources, to reduce their food intake and increase their exercise sufficiently for long enough to bring their weight down all the way to the acceptable range. For someone with a BMI of 35 and a height of 175 cm this means taking off 31 kg (68 lb). It is better to set a **more realistic, intermediate goal** (which could always be extended later). A weight loss of 10 kg brings with it real health benefits.

For any overweight or obese patient the medical adviser can at least hope to help them to **hold their weight stable** and not let it creep up further. To achieve this may involve discovering why the patient has been putting on weight and discussing how these conditions can be modified.

Because there are now so many people in any general practice with overweight and obesity and these increase risks for many degenerative diseases, it is important work for the doctor (1) to recognise overweight and give early warning, and (2) in patients with obesity to take a structured therapeutic role.²⁰ For patients with type 2 diabetes (especially), hypertension, coronary disease, hernias, etc, action to reduce weight is not just preventive medicine, it is a central part of the treatment. The Nutrition Task Force and the Physical Activity Task Force of the UK Health of the Nation strategy proposed that prevention of obesity rather than its treatment should be a national priority.

Second: reducing weight

Two main treatments are indispensable: eating less dietary energy and increasing energy expenditure. Both are needed; they are synergistic. The cupboard of drugs for obesity is rather bare at present, and surgery—perhaps gastric stapling—should only be considered for the very fat minority.

You can lose weight only by achieving a cumulative negative energy balance. Calories in must be less than calories expended. An average loss of 2000 kJ (500 kcal) per day—14 000 kJ (3500 kcal) over a week—is equivalent to a loss of about 0.5 kg (1 lb) per week or more at the start, when water is lost.

The new way of eating

- Try to avoid the word “diet” that has discouraging overtones and suggests temporary hardship rather than a lifestyle that can last. Habits are more important than diets.
- It does not matter what you eat as long as it is less. This may sound irresponsible and obviously could not be taken to extremes (but there is sometimes too much technical detail in weight-loss programmes and malnutrition is a very rare complication).
- Eat smaller portions of what you usually eat, no second helpings, no snacks between meals.
- Have three regular meals each day. It is more difficult to control one’s weight when meal occasions are irregular.
- Eat more low energy (calorie) foods—salads, fruits, vegetables, low fat milk, and yoghurt (left side of “energy values of foods” table on page 75).
- Avoid or ration energy (calorie)-dense foods with a high fat content—and fats in some foods are invisible; cakes, biscuits, cheese, chocolate, nuts, potato crisps, standard meats, chicken skin, and of course fried foods.
- The household should be involved and supportive. Husband and wife or partners should share in discussions with the doctor and dietitian.

Likely benefits of 10 kg weight loss²⁰

- *Blood pressure*
Fall of 10 mmHg systolic Fall of 20 mmHg diastolic
 - *Diabetes*
Fall of 50% in fasting blood glucose
 - *Plasma lipids*
Fall of 10% total cholesterol Fall of 15% LDL
Fall of 30% triglycerides Rise of 8% HDL
 - *Mortality*
Fall of >20% total mortality
-

Starting measurements

If an agreement has been reached between patient and doctor that they will start a weight-loss programme this is a good time to make baseline measurements that are likely to improve. As well as accurate height and unclothed weight, hence BMI, waist circumference should be measured and fasting blood taken for plasma lipids (including triglycerides) and glucose. Risks of metabolic complications are greater in people with abdominal obesity²¹

- For women: increased risk above 80 cm waist circumference (32 inches) substantial risk above 88 cm (35 inches)
 - For men: increased risk above 94 cm waist circumference (37 inches) substantial risk above 102 cm (40 inches)
-

Successes

Klem *et al.*²² collected records of 629 women and 155 men in the United States who successfully lost at least 30 lb (13.6 kg) and maintained the weight loss for at least one year. Their average starting BMI was 35, they lost an average of 30 kg and their new BMI was 24.5 kg/m².

A little over half of this sample lost weight through formal programmes; the rest lost weight on their own. All of them used diet **and** exercise. Three-quarters of them reported that a triggering event had preceded their successful weight loss. Some limited classes of foods, some limited quantities of foods, some counted calories. They said that their weight loss led to improvements in energy, physical mobility, mood, self-confidence, and physical health.

Satiety

Satiety is a function that has been neglected in weight reduction programmes. People stop eating because of internal feelings of satiety, “I’ve had enough, thank you”. But this feeling of having eaten enough is not directly related to the energy (calories) of a meal or food. Some foods give stronger satiety per MJ than others. High fat foods have weak satiety for their energy values compared to predominantly carbohydrate foods.²³ Short-term studies indicate for example that boiled potatoes have twice the satiety effects of chips for the same calories and fruits have greater satiety effect than biscuits or confectionery.²⁴

Representative energy values of (stated) typical servings of some common foods

	kJ	kcal		kJ	kcal		kJ	kcal
Lettuce (30 g)	17	4	Bread (1 slice, 30 g)	280	67	Biscuits (2 digestive)	670	160

Peas (90 g)	209	50	Baked beans (240 g)	606	145	Chips (fried, 180 g)	1902	455
Whisky (25 g)	234	56	Milk chocolate (30 g)	648	155	Pork chops (fried, including fat, 210 g with bone)	2257	540

- Simple food tables can help in planning lifestyle, shopping, meals, and menus. But note that they give kilojoules (kilocalories) and fat per 100 g. Typical servings of some foods are less, of other foods more than this (see “energy values of foods” table).
- A dietitian, preferably nearby and linked with the practice, can help with detailed suggestions.

Crash diets do not work.

A weight loss of 1 kg (2lbs) per week is the most that can be expected but half this is useful (and all that some can manage).

A valuable technique for managing obesity is modification of eating behaviour. Its introduction by RB Stuart in 1967 changed the expectation of treatment from poor to fair and refinements are improving prospects further.

Firstly the patient makes notes of everything he or she eats for a week and where they were at the time, what they were doing, and how they felt. The calories can be worked out later. The therapist guides and encourages the patient to fill in the form. In the process the patient discovers in what circumstances he or she eats most. The doctor or dietitian discusses the completed form with the patient and suggests behaviour modifications. Obese people do not eat so much because they are hungry, but more in response to external cues—boredom, anger, delicious taste, other people eating, food that would be wasted, etc. The patient can make arrangements to minimise these cues.

Rules for modifying eating behaviour

- Buy non-fattening foods. Do not buy foods that specially tempt you. Use a shopping list and stick to it. Do not shop when you are hungry.
- Always eat in one room, in only one place in that room—for example, seated at the dining table—and avoid other activities (except conversation). Make eating a pure experience.
- Look for times when you are most likely to eat unnecessarily—for example, when giving children their tea, or because you cannot bear to throw food away—and take steps to change your routine.
- Always have nearby a variety of low calorie foods to use as snacks—like raw vegetables.
- Recruit others to help you curb your eating—spouse, coworkers, friends—they can help most by praising when you do not over-eat.

Time	Food	Taste rating	Amount	kcal	Where?	Who with?	Mood	Hunger	Associated activity	Why eaten?
4-4:45pm	Chocolate Cake	My weakness V. Good	3 slices	510	Kitchen	Children	Fed up	No	Giving children their tea	Irritated
5-00pm	Egg Sandwich	Nothing special	1½ sandwiches	200	Kitchen	Alone	OK	No	Clearing	Leftovers

Record of what is eaten, where and when

Fatty and thinny eating side by side

ABC of Nutrition

- Build in rewards for sticking to the programme—something you would like to do, or a present. Family and friends are usually happy to cooperate. Of course, the reward cannot be a meal or food.
- Make small portions of food appear to be large (small plate, food cut up and spread all over it). Make second helpings hard to get; do not keep serving dishes on the table. Leave the table as soon as you have eaten.
- Slow down the rate at which you eat. Chew each mouthful for longer. Always use a knife and fork or a spoon and put them down between mouthfuls. Swallow one mouthful before the next.
- Take steps to minimise hunger, loneliness, depression, boredom, anger, and fatigue, each of which can set off a bout of overeating. This needs discussion and planning. Hunger is minimised by three regular meals daily.
- Increase the exercise you take each day.
- Keep a record of how much you eat and exercise, and of your weight.

Exercise

During an hour's walk at ordinary speed, mostly on the level, $21 \text{ kJ/min} \times 60 = 1260 \text{ kJ}$ (or $5 \times 60 = 300 \text{ kcal}$) of energy are used up. But at rest about $4.2 \times 60 = 252 \text{ kJ}$ ($1 \times 60 = 60 \text{ kcal}$) would be spent per hour. The energy used by going for an hour's walk is therefore the difference between 1260 and 252 = 1008 kJ (300 and 60 = 240 kcal). This is equivalent to about two slices of bread and butter (60 g bread + 15 g butter, see "energy value of foods" table). People can be discouraged by the small amount of food which is directly equivalent to the use of quite a lot of precious time taking exercise.

There are, however, additional benefits from increased regular exercise.

- (1) Obese people, with a heavier body to move, use more energy than in the table for the same amount of work.
- (2) Exercise can be valuable as a diversion from sitting indoors and being tempted to eat.
- (3) Exercise is more likely to reduce than increase appetite.
- (4) After exercise, the resting metabolic rate may increase for some hours (though the effect is evidently small, and some experimenters have not been able to measure it).
- (5) When exercise is taken after meals the thermic effect of the meal may be increased.

Exercise also limits the proportion of lean tissues lost in slimming programmes and helps in weight maintenance. Fat people cannot usually manage vigorous sports and may be embarrassed to dress in sports gear. Walking in all its varieties is the most important exercise.

Exercise advice could include²⁰:

- Walking is the key to controlling your weight
- Travel whenever possible by foot and aim for 30 minutes' brisk walking per day
- Walk all or part of your journey to work or the shops
- If you usually travel by bus get off a stop earlier
- Use the stairs instead of a lift
- Avoid sitting for long periods; be active during TV adverts
- If you have a garden, spend more time working in it
- If you have a dog, take it for more frequent or longer walks

Third: maintaining the lower body weight

After a weight-loss programme with the new eating plan, and increased exercise and behaviour modification for 12-20 weeks, the motivated and well-supported patient should have lost near to 10 kg. Now starts the longer phase of keeping the weight off. This is where temptations and disappointment lie in wait.

Walking the dog

At rest (Men +10%, women -10%)	kJ	kcal
	4	1
Moderate exercise For example, walking, gardening, golf	21	5
Intermediate For example, cycling, swimming, tennis	29	7
Strenuous For example, squash, jogging, hill climbing, heavy work	42	10

In SI units: 1 kcal/min = 4.2 kJ/min = 70 watts

Mean weight loss of behavioral programmes post-treatment and at 1, 2, 3, 4, and 5 years follow up. Lines A, B, and C represent hypothetical groups of people against which to compare the results of behavioral programmes. Line A, natural history of obese persons receiving no treatment as gradually weight is gained; line B, stable weight; line C, gradual loss. (Adapted from Brownell and Kramer²⁵)

The graph on page 76 shows combined average results of several behavioural programmes.

Weight loss was satisfactory but gradually the subjects' weight slowly crept up so that after five years about half the weight lost had been put back on. The same slow regain of weight has been reported whatever treatment was used for the weight loss phase (very low calorie diet, appetite suppressant drugs, etc). The challenge, therefore, is for therapist and subject to be aware of this tendency to re-gain and work to minimise it.

If the weight-loss diet was drastic and incompatible with a normal lifestyle, food habits will rebound. Some restriction of diet has to continue in the maintenance phase. An *ad lib* low fat (high carbohydrate) diet has been shown to be more effective for weight maintenance than a fixed energy intake.²⁶ An active lifestyle with regular adequate exercise seems to be essential to keep body weight down.²⁷

Other treatments

Drug therapy

It is futile to prescribe drugs unless the patient is committed to eating less calories and/or exercising more. Only a limited range of drugs are available at present, though pharmaceutical companies are researching hard to find safe additional types.

Orlistat ("Xenical") is an inhibitor of pancreatic lipase. It reduces digestion of fat (triglycerides) and increases faecal fat. Oily spotting and faecal urgency can be controlled by eating a low fat (so lower energy) diet.

Sibutramine inhibits the reuptake of serotonin and noradrenaline in the central nervous system. It decreases appetite and may increase thermogenesis (metabolic rate). Blood pressure can rise.

The serotonergic appetite suppressants fenfluramine and dexfenfluramine have been withdrawn because of rare but severe cardiac valve disease and pulmonary hypertension. Of the catecholaminergic drugs, amphetamines cannot be used because of their potential for abuse. Only phentermine is in the *British National Formulary*. It should only be used to support someone with moderate to severe obesity who is restricted to a 12-week prescription.

Commercial organisations, for example, Weight Watchers or similar organisations, use group therapy and can help some people with mild to moderate obesity. The Scottish Obesity guidelines²⁰ have a set of useful criteria for evaluating the local organisation of this type. Other patients prefer a more individual approach.

More radical treatments sometimes used are **very low calorie diets** and **gastric stapling**. They are in the specialist's domain. Ideally patients with a BMI over 35 kg/m² should be referred to a specialist centre,²⁰ but these are not well developed in all areas.

12 Measuring nutrition

Energy (calories)

Methods of measuring calories (food energy) are different from those for the other essential nutrients.

Energy expenditure

Measurement of energy balance is technically difficult. *Energy expenditure* can be measured in one of five ways.

(1) By measuring a subject's heat output in a special insulated room. This is **direct calorimetry**, a costly and complicated experiment. There are very few direct calorimeter rooms anywhere in the world. The method has been replaced by (2).

(2) **Indirect calorimetry** measures oxygen consumption and the production of CO₂ and urinary nitrogen. From these the mixture of carbohydrate, fat (exogenous or endogenous), and protein metabolised can be calculated. Urinary N indicates protein catabolism and CO₂/O₂ (the respiratory quotient) indicates the ratio of carbohydrate to fat metabolised. Energy production per gramme differs with the metabolic fuel (greater when fat is oxidised). These measurements can be made for up to 24 hours in a *respiration chamber*, in which a subject can live and carry out various somewhat restricted activities.¹

The energy produced per litre of oxygen consumed happens to be much the same whichever of the three macronutrients is oxidised. Oxygen consumption alone gives an adequate quantification of energy expenditure *over short periods*. It can be measured with different types of apparatus: Douglas bag, or a portable electronic respirometer carried on the back, a ventilated hood or a bedside metabolic monitor. The former are used to estimate the energy cost of different activities. The latter apparatus is used clinically to measure resting or **basal metabolic rate**, which can be increased in patients—for example, after burns or trauma or with infections.

(3) The **doubly labelled water** method measures the decay of body water concentrations of the stable isotopes ²H and ¹⁸O. It is an ingenious method, developed for human work in the 1980s, suitable for measuring total energy expenditure over 7-10 days. It depends on the principle that labelled oxygen is lost partly as carbon dioxide and partly as water while the rate of water loss is given by the decay of labelled hydrogen.² The isotopes are given as a very accurately weighed dose of water. Disappearance is measured (by dedicated mass spectrometer) in repeat timed urine specimens. From CO₂ production (knowing the average respiratory quotient from the diet record and estimate of any changes in body fat) energy expenditure can be calculated as for indirect calorimetry. Unfortunately the heavy oxygen is very expensive.

(4) It ought to be possible to assess energy expenditure from an estimate of basal metabolic rate (from the patient's age, sex, and weight) and from recording all his activities (lying, sitting, walking upstairs, etc) throughout the day. Energy values for the different activities have to be assumed from reported values. The method is tedious and inaccurate.

(5) The possibilities for estimating energy expenditure are better by counting the heart rate for a day or more with a small portable cardiac monitor. (Practical details for this and the other methods are reviewed by Murgatroyd *et al.*²)

1 kcal = 4.184 kJ
kilojoules and megajoules are the SI units

The nutritional state for energy, or for any essential nutrient, depends on the balance (B) between intake (I) (dietary or parenteral) and output (O) or expenditure: $B = I - O$.

When the balance is negative the nutritional state tends to go down towards depletion, but there may be an adaptive reduction in output (losses). When the balance is positive the nutritional state tends to go up: the nutrient may be stored somewhere in the body but some nutrients can start to become toxic. "You can have too much of a good thing."

Doubly labelled water measurement of energy expenditure over 14 days. Isotope disappearances from a typical adult subject²

Energy intake

For *energy intake* the energy (calorie) contents of foods eaten should ideally be analysed chemically by measuring the protein, available carbohydrate, fat, and alcohol contents and multiplying each of these by their metabolisable energy values. Energy values in food tables are only estimated averages.

The usual way of estimating *energy balance* is, of course, from the resultant **changes in body weight**. A gain or loss of energy by the body of about 25-29 MJ (6000-7000 kcal) should, respectively, increase or reduce the weight by 1 kg. Most of this weight change is in fat, with a variable amount of water and a minority of muscle. Gain or loss of tissue needs to be over 1 kg to be detectable, because, even with accurate weighing and on a constant regimen, healthy people's weights fluctuate within the day and from day to day. Furthermore, many scales and weighing techniques are not accurate.⁴

Reference standards for body weights at different heights based on body mass index (BMI) are given for adults in chapters 8 and 11 and for children in chapter 6.

It is difficult to weigh deformed or paralysed people. Very sick bedfast people cannot be weighed unless they are in a specially designed weighing bed. It is nearly always easy to weigh an ambulant patient—it just takes a little time and trouble. But in hospital patients confined to bed—for example, those with fluid lines or splints—some idea of loss of tissue can be obtained by measuring the arm circumference with or without one or more skinfold thicknesses.

Measuring arm circumference needs only a tape measure, put round the arm (preferably left) midway between the tip of the acromion and the olecranon. The enclosed area is made up of muscles and subcutaneous fat over the constant humerus.

Reference standards for mid-upperarm circumference (mm)^{5,6}

Age	Men			Women		
	50th	10th	5th	50th	10th	5th
19-24	308	272	262	265	230	221
25-34	319	282	271	277	240	233
35-44	326	287	278	290	251	241
45-54	322	281	267	299	256	242
55-64	317	273	258	303	254	243
65-74	307	263	248	299	252	240

Measuring skinfold thickness requires special calipers. The best are obtainable from Holtain Ltd, Crymych, Dyfed SA41 3UF. Cheap plastic ones are unreliable. The most common sites for measuring skinfold thickness are over the *mid-triceps*, halfway between the acromion and the olecranon, and the *subscapular* skinfold, 1 cm below the inferior angle of the scapula. Reference standards are available for skinfolds at these sites (see table opposite).

The triceps skinfold measurement can be used to calculate the mid-upperarm muscle circumference, AMC.

$$AMC = \text{arm circumference} - \pi \times \text{triceps skinfold (mm)}$$

Before substantial weight changes are detectable, or if weight cannot be measured, a rough idea of energy balance can be obtained by calculating the energy per day in recent food intake from food tables and comparing this with the estimated average requirements for energy published by the DoH.⁷

These reference values for energy intake are estimates and averages. They differ with gender, age, body weight, and

Distribution of day to day weight change (kg) on 2078 occasions on consecutive days in healthy young men³

Weight measurement

Beam or lever balances are most reliable, not the usual bathroom scales. The best scales are not easily portable: they are heavy and the knife edge balancing part can be damaged. The patient should if possible be brought to the scale. It should be serviced regularly (as recommended by the manufacturer) and checked frequently against known weights, such as a heavy weight kept nearby. Subjects should be weighed in light underclothing and no shoes and with any heavy jewellery removed. A meal or full bladder increases the reading and a bowel action reduces it.

Adults and older children should stand straight on both feet on the centre of the scale's platform without touching anything else.

Pictures of how to weigh young children are shown in Valman B, Thomas R. *ABC of the First Year*, 5th edn. London: BMJ Books, 2001.

Reference standards for triceps skinfold thickness (mm)^{5,6}

Age	Men			Women		
	50th	10th	5th	50th	10th	5th
18-24	9.5	5	4	18	11.5	10
25-34	12	6	4.5	21	12	10
35-44	12	6	5	23	14	12
45-54	12	6	6	25	16	12
55-64	11	6	5	25	16	12
65-74	11	6	4	24	14	12

*Figures based on a large sample of healthy US citizens from Frisanco⁵ and Bishop *et al.*⁶

Measuring skinfold thickness with Holtain calipers: left—triceps site; right—subscapular site

especially with activity level.⁷ About half of any group of similar people can be expected to need more, and half to need less, than these values. Individual requirements might well range from 50% to 150% of these averages. Furthermore, on any single day an individual might consume considerably less or more than their average daily intake.

There are no biochemical tests that reliably indicate energy balance. Acetone appears on the breath in people who fast for longer than 12 hours and β hydroxybutyrate concentrations increase in body fluids but these cannot be used to show the extent of energy deficit.

Protein

Tests for protein status estimate two variables: total body protein and visceral protein.

Total body protein

This is predominantly muscle and can be estimated in several ways. At the clinical level:

- Body weight for height —that is, BMI, partly reflects body protein. Though the usual cause of a high BMI is excess fat, a less common cause is unusually well developed muscles in body builders and weight lifters.
- Total protein may also be estimated approximately from the mid-upperarm muscle circumference (mid-upperarm circumference $- \pi \times$ triceps skinfold).
- Twenty-four-hour urinary creatinine gives a biochemical measure of muscle mass because creatinine is a metabolite from the turnover of muscle creatine. One gram of creatinine/day comes from about 20 kg of muscle but urinary creatinine shows quite large day to day fluctuations even if collection is complete, and it is spuriously increased by eating meat and by exercise.

Three research procedures are potentially available to give the most reliable estimates of lean body mass.

- Total body nitrogen may be measured by *in vivo* neutron activation with simultaneous counting of the 10.8 MeV gamma rays produced from the protein nitrogen⁹; then $N \times 6.25 =$ total body protein.
- Potassium is predominantly intracellular and normally proportional to body protein. Total body potassium can be measured non-invasively by placing a subject in a heavily screened whole-body counter and counting the natural weak gamma-ray emissions from the subject's own ⁴⁰K which is mixed as 0.012% with the stable ³⁹K throughout our bodies.
- Body density can be measured by underwater weighing in a special bath (a harmless procedure but only available in research centres). As the density of body fat is 0.9 and of lean body mass 1.1, the proportions of fat and lean can be calculated.

Other methods are available which are more accessible investigations but tend to be less precise.

- Use of bioelectrical impedance depends on the greater electrical conductivity of lean body mass than fat. A weak current is passed from ankle to hand. The equipment is portable and relatively inexpensive.
- Imaging methods such as dual x-ray absorptiometry can also provide estimates of body fat and lean.
- From total body water, by dilution of deuterium, lean body mass can be estimated because body water is in the lean not the fat.
- Total body fat can be estimated approximately by applying a formula to the sum of four skinfolds.¹⁰

Estimated average requirements of food energy for people in the United Kingdom⁷

Age	Males MJ/d (kcal/d)	Females MJ/d (kcal/d)
0-3 months	2.28 (545)	2.16 (515)
4-6 months	2.89 (690)	2.69 (645)
7-9 months	3.44 (825)	3.20 (765)
10-12 months	3.85 (920)	3.61 (865)
1-3 years	5.15 (1230)	4.86 (1165)
4-6 years	7.16 (1715)	6.46 (1545)
7-10 years	8.24 (1970)	7.28 (1740)
11-14 years	9.27 (2220)	7.92 (1845)
15-18 years	11.51 (2755)	8.83 (2110)
19-59 years	10.60 (2550)	8.05 (1920)
60-74 years	9.82 (2355)	7.98 (1900)
75+ years	8.77 (2100)	7.61 (1810)

Values from 0 to 18 years are based on average energy intakes. From 19 years on, however, they are based on measured energy expenditure, assuming low physical activity levels at work and leisure (physical activity level = $1.4 \times$ BMR (basal metabolic rate)). More active people need to consume more than the figures here. In the light of recent measurements, the figures for children under 5 years may be too high by about 10%⁸

Reference nutrient intake for protein*, based on British dietary reference values⁷

Age and sex	Body weight (kg)	Protein (g/kg body weight)	Reference nutrient intake (RNI) (g/day)
0-3 months	5.9	—	13
4-6 months	7.7	1.7	13
7-9 months	8.8	1.6	14
10-12 months	9.7	1.55	15
1-3 years	12.5	1.2	15
4-6 years	17.8	1.1	20
7-10 years	28.3	1.0	28
Males			
11-14 years	43.0	1.0	42
15-18 years	64.5	0.85	55
19-50 years	74.0	0.76	56
50+ years	71.0	0.75	53
Females			
11-14 years	43.8	0.94	41
15-18 years	55.5	0.81	45
19-50 years	60.0	0.75	45
50+ years	62.0	0.76	47
Pregnancy			+6
Lactation			+11

British dietary reference values are based on FAO/WHO (1984) safe levels of protein intake.

*These recommended intakes assume that the protein comes from a mixed diet, as in the average British diet. Requirements may be higher if digestibility of the protein is incomplete or if one (or more) of the indispensable amino acids is poorly represented

Visceral protein

Visceral protein is sometimes disproportionately reduced in protein deficiency, as seen most strikingly in kwashiorkor. There is fatty liver, intestinal mucosal and pancreatic atrophy, and impaired lymphocyte function. The usual tests measure concentrations of plasma albumin or transferrin, proteins synthesised in the liver. These are disproportionately reduced when there is visceral protein depletion and often within normal limits in total body protein depletion. Plasma albumin concentrations are also moderately reduced in the metabolic response to severe injury or infection as well as in liver cirrhosis and nephrotic syndrome. Transferrin concentrations are increased in iron deficiency.

Other nutrients

Other nutrients do not affect anthropometric measurements directly. Inadequate intake can be suspected from the dietary intake or shown by specific biochemical tests.

Assessment of dietary intake

The sequence of assessing nutrient intake is to:

- estimate **food intake** as g/day of different foods
- use **food tables** to convert g/day of each individual food to g, mg, or μg /day of various nutrients. These calculations can, and always used to be done manually but computers are generally used
- compare this patient's intake of one or several nutrients likely to be inadequate with the dietary reference values⁷ of food energy and nutrients. Note: the reference nutrient intake⁷ covers the individual nutrient requirements of the great majority of normal people, which means that an intake somewhat below the recommended daily amount would be adequate for most people (see page 85). The other consideration is whether the day(s) on which food intake was measured were typical.

Food intake measurements

Food intake data may be obtained at the national, household or individual level. **National figures** come from food production plus imports minus exports, divided by the estimated national population. They report **apparent consumption** because some of the food is wasted, fed to tourists or pets, used in industry, etc. All developed countries publish annual figures for average consumption. **Household food consumption** has been measured in large samples across England, Wales and Scotland every year since 1940 and the National Food Survey provides a unique continuous series of national consumption of different foods.¹¹ The survey cannot show average individual intakes because until recently food and drink consumed outside the home was not estimated, and distribution of foods and nutrients within families varies between its members.

Although these macrofigures provide a background of trends in food consumption for clinical work and analytical epidemiology, we want to know what an **individual** has been eating and drinking. There are four types of method used to estimate individual food intake.

- **Dietary history**—"What do you eat on a typical day?" This is a good method in the hands of a skilled and patient interviewer. Food models, cups, plates, and spoons are used to estimate portion sizes.
- **24-hour recall**—"Tell me everything you've had to eat and drink in the last 24 hours." This is less subject to wishful thinking about what the person ought to have eaten. The weakness is that yesterday may have been atypical; 24-hour recalls can, however, be repeated.

Checklist on patient's diet

In a busy practice a short checklist about the patient's eating habits is a useful screening method.

- What is your appetite like?
 - Do you eat more or less than other comparable people?
 - Has what you eat changed—type of food or amount?
 - Are you on a special diet?
 - Is there any food you can't eat because it doesn't agree with you?
 - Are you losing or gaining body weight?
 - What do you usually have for the main meal of the day?
 - Do you eat meat/fruit/fat on meat/salt/etc?
 - What sort of bread do you eat?
 - What sort of alcohol do you drink, how many drinks per week or per day?
 - What do you have for breakfast and lunch?
 - Do you take vitamin or mineral tablets?
-

Individual food intake

There are four types of method used to estimate individual food intake, and these are:

- Dietary history
 - 24-hour recall
 - Food diary or record
 - Food frequency questionnaire
-

3. (CONTINUED) PLEASE FILL IN YOUR **AVERAGE USE, DURING THE PAST YEAR, OF EACH SPECIFIED FOOD**

Example of a page from a food frequency questionnaire

- **Food diary or record**—“Please write down (and describe) **everything** you eat and drink (and estimate the amount) for the next 3 (4 or 7) days.” Amounts are usually recorded in household measures but for more accuracy subjects can be provided with quick reading scales to weigh food before it goes on the plate (and any leftovers).
- **Food frequency questionnaire**—“Do you eat meat/fish/bread/milk ... on average: more than once a day/2 or 3 times a week/once a week/once a month etc?” (see example above).

The self-administered food frequency questionnaire is the newest of the four methods. It is much more economical of investigator’s time and suitable for computer analysis. This method has made possible cohort studies with thousands of subjects’ food intakes related to disease outcome.¹² It asks for usual, typical intake.

Estimating food intake quantitatively is labour intensive (and so expensive). It depends on adequate memory and the honesty and interest of the subject. Some people’s food habits are very irregular and most people eat differently on Saturday and Sunday from during weekdays and on holiday.

There is no “gold standard” method for food intake. Methods that ask subjects to record or remember the food/drinks they really consumed are better for national nutrition surveys of samples of the population. Items may be forgotten (or not listed because of embarrassment) but the exact types of food, product or dish are actually captured, including unusual ones. For large epidemiological surveys food frequency questionnaires have enabled tens of thousands to be included. What these lose in precision they gain in numbers of subjects. Usually quintiles (fifths) of intake of food components

Two pages from The *Composition of Foods*.¹⁴ Each set of foods has four pages of nutrients. Pages 3 and 4 (not shown here) report vitamins and minerals

Cereals and cereal products *continued*

^a Calculated assuming water only was added; savoury rice cooked with fat contains approximately 8.8 g fat per 100 g

^b Wholemeal macaroni contains 8.3 g (raw) and 2.8 g (boiled) Englyst fibre per 100 g. Reproduced by permission of the Royal Society of Chemistry

are related to disease outcomes. Relative consumption across the population is the aim here, rather than precise and specific quantitative results (examples are in chapter 1).

Biomarkers of dietary intake

All estimates of food intake are subjective. Some subjects forget, some did not notice what food they ate, some do not report because they would be ashamed to admit having that food, drink, or amount. The search is on for biomarkers, which are objective biochemical indices of dietary intake. For some food components there are useful biomarkers; for others there is nothing available. Protein intake is reflected by 24-hour urinary nitrogen. Intake of non-endogenous fatty acids (18:2, 18:3, 20:4 and *trans* unsaturated) are reflected well in serum or adipose tissue fatty acid pattern but there is no biomarker for total fat or carbohydrate intake. Intake of individual carotenoids can be seen in the plasma. Plasma lycopene, for example, reflects tomato intake. Of the inorganic nutrients 24-hour urinary sodium is a much better indicator of salt intake than dietary history because the salt content of foods and dishes varies greatly and without the subject's knowledge. Vitamin A and calcium are nutrients whose plasma concentrations cannot serve here; they are held constant across the range of usual intakes. Toenail selenium has been used to reflect selenium intake.

Food tables and nutrient databases

The British food tables are among the best in the world thanks to the original work of McCance and Widdowson,¹³ their continuation by Paul and Southgate and colleagues, and the support of the Medical Research Council; Ministry of Agriculture, Fisheries, and Food; the Agriculture and Food Research Council; and the Royal Society of Chemistry. The 5th edition of *McCance & Widdowson's the composition of foods* was published in 1991,¹⁴ and there is a growing list of supplements.

In the main volume 1188 foods and drinks arranged in 14 groups are given code numbers (which can be used for computer input—software packages are also available). The total publications, including supplements, cover around 2000 foods. Figures are given (per 100 g edible portion) for over 40 constituents.

The two example pages from the *Composition of foods* show the proximate constituents or macronutrients printed in the main tables.¹⁴ Where relevant, alcohol content is also included. The other two pages for each food show inorganic nutrients—Na, K, Ca, Mg, P, Fe, Cu, Zn, Cl, Mn, Se, I—and all the vitamins—retinol, carotene, vitamins D and E, thiamin, riboflavin, niacin, tryptophan/60, vitamins B-6 and B-12, folate, pantothenate, biotin, vitamin C.

Individual amino acids and fatty acids are in the (1978) 4th edition of *McCance & Widdowson*¹⁴ and a 1980 supplement. For any large scale work the nutrient data bank behind *McCance & Widdowson* is used in computer software, from the Royal Society of Chemistry, Letchworth, Herts., SG6 1HN or MAFF or a specialist software company. This software should contain the latest updates, revisions and additions to the database.

Variability of nutrient content

The British tables give a single value for each nutrient in each food—an estimated average. The American tables,¹⁶ which are published in loose leaf sections as analyses are completed, give an indication of variability to be expected round each average figure. There is no legal guarantee that any food contains what the food tables say it should. For some constituents—for example, fat—the food could easily contain 25% less or 25% more.

Food composition tables¹⁵

Food composition analysis is work that is never finished. It is a bottomless pit. No country has food composition tables which have kept up with all the concepts of modern nutritional science, the proliferation of foods and dishes eaten in a country and the ever-growing list of substances in foods that may or could have biological functions.

The numbers in existing food tables are derived in three ways:

- By direct analysis in the country where the food tables are produced. These may be based on multiple samples and a modern, specific analytical method or they may be antique figures based on a single sample.
- From literature. Figures may be a subjective decision (even if experienced) of the best representative one from an array of original results, or they may be “borrowed” from another country's food tables.
- Imputed figures, estimates from similar foods or from the known composition of most of the ingredients of mixed dishes.

As a rule food tables do not say where each number comes from.

Food components/nutrients are not the same if analysed by different methods. Carbohydrate can be obtained by subtracting per cent water, fat, protein and ash from 100—“by difference” or by direct chemical analysis adding up the different classes of carbohydrate. There is still no agreement on which of some four different methods should be the standard one for dietary fibre. Cholesterol may be obtained by an older colorimetric method or by more specific gas-liquid chromatography.

The *Manual of Nutrition* has a useful simplified food table, which gives calories and 11 nutrients for 150 common foods¹⁷

Dietary reference values and requirements

For nutrient intakes to have any meaning they have to be compared against some number representing physiological requirements for each nutrient. The major number for this is the estimated upper end of the range of individual requirements. In Britain, the name for this was changed in 1991 to *reference nutrient intake* (RNI)⁷ from recommended daily amount (RDA). The latter had the same abbreviation as the American term, recommended dietary allowance.

The North American dietary reference intakes are being revised in sections.¹⁸ These new reference values have similar terminology to the British and also have numbers for a **tolerable upper intake level** (above which adverse effects might occur).

Ten of the new North American dietary reference intakes (DRIs) are similar to the 1991 UK set but five are different. A DRI has been added for selenium on which there has been interesting research since 1991 (see chapter 10) and daily requirements for vitamin D are provided. The folate requirement has been increased because prevention of neural tube defects and hyperhomocystinaemia have emerged in the 1990s. The North American committee set higher recommendations for vitamin C by using an optimal blood level of ascorbate rather than prevention of scurvy and maintenance of measurable ascorbate in plasma. The calcium recommendation is also higher, based more on balance data than the British recommendations, based more on epidemiology.

The RNI/RDA values differ for the two sexes and several age groups and are published in tables. They are for intakes averaged over several days. Since the RNI/RDA is estimated to meet the requirements of practically all healthy people, most people's requirements are less than this upper or prescriptive reference value. For assessment of people's intakes a lower, diagnostic, reference should be used, such as the **estimated average requirement** for groups of people and the **lower reference nutrient intake** for individuals.⁷ An intake below this does not necessarily mean inadequacy but the lower it is the greater that probability. As elsewhere in medicine, for complete nutritional diagnosis, findings on examination (clinical, anthropometric, and biochemical) must be considered together with the food intake history.

Sick people have requirements not covered by the reference values. For example with bed rest, energy requirements are reduced; with fever they are increased. Losses of several nutrients are increased in different ways by illness, such as protein loss in nephrotic syndrome, potassium loss in diarrhoea, iron loss with bleeding. The allowances apply to oral feeding of conventional foods. For total parenteral nutrition the requirements are different; absorption is 100%, but minor vitamins like pantothenate and biotin and trace elements like molybdenum, manganese, chromium, etc, which can usually be ignored because there is enough in the diet, cannot be taken for granted and have to be provided in the infusion solution(s).

Biochemical methods for nutritional status

Biochemical tests are an integral part of modern medical diagnosis. Plasma sodium and potassium concentrations, for example, are essential for diagnosing and treating difficult electrolyte disorders, and plasma or red cell folate and plasma vitamin B-12 should be measured before treating a patient with megaloblastic anaemia.

With most of the other nutrients also, biochemical tests have been developed which can be used (a) to confirm the diagnosis of a deficiency disease in places where it is uncommonly seen or where the clinical picture is complicated,

British dietary reference values⁷: estimated average requirement for food energy (calories) and reference nutrient intakes (RNIs) for the other nutrients

Nutrient	Men 19-50 years	Infants 4-6 months
Energy, kcal (MJ)	2550 (10.6)	670 (2.8)
Protein (g)	56	13
Vitamin A (RE, μ g)	700	350
Thiamin (mg)	1.0	0.2
Riboflavin (mg)	1.3	0.4
Niacin (NE, mg)	17	3
Vitamin B-6 (mg)	1.4	0.2
Folate (total, μ g)	200	50
Vitamin B-12 (μ g)	1.5	0.3
Vitamin C (mg)	40	25
Vitamin D (μ g)	—	8.5
Vitamin E (mg)	7	0.4/g PUF
Calcium (mg)	700	525
Iron (mg)	8.7	4.3
Magnesium (mg)	300	60
Iodine (μ g)	140	60
Potassium (mmol)	90	22
Sodium (mmol)	70	12
Zinc (mg)	9.5	4

Some figures are slightly rounded. Figures for women are generally about 75% of those for men, except iron (higher until the menopause) and in pregnancy and lactation. Figures for children are interpolated between infants and adults.

RE = retinol equivalents; NE = niacin equivalents; PUF = polyunsaturated fat

Biochemical methods for diagnosing nutritional deficiencies

Nutrient	Indicating reduced intake	Indicating impaired function (IF) or cell depletion (CD)	Supplementary method
Protein	Urinary nitrogen	Plasma albumin (IF)	Fasting plasma amino acid pattern
Vitamin A	Plasma β -carotene	Plasma retinol	Relative dose response
Thiamin	Urinary thiamin	Red cell transketolase and TPP effect (IF)	
Riboflavin	Urinary riboflavin	Red cell glutathione reductase and FAD effect (IF)	
Niacin	Urinary N' methyl nicotinamide or 2-pyridone, or both	Red cell NAD/NADP ratio	Fasting plasma tryptophan
Vitamin B-6	Urinary 4-pyridoxic acid	Plasma pyridoxal 5' phosphate	Urinary xanthurenic acid after tryptophan load
Folate	Plasma folate	Red cell folate (CD)	Urinary FIGLU after histidine load
Vitamin B-12	Plasma holo-transcobalamin II	Plasma vitamin B-12	Schilling test
Vitamin C	Plasma ascorbate	Leucocyte ascorbate (CD)	Urinary ascorbate
Vitamin D	Plasma 25-hydroxy-vitamin D	Raised plasma alkaline phosphatase (bone isoenzyme) (IF)	Plasma 1,25 dihydroxy-vitamin D
Vitamin E	Ratio of plasma tocopherol to cholesterol+ triglyceride	Red cell haemolysis with H ₂ O ₂ <i>in vitro</i> (IF)	
Vitamin K	Plasma phylloquinone	Plasma prothrombin (IF)	Plasma des- γ -carboxy-prothrombin
Sodium	Urinary sodium	Plasma sodium	
Potassium	Urinary potassium	Plasma potassium	Total body potassium by counting ⁴⁰ K
Iron	Plasma iron and transferrin	Plasma ferritin (CD)	Free erythrocyte protoporphyrin
Magnesium	Plasma magnesium	Red cell magnesium (CD)	
Iodine	Urinary (stable) iodine	Plasma thyroxine (IF)	Plasma TSH
Zinc	Plasma zinc	Red cell zinc	

TPP = thiamine pyrophosphate; FAD = flavin adenine dinucleotide; NAD = nicotinamide-adenine-dinucleotide; NADP = NAD phosphate; FIGLU = formiminoglutamic acid; ⁴⁰K = natural radioactive potassium; TSH = thyroid stimulating hormone

There are no reliable simple methods for assessing *calcium* status (total body calcium can be measured by *in vivo* neutron activation analysis)

or (b) in community surveys and general practice to find individuals with subclinical nutrient deficiencies.

Tests which can be used for the major nutrients are listed in the table on page 85. As with other tests in chemical pathology, there may be false positive and false negative results. For example plasma vitamin B-12 concentrations are increased in acute hepatitis, and alkaline phosphatase may not be raised if rickets is accompanied by protein-energy deficiency.

When the intake of a nutrient is inadequate (less than obligatory losses) an individual generally goes through **three stages**. The first is adaptation to the low intake: urinary excretion of the nutrient or its metabolites typically falls but there is no evidence of abnormal function or of depletion of the cells.

In the second stage there are also biochemical changes indicating either impaired function or cellular depletion, but clinical manifestations of deficiency are absent or non-specific. A good example of a test showing impaired function is red cell transketolase activity. For each blood sample this enzyme is assayed in two test tubes, one with extra thiamin pyrophosphate (TPP), the other without. If the activity is more than 25% higher in the supplemented tube (TPP effect + 25%) this indicates functional thiamin deficiency. The third stage of depletion is that of clinical deficiency disease.

Most clinical biochemistry laboratories provide only some of the methods in the table as a routine but others could be set up in special circumstances or, alternatively, a laboratory specialising in nutrition research could be asked to help.

13 Therapeutic diets

A person may be advised to change his or her diet to help treat or prevent disease.

- For essential or lifesaving treatment—for example, in coeliac disease, phenylketonuria, galactosaemia, hepatic encephalopathy.
- To replenish patients who are malnourished because of diseases such as cancer, intestinal diseases, and anorexia nervosa.
- To produce a negative energy balance in obese people.
- As helpful treatment, alternative or complementary to drugs, as in diabetes mellitus, mild hypertension, dyspepsia.
- To deal with the side effects of some drugs—for example, diets with increased potassium for patients taking long term diuretics or diets with restricted tyramine for patients taking monoamine oxidase inhibiting antidepressants.
- To provide standard conditions for diagnostic tests—for example, for measuring faecal fat. Also, an elimination diet is the mainstay in diagnosis of food sensitivity.
- Prophylactic diets like those described in chapter 7 on nutrition for adults (dietary goals or guidelines for the general public) often combine mild restriction of energy, saturated fat, and sodium with a moderate increase of dietary fibre.

Therapeutic diets ask patients to make one or more of the following changes: reduce or (virtually) eliminate one or more components, increase one or more food components, change the consistency of the diet, or change the feeding pattern. These are all changes to the patient's usual diet (which, of course, varies somewhat from day to day) or in comparison with a hypothetical "normal" or average diet for the country, culture, age, and sex.

The prescription for a diet should state:

- the nature of the modification(s)
- the degree of each modification
- the planned duration of these
- any compensation for essential nutrients compromised by the modifications.

The degree of the modification is as important as the dose in pharmacotherapy. People talk loosely about a "low salt" diet but its sodium intake can range from 25 to 100 mmol/day compared with a normal British sodium intake of around 150 mmol/day. Likewise with protein, a protein restricted diet may vary from 20 to 50 g/day compared with the standard of about 75 g/day (1 g/kg).

The dietary prescription has to be adjusted for the individual patient:

- for the foods disliked and liked
- for any sensitivity or intolerance to food
- for any religious food prohibition (including Ramadan for Moslems, the month when all eating has to be after dark)
- for vegetarians
- to include foods eaten away from home
- for income, occupation, and level of education
- for cooking facilities and the patient's domestic situation
- for the need for variety in foods (some insist on variety; others like the same foods from day to day)
- for the patient's motivation and degree of obsessiveness
- for calorie (energy) expenditure and needs

For the purposes of describing therapeutic alternatives to diets a "normal" or average diet provides for a hypothetical healthy 70 kg Western man something like:

- **Energy** 10.5 MJ (2500 kcal)
- **Protein** 14% of energy or 85 g
- **Fat** 35% of energy or about 100 g
- **Carbohydrates** 48% of energy or 300 g
- **Alcohol** 3% of energy or 1 drink/day.

If the percentages of energy for macronutrients omit alcohol (as some do) carbohydrates here go up to 50% of energy and fat to 36%.

A "normal" diet provides around 75% of these absolute figures for the hypothetical woman (not pregnant or lactating), but the same percentages of energy for the macronutrients.

The naming of diets

Diets are sometimes described eponymously (Giovannetti diet) or as belonging to a specific disease (renal failure diet). But neither type of name is recommended. Diets named after their (supposed) originator give no clue about their composition and particular diets do not necessarily relate to specific diseases. A "renal failure diet" may also be used for hepatic encephalopathy or rare inborn errors of the ornithine cycle. There have been many "diabetic" and "renal failure" diets.

"Cholesterol lowering diet" is ambiguous (and "low cholesterol diet" is worse). Several diets may lower the plasma concentration of cholesterol—low fat, vegetarian, or increased seed oil (ω -6 polyunsaturated fatty acids)—and it is not necessary to lower the dietary cholesterol.

The most reliable way of naming diets is by the major change (from an average diet) in its composition.

Degree of modification

Sodium

- 100 mmol Na (2.3 g) is a mild low sodium diet
- 50 mmol Na (1.2 g) is a moderate low sodium diet
- 25 mmol Na (0.6 g) is a strict low sodium diet

Protein

- 50 g/day (0.75 g/kg) is a mild protein restricted diet
 - 30 g/day (0.5 g/kg) is a moderate protein restricted diet
 - 20 g/day (0.33 g/kg) is a severe protein restricted diet
-

ABC of Nutrition

- for the duration of the diet. If a diet is necessary for only a week or two then it is not serious if it provides less than the recommended daily amount of (say) calcium or magnesium, but if the diet is continued these elements must be provided, by supplements if necessary
- for the patient's prognosis. A strict diet may not be justifiable for someone with a short life expectancy
- when two or more dietary prescriptions are combined. Sometimes these are more or less incompatible—for example, a low calorie plus high potassium diet or a high calcium plus lactose free diet (supplements would have to be used for these).

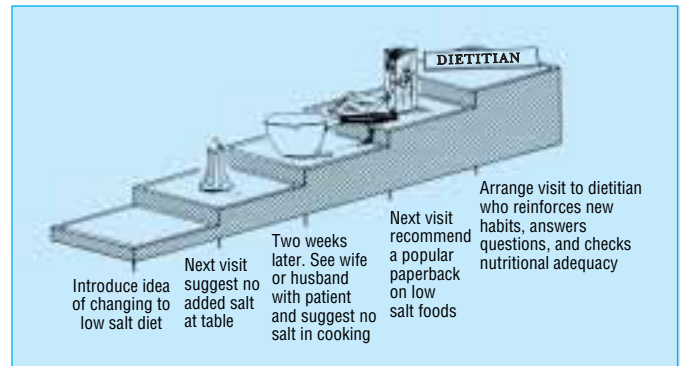

Strategy

Essential, or lifesaving, diets should be looked after in collaboration with a dietitian. For some diseases—for example, gout, mild hypertension, and hyperlipidaemia—drugs or diet are alternative or complementary treatment options. Drugs appear to act more quickly, are easier to administer and more reliable, and take less of the doctor's time, but they may cause more side effects. Diet appears more natural and safer but it will take longer to explain. Sometimes the best choice is a synergistic combination so the dose of drug can be low (hence fewer side effects) and the diet not too irksome.

We know from results with obese people who are on weight reducing diets, and from studies in diabetics, that most people do not follow the diet prescribed. It is difficult and time consuming to explain what is intended and how it may be done. It is difficult too for a patient to make major changes to his or her food habits. Minor changes are much easier to incorporate and some places in the day's food sequence are easier to change than others. Each family and each individual has different feelings and ideas about foods. Some foods are given up more readily than others.

Outside hospital a therapeutic diet ("I'm on a low salt diet") is a strange association of an occasional talk by the doctor or dietitian with daily action by the patient and his or her family in the supermarket, kitchen, dining room, works canteen, and pub. The reality is different from what is on paper.

Building up therapeutic diet at successive visits

Techniques

Essentially the doctor or dietitian has a list of foods rich in the component to be changed and of foods with medium and

Three at the table

'Salt'—Food Standards Agency leaflet

low amounts of it. The trouble with scientific food tables, such as *McCance & Widdowson's The Composition of Foods*,¹ is that they give the content of nutrients per 100 g whereas what matters is the content per usual serving or portion (see box: typical serving sizes).

The patient, with his or her spouse, can produce a list of what the family usually eats and how it is cooked. Ideally the next series of steps is for the doctor or dietitian and these two to work out the most comfortable way for them to incorporate the dietary prescription into the family's food patterns. This cannot be completed at one session. It requires trial and error, questions and compromises.

There are two fairly easy ways of changing the diet. First, a food that tastes and functions like the original but has a different composition may be substituted. Examples are: polyunsaturated margarine for butter; sunflower (etc) oil for dripping; skimmed or 2% fat milk for whole milk; salt free bread for ordinary bread; wholemeal bread for white bread; high fibre breakfast cereal for low fibre brand.

Second, a simple addition may be made to less important parts of the day's diet. Examples are: a sprinkling of bran on the breakfast cereal to increase fibre; casein powder (such as Casilan) sprinkled on to food three times a day to increase protein; spoonful(s) of fish oil (such as Maxepa) to increase long chain highly polyunsaturated fatty acids.

Diets are more likely to be followed and persisted with by patients who are well motivated, have stable mood, normal intelligence, good home support, and lead a well organised life. Indeed, in some obsessional patients there can be the opposite problem of overdoing a diet suggested long ago on thin scientific evidence or for a condition that has since disappeared.

Checking compliance and effectiveness

From an authoritarian viewpoint patients often do not properly **comply** with the doctor's instructions. This can be checked by asking revealing questions, by calling into the home at meal times, or by objective tests (for example biomarkers).

But for an intelligent patient who thinks that dieting is his or her own responsibility and that of his or her partner, with the doctor or dietitian one of their sources of information, what needs to be checked is the **effectiveness** of what they are doing.

Whatever the viewpoint or words used the same objective tests are available:

- change of body weight for reduced or increased energy diets
- increase of faecal weight for high (wheat) fibre diets
- 24-hour urinary sodium and potassium for dietary changes of sodium or potassium
- 24-hour urinary nitrogen for high or low protein diets, and also as general check on food intake (on average protein intake is 10-15% of energy intake)
- plasma fasting triglyceride fatty acid pattern to indicate consumption of polyunsaturated fat
- blood urea, urate, glucose, cholesterol, haemoglobin for respective diets prescribed to moderate these.

A Royal Pharmaceutical Society report urges clinicians to take a more egalitarian view of the relationship between prescribing and medicine taking, between patient and prescriber.³ This is even more needed for dietary management.

Diets for treating diabetes

Diabetic diets changed greatly throughout the 20th century. They have undergone further change since about 1970, as several facts emerged:

- (1) Oral hypoglycaemic drugs may predispose to heart disease.
- (2) There is no evidence that eating sugar **causes** diabetes.

Typical serving sizes, approximate weight in grams

Bread (1 slice)	30 g
Crispbread (1 slice)	10 g
Biscuits	about 12 g each
Breakfast cereal	30 g
Butter or margarine (for 1 slice bread)	7 g
Oil (1 tablespoonful)	20 g
Cake (portion)	40-50 g
Jam (for 1 slice bread)	15 g
Marmite (for 1 slice bread)	2 g
Milk (for 1 cup tea)	30 g
Milk (6 oz glass)	200 g
Cream (1 tablespoonful)	20 g
Sugar (1 level teaspoon)	5 g
Yoghurt (1 carton)	125-150 g
Cheese (1 portion)	30 g
Egg (1 edible portion)	50 g
Meat (chicken or beef) little or no bone	90-120 g
Meat (with bone, for example, chop)	160-200 g
Bacon (1 strip, raw)	30-40 g
Liver	80 g
Sausage (one)	50 g (approx)
Fish (fresh and canned)	110-120 g
1 fish finger	28 g
Macaroni and other pasta (for main course)	100 g (before cooking)
Vegetables (for example, peas, cauliflower)	60-100 g (before cooking)
Potato (1 medium, raw)	90 g
Lettuce	30 g
Parsley (chopped)	3 g
Fruit (1 apple, 1 banana peeled, raw)	100 g (approx)
1 grape	5 g
Nuts	30 g
Pepper	0.2 g
Wine (glass)	110-125 g
Spirits	25 g
Beer (1/2 pint)	285 g
Carbonated soft drink	240-330 g
Coffee powder	2 g

For more detail on individual British foods, see Crawley's handbook.²

History of diets for diabetics 1900-80

1900-25	Fasting (Naunyn, Allen); 5% <i>carbohydrate</i> , 85% fat (Newburgh 1923)
1922	Insulin discovered (but not generally available for a few years)
1930	15% <i>carbohydrate</i> and 70% fat
1940	All <i>carbohydrate low</i> , for example, 40% and fat 50%
1950	Lawrence's lines in UK
1970	<i>Carbohydrate round</i> 40%; sugar prohibited Emphasis on oral drugs or insulin rather than diet
1980	<i>Carbohydrates</i> 50% or more; emphasise "complex" CH ₂ O, fibre and legumes; restrict sugar
2000	Emphasis on lower glycaemic index foods

- (3) Asian people with diabetes on high starch diets have fewer complications (especially atherosclerotic) than their counterparts in Western Europe and North America.
- (4) Westerners with diabetes are dying of excess atherosclerotic disease, have higher plasma cholesterol values, and have been eating higher saturated fat diets than people with no diabetes.
- (5) Viscous dietary fibres such as that in guar, pectin, and legumes (though carbohydrates) improve diabetic control.
- (6) Increased dietary carbohydrate improves the response to a glucose tolerance test. Increasing the (complex) carbohydrate of diabetic diets is not usually followed by deteriorating control.
- (7) Individual foods containing carbohydrate do not give the same glucose and other metabolic responses at a standard intake. When put to the test, in human subjects some foods give much higher blood glucose curves than others. They have a higher or lower **glycaemic index** (area under the 2-hour blood glucose curve after eating a food containing 50 g carbohydrate as percentage of the corresponding area after the same weight of glucose). This means that carbohydrate exchange lists can no longer be relied on. (It was always hard to believe that 2 oz of grapes had the same effect in the body as 7 oz of whole milk.) The main cause of a low glycaemic index is that the starch in some foods is digested slowly by pancreatic amylase.
- (8) Diabetics also have an increased chance of developing hypertension. The sodium content of their diets has been largely ignored.

Principles of dietary treatment for diabetes^{6,7}

Type 1: insulin dependent diabetes (IDD)

- (1) **Integrate and synchronise meals (that is, the metabolic load) with the time(s) of action of the insulin treatment** to minimise high peaks of blood glucose as well as episodes of hypoglycaemia. The American Diabetes Association, for example, recommended that the individual's usual food intake is used as a basis for integrating insulin therapy into the eating and exercise patterns. Patients on insulin therapy should eat at consistent times synchronised with the time-action of the insulin preparation used.
- (2) **Reduce saturated fat to 10% of total energy or less.** People with diabetes have an increased risk of coronary heart disease and this dietary change may reduce it.
- (3) **Keep salt intake low,** because people with diabetes have an increased risk of hypertension.
- (4) **Be very moderate with alcohol.** Large intakes carry the risk of hypoglycaemia; irregular drinking can disturb glycaemic control. But regular 1 to 2 glasses with a meal are acceptable and might be beneficial (except in pregnancy).
- (5) **If still growing** make sure intakes of essential nutrients are adequate.

Type 2: non-insulin dependent diabetes (NIDD)

Dietary change has a greater potential to improve type 2 diabetes.

- (1) **Reduce body weight by eating fewer kilojoules and taking regular exercise, and keep at it!** Even modest losses of weight improve metabolic control.⁸ About three-quarters of type 2 diabetics are overweight or obese, and weight reduction is the first line of dietary management. To help patients lose weight and keep it off is a challenge for the physician and dietitian (cf chapter 11). Diabetics have a stronger incentive to lose weight because this improves their disease as well as their figure, but sulphonylureas or insulin (not metformin) tend to stimulate appetite. Some

Measurement of glycaemic index

Mean rise of blood glucose after 50 g carbohydrate from four different foods. In the top graph the six subjects were not diabetic: lentils gave very low rise of blood glucose but at 2 hours lentil levels were higher than bread (now below fasting level).⁴ In the lower graph the seven subjects had type 2 diabetes (two on insulin, two on glibenclamide). Blood glucose rises were higher than in the subjects with no diabetes and more sustained but over five hours area under the blood glucose curve for spaghetti was 60% that of bread⁵

who succeed in losing weight may be able to go off medications or go off insulin.

- (2) **Reduce saturated fat.** Increased LDL-cholesterol may be more pathogenic in type 2 diabetes than non-diabetic people.¹⁰
- (3) Emphasise **low glycaemic index** foods.⁹
- (4) Increase intake of **vegetables, fruit, legumes, and whole grain cereals** (which increase fibre intake and mostly have low glycaemic indices).
- (5) Keep **salt intake low**.
- (6) **Avoid excess alcohol** but 1-2 drinks per day with meals are acceptable.
- (7) Forget carbohydrate exchanges
- (8) There is no need to be obsessional about reducing sucrose. The glycaemic effect of sucrose is about the same as that of most starchy foods.⁷

Complex carbohydrates

The term “complex carbohydrates” has been used since 1977 for carbohydrates other than sugars (designated “simple carbohydrates”)—that is, for polysaccharides, or for carbohydrates in whole grains, vegetables, and fruits. Diabetic patients have been advised to eat foods containing complex carbohydrates rather than simple carbohydrates. But the carbohydrates in fruits and many vegetables are predominantly sugars and food starches vary in rate of digestion so that some give higher rises of blood glucose than sucrose. The term has become confusing.¹¹ It is better to discuss carbohydrate components by using their chemical names or the names of the foods that contain them and in general to choose those with lower glycaemic index.

An up-to-date book written for the interested diabetic patient⁹

Foods that have been shown to have low glycaemic indices (55 or less) compared to glucose = 100¹²

Soya beans (18)	Pearl barley (28)	Bananas (53)
Lentils (29)	All pastas (40-45)	Apples (36)
Dried peas (31)	Rolled oats (55)	Apple juice (36)
Canned baked beans (40)	Oat bran (50)	Grapefruit (25)
Frozen peas (boiled) (48)	All Bran (40)	Oranges (43)
Other dried legumes, (around 30)	Pumpnickel (rye) bread (41)	Orange juice (57)
		Plums (24)
		Peaches (28)
		Milk (full cream or low fat) and yoghurt (25-35)

The glycaemic index of glucose is 100, of fructose 20, of sucrose (half way between) 60, of lactose 45.

High fat foods may also give a low glycaemic index, because of delayed gastric emptying, but are not recommended and are not on this list.

These dietary prescriptions look very similar to the general dietary guidelines in chapter 7. Indeed it can be said that a modern diabetic diet is the dietary guidelines for the general population pursued with more seriousness. At Birmingham General Hospital “Rather than tell the patients that this is a diabetic diet, we emphasise that it is a normal, healthy diet that everyone should be adhering to”.¹³

Diets for renal failure

A strict therapeutic diet is needed for patients with renal failure during the few days between diagnosis and dialysis and for the minority for whom dialysis will not be used. The diet should be low in protein (40 g/day) or very low in high biological value protein (25 g/day) with low potassium and a controlled sodium and water intake.

Most patients with chronic renal failure in Western countries however, are nowadays treated with regular dialysis while awaiting a transplant. For them the outpatient diet is not very different from a normal one. Protein should be about 1.2 g/kg body weight, a little more than the recommended daily intake for healthy people. Rather more protein is lost, and

ABC of Nutrition

so is needed, on continuous ambulatory peritoneal dialysis than on haemodialysis. Potassium is carefully monitored but usually needs to be only a little restricted, sometimes not at all. It is controlled by adjusting the concentration in the dialysing fluid; 50 mmol/day is an average amount for the diet. This is achieved by eating fruits which have a low potassium content (apples, pears, and canned fruits) and boiled leafy vegetable and avoiding higher potassium vegetables (legumes), nuts, dried fruits, chocolate, and potato chips and crisps.

Patients can usually take an ordinary amount of sodium (about 110 mmol/day) or need only mild restriction. Fluid intake is restricted to about 1000 ml/day. Supplements of water soluble vitamins should not be given above nutrient requirement dosage.¹⁴ Fat soluble vitamin supplements are not required; they tend to accumulate.

Other conditions

Diets for phenylketonuria

Phenylketonuria is one of the better known examples of an inborn error of amino acid metabolism. It leads to mental retardation and other abnormalities if patients are not started on a low phenylalanine diet in the first few weeks of life. Diagnosis is by routine screening of blood phenylalanine after adequate intakes of milk, on about the seventh day of life. Bottle feeding is essential in infancy and a special low phenylalanine formula has to be used, such as Lofenalac or Minafen. When the child is weaned, the diet has to be very different from that of other children: a combination of low protein foods (controlled by phenylalanine content) and a phenylalanine free mixture of other essential amino acids—for example, Aminogran—with sugars and fats and vitamin and mineral supplements. The relative amounts of the first two are adjusted to maintain plasma phenylalanine neither too high (toxicity) nor too low (inadequate growth). The diet has to be strictly maintained and monitored until the child is about 8 years old, after which it can usually be relaxed. But it is required again in women during pregnancy.

Diets for gluten-sensitive enteropathy

Patients with gluten-sensitive enteropathy, coeliac disease, and dermatitis herpetiformis have to modify their diets to eliminate all wheat gluten, rye and barley gluten, and possibly oats. Fresh milk, fresh meat, fish and eggs, fresh vegetables and fruit, rice and maize, tea, coffee, sugar, wine, and spirits are all safe but many processed foods have wheat flour or gluten added. With many of these foods some brands contain gluten, others do not. The only thing to do is to check ingredients on the label or check brands against an up-to-date copy of Coeliac UK's list of gluten free manufactured products (PO Box 220, High Wycombe, Bucks HP11 2HY, <http://www.coeliac.co.uk>). Gluten free breads and pasta and other products, even communion wafers, are available, some on prescription. Unlike many other diets, even a small lapse and inclusion of the harmful component can lead to prompt return of symptoms.

Diets for dyspepsia

These diets present a contrast to the two preceding essential diets. Classic diets for peptic ulcer have not been found to accelerate healing in controlled barium meal studies. Modern drug treatment, especially with H₂ receptor antagonists and antibacterial treatment for *Helicobacter pylori* is usually effective. Diet is therefore much less emphasised than before for gastroduodenal diseases. Nevertheless, some foods are known to cause gastric irritation or stimulate acid secretion, including

Coeliac booklet (produced with permission from Coeliac UK)

chilli powder, coffee, tea, peppers, alcohol, and cola beverages. Other foods commonly cause heartburn by lowering the tone of the lower oesophageal sphincter: peppermint, garlic, onion, fatty meals. Frequent, small volume feeds are beneficial in oesophageal reflux. Traditional bland foods such as milk, chicken, mashed potatoes, bananas, apples, and ice cream usually relieve symptoms in patients with dyspepsia, though individuals vary.

Diets for diagnostic tests

For several days before a **glucose tolerance test** patients should be standardised on enough carbohydrate—that is, about 300 g or at least 50% of calories, the amount of carbohydrate in ordinary Western diets. Before a **faecal fat** test for malabsorption, patients should be on a known, controlled, and adequate fat intake, 70 to 100 g/day. Before **urinary screening for hypercalciuria** patients should be on a high normal calcium intake of about 1000 mg/day. Before urine is collected for **5-hydroxyindoleacetic acid (5-HIAA)** measurement dietary sources of it or of serotonin should be excluded: bananas, plantains, tomatoes, plums, avocados, pineapples, passion fruit, and walnuts. For urinary **4-hydroxy-3-methoxy-mandelic acid (VMA)** specific laboratory methods are now used, and dietary preparation should be unnecessary. Even urinary **creatinine** is affected (increased) by meat consumption.

Diet for patients taking monoamine oxidase inhibitors

The diet for depressed patients taking these antidepressants is the most striking example of dietary adjustment to prevent side effects from drugs. Monoamine oxidase inhibitors interfere with the normal breakdown of tyramine, dopamine, and other amines that occur naturally in foods in which flavour is enhanced by protein breakdown. Dangerous increases of blood pressure may follow ingestion of cheese, but other foods contain these amines and should be excluded too: wines, bananas, aged game, salami, pickled herrings, broad beans, and yeast and meat extracts, and any stale foods. The drugs which require this dietary modification include tranlycypromine, phenelzine, and isocarboxazid.

In practice the most commonly needed diet is one with reduced energy and the second most needed is a regimen with reduced alcohol intake. Both are prescribed much more often than they are successfully followed. This discrepancy remains a challenge for medical practice and research.

Elsewhere in this book, diets are described which are low in saturated fat, with increased polyunsaturated fat (chapter 1); low in sodium (chapter 2); low in oxalate (chapter 3); low in energy (calories) (chapter 11); and elimination diets (chapter 15).

14 Food poisoning

Patrick G Wall, Ciara E O'Reilly

Bovine spongiform encephalopathy/new variant Creutzfeldt–Jakob disease (CJD), foot and mouth disease, *E. coli* O157:H7, salmonella in poultry and eggs, antibiotic-resistant strains of bacteria and residues in food, listeria in paté and cheeses, have all damaged the public's confidence in our food supply. Coupled with this, consumers' confidence in the ability of the regulatory agencies to protect the food supply, and in the commitment of the food industry to protecting consumers' health, has also been damaged. There are many factors contributing to consumers' concerns regarding food safety as outlined in the box opposite.

Changes in consumer behaviour including more eating out, bulk shopping, and a desire for more convenience foods have contributed to the increasing incidence of foodborne infectious disease. Busy lifestyles, two parents working outside the home and a decreasing knowledge of cooking are contributing to an increasing demand for convenience “ready to cook” and “ready to eat” food, and more and more food is being prepared outside the home. This is increasing the length of the food chain, providing more opportunities for things to go wrong. Microbes do not respect national frontiers and the increasing global distribution and mass processing of food products has given microbes the opportunity to disseminate widely.² In the poorer non-industrialised countries other factors that contribute to an unsafe food supply are expanding urbanisation, the increased dependence on stored foods, insufficient access to safe water and essential facilities for safe food preparation. For example an increased volume of street foods prepared under poor sanitary conditions increases the risk of foodborne illness.

Producing safe food involves a chain of responsibility including primary producers, processors, distributors, wholesalers, retailers, commercial caterers and consumers. Everyone in the chain from “plough to plate” has a role to play. See box on page 100 for details. There is no room for complacency with foodborne diseases, as what may be a mild dose of diarrhoea for a robust young adult can be a life-threatening illness for an infant, a frail elderly person or an individual suffering from some concurrent morbidity. Globally hundreds of millions of people are affected by illnesses caused by contaminated food. The toll in terms of human life and suffering is enormous, particularly among infants and young children, the elderly and other vulnerable groups. Over the next few decades the number of elderly people in the world is predicted to increase rapidly. By the year 2025 more than 1000 million of the global population will be over 60 years old and more than two-thirds will live in developing countries.³ There are several key factors which relate to an increased risk of foodborne disease among the elderly: (a) the increase in the proportion and number of elderly people,³ (b) physiological factors, such as changes in the functions of the gastrointestinal tract and immune systems, that predispose an elderly person to infections, (c) pathological factors associated with ageing, such as disability and losses in sensory functions, and (d) social changes in health care of the elderly.¹

Animals and poultry are the reservoir for many foodborne infections (salmonella, campylobacter, *E. coli* O157:H7, cryptosporidia, and yersinia). Intensive farming of livestock to produce more and cheaper food has brought with it inherent dangers. It is possible to control the food, water, air and environment in these units and produce virtually disease-free

Factors contributing to food safety concerns¹

- New food preparation
- New storage methods
- Changing lifestyles—convenience foods
- Globalisation in food trade
- Changes in food production on the farm
- New systems of food processing
- Longer distribution chains
- Increasing number of vulnerable groups (the elderly, immunocompromised individuals, etc)

Summary of the effects of temperature on bacterial growth

animals. Husbandry practices are not always ideal, however, and the high stocking density facilitates the transmission of microbes, which can result in large amounts of contaminated material entering the food chain. Farms and abattoirs are not operating theatres and even with the best operational procedures a proportion of raw meat and poultry may contain harmful microbes. Care must be taken, therefore, to avoid transferring microbes from raw product to other foods that will not be heat-treated before consumption. Raw meat and poultry should be sufficiently cooked to kill all harmful microbes and refrigerated prior to cooking to prevent multiplication of harmful microbes. Bacteria such as *Listeria monocytogenes* (found in soil and silage as well as animals) and *Bacillus* species (soil, dust, etc) are widely distributed in the environment and may thus be found in plant (for example, coleslaw, rice) as well as animal (for example, soft cheeses, unpasteurised milk) products.

Protozoal pathogens

Causative agent	Incubation period	Usual duration of symptoms	Common clinical features*	Mode of transmission*
<i>Cryptosporidium</i> sp	2-5 days	<3 weeks	D	W, An, X
<i>Entamoeba histolytica</i>	2-4 weeks	Variable	D, B	X
<i>Giardia intestinalis</i>	5-25 days	Variable	D, P	X, F, W

* See key in table on page 97

Adapted from Department of Health⁴

Bacterial pathogens

Causative agent	Usual incubation period	Duration of symptoms	Common clinical features	Mode of transmission
<i>Aeromonas</i> sp	Unknown	Varied	V, D	W, F
<i>Bacillus</i> sp		<36 h		F
<i>B. cereus</i>				
Emetic syndrome	1-5 h		N, V, D, P

 HUS Haemolytic uraemic syndrome
 N Nausea
 P Abdominal pain
 J Jaundice
 V Vomiting

Mode of transmission:

Aer Aerosol
 An Animal contact
 F Food
 W Water
 X Person to person (faecal-oral)
 DC Direct contact with infected material

Food poisoning is defined by WHO as: “Any disease of an infectious or toxic nature caused by or thought to be caused by the consumption of food and water”.⁵ This definition includes all food and waterborne illness regardless of the presenting symptoms and signs. Thus it includes not only acute illnesses characterised by diarrhoea and/or vomiting, but also illnesses presenting with manifestations not related to the gastrointestinal tract. Heavy metals, pesticides, and other chemicals can also cause food poisoning.

Most food poisoning whether caused by bacteria, viruses, protozoa or toxins usually results in symptoms which include diarrhoea, vomiting, nausea, abdominal pain, and occasionally fever. However, there are other agents that result in food poisoning but do not usually result in gastrointestinal symptoms. These include *Clostridium botulinum*, *Listeria monocytogenes*, hepatitis A virus, and poliovirus. Laboratory tests are required to identify the aetiological agent but the symptoms, incubation period, and duration of illness may suggest the likely cause.

National figures on the incidence of food poisoning in most countries arise from a combination of notifications of clinical disease, reports of laboratory-confirmed infections, and details on outbreaks. In the United Kingdom all clinicians have a statutory duty to notify to the proper officer of the local authority, cases, or suspected cases, of food poisoning. The meaning of the term “food poisoning” is not defined in the relevant UK legislation, the Public Health (Control of Diseases) Act 1984, and this has previously led to confusion as to which cases should be notified, but in 1992 the WHO definition was adopted. Notification is not contingent on laboratory confirmation of infection, and delaying notification until laboratory confirmation is available defeats the purpose of a rapid notification system designed to enable effective timely intervention at local level. An outbreak is defined as an incident in which two or more people, thought to have a common exposure, experience a similar illness or proven infection.⁵ A general outbreak is defined as one that affects members of more than one household or residents of an institution, distinguishing it from an outbreak affecting one family.⁵

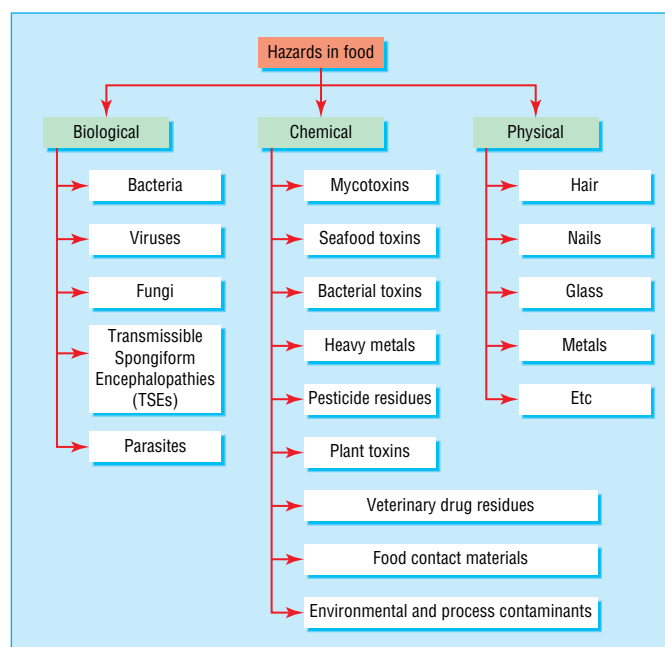

Notifications of food poisoning based on clinical diagnosis are a very crude estimation of the true extent of the burden of ill health due to food poisoning. The symptoms can occur unrelated to food poisoning and only a proportion of cases are actually notified (clinicians being unaware of the need to notify or omitting to do so). Gross under-notification of food poisoning occurs as is well documented for more serious infections.⁶ Furthermore, many cases do not seek medical attention.⁶

Similarly the reports of laboratory-confirmed gastrointestinal pathogens represent just a fraction of the true incidence of these pathogens, as only a proportion of cases seek medical attention and only a subset of these have a sample submitted for analysis.⁷ Not all of these will have a pathogen

Viral pathogens

Virus	Incubation period	Duration of symptoms	Common clinical features*	Mode of transmission*
Adenovirus	7-8 days	9-12 days	D, V	X

identified (particularly if the agent is a virus) and not all pathogens identified are reported centrally. The exact proportion in each category is unclear and may vary for different organisms. The National Infectious Intestinal Diseases Study attempts to estimate the true prevalence of the different pathogens and the degree of under-diagnosis and under-reporting.⁴ Laboratory reports most likely represent patients at the severe end of the spectrum of diarrhoeal disease and are therefore a biased sample. In addition, laboratory reports of potentially foodborne microbes may not all have arisen by this route, with animal contact and person-to-person transmission accounting for a proportion. It is often only when cases are investigated epidemiologically that the exact route of transmission is identified. In England and Wales reports of laboratory confirmed infections are collated and published by the Communicable Disease Surveillance Centre (CDSC), the Epidemiology Unit of the Public Health Laboratory Service (PHLS). Similar national surveillance centres exist in most countries. Campylobacter and salmonella are by far the most commonly reported enteric pathogens and the most likely aetiological agents in a lot of the food poisoning notifications.

Diagnosis

A microbiological diagnosis is often not necessary for successful treatment of an individual suffering from food-related gastroenteritis (see box opposite for details when it is necessary).

Faecal culture remains the gold standard for the identification of most foodborne pathogens. Electron microscopy is used for the identification of Norwalk and other viruses. Newer more rapid molecular methods are coming on stream. Clinicians should consult their local laboratory for information on the exact diagnostic tests on offer so that they can take the appropriate specimens and request the optimum investigations.

Treatment

In uncomplicated cases of acute gastroenteritis, symptomatic therapy alone is recommended; that is oral rehydration combined with antipyretics. Antimotility drugs are not advised for acute attacks as they have a very limited role as adjuncts to fluid and electrolyte replacement. Antibiotic therapy is only recommended in high-risk groups, for example, patients with underlying disease such as sickle cell anaemia, immunocompromised patients, cases who are more likely to develop complications, and those with prolonged fever and extraintestinal infections. Metronidazole is indicated if symptoms are caused by giardia.

Economic consequences of foodborne illness

As well as morbidity and mortality associated with foodborne diseases, there are direct economic costs to society in treating sick people. There are also economic losses due to food being rejected in export markets, and loss of consumer confidence in brand names on the domestic market. The US government has estimated the cost of human illnesses of seven foodborne pathogens to be between US\$ 5.6 to 9.4 billion annually. The cost of salmonellosis in England and Wales in 1992 was estimated at between US\$ 560 and 800 million.

Food poisoning notifications and laboratory reports of campylobacter and salmonella: England and Wales 1992-2000 (Source: PHLS CDSC)

Microbiological diagnosis and food-related gastroenteritis

Microbiological diagnosis is necessary for individuals suffering from food-related gastroenteritis:

- in severely ill, septicaemic or immunosuppressed patients;
 - if clusters of similar cases are to be recognised and outbreaks controlled early;
 - if the priority pathogens are to be identified to permit tailored public health interventions;
 - to monitor ongoing trends and evaluate interventions;
 - in nursery children, special needs children and the elderly in institutions where personal hygiene may be poor and there is a risk of secondary spread;
 - for food handlers and healthcare workers to exclude excretors of typhoid and verocytotoxic *E. coli* (VTEC);
 - when a patient wishes to take legal action against a restaurant or food retailer.
-

Economic consequences contributing to food safety concerns¹

- Economic costs to society in treating sick people
 - Economic losses due to rejection of food in export markets
 - Loss of consumer confidence in brand names
-

Over 70% of costs were directly associated with treatment and investigation of cases, and costs to the economy of sickness related to absence from work. Estimates in 1999 showed that foodborne diseases annually cause approximately 76 million illnesses, 325 000 hospitalisations and 5000 deaths in the United States each year.⁸ The BSE crisis in Britain is predicted to cost over US\$ 5.5 billion. These costs are associated with the loss of export sales, compensating farmers, paying slaughterhouses and renderers, and research and control measures. The dioxin crisis in Belgium in 1999 saw the fall of the national government and economic costs in excess of US\$ 2 billion to the Belgium economy.¹

The true estimates of foodborne disease and the likely economic costs are unknown. In industrialised countries only a small proportion of cases of foodborne diseases come to the notice of health services and even fewer are investigated. Very few non-industrialised countries have established foodborne disease reporting systems, and in those that have, only a small fraction of cases are reported. The incidence of foodborne disease is likely to be far higher than in industrialised countries because of such factors as poor nutritional status, inadequate sanitation, low standards of hygiene and reduced likelihood of immediate medical attention. There are many hidden costs associated with foodborne illnesses. Tourists will shun regions with a high incidence of foodborne illness as will multinational firms choosing the location of foreign investment. Repeated bouts of diarrhoea damage children's mental and physical development and play havoc with their schooling.¹

Principal foodborne pathogens

Bacteria

Campylobacter

The importance of campylobacter as a human pathogen was recognised in the 1970s and it is the commonest gastrointestinal pathogen isolated from humans in the United Kingdom.⁹ These bacteria do not usually multiply on food as they will not grow at temperatures below 28°C and grow best at 42°C. Infection in humans usually causes an acute self-limiting enterocolitis. Bacteraemia and reactive arthritis are rare complications and an association with Guillain-Barré syndrome has been observed.¹⁰ Large outbreaks are rarely recognised and reported to the Communicable Disease Surveillance Centre in England and Wales: only 240 (0.2%) of 122 250 cases of campylobacter infections reported between 1992 and 1994 were associated with general outbreaks.¹¹ There are two principal species, *C. jejuni* and *C. coli*, although most cases are reported without a species. *C. jejuni* is the most common cause of bacterial food poisoning in many industrialised countries. These are fragile organisms which require micro-aerophilic conditions for growth and do not survive or multiply very well on foods. However, the low infectious dose means that a small level of contamination may result in illness. Campylobacter may be transmitted by food, particularly poultry,¹² unpasteurised milk,¹³ and contaminated water.¹⁴ *Campylobacter* spp are especially common in birds but have also been isolated from a wide range of animals. Wild birds are considered to be an important reservoir of infection for domestic and food animals. Cases have also been associated with the consumption of pasteurised milk where the milk bottle tops had been pecked by birds, who presumably transferred the bacteria on their beaks.¹⁵ Although many foods may be contaminated with campylobacter, it is considered by many authorities that poultry and poultry products are of particular importance as a source of human infection. *Campylobacter* spp do not multiply very effectively in most foods, however, *Campylobacter* spp may

Principal faecal pathogens identified in humans: England and Wales 1992-97 (Source: PHLS CDSC)

Recommendations to control transmission of *Campylobacter* spp in the food chain¹⁶

Recommendations to control transmission of *Campylobacter* spp (and other foodborne pathogens) from farm to fork include:

- poultry industry complying with the highest possible degree of biosecurity measures
- industry development and implementation of evidence-based standard operating procedures, in order to prevent or minimise product contamination with *Campylobacter* spp
- food businesses should implement and document a food safety management system based on the principles of the Hazard Analysis Critical Control Point (HACCP)
- staff involved in food production should be appropriately trained in food safety to a level commensurate with their work activities
- the provision of a supply of potable water for food preparation
- consumers should practise basic good hygiene when handling food and should cook high-risk raw foods thoroughly¹⁶

survive through the food distribution system and because consumption of a small number of organisms (500 or less) may be associated with illness, proliferation in food is not a prerequisite for infection.¹⁶

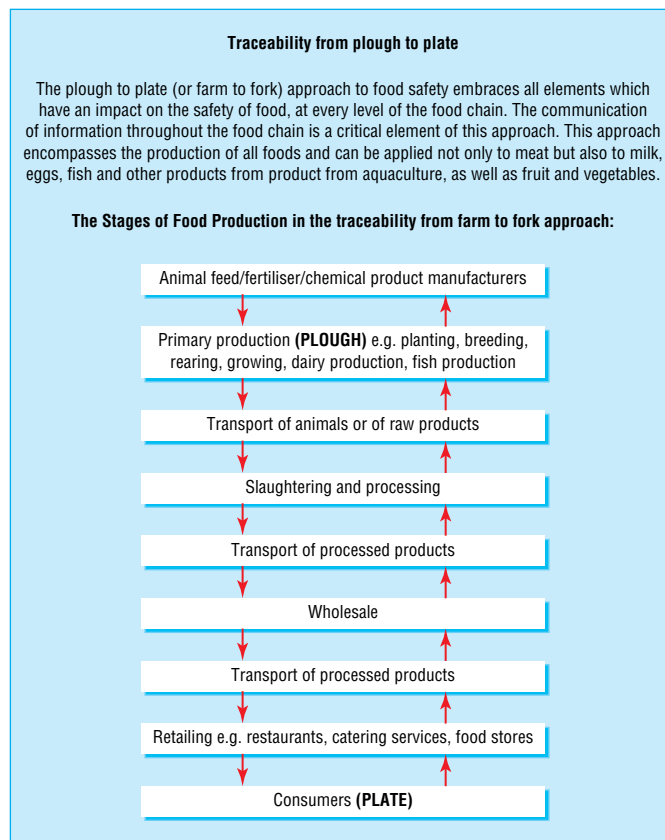

In the United Kingdom there is a characteristic seasonal distribution of reports, with a peak in the early summer, in contrast to reports of salmonella which reach their maximum in the late summer and autumn. There are also regional variations in the reporting of campylobacter infections which may reflect a higher incidence in rural than urban populations.

Salmonella (non-typhoid)

Salmonella is a genus made up of over 2200 serotypes. They are widely dispersed in nature, being found in the gastrointestinal tracts of domesticated and wild mammals, reptiles, birds, and insects (apart from *S. typhi* and *S. paratyphi* which only colonise humans). Although there is a vast range of serotypes, a small number predominate. Salmonella is the second most commonly reported bacterial cause of gastroenteritis after campylobacter. In England and Wales in 1997 there were 32 169 human cases of salmonellosis but four serotypes accounted for 90% of cases (*S. enteritidis* 22 806, *S. typhimurium* 4695, *S. hadar* 692, and *S. virchow* 650). Although the clinical management of most cases infected with the different serotypes is similar, for epidemiological purposes, it is important that isolates are sent to a reference laboratory for definitive typing. Salmonella can be phenotyped using serotyping, phage typing and antibiograms, and genotyped using molecular methods including plasmid profile analysis, pulsed field gel electrophoresis, and DNA sequencing. The National Reference Laboratory in England and Wales is the PHLS Laboratory of Enteric Pathogens. Most countries have such a facility and in the European Union all such labs are collaborating in the Enter-net Project to standardise methodology and share surveillance and outbreak data. Detailed typing can be used to link strains identified in humans, food samples, environment samples and livestock in the course of outbreak investigations. The standardisation of phage typing techniques, the electronic transfer of molecular typing patterns, formal and informal links established through international networks including Enter-net and the notification of national outbreaks to these networks are extremely important, particularly in the case of an international outbreak.

Incidence rates of infection are highest in children under 10. This may reflect increased susceptibility but is also likely to be due to these young children being brought to medical care and having faecal specimens submitted for examination. Most cases suffer from gastroenteritis with a subset (<1%) suffering from invasive disease.

Undercooked (or improperly heat treated) food from infected food animals is most commonly implicated. There has been a dramatic rise in human salmonellosis in the United Kingdom since the mid 1980s due to an unprecedented increase in one subtype, *S. enteritidis* phage type (PT) 4. The reservoir for this subtype is infected poultry. Humans become infected from consuming under-cooked poultry, raw eggs, dishes made from the same, or foods cross-contaminated from these.¹⁷⁻¹⁹ Egg-associated salmonellosis is caused when *S. enteritidis* infects the ovaries of apparently healthy hens and these hens lay contaminated eggs. If the eggs are eaten raw or undercooked, salmonellosis may result. The increase in

S. enteritidis PT4 in the United Kingdom has been seen in many countries and this pathogen is now a global problem.

Although *S. enteritidis* has declined by 50% since its peak year of 1997 and *S. typhimurium* by 40% in England and Wales since 1995, these serotypes continue to dominate. The decline in *S. enteritidis* phage type 4 (PT4) is the result of vaccination of poultry flocks but in its place new types are emerging.

In 2001 in England and Wales there was a significant increase in salmonellosis which is associated with a range of salmonellas that have links with foreign travel and the importation of food stuffs (for example, contaminated desiccated coconut).²⁰ Another emerging global problem is *S. typhimurium* definitive type 104 (DT 104). It is the second most prevalent salmonella found in humans in England and Wales, increasing from fewer than 250 in 1990 to 4006 cases in 1996. Over 90% of isolates are multi-antibiotic resistant to ampicillin, chloramphenicol, streptomycin, sulphonamides and tetracyclines, with a subset of the strains having reduced susceptibility to trimethoprim and ciprofloxacin.²¹ This subtype is prevalent in cattle, sheep, pigs, and poultry, and therefore a wide array of foods can be contaminated. Reduced susceptibility to fluoroquinolone drugs has also emerged in the poultry-associated serotypes *S. hadar* and *S. virchow*. The development of these strains is a consequence of the use of antibiotics in animal husbandry.²² This acquisition of resistance has resulted in a progressive reduction in options for the management of invasive salmonellosis in humans.

Enterovirulent *E. coli* including *E. coli* O157

The enterovirulent *E. coli* include all those *E. coli* believed to be associated with diarrhoea. Enterotoxigenic *E. coli* are an important cause of travellers' diarrhoea, enteropathogenic *E. coli* are an important cause of childhood diarrhoea, enteroinvasive *E. coli* cause a disease that is similar to shigella-like dysentery, enteroaggregative *E. coli* have been associated with diarrhoeal disease in infants and travellers, and enterohaemorrhagic *E. coli* are associated with haemorrhagic colitis and haemolytic uraemic syndrome.

Of the latter, currently the most important is verocytotoxin (VT) producing *E. coli* O157. It is now a major foodborne public health problem, with one outbreak in central Scotland in 1996 resulting in 500 cases and 20 deaths.²³ Diarrhoea caused by VTEC O157 is often accompanied by bleeding or haemorrhagic colitis and may be complicated by haemolytic uraemic syndrome (HUS) or thrombotic thrombocytopenic purpura.²⁵ HUS is most likely in children under 5 years and is a major cause of renal failure in children.

E. coli O157 is part of the normal gut flora of cattle primarily, and to a lesser extent sheep. Raw or undercooked minced beef or cooked meats cross-contaminated from raw meat are the high risk foods.²⁵⁻²⁷ However, any food that could possibly be contaminated with ruminant faeces poses a risk and infections have been associated with vegetables, cheese, milk, fruit juice, and water. The organism is not particularly heat-resistant and is easily killed by cooking; however the low infective dose means that foods must be cooked thoroughly and be protected post-cooking from cross-contamination with raw foods. *E. coli* O157 first came to prominence as a human pathogen in 1982.²⁸ In addition to the foodborne route, infections are transmitted by the person to person route, particularly in nurseries and old people's homes, and by direct contact with farm animals.²⁶ Nobody knows where this strain of *E. coli* came from and, more worryingly, nobody knows where it is going to, as the incidence is increasing in many countries including the United Kingdom where rates of infection vary geographically. In 1996 the highest rate of infection was seen in

Low infectious dose of verocytotoxigenic *E. coli* (VTEC)

The number of VTEC required to cause illness is very low. The precise infectious dose is not known but it has been reported to be as low as 10 cells. VTEC can survive the high acidity of the stomach and with such small numbers, infection can occur without any growth of the bacteria in food.^{24,25}

Human *E. coli* O157 infections: UK 1992-97 (Source: Department of Health)

Scotland with a rate of 9.25 per 100 000 population compared with 1.27 in England and Wales and 0.85 in Northern Ireland.

Listeria monocytogenes

L. monocytogenes causes serious human illness such as perinatal infections, septicaemia, and meningitis. In pregnant women it can cause a flu-like illness, which can result in miscarriage, stillbirth or birth of a severely ill infant. More recently, it has been recognised that *L. monocytogenes* can cause mild gastrointestinal symptoms. Listeriosis is a comparatively rare but very serious human illness with a case fatality ratio of ~20%.

Highly susceptible individuals include pregnant women, neonates, elderly people and immunocompromised individuals.

L. monocytogenes is ubiquitous in the environment and so can be transferred to foods from a wide variety of sources. Foods associated with transmission are characteristically highly processed, have extended shelf lives at refrigeration temperatures, are capable of supporting the growth of *L. monocytogenes* and are consumed without further cooking.

L. monocytogenes is psychrotrophic, —that is, potentially capable of growing, albeit slowly, at refrigeration temperatures as low as 0°C.¹

Clostridium botulinum

C. botulinum produces a neurotoxin which is one of the most poisonous substances known to man. Foodborne botulism occurs when food becomes contaminated with spores from the environment, which are not destroyed by initial cooking or processing. If the food provides a suitable environment for growth the spores will germinate leading to toxin production. The toxin itself is heat sensitive and so a further heat treatment of the food would prevent illness. Botulism can be prevented by using food preservation methods that are designed to inhibit the growth of *C. botulinum*. For example, low acid food, (pH > 4.4) canned foods are heat treated to 121°C for three minutes (known as the “botulism cook”) or equivalent.¹

Parasites

Foodborne parasitic diseases are a major public health problem that affects millions of people, predominantly in non-industrialised countries. The incidence of parasitic disease associated with the consumption of foods of animal origin has declined in industrialised countries in recent years, where improvements in animal husbandry and meat inspection have led to considerable safety and quality gains. The situation in non-industrialised countries is very different in that these diseases are associated with poor standards of sanitation and hygiene, low educational standards, and extreme poverty.

Parasites are organisms that live on other living organisms known as hosts. They may be transmitted from animals to humans, from humans to humans, or from humans to animals. Foodborne parasitic disease occurs when the infective stages of parasites are eaten in raw or partially cooked protein foods, or in raw vegetables and fruits that are inadequately washed prior to consumption. These organisms then live and reproduce within the tissues and organs of infected human and animal hosts, and are often excreted in faeces. The parasites involved in foodborne disease usually have complex life cycles involving one or two intermediate hosts. The foodborne parasites known to cause disease in man are broadly classified as helminths (multicellular worms) and protozoa (single-celled microscopic organisms). These include the major helminthic groups of trematodes, nematodes, and cestodes and some of the emerging protozoan pathogens, such as cryptosporidia and cyclospora. The illnesses they can cause range from mild discomfort to debilitating illness and possibly death.^{1,27,29}

Individuals highly susceptible to listeriosis include

- Pregnant women
 - Neonates
 - Elderly people
 - Immunocompromised individuals
-

Foodborne parasitic diseases

Foodborne parasitic diseases are a major public health problem that affect millions of people, predominately in non-industrialised countries. The incidence of parasitic disease associated with the consumption of foods of animal origin has declined in industrialised countries in recent years, where improvements in animal husbandry and meat inspection have led to considerable safety and quality gains. The situation in non-industrialised countries is very different in that these diseases are associated with poor standards of sanitation and hygiene, low educational standards and extreme poverty.

Principal foodborne parasites^{1,27,29}

Parasite	Food involved in transmission to man	Pathogenesis
(a) Helminths		
(i) Trematodes		
<i>Opisthorchis</i> (liver fluke)	Many species of freshwater fish including the family <i>Cyprinidae</i> (for example whitefish, carp, tench) Ingestion of infective larvae (metacercariae) in fish muscle and subcutaneous tissue	The liver flukes, <i>Opisthorchis viverrini</i> , <i>O. felineus</i> and <i>Clonorchis sinensis</i> , are biologically similar; foodborne trematodes which chronically infect the bile ducts and, more rarely, the pancreatic duct and gallbladder of human beings and other mammals
<i>Clonorchis</i> (liver fluke)	Many species (ca. 110) of freshwater fish, mainly <i>Cyprinidae</i> (carp, roach, dace). Ingestion of infective larvae (metacercariae) in fish muscle	Paragonimiasis—symptoms include cough, hemoptysis and pleuritic chest pain
<i>Paragonimus</i> (lung fluke)	Raw, salted or partially cooked flesh of fresh and brackish-water crabs, crayfish and shrimps. (Wild boar meat suspected as a source of infection)	
(ii) Cestodes (tape worm)		
<i>Diphyllobothrium</i>	Humans acquire infection by eating raw or inadequately cooked fish	Symptoms commonly are trivial or absent. Where worms attach to the jejunum patients develop B-12 deficiency anaemia. Massive infections may be associated with diarrhoea, obstruction of the bile duct or intestine and toxic symptoms
(iii) Nematodes (round worm)		
<i>Anisakis</i>	Humans acquire infection by eating raw or lightly cooked fish	Usually manifests as cramping, abdominal pain and vomiting
(b) Protozoa		
<i>Giardia intestinalis</i>	Transmission is foodborne, waterborne (faecally contaminated food or water) or person to person spread	Chronic diarrhoea, malabsorption, weight loss
<i>Toxoplasma gondii</i>	Transmission is foodborne (from raw or inadequately cooked infected meat) waterborne or by faecal-oral route (infected cats)	Mostly asymptomatic. In severe cases: hepatitis, pneumonia, blindness, severe neurological disorders. Can also be transmitted transplacentally resulting in a spontaneous abortion, a stillborn, mental/physical retardation
<i>Cryptosporidium parvum</i>	Transmission is foodborne, waterborne, animal-person or by faecal-oral route	Often asymptomatic Abdominal cramps, vomiting, weight loss, diarrhoea

Cryptosporidium

Cryptosporidium parvum is a coccidian protozoan parasite which was identified as an important human pathogen in 1976. Infection rates in the United Kingdom show variation in both age and seasonal distribution. The age distribution reflects endemicity; few infections occur under the age of 1 year, probably due to passive maternal immunity and protection from exposure to the environment. An almost logarithmic increase is observed in toddlers and young children, moderately high rates in young adults, and few cases after the age of 40 years. Seasonal peaks occur in the spring and late autumn. Cryptosporidiosis is a zoonoses with its primary reservoir in calves and lambs. The oocysts are resistant to chlorination and outbreaks associated with drinking water and swimming pools are common.^{30,31} *Cryptosporidium* is highlighted here because it can contaminate the public water supply and extensive outbreaks of gastroenteritis can result.³⁰ Transmission can also occur by direct contact with animals and by the person to person route. Before the advent of effective antiretroviral therapy, cryptosporidiosis in patients infected with HIV was life threatening.

Viral gastroenteritis (see box on page 96)

Although primarily transmitted by the person to person route, transmission by the food or waterborne route has been documented for astrovirus and calicivirus (human calicivirus

and Norwalk-like virus).³² Norwalk-like virus, also known as Small Round Structured Virus (SRSV), is the most commonly identified foodborne virus.³³ Humans are the reservoir for SRSV and shellfish, particularly oysters grown in sewage-contaminated water, are a source of infection. Infected foodhandlers are another source and can contaminate food during preparation. Aerosolisation of vomitus-containing virus particles has been proposed as a mode of transmission of the virus and may also be a source of food contamination. Clinical and epidemiological features, including stool culture negative for bacteria, duration of illness 12-60 hours, incubation period 24-48 hours and vomiting in >50% of cases, can assist in making the diagnosis when no laboratory results are available.³⁴ Sensitive detection assays have now revealed that shedding of the virus in faeces may continue for up to a week after the illness subsides.

Principal chemicals affecting food safety

Pesticide residues

Pesticides are chemicals or biological products used to control harmful or undesired organisms and plants, or to regulate the growth of plants as crop protection agents.

Pesticides can also be toxic to humans since certain biochemical pathways are relatively conserved across species as are some enzymes and hormones. In the context of food safety, exposure to pesticides is classified as acute or chronic. An acute intoxication usually has an immediate effect on the body whilst a chronic effect may reveal itself over the life span. The severity depends on the dose and the toxicity of the pesticide compound or breakdown product. Toxic effects that have been identified can include enzyme inhibition, endocrine disruption, and carcinogenic action, depending on the compound in question.

In Europe the control of pesticides is based on Council Directive No 91/414/EEC. Under this regulation, pesticides must be evaluated for safety based on dossiers prepared by their manufacturers. If a pesticide is accepted it is placed on a positive list with a maximum residue limit (MRL) assigned to it.

Veterinary drug residues

Veterinary drugs include antibacterial compounds, hormones and non-steroidal anti-inflammatory preparations. As animal husbandry practices have intensified over the past few decades, antibacterial substances have been increasingly used as growth promoters to increase feed conversion efficiency and for prophylaxis and therapy to prevent outbreaks and treat disease. Similarly, hormones are administered to increase growth rate and meat yield.

The excessive use of antibacterial compounds in animal husbandry has raised concerns about the development of resistant bacteria and the effect that this may have on the usefulness of antibiotics in human medicine. There have also been concerns about the risk of allergic reactions in humans to antibacterial residues in food of animal origin.¹

Environmental/industrial contaminants

This group of contaminants are of environmental origin or are by-products of industrial processes. Polyhalogenated hydrocarbons (PHH) are a category of environmental contaminants that includes toxophene, dioxins, and polychlorinated biphenyls (PCBs). Certain PHH are manufactured for use in plastics, paints, transformers, and herbicides although their use is now either banned or severely

restricted. In most industrialised nations the compounds have become ubiquitous in the environment. Hence contamination of the food chain is inevitable and it has been estimated that in Western industrialised countries, 90% of human exposure is through ingestion of contaminated foods like fish and milk.

Foods that are rich sources of fats and oils tend to accumulate PHH because the compounds are lipophilic and bioaccumulate in lipid rich tissues and fluids. Oily fish from areas such as the Baltic Sea, where levels of PHH in the water are high, may contain elevated levels of these contaminants. Similarly, cows that graze on polluted pasture can accumulate unacceptable concentrations of PHH in their milk. A recent incident in Belgium introduced PCBs and dioxins into the food chain via contaminated animal feed resulting from the accidental incorporation of industrial oil into the feed ration.¹

Prevention and control of foodborne infectious disease

If the incidence of food poisoning is to be reduced, everyone from primary producers, workers throughout the industry to consumers has a role to play. Farms are the reservoir for many foodborne pathogens and these harmful microbes need to be controlled in livestock. Best husbandry practices will assist farmers to deliver livestock and produce free of pathogens and residues to the next link in the chain. Processors must have rigid process controls to ensure that the food is produced with safety paramount. The distribution, wholesale and retail networks must adhere to the best hygienic practices so that food is delivered to the point of sale in the best possible condition.

Modern food control programmes take consideration of the role of the food producers and food processors in managing the safety of their products. The various sectors of food production, processing and distribution possess knowledge about the safety and shelf-life of their products and have an important role in assisting regulators in achieving national food safety goals. One of the most effective ways for the food sector to protect the health of consumers is to base their food safety management programmes on the seven principles of the Hazard Analysis Critical Control Point (HACCP) system. European food hygiene law requires that food businesses identify the steps in their activities which are critical to ensuring food safety and make certain that adequate safety procedures are identified, implemented, maintained and reviewed.

Even with the best control measures in place a proportion of raw meat and poultry may contain harmful microbes. Food handlers, whether working in the commercial setting or in a domestic kitchen, must be aware of this and take appropriate hygienic precautions.

Raising awareness through continuous innovative education programmes for everyone from consumers including school children to workers throughout the food industry is the mainstay for reducing the incidence of foodborne infectious diseases. Foodhandlers must be aware of their responsibility to handle food hygienically. Infected humans are the reservoir for typhoidal salmonellas and SRSV but can potentially spread any infection by contaminating food during preparation if their personal hygiene is poor. Symptomatic individuals should be excluded from preparing food until they have been at least 48 hours symptom free for most microbes, and until microbiological clearance has been confirmed if infected with enteric salmonellas and VTEC.³⁵ Any individual incapable of

The seven basic principles of a HACCP system*

1. Conduct a hazard analysis.
2. Determine the Critical Control Points (CCPs) in the process.
3. Establish critical limit(s) for each CCP.
4. Establish a monitoring programme to ensure control of the CCP.
5. Establish corrective action to be taken when monitoring indicates that a CCP is not under control.
6. Establish verification procedures to demonstrate the effectiveness of the HACCP system.
7. Establish documentation concerning all procedures and records appropriate to these principles and their application.

*HACCP means Hazard Analysis and Critical Control Points.

It is a systematic approach to identifying and controlling hazards (microbiological, chemical, and physical) that could pose a threat to the production of safe food—in simple terms, it involves identifying what could go wrong and planning to prevent it.

Prevention of food poisoning outbreaks¹⁹

The same four readily preventable faults repeatedly contribute to outbreaks in food poisoning:

- grossly contaminated raw product
 - inadequate refrigeration allowing harmful microbes to multiply at warm temperatures to dangerous levels
 - cross contamination from raw to cooked food
 - insufficient heat treatment when cooking¹⁹
-

practising basic personal hygiene should be excluded from working with food.

The table on page 106 provides a list of useful websites.

New variant Creutzfeldt–Jakob disease (nvCJD): is it a foodborne disease?

The magnitude of the epidemic of bovine spongiform encephalopathy (BSE) in the United Kingdom is without precedent in the recorded history of the transmissible spongiform encephalopathies. The public health and the scientific issues have become entwined in the political and commercial response, to increasing national and international concern over the possibility of transmission of spongiform encephalopathy from cattle to man. Medical practitioners and other public health professionals are having to respond to the intense public anxiety regarding the risk of exposure to BSE contaminated material. Documented transmission of BSE to non-human primates indicates that such anxiety is not without some scientific foundation.³⁶ We are left facing possible present consequences of past events over which we now have no control.

In March 1996 the UK CJD Surveillance Unit described a distinct variant of CJD in 10 people aged under 42 (average age 27 years) with dates of illness since January 1995.³⁷ This variant had not been previously recognised and is characterised by behavioural change, ataxia, progressive cognitive impairment, and a prolonged duration of illness (up to 23 months) compared to classical CJD. In addition the EEG is not typical of classical CJD and the brain pathology, although showing marked spongiform change and extensive amyloid plaques, is also not typical. The most striking features of these cases are the extensive plaque formation and a pattern of prion protein immunostaining which is unique and remarkably consistent between cases. After reviewing the data on these variant CJD cases the UK Spongiform Encephalopathy Advisory Committee (SEAC) advised the British Government “that in the absence of any credible alternative, the most likely explanation at present is that these cases are linked to exposure to BSE material before the Specified Bovine Offal (SBO) ban was introduced in 1989”.³⁸ The SBO ban prohibits the use of those tissues (brain, spinal cord, thymus, tonsils, spleen, and intestine) most likely to contain the infective agent of BSE in products for human consumption.

Ten nvCJD cases were announced in March 1996. By the end of June 2002, a total of 124 cases of nvCJD (number of deaths from definite or probable nvCJD: 115, number of probable nvCJD cases still alive: 9) had been reported in the United Kingdom. The overall median age at death was 28 (range 14–74 years). The median number of days from onset to diagnosis was 334 days and from onset to death 411 days. Of the 124 cases, 68 (55%) were male. The recent analyses showed that the underlying incidence is increasing by an estimated 18% per year based on date of symptom onset, or 20% per year based on date of death.⁴¹ In relation to the number of nvCJD cases in countries other than the United Kingdom, as in March 2002 there were five definite and probable cases of nvCJD in France, one in Italy,⁴² one in the Republic of Ireland and one in Hong Kong (reported to be associated with the United Kingdom).⁴³ With a possible incubation period of up to 25 years, nobody knows how many people in the United Kingdom and elsewhere worldwide may be currently incubating this new variant CJD. If further cases continue to appear, we could be witnessing the unfolding of one of the greatest man-made public health catastrophes ever.

Possible vehicles associated with principal aetiological agents of food poisoning

Aetiology	Principal possible vehicles
<i>Bacillus</i> species	Reheated rice
<i>Campylobacter</i>	Poultry, raw milk, water
<i>Clostridium perfringens</i>	Cooked red meat and poultry
<i>Clostridium botulinum</i>	Canned products, honey
<i>Cryptosporidium</i>	Water
<i>E. coli</i> (non-VTEC)	Salads, raw milk, vegetables, cheese, water
<i>E. coli</i> (VTEC)	Undercooked meat, unpasteurised milk and cheese, vegetables, water
Hepatitis A	Seafood, water, (any food contaminated by infected food handler)
<i>Listeria monocytogenes</i>	Cheese, pâté
Salmonella (non-typhoid)	Poultry, eggs, red meat, dairy products
Salmonella (typhoid)	Water, (any food contaminated by sewage or infected food handler)
Scombrotoxin	Mackerel, tuna, and other scromboid fish
<i>Staph. aureus</i>	Food contaminated by infected food handler
SRSV	Oysters and other seafood (any food contaminated by infected food handler)

Adapted from Department of Health (2000)⁵

Factors reported to BSE agent support the responsibility for nvCJD in humans

There are several factors supporting the hypothesis that the BSE agent is responsible for the emergence of the new form of CJD in humans. These include:

- the temporal association—BSE came first followed by nvCJD
- the geographical association—the UK has had the bulk of the BSE cases and the majority of the nvCJD cases
- a report describing similar clinical, molecular, and neuropathological features in three BSE experimentally infected macaque monkeys³⁹
- molecular typing of prion proteins from cases of BSE and nvCJD has revealed that they are indistinguishable from each other and different from sporadic CJD cases, supporting the hypothesis of a causal link⁴⁰

Conclusion

As society changes, so do the bacteria involved in foodborne disease and this trend is likely to continue. The globalisation of our food supply poses greater risks to consumer health from the mass production and distribution of foods and increased risk for

food contamination. If the regulators and all stakeholders in the food production chain are to ensure that consumers' health is adequately protected and that they are provided with the reassurances that they are seeking, then issues such as BSE, dioxin contamination, antibiotic resistant bacteria, *Salmonella enteritidis* in poultry, *E. coli* O157, and the increasing incidence of campylobacter infection will have to be dealt with. The solution is sequential incremental risk reduction along the food chain with all stakeholders playing their part; also, the communication of any unavoidable residual risk to consumers with clear instructions on how to manage such risks. While there are specific control programmes required, and more research and surveillance needed to understand the epidemiology of different agents, increased hygiene standards across the food chain will have the effect of reducing foodborne disease.

The authors acknowledge the work of Dr David Thomkins, Consultant Microbiologist, Public Health Laboratory Leeds and his colleagues on the National Infectious Intestinal Diseases Study⁵ team, in preparing the tables: Bacterial pathogens, protozoal pathogens, and viral pathogens.

15 Food sensitivity

One man's meat is another's poison

Lucretius 96-55 BC

In affluent countries the idea is now widespread that a variety of symptoms (not just those of classical allergy) are caused by individual (hyper)sensitivity to certain foods or substances in them; that such sensitivity has become more common; and that food processing may have something to do with it. The media, various unorthodox practitioners, and some groups of lay people have spread the "news". Medical practitioners meanwhile are equipped with little information, most of it confusing, and no reliable diagnostic test to answer their patients' needs.

This is one of the most polarised topics in human nutrition. On one hand many lay people are concerned about sensitivity to food and believe that they suffer from it. On the other hand the medical and food science establishment has been fairly dismissive and declares that most food sensitivity (except adult lactase insufficiency) is uncommon.

The subject is at the interface between scientific immunology, food technology, and quackery. Good clinical research has been lacking, but recently a few academic departments have started to apply the methods of clinical science to unravel this confusing area. At present it is impossible to give estimates of the objectively confirmed prevalence of most types of sensitivity to food.

Terminology

The words describing food sensitivity are imprecise and often used to mean different things.

- **Food allergy** is commonly used by lay people (and by doctors talking to patients) as the broad term, including non-immunological (and sometimes even psychosomatic) reactions. In technical communication the term 'allergy' should be confined to immunological reactions.^{4,6}
- **Food sensitivity or hypersensitivity** is sometimes used in the narrow sense to mean only immunological reactions.
- **Adverse reaction to food** is not used in this chapter because it conveys no meaning of individual susceptibility and includes food poisoning (dealt with in chapter 14).
- **Pseudoallergic** and **anaphylactoid** reactions are used for, for example, asthma or angio-oedema after food with no immunological abnormalities detectable in the patient.
- **Food idiosyncrasy** is used in some classifications for non-allergic food intolerance.

The classification shown opposite is developed from and compatible with the definitions in the report of the Royal College of Physicians.⁵

Diagnosis

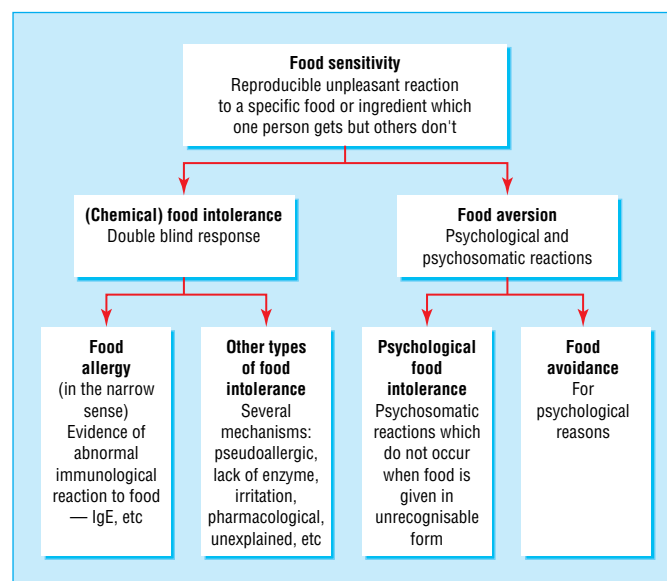

Diagnosis of food sensitivity is easy when there is a characteristic early response to a food that is eaten at least occasionally. The patient often notices the association and its reproducibility and tells the doctor the diagnosis.

Diagnosis is more difficult, however, if the clinical reaction is delayed or varies or does not always happen, and if the food

A little epidemiology

Young *et al.*¹ sent questionnaires to 15 000 households, half across the UK, half in their local (High Wycombe) area. 20% of individuals who replied said they had some form of food intolerance. Those who did and were living locally were asked further standard questions. About half had relevant symptoms and some of them agreed to take eight, double-blind, placebo-controlled challenges with cows' milk, egg, wheat, soya, orange, prawns, nuts, and chocolate (disguised in cans of cornflour and suitable flavouring). Each challenge was taken for three days, followed by three days of placebo in random order. Nearly a quarter reacted. From this painstaking work the authors estimated that 2% of British adults have objectively verifiable sensitivity to the eight foods, and a few more may be sensitive to other foods less commonly reported in their questionnaire.

In children 5-7%² and 4-10%³ are estimated to have allergy to one or more foods. This is most prevalent in the first three years of life and fades as children grow older for most foods but not usually for peanuts.

Classification of types of food sensitivity

Four ways of presentation

- "Whenever I eat peanuts I get swollen lips, then itchy spots and I sometimes vomit"
- "I can't eat peanuts" (reason why, vague or based on a single episode long ago)
- "I wonder if this rash could be caused by something in my diet?"
- "I've given up eating peanuts because the lady in the health food shop (or the lady next door) says I must be allergic to them"

is eaten most days. Such reactions are also made more difficult to judge if someone else has already incriminated a food on circumstantial evidence or because of prejudice. There are no straightforward diagnostic tests for food sensitivity comparable with the electrocardiogram for coronary disease or the blood urea for renal failure.

Skin tests—Drops of extracts of one or more suspected food antigens are dropped on to the skin and the skin is then pricked or scratched through the drop. A positive response is a wheal and flare within 20 minutes. This indicates the ability of skin mast cells to degranulate in response to the antigen, because they have on their surface IgE specific to the food antigen. Reliability of the test result depends on the quality (specificity) and concentration of the antigen.

The **radioallergosorbent test (RAST)** is a radioimmunoassay performed on serum to show the presence of IgE specific for the food antigen. It is positive in association with IgE mediated food sensitivity.

The skin test and RAST are both sensitive and specific methods for detecting specific IgE, but they do need to be interpreted with care. The **presence** of IgE antibodies to a food does not mean that the patient is **clinically** allergic to it. Many atopic people have IgE antibodies but no symptoms, so positive results must be interpreted in conjunction with a careful history. Foods should not be restricted on the basis of a positive result if no clinical symptoms exist. On the other hand, a negative skin test (or RAST) result is good evidence that a reaction to food is **not** mediated by IgE. A negative skin test result does not exclude food sensitivity mediated by a mechanism other than the IgE immunological reaction.

Dietary manipulation

The more general diagnostic procedure to indicate food sensitivity is dietary manipulation and recording of symptoms. Such procedures give diagnostic information in food sensitivity of all types. There are several strategies.

Diet diary

The patient or parent keeps a list of all foods eaten and notes any symptoms. This is simple and cheap and can be done at home for several weeks. It is liable to subjective bias, not suitable if the reaction was serious, and difficult to interpret if the responsible agent is present in several foods.

Temporary exclusion of one or a few suspected foods

Avoidance can be for about a week each time. This is an open trial, liable to subjective bias, but it causes little inconvenience. The method is not suitable if the reaction was serious. It is relatively easy to carry out for foods not eaten every day, such as strawberries and shellfish, but more difficult for wheat and milk, which are widely distributed in the diet.

Few foods (oligoantigenic) diet followed by reintroduction of foods one by one

All the foods that commonly provoke sensitivity reactions are eliminated from the diet for two or three weeks. One food is then added back every three to seven days. Elimination diets carry a risk of nutritional deficiency if taken for long or not properly managed.

Patient-blind or double-blind challenges

After the patient has been stabilised on a standard or elimination diet, foods or ingredients are given in capsules or incorporated into oligoantigenic masking foods. The patient is “blind” to what the foods are. Injection of adrenaline should be available if the reaction was of allergic type.

Time course of symptoms of intolerance⁷

Responses expected with different types of food sensitivity

Type of food sensitivity	Open trial	Blind trial	Immune response
Food allergy	+	+	+
Food intolerance	+	+	-
Psychosomatic	+	-	-
Food aversion	-	-	-

Few foods diets

- The meat least likely to cause reactions is *lamb*
- The least antigenic cereal is *rice*
- Vegetables: *peeled potatoes* and *lettuce*
- Fruits: *pears* (peeled)
- Fat: a refined vegetable *seed oil*, for example, (cold pressed) *sunflower* or *safflower*
- Drink: *water* and *sugar*
- If the diet continues for more than a week an uncoloured multivitamin supplement should be taken
- Other foods are included in some elimination diets, depending on the type of reaction and the suspected ingredients

Clinical reactions

Urticaria, angio-oedema and anaphylaxis

True food protein allergy, IgE mediated, is potentially the most serious sensitivity reaction to food, and the best understood. A small amount of ingested protein crosses the intestinal wall, and attaches to receptors on T lymphocytes. In an allergic response these secrete interleukin 4 which influences B lymphocytes to secrete IgE. Antibodies of this class bind to mast cells in the tissues and sensitise them. Then when the allergen contacts the sensitised mast cells they react by degranulation and liberation of histamine and other kinins. Reactions occur very quickly, starting with the oral allergy syndrome—lips, cheeks, tongue or throat swell and itch within minutes of contact with the food. Soon reactions may occur in the larynx (oedema, the most dangerous reaction), gastrointestinal tract (vomiting or diarrhoea), the skin (urticaria), and the bronchi (wheezing). Or several systems can be affected, with an acute drop of blood pressure and respiratory difficulty—**anaphylaxis**. Treatment of anaphylaxis is with prompt injection of adrenaline, followed by hydrocortisone.⁸ For urticaria and other localised reaction the main line of treatment is with a non-sedative antihistamine.

Urticarial reactions can also be mediated without IgE, for example, be caused by eating large amounts of foods which contain histamine-releasing agents, such as, strawberries, shellfish, papaya, or those that contain histamine itself or other amines, such as some wines, fermented cheeses, and sausages.

Chronic urticaria is not usually associated with IgE-mediated food allergy and there is not usually a history linking it with a particular food. A minority of cases have been found sensitive to certain food additives—benzoic acid and compounds (E210, 211, 212, 213, 216, 218) or the azo dyes tartrazine (E102) or sunset yellow (E110).¹⁰ This can be demonstrated by placebo-controlled challenge testing in a specialist clinic. Physical factors, for example, exercise and warmth, tend to cause urticaria on their own and may exacerbate a reaction to food.

Asthma and rhinitis

Foods can precipitate some attacks of asthma in infancy but come well behind infections. The role of foods in asthma diminishes during childhood and it is an uncommon precipitant in adults. Inhalants, irritants, infections, pollens and moulds, changes in the weather, and exercise are then all more important. Food sensitivity asthma in adults is largely confined to those exposed to dusty grain, flour, coffee, etc, in their work.

Eggs, seafood, and nuts are among the foods most likely to provoke asthma in children. Skin tests are usually positive, indicating that IgE is implicated, but if the skin test is positive for a food in an asthmatic child, asthma may not follow a double blind challenge. In addition, the response to foods is sometimes psychosomatic.

The food preservatives sulphur dioxide (SO₂) and sodium metabisulphite can aggravate bronchospasm in established asthmatics. These patients are very sensitive to the irritant effect of SO₂ gas, which is liberated from sodium metabisulphite in acid foods and inhaled in low concentration as the food is swallowed.

Eczema

Infantile eczema and flexural eczema in adults are associated with high serum titres of IgE and often with multiple positive skin tests. In infantile eczema the response to food taking or elimination is slower and less clear cut than in urticaria.

Foods that can cause allergic reactions including anaphylaxis

- Cows' milk (esp. young children)
- Hens' eggs (esp. young children)
- Peanuts
- Tree nuts: brazil, almond, hazel
- Fish
- Shellfish
- *Also* wheat, legumes (peas, soya), fruits (citrus, strawberries, apples), vegetables (tomato, celery), sesame, etc

Peanuts top the list of foods responsible for anaphylaxis. Most fatal reactions have occurred from foods eaten outside the sufferer's home. Waiters, hosts, and food-pack labels cannot always be relied on. People with peanut allergy must be constantly vigilant with any unfamiliar food and consider carrying self-injectable adrenaline. In atopic families the lactating mother should not eat peanuts (or products containing peanuts) herself or give any to the child for at least three years.⁹

Foods likely to contain tartrazine (food colour E102) include:

- | | |
|----------------------------|-------------------------|
| • fruit squash and cordial | • instant puddings |
| • coloured fizzy drinks | • coloured sweets |
| • pickles | • filled chocolates |
| • bottled sauces | • jelly |
| • salad cream | • ice cream and lollies |
| • cakes (shop bought) | • jam |
| • cake mix | • marmalade |
| • soups (packets and tins) | • curry powder |
| • custard | • mustard |
| | • yoghurt |

Tartrazine is water soluble and gives a pleasant lemon yellow colour to foods. It is also used in some medicine capsules. Incidence of sensitivity appears to be between 1 in 10 000 and 1 in 1000.

Tartrazine is one of several permitted azo colours. It has been the most tested and incriminated in reactions, but some of the other colours (if eaten in comparable "dosage") might possibly cause reactions in the rare people who are sensitive to tartrazine.

Foods likely to contain sulphur dioxide

- Wines, chilled fruit juices
- Pickled onions, dried fruits
- Commercial pre-cut chips
- Salads in salad bars*
- Fresh fruit salad in hotels*

*From "stay fresh" spray

Statistically significant responses to skin tests have been reported in infants apparently sensitive to a food—for example, exacerbation after milk or improvement after withdrawing egg. A controlled trial showed improvement in 14 out of 20 children with infantile eczema when egg and milk were removed. Elemental diets (glucose, oil, amino acid mixture, vitamins, and minerals), though expensive, have been helpful in severe infantile eczema. Breast feeding reduces the chance of eczema but only partly in babies with a strong atopic family history. In such cases the mother should avoid eating common allergenic foods.

In adults with eczema a response to few foods diets is less likely.

Migraine

Tension, relaxation, menstruation, bright lights, and hypoglycaemia are among the major precipitants of migraine. Foods can also precipitate attacks. The different factors can be cumulative; several may be needed before an attack occurs. Attacks may come on many hours after eating a provoking food. Suggestibility and placebo effect have been well established in the responses of migraine sufferers.

Chocolate, cheese, and citrus fruits are reported to precipitate migraine. They contain pressor amines—tyramine, phenylethylamine, and synephrine, respectively. Alcoholic drinks are another precipitant, notably related to cluster headaches: red wines and some other drinks contain histamine. Other attacks may come about from foods that produce nausea, such as fatty foods. Nitrates, found in some sausages, occasionally cause headaches (“hot dog headache”).

True food allergy via IgE is not the usual mechanism in migraine. In a trial at Great Ormond Street, in children with severe recurrent migraine most recovered on an exclusion diet. Reintroduction of foods, first “open”, later disguised, showed that cows’ milk, eggs, chocolate, orange, and wheat were most likely to provoke an attack and tartrazine less commonly.

Gastrointestinal reactions

Many different gastrointestinal sensitivity reactions to food are known and they can act through several different mechanisms. Early symptoms are lip swelling, tingling in the mouth or throat, and vomiting. Later symptoms include diarrhoea, bloating, or even steatorrhoea. Remote symptoms—urticaria, asthma, headache, joint pains—can be associated.

In young children immediate intolerance is not uncommon to cows’ milk or egg white, nuts, seafood, and some fruits. Tolerance increases with age. Cows’ milk allergy can produce a variety of effects, including gastrointestinal bleeding or protein losing enteropathy; eosinophilia may be present.

Coeliac disease

Sensitivity to wheat gluten is the cause of coeliac disease with jejunal atrophy. It took from 1888, when coeliac disease was classically described, to 1953 before it was found that a fraction of wheat was responsible. A few other foods have been linked with occasional mucosal damage in children, such as cows’ milk and soya. (See diets for gluten-sensitive enteropathy in chapter 13.)

Infantile colic

When it occurs, this lasts for about the first three months. It occurs at least as often in breast fed as in bottle fed infants. In the former there is no consistent evidence that the colic is related to anything the mother eats.

Irritable bowel syndrome

Evidence for food sensitivity in the irritable bowel syndrome is conflicting. One study, which performed exclusion and double-

Foods reported to precipitate migraine

The Gluten-free Food & Drink directory (reproduced with permission from Coeliac UK)

blind challenge, indicated that food sensitivity was common: wheat, dairy foods, maize, some fruits, tea, and coffee were mostly implicated. Another study could not show food sensitivity in most patients.

Intestinal lactase insufficiency

This is the rule in most adults of Asian and African origin and seen in a minority of white people. There is diarrhoea, abdominal distension, discomfort, and flatus after milk, but this usually has to be a cupful or more.

Attention-deficit/hyperactivity disorder

Feingold in the USA suggested that children (usually boys) with overactivity, short attention span, and impulsive behaviour might improve on a diet which omitted foods containing artificial colours or natural salicylates, or both. Although organisations of parents of difficult children have had faith in this hypothesis, objective confirmation is sparse. Most double-blind tests with food colours reported significant effects in either none or only one or two of the hyperactive children tested, and much of the information Feingold used on the salicylate content of foods was wrong. The salicylate content of most diets, by modern specific analysis, is only 1-2 mg/day.¹¹ Nevertheless, there are some children with a combination of overactivity and physical symptoms (rashes, rhinitis, headaches) suggestive of food sensitivity that have improved on an elimination diet, at Great Ormond Street. They appeared on challenge to be sensitive to different foods, but tartrazine and benzoic acid were top of the list.¹²

Arthritis

Gouty arthritis is aggravated by alcohol and by high purine and high protein diets. Although most patients with rheumatoid arthritis do not respond to food exclusions or challenges, a patient whose arthritis was clearly shown to be aggravated by milk and cheese was reported from the Hammersmith Hospital. A small minority of similarly reacting rheumatoid patients was found in a subsequent study in Florida.¹³

Pseudo food allergy¹⁴

Apparent reactions to food are quite often psychological rather than organic in origin. Patients may be convinced, but on circumstantial or no real evidence, that they are sensitive to certain foods. These beliefs are encouraged by some popular books and unorthodox practitioners, and are not easy for the busy general practitioner to change. Avoiding a broad range of foods carries a risk of malnutrition. Parents have also been reported as having inflicted supposed allergies on their children—a variant of Meadow's syndrome.

Specialist food "allergy" (sensitivity) clinics are available at some of the teaching hospitals, such as Addenbrooks, Cambridge; Great Ormond Street, London; Guy's, London, etc.

Food intolerance databanks have been set up in several European countries. In the United Kingdom the Leatherhead Food Research Association manages the databank.

Some less common food sensitivities

- *Favism*—haemolytic anaemia after eating broad beans. The basic defect is red blood cell glucose-6-phosphate dehydrogenase deficiency.
- *Bitter lemon purpura*—"bitter lemon" contains quinine, which may rarely precipitate thrombocytopenic purpura.
- *Chinese restaurant syndrome*—as first described, the symptoms were facial pressure, burning sensation in upper trunk and shoulders, and chest pain soon after eating foods rich in monosodium glutamate, particularly Chinese wonton soup. But delayed headache and nausea have subsequently been found to be more common, and asthma has sometimes been precipitated.
- *Sensitivity to tea or coffee*, or both—these common social beverages can cause a variety of pharmacological effects, for example, vomiting, headaches, tachycardia, which have sometimes been proved by objective tests.⁶

16 Processing food

In the guessing game, “Animal, vegetable, or mineral?” nearly all foods are animal or vegetable or the two combined. What we eat is other organisms, some of them—fruits and cereals—still viable. The basic material of our foods has an anatomy and a histology. It is made of cells which contain numerous enzymes and biochemical compounds that are the same as or similar to those in the human body. Foods are also inhabited by micro-organisms. These multiply after slaughter or harvesting and nearly all our basic foodstuffs deteriorate rapidly because of autolytic decay and microbial activity. Foods can become dangerous because of these unless we treat them in some way. Cereal grains are the major exception. They have a lower water content and normally keep for years when dry at ambient temperatures. The major early civilisations were built on this property, and even today the only staple foods that are kept in savings banks are the cereals. Insect activity also leads to appreciable losses of food.

Why foods have to be processed or prepared

- (1) Foods are preserved so that they can be kept edible for longer. Preservation reduces wastage and hence cost. It enables people in affluent communities to eat their favourite foods all the year round and also enables us to benefit from economies of scale by growing large quantities of a food on large areas of suitable land. Preservation helps to feed the growing world population.
- (2) Processing or preparation makes foods safe to eat by destroying or retarding the growth of pathogenic micro-organisms (such as salmonella, clostridia, or fungi) or inactivating natural toxins (such as trypsin inhibitors and goitrogens).
- (3) Processing or preparation improves the attractiveness of food, its flavour, and its appearance. This is not a frivolous function. Poorly prepared food is often the chief complaint of patients in hospitals and nursing homes.
- (4) Processing also provides convenience. In Mrs Beaton’s time most women spent their lives working for hours each day in the kitchen. Modern convenience foods have liberated women in countries like Britain. Much of the work that used to be done by hand in the Victorian kitchen is now done by machines, some controlled by computer, in the food processing plant or factory.

Methods of food preservation and processing

Drying

Traditionally this was sun drying or smoking, but nowadays tunnel drying, spray drying, and freeze drying produce concentrated forms of the foods—for example, milk powder or instant coffee powder. Bacteria, which require water, cannot grow and autolytic enzymes are inhibited.

Freezing

This prevents bacterial growth because bacterial enzyme activity slows then stops as temperature is lowered. In addition, water in the food is not in an available form.

Doctors need to know about food

- “Doctors need to know as much about foods as they do about drugs.”
- “Each medical school should have an expert on the biochemistry of foods among their preclinical lecturers.”

Two recommendations from the International Union of Nutritional Sciences Workshop on Nutrition Education for Medical Practitioners, held at the Royal College of Physicians, London, March 1984.¹

Food technology

- **Handling after harvest**—Foods must be kept at the best temperature, atmosphere, etc, between the farm and market or factory.
 - **Food processing** is treatment of food in a plant or factory before it is sold in the shop.
 - **Food preparation** is treatment of food in the kitchen, at home, in a catering establishment or take-away shop. It is a wider term than “cooking”, which implies the use of heat.
 - Between each treatment stage food has to be **stored**; the conditions affect how long it keeps and its quality.
-

ABC of Nutrition

Refrigeration

Does not destroy micro-organisms but ensures that those present cannot multiply or do so only slowly; it also slows autolysis by enzymes in the food.

Addition of salt or sugar

This is a third way of lowering the “water activity” by increasing osmotic pressure and preventing bacterial growth, just as sugar has been shown to reduce infection in wounds.

Acidification

Acids also prevents microbial growth, for example, foods pickled in vinegar.

Heat

This is used in several ways. Blanching (1-8 min at 100°C depending on the food) before freezing and canning inactivates enzymes, that would otherwise continue autolysis of the food. Pasteurisation of milk (72°C for 15 seconds) destroys pathogenic organisms but not others. Cooking destroys all or nearly all organisms (except spore formers, depending on conditions). Sterilisation of canned and other sealed foods is performed by subjecting the food to a high temperature with or without pressure.

Food irradiation

A new technique, food irradiation, is useful for replacing ethylene oxide in sterilising spices (whose flavour would change on heating). It can also extend the shelf life of strawberries and mushrooms, inhibit sprouting of potatoes and onions, and destroy pathogens on poultry.²

Fermentation

This produces acid or ethanol, or both, which inhibit pathogenic and spoilage organisms.

Chemical preservatives

Benzoic acid, propionic acid, and sorbic acid, naturally present in cranberries, Gruyère cheese, and rowanberries, respectively, are added to certain specified foods in controlled amounts to prevent microbial growth. Sodium metabisulphite, which liberates sulphur dioxide in the food, is used for the same purpose.

Packaging

Once a food has been heat sterilised reinfection is prevented by sealing it in a can or airtight plastic bag or multilayer paper or plastic carton. Packaging of unsterilised food, though not preventing bacterial growth, reduces contamination and prevents loss of water through evaporation, etc.

Separation methods

Unlike the methods above these are not used to preserve foods. Milling produces different fractions of cereal flours. Pressing produces oils from oil seeds and juice from fruit.

Fresh or processed?

Most “fresh” fruit in the greengrocers comes from overseas or has been stored for weeks or months. “Fresh” vegetables too, though mostly home grown, are often stored. Bananas are picked in the tropics before they are ripe, shipped and stored at a controlled even temperature (>13°C), and ripened by exposure to ethylene gas (which is given off naturally by ripening fruit). Oranges are picked ripe, shipped, and stored at a lower temperature (3°C) in dry air with a raised carbon dioxide level. The skins have to be protected from mould

From the earliest civilisations

Some of the most important processes used for our foods go back to the earliest civilisations.

- The Sumerians had a simple dairy industry. Butter is mentioned several times in the Bible (for example, Isaiah vii, 15).
 - The ancient Egyptians brewed beer and discovered how to make raised bread. Beer has been called “liquid bread”.
-

Many processes are very old

- Wine was part of the way of life of the ancient Greeks. Wine and raisins (another very old food) are two different ways of preserving the energy of grapes in palatable forms.
 - Salted pork—forerunner of our ham and bacon—was a common meat for the ancient Greeks.
 - Cheese is mentioned in the Bible (for example, II Samuel xvii, 29). It is a remarkable method for preserving the energy, calcium, and other nutrients of milk.
 - Jam, another way of preserving fruit, was being made long before the Industrial Revolution.
-

Nutrients per 100 g in wholemeal (100%) and white [breadmaking] (72%) wheat flour³

Nutrients	Wholemeal	White
Energy kJ (kcal)	1318 (314)	1451 (346)

Total phosphorus (mg)	320	120
Phytate phosphorus (mg)	240	30

*As fortified in the UK. *Note:* These are wheat **flours**. In bread nutrient contents are lower because over a third of the fresh weight is water

infection, for example, by treating with fungicides mixed with waxes after they have been washed. Although these fruits have been in artificial environments, they are intact and alive and their cells are absorbing oxygen and producing carbon dioxide.

Likewise, it is worth money to understand what factors determine tenderness and flavour in meat. There is a speciality of meat science, which shares some of the histological and biochemical knowledge used by clinicians who specialise in muscular diseases.⁴ Before slaughter, animals should have adequate muscle glycogen. This is converted to lactic acid, which acts as a weak preservative. Fresh meat is tough because of rigor mortis. This disperses during hanging in a controlled chilled temperature of -1.4°C and the meat is tenderised.

Food additives

Salt, vinegar, nitrates, and sugar have been used for centuries and are still among the most used food preservatives today.

Hops are a traditional preservative for beer. Many of history's great voyages of exploration were made in search of food additives. Marco Polo journeyed to the East to obtain exotic spices. Cortez brought back vanilla from the Aztecs.

Food additive controls in Europe are now harmonised throughout the EU. The use of food additives is subject to strict legislative controls and they are only permitted if considered safe following scrutiny by independent experts, particularly the EC Scientific Committee for Food. To ensure that safe intake levels are not exceeded, many of the additives are only permitted in certain foods and up to specified maximum levels.

- **Preservatives** such as nitrates in bacon and ham and sulphur dioxide in dried fruit prolong the shelf life of foods by protecting them against deterioration caused by micro-organisms.
- **Antioxidants** are used to prevent the slow oxidation of oils and fats by atmospheric oxygen and development of rancidity.
- **Emulsifiers** keep oil and aqueous phase together in sauces. Lecithin is an example.
- **Humectants** prevent foods from drying out. Glycerol is an example.
- **Food acids** are acids that occur naturally. They are used for flavour or for technical reasons—for example, to adjust the pH in certain jams so that the pectin sets—and can also act as preservatives.
- **Anti-caking agents** stop lumps forming in powdery foods.
- **Thickeners** may be vegetable gums, cellulose derivatives, or starch derivatives.
- **Added nutrients** are now given by name on the label. A number of foods are fortified or enriched with nutrients—for example, margarine includes vitamins A and D, flour and bread and some breakfast cereals contain some B vitamins, and iron, and textured vegetable proteins contain vitamin B-12.
- **Miscellaneous**—Other additives include: flour treatment agents, firming agents, stabilisers, flavour enhancers, propellants, and glazing agents.
- **Colours**—Forty-three colours are permitted in the European community. More than half of them are natural, for example, beetroot red, chlorophyll and various carotenoids. Twenty of the permitted colours, such as some azo dyes and erythrosine (an iodine compound), are synthetic.
- **Flavourings**—Flavourings are added to foods in minute quantities and without hazard to public health. They are either natural flavour preparations (for example, essential oils) or chemically defined flavouring substances. These may be natural (isolated from products of plant or animal origin,

for example, menthol from peppermint oil) or nature-identical (made synthetically but chemically identical to a substance that occurs naturally, for example, citral) or artificial (not yet found in nature, for example, ethyl vanillin). There is no EU-wide flavouring legislation at present, but the EU is working towards creation of a list of permitted flavouring substances. The names of individual flavours are not declared on labels and they are not in the E code, but if flavourings are used this is mentioned (non-specifically) in the ingredients list. Flavour recipes in food are regarded as trade secrets.

- **Artificial sweeteners** permitted under EU law include saccharin, aspartame, and acesulfame K.

Contaminants

Unintentional additives can get into foods somewhere along the chain from farm to plate. Examples are pesticides, other farm chemicals, veterinary residues, drugs, heavy metals (lead, cadmium, mercury, and arsenic), industrial chemicals—for example, polycyclic aromatic hydrocarbons and polychlorinated biphenyls (PCBs), atmospheric and water pollutants, radionuclides, and phthalate plasticisers. Foods should be monitored for most of these by government agencies, such as, in Britain, the Food Standards Agency.

Foods and ingredients derived from gene technology⁵⁻⁸

Direct genetic manipulation of our food production is new and controversial. For centuries desirable genetic evolution was achieved by selective breeding of plants and animals used for food, mainly for external characters, recently for chemical composition. Rape plants were selectively bred in Canada 'to not' express the characteristic (but potentially toxic) erucic acid in their seed oil—hence canola oil. With the traditional selective breeding many genes change one way or the other, along with the desired modification. With the new GM (genetically modified) technology a single gene from another species or an extra copy of an indigenous gene is inserted into the plant or animal, on a virus or bacterium, or is shot in on gold particles. The source of the new gene may be from a very different species; genes isolated from fish have been inserted into strawberries to give resistance to cold.

Gene technology is being developed—or already used—for several purposes:

- to make it easier to grow the food, for example, to introduce resistance to an endemic plant virus or to a particular herbicide that keeps the weeds down ("Roundup Ready" soyabeans)
- to make processing easier, for example, to reduce a spoilage enzyme and so prolong shelf life
- to make a food more palatable, for example, "Flavr Savr" tomatoes
- to produce a desired change in nutritional composition, for example, rice which contains (pro-vitamin A) β -carotene in the grain.

A primary aim of regulatory authorities is to determine if there can be any difference between, say, GM maize and conventional maize as food that could affect health—loss of nutrient(s) or appearance of a potential toxin or allergen. This is the concept of **substantial equivalence** and is the responsibility of food standards agencies. But the question of approving GM crops also has environmental and legal aspects. Not all GM crops are used for food (for example cotton, carnations).

Foods can be altered with gene technology in five ways:

- a chemically defined substance, obtained by gene technology, is used in production of the foods, for example, porcine somatotrophin (to improve the growth of pigs) or chymosin (replacing rennet in cheese making)
 - less well defined ingredients in the food, for example, starch from insect-resistant maize, mycoprotein from genetically modified yeast
 - foods/drinks produced using genetically modified organisms (GMOs), for example, wine or beer from yeast modified to result in an altered flavour profile
 - transgenic plants or animals—that is, containing new or altered DNA, for example, soyabeans containing a gene that makes them resistant to a particular herbicide ("Roundup Ready" soyabeans)
 - foods in which the genetically modified micro-organism is still present, for example, a "live" yoghurt with new properties.
-

Why all the fuss about GM foods?

- The process of GM technology is not natural. People object on religious grounds.
 - Multinationals are controlling agribusiness vertically and globally. Though the inserted genes are natural, GM seeds are patented. Farmers have to contract with the seed company not to re-plant the seeds they harvest.
 - GM crops will not help peasant farmers in developing countries who cannot afford to pay the premium and then not re-use seeds after harvest. Yields may not necessarily be better. The market price may be lower if the demand is for non-GM.
 - The first generation of foods from GM crops has no advantage for consumers. Maize that is resistant to a herbicide does not taste any better, is not more nutritious and could possibly have some deleterious effect long term.
 - Antibiotic resistant genes have often been used as markers for successful implantation of the new gene in seedling plants.
 - There may be environmental damage, for example spread by pollen to weeds of the same botanical family, resulting in "superweeds", or "superbugs".
 - GM food crops are based on a concept of fighting, rather than adapting to the ecology. We would be placing living things in an environment where there is no evolutionary history of how to accommodate them.
-

The growing of GM crops has to be considered and approved by a country's Department of the Environment. Here the **precautionary principle** should be used, and approval to grow a GM crop should start with experimental plots, well separated from conventional crops of the same botanical family.

The United States has been more permissive and the European Union has been and still is very cautious about approving GM foods. In the United States about 30% of the soyabeans now grown, and a lot of the maize, is from plants genetically modified to be resistant to the herbicide glyphosate ("Roundup"). These foods are not segregated or labelled in the wholesale markets; there is no way they can be identified by simple chemical analysis and they are likely to be present of course in soya and maize products being exported from north America. But these soyabeans and maize plants are not permitted to be grown in the European Union at present.

In the European Union multiple authorities, both national and in Brussels, both environmental and food authorities, have to scrutinise applications to grow GM plants. Consumers want any GM foods eventually approved, to be clearly labelled. Major supermarkets have a policy of not stocking GM foods and are giving increased shelf space to "organic" foods, a term which now covers non-GM.

In mid 2002 food aid maize shipped from the America to Zambia was impounded and not distributed to hungry people. The government feared that some might be sown with the result that next year's maize could not be exported to Europe.

Scientific developments in plant breeding have made a huge leap. Regulators, politicians and consumers are in disarray. Meanwhile there is no present likelihood that doctors will be able to diagnose any disease caused by eating a GM food.

Are our foods safe?

Britain had the first food safety legislation in the world, the Sale of Food and Drugs Act 1875; this and subsequent acts have been replaced by the Food Act 1984. Food safety became the responsibility of the Food Standards Agency in 2000. Its expert committees are in regular informal communication with the EC Scientific Committee for food, the Joint FAO/WHO Expert Committee on Food Additives, the US Food and Drug Administration, and food toxicologists round the world.

Deliberate food additives are not intrinsically toxic substances. They have been tested in several animal species and are kept under review continuously by food toxicologists. Amounts permitted in foods are such that the maximum intake does not exceed the acceptable daily intake (usually 1/100 the highest level that has no effect in animal tests). Toxicological tests have not so far systematically examined the chances of hypersensitivity reactions in man, and such occasional reactions to tartrazine, sulphur dioxide, and monosodium glutamate are described in chapter 15.

Whereas some natural components in the diet are risk factors for certain types of cancer (chapter 3), the World Cancer Research Fund's expert panel⁹ agrees with previous reviewers that intentional food additives do not cause cancer (when used in quantities prescribed by the regulations).

Losses of nutrients

Some losses of nutrients occur during food processing but they are qualitatively and quantitatively similar to the losses that happen in domestic cooking. Most processes in the food factory are scaled up versions of one or another home recipe. Factory processes are standardised and controlled, but home

Potentially toxic substances in foods

Natural

Inherent, naturally occurring

Usually present in the food and affect everyone if they eat enough, for example, solanine in potatoes

Toxin resulting from abnormal conditions of animal or plant used for food

For example, neurotoxic mussel poisoning; honey from bees feeding on rhododendron nectar

Consumer abnormally sensitive

For example, coeliac disease from wheat gluten; allergy to particular food; or drug induced, for example, cheese reaction

Contamination by pathogenic bacteria

Acute illness, usually gastrointestinal, for example, infection with *Salmonella* spp, or campylobacters or toxins produced by *Staphylococcus aureus* or *Clostridium botulinum* (food may not appear spoiled)

Mycotoxins

Food mouldy or spoiled, for example, aflatoxin B₁, from *Aspergillus flavus*, is a liver carcinogen

Manmade

Unintentional additives: manmade chemicals used in agriculture and animal husbandry

For example, fungicides on grain, insecticides on fruit, antibiotics or hormones given to animals

Environmental pollution

For example, organic mercury, cadmium, polychlorinated biphenyls, and radioactive fallout can affect any stage of food chain

Intentional food additives: preservatives, emulsifiers, flavours, colours, etc

The most thoroughly tested and monitored of all chemicals in food

Testing food additives

- Acute toxicity is tested in male and female animals of at least three species.
 - Distribution of the compound in the body and its metabolism are studied.
 - Short-term feeding trials are done on at least two species of animal (one non-rodent).
 - Long-term toxicity is assessed in at least one metabolically appropriate animal species.
 - Reproduction studies involve giving the compound to experimental animals over at least two generations.
 - Testing for mutagenicity (in bacteria) and carcinogenicity (in tissue culture) is undertaken.
 - Observations in man are reviewed.
-

ABC of Nutrition

cooking varies from excellent to bad. Nutrient losses are roughly predictable and can easily be measured by analysis at different stages.

Two vitamins are more unstable than the others when heated, vitamin C and folate, but whereas vitamin C lasts better in acid medium, folate does not. Thiamin (vitamin B₁) is moderately unstable when heated. Riboflavin decomposes in ultraviolet light. Water soluble vitamins dissolve into the cooking water and the more water used the more vitamins are likely to be wasted. Mineral nutrients are stable but can also be washed out if large amounts of cooking water are used. Lysine, the limiting amino acid in cereals, is the most unstable of the essential amino acids. The golden crust of bread is coloured by a complex of sugars and lysine which becomes biologically unavailable. There is some loss of linoleic acid in oils when they are reused for frying, especially at high temperatures.

Losses of **vitamin C** are worth considering in detail. The factors that cause the oxidative breakdown of vitamin C are tissue damage (which liberates ascorbic acid oxidase) by bruising or freezing of leafy vegetables, heating in alkaline water—for example, with sodium bicarbonate added—contact with copper, and leaching into the processing or cooking water. Moderate losses occur between harvesting and cooking fresh vegetables and when a bottle of fruit juice is opened and kept at room temperature. There is little difference in losses of vitamin C between these three methods of cooking: boiling, microwave, and pressure cooking, but the less water used the less vitamin is thrown away in the water. There are substantial losses of vitamin C when cooked vegetables are kept warm before they are served, or refrigerated until the next day.

Percentage retention of vitamin C in peas after different stages of preparation (after Mapson)¹⁰

Fresh	Frozen	Canned	Air dried

Cooking 44	Cooking 39	Heating 36	Cooking 25

Effect of different conditions on stability of nutrients in foods (based on Harris and Karmas¹¹)

Nutrients	Effect of solutions			Effect of exposure to			Cooking losses (% range)
	Acid	Neutral	Alkaline	Oxygen	Light	Heat	
Vitamins							
Vitamin A	U	S	S	U	U	U	0-40
Vitamin D		S	U	U	U	U	0-40
Vitamin E	S	S	S	U	U	U	0-55
Thiamin	S	U	U	U	S	U	0-80
Riboflavin	S	S	U	S	U	U	0-60
Niacin	S	S	S	S	S	S	0-50
Folate	U	U	S	U	U	U	0-80
Vitamin C	S	U	U	U	U	U	0-100
Amino acids							
Leucine, isoleucine, methionine, valine and phenylalanine	S	S	S	S	S	S	0-10
Lysine							
Tryptophan	U	S	S	S	U	S	0-15
Threonine	U	S	U	S	S	U	0-20
Mineral salts	S	S	S	S	S	S	0-3

U = unstable, S = stable

On average, losses of vitamin C in cooking may be taken as 70%—that is, 30% retention—in leafy vegetables and 40% in root vegetables. Food tables usually give values for cooked vegetables, as well as for the raw food (see table opposite).

Perspective

- Some loss of nutrients is inevitable in food processing, but for most nutrients losses are small.
- Manufacturing losses, when they occur, are often in place of similar losses through cooking at home.

	mg/100 g
Peas	
raw	24
boiled	16
frozen, boiled	12
canned, reheated	1
Mangetout peas	
raw	54
boiled	28
stir fried in oil	51

- The importance of the losses in a particular food has to be considered in relation to the whole diet. If a food makes only a small contribution to the intake of nutrients, processing losses are not of practical importance. On the other hand, changes in any food that makes a major contribution to nutrient supply—for example, milk for babies and cereals in some adults—need continued vigilance.
- There are some beneficial effects of processing or preparation: destruction of trypsin inhibitor in legumes and liberation of bound niacin in cereals. Nutrient enrichment is possible.
- Other advantages of food processing are protection from pathogenic organisms, better flavour, and cheaper price. Often the ultimate choice is between dried, canned, or frozen peas (say) in late winter or no peas at all.

Geography of food processing

Last century cows were kept in towns because there was no way of preventing milk from souring.

To provide the milk, cheese, yoghurt, and cream for the people of London today about 0.5 million cows are needed. They in turn each need about 7 acres of farm land to feed them through the year. From these 3.5 million acres scattered across the south of England fresh milk is pooled, transported, pasteurised, bottled, and distributed or processed in other ways. Other foods—fruits, meat, fish in Britain—may come from half way around the world. This complex movement and distribution of foods would be impossible without food processing.

17 Nutritional support

Nigel Reynolds, Christopher R Pennington

Nutritional support is required for the prevention of starvation and the treatment of malnutrition in patients who are unable to ingest or absorb sufficient nutrients. There is controversial evidence that the provision of specific nutrient substrates may modify the response to disease. This chapter will review current concepts with respect to the need for nutritional support, the route of nutrient delivery, the prescription of nutrient substances, and the quality of nutritional management.

The problem of malnutrition

Studies have demonstrated that malnutrition is common in hospital patients although often it goes unrecognised. Unless nutritional management is initiated nutritional status declines in most patients during hospital stay, particularly in those who are malnourished on admission. Furthermore, nutritional depletion has been shown to continue for two months after discharge in malnourished postoperative patients.

Malnutrition is defined in terms of tissue wasting which may arise through starvation and the metabolic action of cytokines generated in response to tissue injury. There is evidence that nutrient deprivation is of major importance in most patients through a reluctance or inability to eat, the lack of available food for prolonged periods in hospital, and impaired intestinal function. Common causes of malnutrition are given alongside.

Some causes of malnutrition in hospital patients

Anorexia

- Depression
- Chronic disease

Inability to eat

- Neurological disorders
- Swallowing disorders

Intestinal disease

- Inflammatory bowel disease
- Radiation enteritis
- Gluten enteropathy
- Short bowel syndrome
- Hollow visceral myopathy

Inflammatory response to infection

Studies of starvation in normal healthy subjects reveal that death is likely from 60 days when weight loss in excess of 30% has been sustained. The time before tissue loss becomes irreversible is significantly reduced in hospital patients who have already lost weight before admission and in whom the process is accelerated in the presence of inflammatory mediators. Cytokines lead to proteolysis and lipolysis combined with the suppression of appetite.

There are other reasons for the early recognition of malnutrition and where appropriate the provision of nutritional support. When patients are metabolically stressed through infection or trauma, tissue wasting can only be retarded not reversed. Data from the Minnesota experiment and from re-feeding patients with anorexia nervosa have demonstrated that a very long time is required for tissue

A malnourished patient

repletion. Of more importance is the fact that organ function is impaired by starvation, long before current indices of nutritional status become abnormal. Thus obese subjects who starved for two weeks demonstrated loss of muscle power and increased muscle fatiguability of comparable magnitude to malnourished hospital patients. This has implications for the mobilisation of patients after surgery and illness. Furthermore respiratory muscles are also affected, adding to the risk of clinical complications of malnutrition. Other clinically important consequences of nutritional depletion include impairment of wound healing, and of immune response and digestive function.

The recognition of malnutrition

There is no single clinical method that will reliably diagnose malnutrition. The measurement of weight and height is used to calculate the Body Mass Index (BMI) by the formula: weight (kg) divided by the height² (m). The normal range is 20-25. Adult patients with values of 19 or below are malnourished. Information from the BMI may be supplemented by measuring the mid-arm muscle circumference and triceps skinfold thickness which respectively correlate with protein and fat stores. Values are compared with standard reference ranges for the patient population (see page 72).

There are significant limitations in the interpretation of these measurements. They are affected by changes in the hydration status and inter-observer error, and the patient may suffer from the effects of starvation due to impaired organ function long before such measurements become abnormal. Some clinicians employ hand grip dynamometry as a method of detecting nutritional influences on muscle power. All these measurements are time consuming. Nutritional screening of all patients admitted to hospital has been recommended as a simple method of detecting patients at nutritional risk who may merit further investigation. Such a scheme is summarised in the box opposite.

The role of nutritional support

Nutritional support is clearly indicated in patients who are unable to eat or who have prolonged intestinal failure. Under these circumstances it is required to prevent death from starvation. When used to treat malnutrition, nutritional support will reduce morbidity in many patient groups and some of the studies which demonstrated benefit are summarised in the table opposite. There are other studies in which no benefit or increased morbidity has been observed with nutritional treatment. Many of these studies were characterised by the inappropriate use of nutritional support and in particular parenteral nutrition with excessive substrate administration.

Nutritional support may be administered in the form of oral supplements, enteral tube feeding or parenteral (intravenous) nutrition. Estimates suggest that 3-4% of hospital beds are occupied by patients who are receiving nutritional support by parenteral or enteral tube feeding. Approximately four times the number of patients are tube fed compared to those who receive parenteral nutrition.

Enteral nutrition

Oral supplements

Oral supplements containing the recommended provision of micronutrients (vitamins and trace elements) should be used when it is anticipated that they will provide a large part of the diet. These preparations include a range of flavours and when

Some of the effects of malnutrition

Impaired mental function

- Apathy, fatigue, poor cognition

Impaired muscle function

- Respiratory failure
- Delayed mobilisation

Impaired immune function

- Increased incidence of infection

Miscellaneous

- Impaired thermogenic response
- Impaired wound healing

Nutritional screening*

Questions

- Reduced food consumption
- Unintentional weight loss

Measurements

- Weight
- Height

Study*	Patient group	Nutritional management	Reduction of LOS days
Bastow <i>et al.</i> 1983	122 elderly females with fracture of neck of femur	Nocturnal nasogastric supplementary EN	9 (in very thin group)
Askanazi <i>et al.</i> 1986	35 radical cystectomy	Postoperative PN	7
Delmi <i>et al.</i> 1990	59 elderly patients with fracture of neck of femur	Oral supplements postoperatively	16
Rana <i>et al.</i> 1992	40 patients undergoing moderate or major abdominal surgery	Oral supplements postoperatively	3.3
Eisenberg <i>et al.</i> 1993	459, 86% general surgical, 14% general medical	Preoperative PN	0
Mac Burney <i>et al.</i> 1994	43 bone-marrow transplant patients	Glutamine-supplemented PN	7
Bower <i>et al.</i> 1995	368 intensive care patients	Early EN with formula supplemented with arginine, nucleosides, and fish oil	8 (in patients who tolerated at least 821 ml per day)
Keele <i>et al.</i> 1997	100 patients following moderate or major abdominal surgery	Postoperative supplements	0

*For details of the studies see Booth and Morgan 1995³ and Pennington¹ EN enteral nutrition; PN parenteral nutrition

used between meals they do not significantly reduce the consumption of food. Oral supplements augment dietary intake in patients who experience difficulty in taking an adequate diet. They are unsuitable when patients are profoundly anorexic or suffer from swallowing disorders.

Enteral tube feeding

Enteral nutrition delivered by tube is cheaper, safer, and more physiological than parenteral nutrition. In particular, in common with oral nutrition, it stimulates intestinal and biliary motility and provides a greater range of nutrients. These include glutamine and short chain fatty acids, important substrates for the enterocyte and colonocyte respectively, yet which are not part of routine parenteral nutrition prescriptions because of potential problems with the stability of the solution. Enteral nutrition may have a role in the protection of the mucosal barrier function in the ill patient, although studies on the prevention of intestinal translocation of micro-organisms by enteral nutrition in the animal model have not been replicated in the human. Some of the indications for enteral tube feeding are summarised in the box opposite. The ability to infuse nutrients over prolonged periods can fully exploit residual intestinal function in patients with intestinal impairment.

The methods of delivering enteral tube feeding are given in table opposite. Post-pyloric placement is required for patients with gastric stasis, notably in the postoperative period in the critically ill patient. Percutaneous tubes are needed when prolonged treatment is envisaged, notably in patients with swallowing disorders due to chronic neurological disease. This approach is also useful in the younger patient with cystic fibrosis. These younger patients may prefer to have a conventional gastrostomy replaced with a button gastrostomy giving a more acceptable cosmetic appearance.

Enteral feeding solutions most commonly used are based on whole protein substrates and are termed polymeric. Occasionally feeds with a low sodium content are useful in patients with liver cirrhosis and some patients with intestinal failure may benefit from a peptide feed in which much of the lipid is in the form of medium chain triglycerides. Feeds supplemented with glutamine, arginine, nucleotides, and fish oils have been formulated for nutritional support in the critically ill patient. So far there is no convincing clinical evidence to support the use of these more expensive products. However, polymeric feeds containing fibre are useful for the regulation of bowel function in patients who are dependent on artificial nutritional support, particularly elderly patients with chronic neurological disease.

The complications of enteral feeding may be considered in three groups:

- (1) Metabolic complications include disorders of glucose and electrolyte balance. Very malnourished patients are prone to a condition termed the **re-feeding syndrome**. During starvation the body adapts to use less carbohydrate and more fat metabolism such that metabolic tolerance of carbohydrates can be impaired. With the introduction of artificial nutritional support there is rapid intracellular passage of phosphate, magnesium, and potassium resulting in low serum concentrations. Thiamin depletion can be dangerous in this situation, so the vitamin should be routinely provided. There are potentially serious life-threatening effects on cardiac, bone marrow, brain, and respiratory function. Intravenous replacement of electrolytes may be required.
- (2) Gastrointestinal symptoms are common. Diarrhoea is often associated with the use of antibiotics which suppress the

Some indications for enteral tube feeding

Problem	Examples
Anorexia	Cirrhosis, Crohn's disease, some forms of malignancy
Swallowing disorders	Cerebrovascular disease, motor neurone disease, oesophageal stricture
Gastric stasis	Postoperative patient, intensive care patient
Intestinal malfunction	Crohn's disease, cystic fibrosis

Examples of common methods of enteral tube feeding

Route	Placement	Comment
Nasogastric	Nurse or patient	Easy access Commonly displaced Suitable for short-term or intermittent feeding
Nasojejunal	Surgeon at operation Endoscopist	Useful in patients with gastric stasis, postoperative or ITU Readily displaced
Percutaneous gastrostomy	Endoscopist Radiologist using fluoroscopy Surgeon laparoscopically	More suitable for prolonged feeding Relatively safe Can be converted to a button gastrostomy
Percutaneous jejunostomy	Surgeon at operation Endoscopist	Alternative to parenteral nutrition for some postoperative patients Significant short- and long-term morbidity

(Reproduced from Lennard-Jones *et al.* 1995²)

(a) A gastrostomy tube, (b) a button gastrostomy. (Reproduced from Pennington CR, 1998⁴ by kind permission of The Medicine Publishing Company)

activity of colonic bacteria, thus reducing the availability of short-chain fatty acids from fibre. Short-chain fatty acids are an important fuel for the colonocyte; they stimulate sodium and water transport across the colon. The problem of diarrhoea can be reduced with fibre-containing feeds and possibly by post-pyloric feeding.

- (3) Complications of nutrient delivery include pneumonia as a result of aspiration or displacement of the gastric tube. Stomal infection is common in patients with percutaneous feeding tubes; peritonitis can occur when the stomach or jejunum are not opposed to the abdominal wall at the time of percutaneous tube insertion.

Parenteral nutrition

Parenteral nutrition is needed when the intestinal tract is unavailable or intestinal function is inadequate. Examples of some potential indications for short-term and prolonged parenteral nutrition are given in the box opposite.

The nutrient solution is compounded in a large multilayer bag under sterile conditions in the pharmacy, or provided as a standard solution available commercially. The solution contains glucose, lipid, amino acids, electrolytes, minerals, vitamins, and trace elements. Typically the volume ranges from 2 to 3 litres, the non-protein energy provision is 20-40 kcal per kg and the nitrogen provision 0.2-0.3 g per kg. These solutions contain all the essential amino acids, but not all the non-essential amino acids are included because of potential problems with the stability of the lipid solution. There is evidence that under some circumstances some of these “non-essential” amino acids are required. Thus in the stressed patient glutamine is considered to be conditionally essential. There is debate about the potential benefit of adding glutamine, in the form of dipeptides, to the parenteral nutrition prescription in critically ill patients to improve immune and gut barrier function. Furthermore as conventional fat solutions contain n-6 fatty acids that promote the formation of pro-inflammatory cytokines, there may be theoretical merit in deploying structured lipids which contain n-3 fatty acids. More clinical evidence is needed to support the use of these newer substrates.

In hospital parenteral nutrition is commonly needed for only two weeks, when it is conveniently administered by finebore peripheral cannulae. Peripheral cannulae have the advantage of avoiding the risks of central vein cannulation but have the drawback that it may be difficult to meet predicted energy and protein needs using tolerable volumes of fluid and lipid. The hypertonic nature of nutrient solutions can lead to phlebitis and loss of venous access. Critically ill patients and patients who need prolonged parenteral nutrition require central venous access. Venous access for parenteral nutrition is summarised in the box opposite.

Parenteral nutrition is infused continuously in the stressed unstable patient. Cyclical feeding, with overnight infusion and a heparin lock during the day, has metabolic advantages in the majority of patients as mobilisation can be facilitated. The complications of parenteral nutrition are summarised in the box on page 124. Catheter-related infection can be prevented with appropriate protocols dictating catheter care and guiding the training of staff and patients. The hepatobiliary complications which accompany prolonged treatment in some patients may reflect the lack of enteral nutrition, with the formation of biliary sludge or the excess administration of glucose or other nutrients. There is good evidence that nutritional care of a high standard can be most cost-effectively established by using multidisciplinary nutritional support teams.

Some indications for parenteral nutrition

Short-term

- Severe inflammatory bowel disease
- Mucositis following chemotherapy
- Patients with multiorgan failure
- Major surgery
- Severe acute pancreatitis

Long-term

- Inflammatory disease
Crohn's disease, radiation enteritis
 - Motility disorders
Hollow visceral myopathy, scleroderma
 - Short bowel syndrome
Mesenteric infarction, Crohn's disease
-

Parenteral nutrition solution compounded in the pharmacy

Peripheral parenteral nutrition catheter

Venous access for parenteral nutrition

- | | |
|--|--|
| • Peripheral parenteral nutrition | Venflon
Ultrafine 15 cm cannula |
| • Peripherally inserted central catheter | PICC Line |
| • Central parenteral nutrition | Non-cuffed catheter with detachable hub
Cuffed Broviac type of catheter
Subcutaneous vascular port |
-

Some complications of parenteral nutrition

Nutritional and metabolic

- Problems of glucose homeostasis
- Electrolyte imbalance
- Micronutrient deficiencies
- Micronutrient excess, for example manganese

Catheter-related

- Infection: exit site, tunnel, lumen
- Occlusion: lipid, fibrin
- Central vein thrombosis
- Fracture of catheter

Effect on other organ systems

- Liver disease
- Biliary disease
- Osteoporosis

18 Some principles

There are two questions affecting health about any food.

- (1) Is it safe, or will it harm me (a) immediately or (b) later if I eat it repeatedly?
- (2) Is it good for me?

Is it “food”?

For a food one has not eaten before question 1 (a) predominates. If it has not been contaminated or infected the answer depends ultimately on folklore. In every culture there are parts of plants and animals that the group recognises as food but other cultures do not. Only a minority of plants can be expected to be freely edible. For most plants it would be an evolutionary advantage to possess a toxin that discourages animals from eating it. Our folklore about which plants are edible comes down from unknown ancestors who took the risk of eating an unfamiliar plant, sometimes with unfortunate results.

Is this food good for me?

Simple trial and error by people with primitive technology cannot answer questions 1 (b) or 2. One of the difficulties for professionals who give advice about healthy diets is that there is no immediate symptom of well-being corresponding to the surge of amino acids or vitamins that blood samples can show. The feelings of satiety and of inner warmth after a meal are much the same after a good nutritious one as after a meal that contains only “empty calories”. One rare exception is the gratifying faecal results that occur within hours of eating wheat bran in people inclined to constipation. This is probably why the fibre hypothesis was accepted by lay people years before it was well supported by scientific human experiments. The only reliable way to answer questions 1 (b) and 2 is by the methods of nutritional science.

Origins of our scientific knowledge about human nutrition

Comparative and evolutionary

Homo sapiens and their predecessors have been on the earth one million years or more. Ninety-nine per cent of this time our ancestors lived as hunter-gatherers. Agriculture started only 10 000 years ago. There has not been enough time for our species to evolve new metabolic mechanisms required by the recent food supply. Natural selection, which must work chiefly via reproductive success, has been distorted by inequality of wealth and lately by technology. It is difficult to see how it could modify diseases that start in middle age. But presumably our bodies have evolved well-adapted for doing what hunter-gatherers did and eating what they ate. We have information from archaeological records and from studies of the few, fast disappearing groups of contemporary hunter-gatherers.^{1,2}

Experiments of nature and travellers’ tales

From people who eat different foods from us, under stable conditions or during a disaster, we can form hypotheses about the physiological effects of different food patterns that we could not easily persuade our fellow countrymen to adopt.

Hunter-gatherers were lean. Some groups ate more plant than animal foods; others (especially in the cold northern winters) ate mostly meat (not only the muscle) or seafoods. They ate a large variety of foods, depending on the season but had no salt or alcohol and concentrated sugar only rarely (as wild honey) and only occasionally cereal. The photograph shows hunters about to set out, !Kung bushmen in the northern Kalahari, Botswana (taken by the author in 1968¹)

ABC of Nutrition

We have, for example, learnt about the physiological role of ω -3 polyunsaturated fatty acids from the Eskimos,³ and about deficiency diseases from nutritional experiences of prisoners of war.⁴

Epidemiological studies

These studies range in the power of their design. Associations and correlations of disease characteristics and dietary variables do not prove cause and effect, but prospective studies, especially if repeated in different groups, give valuable information on the relation between usual diets and chronic diseases.⁵

Animal experiments

Animal experiments were the principal technique for working out the vitamins.⁶ The right animal model has to be used. Understanding of scurvy was static and controversial until Norwegian workers found (in 1910) that guinea pigs are susceptible like man because, unlike most animals, they cannot synthesise ascorbic acid from glucose.

Clinical records

Clinical records have been informative about the role of diet in disease, including inborn errors of metabolism. Information about requirements for trace elements has come from experiences with total parenteral nutrition.⁷

Food analysis

The independent variables in nutritional epidemiology and in dietetic treatment of disease are food constituents. Food analysis is work that is never finished; foods keep changing and demand develops for constituents not measured before, such as different types of fatty acids and potentially protective phytochemicals. To facilitate international sharing of what food composition data there is INFOODS (the International Network of Food Data Systems) set up in 1983.

Human experiments and trials

These last from hours to years and many different variables can be measured.

Evidence-based nutrition advice⁸

Official dietary guidelines and (if permitted) health claims on foods should be judged on the best available evidence. For judging the efficacy of drugs the best evidence is a meta-analysis or systematic review of all randomised controlled trials (RCTs) of the effect of drug versus placebo on disease outcome. These are paid for by pharmaceutical companies as part of the cost of developing new drugs. For nutrition RCTs with disease outcome are scarce. Available evidence may be epidemiological—cohort/prospective studies are more reliable than case-control or ecological studies. Or they may be short-term controlled trials with a physiological variable as outcome, for example plasma lipids or blood pressure. The evidence, say about vegetables and health, will never consist mostly of RCTs. Emphasis instead has to be on **all** the evidence, including animal studies and molecular biology and critical interpretation of the observational epidemiology.

The three groups of substances in foods

Energy and nutrients

Man needs oxygen, water and enough food energy (calories), 9 or more indispensable amino acids in proteins, essential fatty acids (ω -6 and ω -3 polyunsaturated) a small amount of

Some examples of human experiments and trials

- Intervention trial of low saturated fat diet in half of 850 middle-aged male veterans in Los Angeles over five years
 - Trials of vitamin C against placebo for preventing colds during winter
 - Experimental depletion of a single nutrient in human volunteers
 - Long-term testing of the value of novel protein foods
 - Experiments measuring energy expenditure
 - Metabolic studies—for example, to assess the effect of diet on plasma cholesterol
 - Absorption and uptake studies—for example, glycaemic index after different foods containing carbohydrates
-

The three groups of substances in the edible portion of foods

Energy and nutrients

Water and packing

Other substances

Colour, flavouring, etc.

Natural non-nutritive substances, some of which appear to be protective, some of which are potentially toxic

carbohydrate, 13 vitamins, and 17 elements scattered across the upper half of the periodic table (in addition to hydrogen, carbon, nitrogen, and oxygen: see figure on page 126).

Together they add up to over 40 nutrients, many of which are normally taken for granted; the minor nutrients are present in sufficient amounts in a diet of mixed foods. But for long-term total parenteral nutrition all the minor vitamins and trace elements must be included in the required postabsorptive amounts.

For some of the nutrients **you can have too much of a good thing**. Generous intakes of saturated fat raise the plasma cholesterol concentration and contribute to coronary heart disease. People with high salt intakes have more hypertension. Too much food energy leads to obesity.

Water and packing

All foods contain water. In many it is more than half the weight. The percentage of water is higher in some fruits and vegetables than in milk. The more water a food contains, the fewer calories. But this water has to be counted in the diet of patients with anuria. The “packing” of plant foods—that is, dietary fibre—is not all inert. Some fractions have physiological effects: arabinoxylans (hemicelluloses) of wheat increase faecal bulk and speed colonic transit; pectins slow absorption of lipids and glucose.

All the rest

There are many other substances in most foods. They include flavours and colours.

Potentially beneficial substances

It has long been noticed that higher intakes of vegetables and fruits are associated with lower rates of chronic degenerative diseases.¹⁰ In the 1970s this was attributed to fibre or β -carotene or vitamin C. But in the 1990s it looked as if other bioactive substances that are not among the classical nutrients might also be protective. Some of these have antioxidant activity, and antioxidants in food and drink have attracted research interest since publication of the oxidised LDL hypothesis of atherosclerosis. But phytochemicals may act by other mechanisms; one group are weak oestrogens, phytoestrogens. Evidence about these substances is indirect, mostly epidemiological association¹¹ or effects *in vitro* or in animals. Some promising possibilities are shown in the box opposite.

Potentially toxic substances

In most natural foods there are inherent substances that are potentially toxic but usually present in small amounts—for example, solanine in potatoes, nitrates and oxalates in spinach, thyroid antagonists in brassica vegetables, cyanogenic glycosides in cassava and apricot stones, etc. Then there are substances that only some people are sensitive to—for example, in some people wheat causes gluten enteropathy, broad beans favism, and cheese a tyramine effect in patients taking monoamine oxidase inhibitors.

Other toxins get into foods when their environment is unusual—for example, toxic shellfish after a “red tide”—or if polluted with industrial contaminants, such as methyl mercury, polychlorinated biphenyls, etc. Microbiological infection can produce very potent toxins, such as botulism and aflatoxin. Deliberate food additives are not known to be toxic—if they were they would not be permitted by international or national food administrations. A few can cause sensitivity reactions in a minority of people (see chapter 15 on food sensitivity).

Amount of adult requirements for different nutrients

Adult daily requirements in foods	Essential nutrients for man
2-10 μg	Vitamin D, Vitamin B-12
<i>c</i> 50 μg	Vitamin K, Se, biotin, Cr
<i>c</i> 100 μg	Biotin, I, Mo
200-400 μg	Folate
1-2 mg	Vitamin A, thiamin, riboflavin, vitamin B-6, F, Cu
<i>c</i> 5 mg	Mn, pantothenate
<i>c</i> 15 mg	Niacin, vitamin E, Zn, Fe
<i>c</i> 50 mg	Vitamin C
300 mg	Mg
<i>c</i> 1 g	Ca, P
1-5 g	Na, Cl, K, essential fatty acids
<i>c</i> 50 g	Protein (10 or more essential amino acids)
50-100 g	Available carbohydrate
1 kg (litre)	Water

Figures are approximate and in places rounded. The range of requirements for different nutrients is about 10^9

Periodic table of the elements. Those essential for man are blocked in. In addition, boron, silicon, nickel, arsenic, and vanadium are still under consideration as ultra-trace nutrients⁹

Non-nutrient bioactive substances in food and drink that might help protect against chronic diseases

- **Carotenoids** other than β -carotene: *lycopene* (red pigment of tomatoes) and *lutein* (xanthophyll, in leafy vegetables). Though not pro-vitamin A they are antioxidants, are absorbed and seen in the plasma, and lutein is one of the pigments of the retinal macula lutea.
- **Polyphenols (flavonoids)**, antioxidants that occur in tea (especially green tea), wine (especially red)¹²: *catechins*, and in apples and onions: for example, *quercetin*.
- **Phytoestrogens**, especially isoflavones in soya: *genistein* and *daidzein*. Higher consumption of soya and soya products in East Asia might contribute to the lower incidences of breast and prostate cancers in that region.¹³

Patterns of nutrients in different foods

If animals are fed only one food sooner or later they will become ill and die. No single food contains all the essential nutrients. Wheat (wholemeal flour) lacks vitamins A, B-12, C, and D and is very low in iron and calcium (if unfortified); beef (muscle) contains little or no calcium, vitamins A, C, or dietary fibre. On the other hand, wheat is a good source of dietary fibre and beef of iron and vitamin B-12. The two together provide more nutrients than either alone but between them have no vitamin C or D and hardly any calcium. Addition of citrus fruit or salad brings vitamin C into the mixture, and milk or cheese adds the missing calcium and a little vitamin D.

This is the theory behind the “basic four” food groups for educating the public about nutrition. Each group has some deficiencies which the other three make up between them. You should aim to eat each day from each of: the bread and cereals group; the meat, poultry, and fish group; the vegetable and fruit group; and the milk group.

Variety

It is not enough to have daily servings of the same food from each group. One should also choose variety within food groups for two reasons. First, the characteristic nutrients in each group vary greatly for individual foods. Among fruits the vitamin C ranges from negligible (for dried fruits, grapes, and figs) up to 115-180 mg/100 g for stewed blackcurrants and canned guavas (this is in the British food tables; the international range goes up to about 3000 mg/100 g).¹⁴

Second, natural toxins do not follow any of our arbitrary groupings of foods. The wider the variety of individual foods that people eat, the less their chance of acquiring harmful amounts of the toxins that are inevitable in foods but usually in small and subclinical amounts.

Blending dietary guidelines with food groups

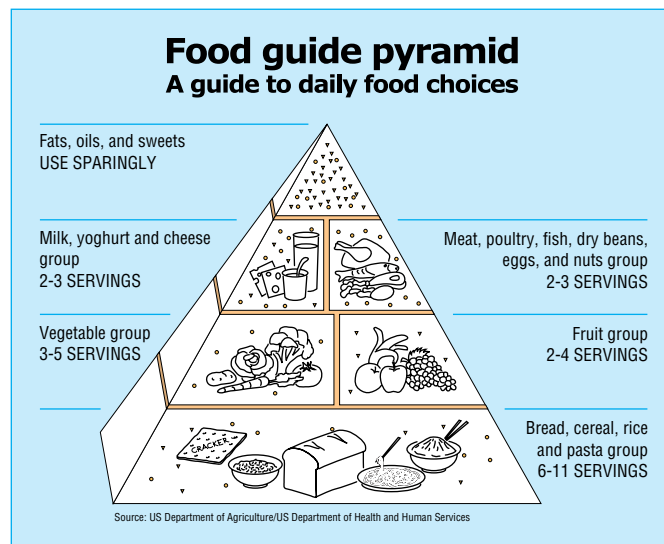

The four groups are intended to minimise deficiency of traditional nutrients—protein, calcium, vitamin C, etc. In affluent countries, however, more disease is probably caused by too much fat, salt, and alcohol and not enough fibre. So we have to modify the older message. In the United States the Departments of Agriculture and of Health use a pyramid for nutrition education.¹⁵ In the base (largest) layer (“eat most”) is the cereal food group. The middle layer (“eat moderately”) is for the vegetable group and the fruit group. The upper (smallest) layer (“eat least”) is for the dairy group and the meat, etc. group. The areas allocated to each group convey broad quantitative recommendations and are accompanied by recommendations for numbers of servings. The divided plate on page 37 is based on the same principle.

Possible modifications of four food groups to incorporate dietary guidelines

- **Bread**—Yes, but wholegrain and with lower salt. Prefer lower fat, low salt *cakes* and *biscuits*
- **Meat**—Lean cuts with the fat removed and not fried. Alternate with *fish* (grilled) and *legumes*
- **Vegetables** slightly cooked, not with salt
- **Fruit** fresh, not canned in syrup or dried
- **Milk** with half or all the cream removed

A Canadian food guide

Junk foods and nutritious foods

Whether a food is nutritionally bad or good depends on the rest of the diet. As Hippocrates taught, “All things in nutriment are good or bad relatively”. An extra portion of saturated fat is bad in Britain but would be good for starving children in north east Africa. An orange does nothing for someone who takes vitamin C tablets but is important for an elderly person who eats no vegetables. Value judgements about foods are being made all the time; they are nearly always subjective and often wrong.

A good objective method is to work out for a typical serving of the food its provisions of important nutrients, as a percentage of their recommended dietary intakes, compared with its content of energy (calories), also as a percentage of a standard daily intake. For each nutrient:

$$\text{the index of nutritional quantity} = \frac{\text{nutrient as \% standard}}{\text{energy as \% standard}}$$

“Nutrient dense” foods have high ratios of important nutrients to energy (calories).

The profile of indices for major nutrients can be put in an array. Other components in the food, like cholesterol, saturated fatty acids, and dietary fibre can be treated in a similar way by using a dietary goal as the standard.

The table below, modified from an American book,¹⁷ shows that egg contains a smaller proportion of fat per energy (calories) than butter; the fat is less saturated and egg is also a good source of protein and some other nutrients. Egg and butter both contain some vitamin A but egg contains thiamin, riboflavin, iron, calcium, protein—not found in butter. However, an egg contains much more cholesterol than $\frac{1}{2}$ oz (14g) butter.

Calculations of this type should be made before authorities advise communities to eat more or less of a food. Applying them to the 1995 Department of Health recommendations¹⁸ about diet to prevent cardiovascular disease means that the amount of butter eaten should be reduced more than the amount of egg, because reduced saturated fat is recommended but current cholesterol intake is not considered excessive. In the United States, however, a dietary guideline¹⁵ advises against high levels of dietary cholesterol and so recommends the general public to moderate its consumption of egg yolks.

Nutrient density is the ratio of a nutrient (expressed as % of recommended daily intake) to energy (expressed as % of a standard energy intake). In the total diet of mixed foods the density for each nutrient should exceed 1.0. (From Hansen¹⁶)

Indices of nutritional quality (INQ) for butter and egg

	Butter ($\frac{1}{2}$ oz; 14 g)			Egg (50 g), hard boiled		
	Amount	% of standard	INQ	Amount	% of standard	INQ
Energy (kcal)	100	5	1.0	80	4	1.0
Vitamin A (mg)	0.129	11	2.2	0.078	7	1.6
Thiamin (mg)	0	0	0	0.04	4	1.0
Riboflavin (mg)	0	0	0	0.14	12	2.9
Niacin (mg)	0	0	0	0.03	0	0
Vitamin C (mg)	0	0	0	0	0	0
Iron (mg)	0	0	0	1.0	6	1.5
Calcium (mg)	3	0	0.07	28.0	3	0.8
Potassium (mg)	4	0	0.02	65	1	0.3
Protein (g)	0	0	0	6	12	3.0
Carbohydrate (g)	0	0	0	1	0	0.1
Fat (g)	12	15	3.1	6	8	1.9
Oleic acid (g)*	2.9	12	2.4	2	8	2.0
Linoleic acid (g)	0.3	2	0.3	0.6	3	0.8
Saturated fatty acids (g)*	7.2	25	5.1	1.7	6	1.5
Cholesterol (mg)*	32	11	2.2	225	75	19

Based on Hansen RG *et al.*¹⁷ [The standards they used are energy 2000 kcal (8.4MJ), vitamin A 1.2 mg, thiamin 1 mg, vitamin C 60 mg, riboflavin 1.2 mg, niacin 14 mg, iron 16 mg, calcium 900 mg, potassium 5000 mg, protein 50 g, carbohydrate 275 g, fat 78 g, oleic acid 24.5 g, linoleic acid 20 g, saturated fatty acids 28.5 g.] I have taken 300 mg as standard for cholesterol. These are all intakes per day

*Not essential nutrients

Calories do count

The law of conservation of energy applies to human nutrition as in the rest of nature. Atwater established this around 1900. A little more heat may be produced after some foods or in some people but the more calories (or kilojoules) you eat the more you can expect to store as adipose tissue.

Foods differ in their calorie content from 32 kJ/100 g (7kcal/100 g) for celery, up to 3.7MJ/100 g (899kcal/100 g) for vegetable oils—a 128-fold range. This great range depends on the different energy values of fat, alcohol, protein, and carbohydrate and how much these are diluted by water. It is useful for doctors to know the energy values of average servings of common foods (there is a short list in chapter 11 on obesity).

No perfect diet

There are several diets that appear (in our present state of knowledge) to be good. We can advise on a better diet for Mr Smith or, as in a United States report, make recommendations “towards healthful diets”, but there is no best diet. The reason is that man is an omnivore with enzyme systems that can adapt to ranges of intakes of many food components. There is, for example, an inducible enzyme, sucrase, in the small intestinal epithelium; if people eat sucrose this enzyme appears and digests it. There are several enzymes in the liver which oxidise amino acids; their activity increases when protein intake is high and falls in people on low protein diets.

The dose determines the effect

When the intake of one essential nutrient is varied, with the rest of the diet adequate in other nutrients and energy, the individual’s state of health is likely to be very poor if intakes of the essential nutrient are inadequate and sustained. Health improves as the intake is increased, up to the nutritional requirement level. Above this, it has been thought that the state of health remains on a plateau up until the nutrient intake becomes undesirably high, beyond which toxicity may be seen. Recent experience with some nutrients suggests, however, that above the requirement level, which cures deficiency disease, there can be an optimal range of intake. The individual may not feel or function differently but has a reduced risk of degenerative disease or more favourable biochemical profile. Folate is a good example. Above the level that cures or prevents megaloblastic anaemia women have a reduced risk of a malformed baby, and older adults are less likely to have a raised plasma homocysteine.

Replacement

For every food you remove from the diet another has to take its place. This principle is prominent in the design and interpretation of nutritional experiments. Does consumption of milk raise or lower the plasma cholesterol concentration? To test this an adequate but physiological amount of milk is to be given in a middle two or three week period. The plasma cholesterol value is measured at the end of this period and at the end of equal length control periods before and after.¹⁹ But what should be given to replace the calories of the milk in the control periods? If nothing is given the periods will not be isocaloric.

To some extent the effect of milk on plasma cholesterol could be manipulated by the choice of the control food. We do not want to influence the experiment so might ask, “If people here stop drinking milk what would they drink (or eat) in its place: beer, water, fruit juice, fizzy drink, etc?” A similar situation applies in outpatients when the doctor or dietitian instructs a patient to cut out one food from his/her diet.

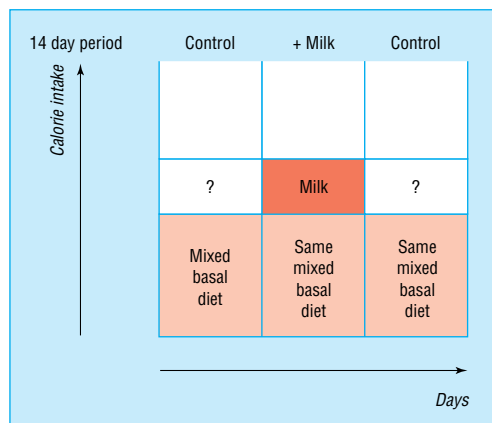

Energy values as metabolised in the body of the main energy-yielding groups of food components (Atwater factors)

	kcal/g	kJ/g
Fat	9	37
Alcohol	7	29
Protein	4	17
Carbohydrate*	3.75	16

*This is for available carbohydrate. The energy provided by dietary fibre from its fermentation to volatile fatty acids in the large intestine is less than half this amount

Ingestion of the RDI should guarantee no deficiency disease but beyond the RDI there may still be additional health benefits (for example, partial protection from a degenerative disease). The top of the dome beyond the RDI is then the optimal intake range. RDI corresponds to Reference Nutrient Intake. (Adapted from Truswell²⁰)

Unless he/she is to lose weight he/she will sooner or later choose other food(s) as replacement, which may affect the outcome.

Some concluding proverbs

People have been thinking about the safety and goodness of food, as well as its social roles and tastiness, ever since the Garden of Eden or its evolutionary counterpart. So it is perhaps not surprising that a number of proverbs about food and eating are being confirmed by nutritional science.

Moderation in all things

The recommendation of many expert committees on nutrition. Do not eat too much or too little of anything, and do not follow one of the extreme unorthodox regimens.

Man cannot live by bread alone

Though the original was about spiritual nourishment, it is also true that people have to eat more than one (type of) food.

Variety is the spice of life

You should eat a mixed and varied choice of foods.

Enough is as good as a feast

More leads to obesity. People's energy requirements differ. "Enough" is an individual amount.

You can have too much of a good thing

For example, saturated fat, salt, dietary cholesterol, vitamins A, D, and B-6, and alcohol.

One man's meat is another man's poison

The subject of chapter 15 on food sensitivity. For each of us there are foods we dislike and may well be foods that can make us ill.

There's no accounting for taste

Taste has to be considered in planning therapeutic diets.

A little of what you fancy does you good

Dietary prescriptions are sometimes more rigid than they need be. This proverb also speaks of the placebo effect; if someone believes a food is doing him good he may feel better for a time after eating it.

Old habits die hard

Food habits must be respected. Prescribed dietary changes are likely to be followed better if they are fitted into the least strongly held of an individual's food habits.

There's many a slip twixt cup and lip

People do not necessarily eat what they intend or say they eat. That patient you just put on a diabetic diet may not have understood you.

Preface

Although work is generally considered to be good for your health and a healthy working population is essential to a country's economic and social development, certain kinds of work can be damaging. Occupational health is the study of the effect—good and bad—of work on peoples' health and, conversely, the effect of peoples' health on their work: fitness for work in other words.

Work places are specialised environments, capable of being closely controlled. Generally, it is the lack of control imposed by employers that is the cause of ill health because of exposure to hazardous materials and agents at work, and of injury caused by workplace accidents.

Working life does not, however, begin and end at the factory gate or the revolving office door: many people walk, cycle, or drive to work—a journey that often constitutes the major hazard of the day. Others have to drive or travel by other means as part of their job, live away from home, be exposed to other food, other people, other parasites. Even work from home, increasing in some countries, can have its problems. Occupational health practitioners deal with all these aspects of working life.

A working population consists of people mainly between 15 and 70 years (disregarding for the moment the ongoing scandal that is child labour), who may be exposed for 8-12 hours a day to a relatively high concentration of toxic substances or agents, physical or psychological. At least that population is likely to be reasonably fit—unlike those who cannot work because of illness or disabilities, the young, and the very old, who are more vulnerable and spend a lifetime exposed to many of the same agents in the general environment at lower concentration. This enters the realm of environmental medicine of such concern to those who monitor the degradation of our planet, track pollution and climate change, and note the effect of natural disasters and man made ones, especially wars.

This book was first published in 1997 as the *ABC of Work Related Disorders*. It is a much expanded and updated version that attempts, in a compressed and easy to assimilate fashion, to describe those problems of health relating to work in its widest sense and to the environment.

The pattern of work is changing fast. There is pretty full employment in most economically developed countries now. Manufacturing industry is now mainly concentrated in developing countries where traditional occupational disease such as pesticide poisoning and asbestosis are still depressingly common. Occupational accidents are particularly common in places where industrialisation is occurring rapidly as was once the case during the industrial revolution in 19th century Britain. Work is also more varied, more intense, more service oriented, more regulated, and more spread around the clock in order to serve the 24 hour international economy. There are more women at work, more disabled people, and a range of new illnesses perhaps better described as symptom complexes which represent interactive states between peoples' attitudes and feeling towards their work, their domestic environment, and the way in which their illness behaviour is expressed.

All occupational disease is preventable—even the more “modern” conditions such as stress and upper limb disorders can be reduced to low level by good management and fair treatment of individuals who do develop these kinds of problems and who may need rehabilitation back into working life after a period of disability. These areas are covered in the chapters on musculoskeletal disorders, stress, and mental health at work. There are chapters also on the traditional concerns of the occupational health practitioner such as dermatoses, respiratory disorders and infections, and other chapters reflecting occupational health practice covering workplace surveys, fitness for work, sickness absence control issues, and, unfortunately increasing in prevalence, legal considerations. Genetics and its application to work and the effects of work on reproduction are described in chapter 17.

Concerns beyond the workplace are covered in the chapter on global issues and on pollution. The control of hazards in the general environment presents issues of problem solving at a different level. Ascertainment of exposure is more difficult than in workplaces, and to find solutions needs transnational political will and commitment as well as science to succeed. Many believe that the rash of “new” illnesses attributed to environmental causes are manifestations of a risk-averse public's response to poorly understood threats in the modern world and an unconscious wish to blame “industry,” or some state institution—agencies that represent irresponsible emitters of toxins, inadvertent releasers of radiation, regardless sprayers of pesticides, or unwitting providers of vaccinations. Chapter 20 addresses this important subject.

In common with the previous edition, this new edition of *ABC of Occupational and Environmental Medicine* will still appeal to non-specialists who wish to practise some occupational medicine; but will also provide all that students of occupational and environmental medicine and nursing will need as a basis for their studies. Each chapter has an annotated further reading list. Most, but not all, of the book is written with an international audience in mind.

David Snashall

1 Hazards of work

David Snashall

Most readers of this book will consider themselves lucky to have a job, probably an interesting one. However tedious it might be, work defines a person, which is one reason why most people who lack the opportunity to work feel disenfranchised. As well as determining our standard of living, work takes up about a third of our waking time, widens our social networks, constrains where we can live, and conditions our personalities. “Good” work is life enhancing, but bad working conditions can damage your health.

Global burden of occupational and environmental ill health

According to the International Labour Organisation (ILO), between 1.9 and 2.3 million people are killed by their work every year—including 12 000 children—and 25 million people have workplace injuries, causing them to take time off. Two million workplace associated deaths per year outnumber people killed in road accidents, war, violence, and through AIDS, and cost 4% of the world’s gross domestic product in terms of absence from work, treatment, and disability and survivor benefits.

The burden is particularly heavy in developing countries where the death rate in construction—for example, is 10 times that in industrialised countries, and where workers are concentrated in the most dangerous industries—fishing, mining, logging, and agriculture.

In the United States some 60 000 deaths from occupational disease and 860 000 cases of work related injury occur each year.

Environmental disease is more difficult to quantify because the populations at risk are much larger than the working population. As an example, the US Centers for Disease Control and Prevention reckons that one million children in the world have lead poisoning.

Reporting occupational ill health

Occupational diseases are reportable in most countries, but are usually grossly underreported. Even in countries like Finland (where reporting is assiduous), surveys have shown rates of occupational disease to be underestimated by three to five times.

Classifications of occupational diseases have been developed for two main purposes: for *notification*, usually to a health and safety agency to provide national statistics and subsequent preventive action, and for *compensation* paid to individuals affected by such diseases. There are no universally accepted diagnostic criteria, coding systems, or classifications worldwide. Modifications of ICD-10 (international classification of diseases, 10th revision) are used in many countries to classify occupational diseases, along with a system devised by the World Health Organization for classifying by exposure or industry. It is the association of these two sets of information that defines a disease as being probably occupational in origin. A number of reporting systems exist in the United Kingdom but these are not comprehensive, nor coordinated. After all, they arose at different times and for different purposes.

Estimated global work related mortality (1.1 million every year, based on 1990-5 data). Other diseases include pneumoconiosis, nervous system, and renal disorders

Children are more vulnerable to occupational disease—they are smaller, have the potential to be exposed for many years, and their tissues are more sensitive. They are also more likely to be exploited and, being less aware, more accident prone

Classification and notification of occupational diseases

The World Health Organization gives the following classification:

1. Diseases caused by agents
 - 1.1 Diseases caused by chemical agents
 - 1.2 Diseases caused by physical agents
 - 1.3 Diseases caused by biological agents
2. Diseases by target organ
 - 2.1 Occupational respiratory diseases
 - 2.2 Occupational skin diseases
 - 2.3 Occupational musculoskeletal diseases
3. Occupational cancer
4. Others

Notification

In addition to the diagnosis of occupational disease, additional information should be included in the notification. The ILO has defined the minimum information to be included:

- (a) Enterprise, establishment, and employer
 - (i) Name and address of employer
 - (ii) Name and address of enterprise
 - (iii) Name and address of the establishment
 - (iv) Economic activity of the establishment
 - (v) Number of workers (size of the establishment)
- (b) Person affected by the occupational disease
 - (i) Name, address, sex, and date of birth
 - (ii) Employment status
 - (iii) Occupation at the time when the disease was diagnosed
 - (iv) Length of service with the present employer

Classification for labour statistics

- International Standard Classification of Occupations (ISCO)
- International Classification of Status in Employment (ICSE)
- International Standard Industrial Classification of all Economic Activities (ISIC)
- International Standard Classification of Education (a UNESCO classification) (ISCED)
- Classifications of occupational injuries

Occupational injuries are also reportable in Great Britain under the Reporting of Injuries, Diseases and Dangerous Occurrences Regulations 1995 and, for purposes of compensation, to the Department of Work and Pensions' Industrial Injuries Scheme. The recording of injuries is generally more reliable because the injuries are immediately obvious and occur at a definable point in time. By contrast, cause and effect in occupational disease can be far from obvious, and exposure to the hazardous material may have occurred many years beforehand. Given that, worldwide, industrial injuries and, in particular, occupational ill health are poorly recorded and reported, the economic losses to the countries concerned are massive.

Breakdown of costs for work related injuries and diseases. Other diseases include cancer, skin diseases, and mental disorders

Occupational or work related?

Some conditions, such as asbestosis in ladders, and lead poisoning in industrial painters, are hardly likely to be anything other than purely occupational in origin. (About 70 of these "prescribed" occupational diseases are listed by the Department for Work and Pensions.) However, mesothelioma can be the result of environmental exposure to fibrous minerals (as in the case of cave dwellers in Turkey), and lead poisoning can be a result of ingesting lead salts from—for example, low

The cost of disease and injury at work

- **1992: European countries**
Direct costs for compensation of work related diseases and injuries:
27 000 million ECUs
- **1995-1996: United Kingdom**
Overall costs to society for workplace injuries and ill health (including net present value of costs in future years):
£14-18 billion (2-2.5% of gross domestic product). Ratio of illnesses/injuries about 3:1
- **1992: United States**
Total direct and indirect costs associated with work related injuries and diseases: US \$171 000 million. This is more than AIDS and on a par with cancer and heart disease

United Kingdom occupational ill health statistics

No single source of information is available in the United Kingdom on the nature and full extent of occupational ill health. The statistics in the 2000-1 report by the Health and Safety Executive are based on the following sources:

- Household surveys of self reported work related illness (SWI): these have been held in 1990 and 1995, linked to the Labour Force Survey (LFS). Health and safety questions were also included in the Europe-wide LFS in 1999
- Voluntary reporting of occupational diseases by specialist doctors in The Health and Occupation Reporting (THOR) network (which succeeded the Occupational Disease Intelligence Network (ODIN) in 2002). THOR and ODIN comprise the Occupational Physicians Reporting Activities (OPRA) scheme, and six other schemes covering mental illness and stress, musculoskeletal disorders, skin diseases, respiratory disorders, hearing loss, and infectious diseases
- New cases of assessed disablement under the Department of Work and Pensions' Industrial Injuries Scheme (IIS): the most longstanding source, based on a list of prescribed diseases and associated occupations, again giving annual figures
- Statutory reports under the Reporting of Injuries, Diseases and Dangerous Occurrences Regulations (RIDDOR): these were expanded when RIDDOR 1995 replaced RIDDOR 1985 and are similar to the IIS list
- Deaths from occupational lung diseases recorded on death certificates (principally mesothelioma and other asbestos related diseases)

temperature, lead glazed ceramics used as drinking vessels, mainly in developing countries. In these situations the history and main occupation will differentiate the causes. The situation may be far less clear in conditions such as back pain in a construction worker or an upper limb disorder in a keyboard operator when activities outside work may contribute, as might psychological factors, symptom thresholds, etc. A lifetime working in a dusty atmosphere may not lead to chronic bronchitis and emphysema, but when it is combined with cigarette smoking this outcome is much more likely. Common conditions for which occupational exposures are important but are not the sole reason or the major cause can more reasonably be termed “work related disease” rather than occupational disease.

Some important prescribed diseases such as chronic bronchitis, emphysema, and lung cancer are work related in the individual case only on the “balance of probabilities.” Certain occupations carry a substantial risk of premature death, whereas others are associated with the likelihood of living a long and healthy life. This is reflected in very different standardised (or proportional) mortality ratios for different jobs, but not all the differences are the result of the various hazards of different occupations. Selection factors are important, and social class has an effect (although in the United Kingdom this is defined by occupation). Non-occupational causes related to behaviour and lifestyle may also be important.

Presentation of work related illnesses

Diseases and conditions of occupational origin usually present in an identical form to the same diseases and conditions caused by other factors. Bronchial carcinoma—for example, has the same histological appearance and follows the same course whether it results from working with asbestos, uranium mining, or cigarette smoking.

The possibility that a condition is work induced may become apparent only when specific questions are asked, because the occupational origin of a disease is usually discovered (and it is discovered only if suspected) by the presence of an unusual pattern. For example, in occupational dermatitis, the distribution of the lesions may be characteristic. A particular history may be another clue: asthma of late onset is more commonly occupational in origin than asthma that starts early in life. Indeed, some 40% of adult onset asthma is probably occupational. Daytime drowsiness in a fit young factory worker may be caused not by late nights and heavy alcohol consumption but by unsuspected exposure to solvents at work.

The occupational connection with a condition may not be immediately obvious because patients may give vague answers when asked what their job is. Answers such as “driver,” “fitter,” or “model” are not very useful, and the closer a health professional can get to extracting a precise job description, the better. For example, an engineer may work directly with machinery and risk damage to limbs, skin, and hearing, or may spend all day working at a computer and risk back pain, upper limb disorders, and sedentary stress. Sometimes patients will have been told (or should have been told) their job is associated with specific hazards, or they may know that fellow workers have experienced similar symptoms.

Timing of events

The timing of symptoms is important because the symptoms may be related to exposure events during work. Asthma provides a good example of this: many people with occupational asthma develop symptoms only after a delay of

Proportional mortality ratios (PMR) in selected occupations

Occupation	High PMR	Low PMR
Teachers	Multiple sclerosis Leukaemia Aplastic anaemia Parkinson disease Bicycle accidents	Lung cancer Bronchitis Alcohol related disease
Doctors, dentists and nurses	Suicide Alcohol-related disease Hepatitis (doctors) Prostatic cancer (dentists)	Ischaemic heart disease
Farmers	Allergic pneumonitis Influenza Hernia Poisoning Accidents Epilepsy Suicide Haemolytic anaemia	Cancer Heart disease Alcohol related disorders
Construction workers	Cancer of pleura and peritoneum Asbestosis Nasal cancer Falls	Suicide

Exposure to solvents at work can be the cause of erratic behaviour at home

How to take an occupational history

Question 1

What is your job? or What do you do for a living?

Question 2

What do you work with? or What is a typical working day for you? or What do you actually do at work?

Question 3

How long have you been doing this kind of work? Have you done any different kind of work in the past?

Question 4

Have you been told that anything you use at work may make you ill? Has anybody at work had the same symptoms?

Question 5

Do you have any hobbies, like do-it-yourself or gardening, which may bring you into contact with chemicals?

Question 6

Is there an occupational health doctor or nurse at your workplace who I could speak to?

some hours and the condition may present as nocturnal wheeze. It is essential to ask whether symptoms occur during the performance of a specific task and if they occur solely on workdays, improving during weekends and holidays. Sometimes the only way to elucidate the pattern is for the person to keep a graphic diary of the time sequence of events.

Working conditions

Patients should be asked specifically about their working conditions. Common problems are dim lighting, noisy machinery, bad office layout, dusty atmosphere, draconian management, and bad morale. Such questioning not only investigates possibilities, but also gives the questioner a good idea of the general state of a working environment and how the patient reacts to it. A visit to the workplace may be a revelation, and just as valuable as a home visit if one wants to understand how a patient's health is conditioned by their environment and how it might be improved. Knowing about somebody's work can help to provide a context and to gain insight. Patients are often happy to talk about the details of their work: this may be less threatening than talking about details of their home life and can promote a better relationship between patients and health professionals.

The causes of occupational disease can extend beyond the workplace and can affect local populations through water or soil pollution. Overalls soiled with toxic materials such as lead or asbestos can affect members of workers' families when the overalls are taken home to be washed.

Trends in work related illnesses

Changes in working practices in the industrialised world are giving rise to work that is more demanding in a psychosocial sense but less so in terms of hard physical activity. Jobs are also safer (although this may not be true in those countries where extremely rapid industrialisation is occurring)—the result of a shift in many countries from agricultural and extractive industry via heavy factory industry to technology intensive manufacturing and services, which are inherently safer. Also, most countries have a labour inspectorate that can orchestrate a risk based strategy of hazard control with varying degrees of efficiency. Life outside work has also become safer, although rapid industrialisation and growing prosperity in some countries have meant huge increases in road traffic, with an accompanying increase in accidents. Traditional occupational diseases such as pneumoconiosis and noise induced deafness can be adequately controlled by the same strategies of hazard control used to limit accidental injury. However, the long latent period between exposure and appearance of occupational diseases makes attribution and control more problematic. Thus, the modern epidemic of musculoskeletal disorders and complaints of work induced stress may reflect a new kind of working population with different characteristics from its forebearers, as well as changes in the work environment itself.

Completely new jobs have appeared, with new hazards—for example, salad composers (dermatitis), aromatherapists (allergies), and semiconductor assemblers (exposure to multiple toxins).

Although working conditions are undoubtedly cleaner, safer, and in many ways better than before, work itself has changed. In the economically developed world there has been a shift from unskilled work to more highly skilled or multiskilled work in largely sedentary occupations. There is greater self employment and a remarkable shift towards employment in small and medium sized enterprises. The percentage of women in employment has been growing for

An example of the interface between occupational and environmental disease was the pollution of Minamata Bay in Japan by discharges of mercury from industrial sources and the severe neurological consequences on those who consumed the resulting contaminated fish

Annual death risks: some examples from the United Kingdom

Cause of death	Annual risk
Whole population	
Cancer	1 in 387
All forms of road accidents	1 in 16 800
Lung cancer caused by radon in dwellings	1 in 29 000
Lightning	1 in 1 870 000
Workers	
Fatalities to employees	1 in 125 000
Fatalities to the self employed	1 in 50 000
Construction	1 in 17 000
Agriculture, hunting, forestry, and fishing (not sea fishing)	1 in 17 200
Service industry	1 in 333 000
Activities	
Surgical anaesthesia	1 in 185 000 operations
Scuba diving	1 in 200 000 dives
Fairground rides	1 in 834 000 000 rides
Rock climbing	1 in 320 000 climbs
Rail travel accidents	1 in 43 000 000 passenger journeys
Aircraft accidents	1 in 125 000 000 passenger journeys

Antidiscrimination legislation in many countries has provided more working opportunities for disabled and older workers, and has provided their employers with some challenges. Occupational health professionals need to understand organisational development as well as occupational disease

decades. Not everyone can cope with the newer, more flexible, less stable, intensively managed work style demanded by modern clients and contractors.

Public perceptions and an expectation of good physical health and associated happiness, allied to improved sanitation and housing, availability of good food, and good medical services, have highlighted those non-fatal conditions which might hitherto have been regarded as trivial but which have large effects on social functioning (such as deafness), work (such as backache), and happiness (such as psychological illness), contributing in turn disproportionately and adversely to disability-free years of life. The public is also more environmentally aware and concerned that some of the determinants of ill health are rooted in modern life and working conditions, giving rise to allergies, fatigue states, and various forms of chemical sensitisation. The estimation, perception, and communication of risk—a social construct—may still, however, be quite primitive even in the most sophisticated of populations. The media definition of risk remains “hazard plus outrage,” and life as a threat has become a reality for many.

The figures showing global work related mortality and the breakdown of costs for work related injuries and diseases use data from ILO, 1999 and ILO, 1995.

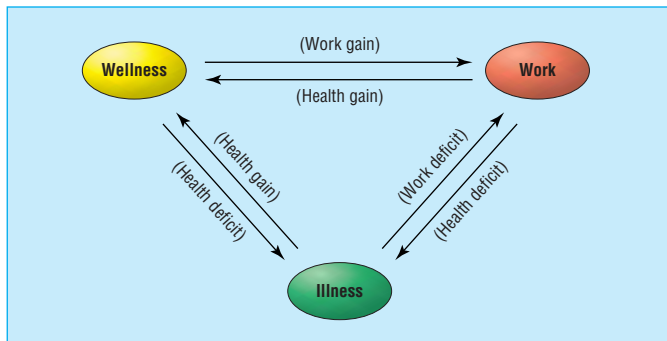

2 Occupational health practice

Anil Adishes

Occupational health is a multidisciplinary activity that draws on a wide base of sciences for its implementation. The range of practitioners employed in any one organisation will tend to reflect the resources allocated, hazards identified, and the prevailing regulatory requirements of the host country. Occupational health is practised by physicians, nurses, safety and risk assessors, and occupational hygienists, sometimes with support from ergonomists, psychologists, toxicologists, and epidemiologists. The competent occupational health practitioner will have some understanding in all these fields but will have an area of special knowledge—for example, the physician will be primarily expert in occupational medicine.

The work of occupational health teams may contribute directly or indirectly to the intrinsic health values of the product (or service). For example, a cement manufacturer might add ferrous sulphate to reduce the likelihood of occupational allergic contact dermatitis in the product users; a hospital may screen and immunise healthcare workers for hepatitis B to prevent occupational acquisition but thereby also prevent iatrogenic disease in patients.

In the course of making recommendations to the UK government on improving access to occupational health support services, the Occupational Health Advisory Committee formed the view that occupational health embraced a range of functions.

The occupational health paradigm

The integration of safety and occupational health is common and many units are described as “occupational health and safety services.” In private industry, in particular, environmental responsibilities have also been incorporated, to form a “safety, health, and environment” function, with management board level representation. The amalgamation of these activities can provide a global focus for occupational health, which then needs to engage with a wider public and political agenda.

The interaction between health and work has been a long held paradigm for occupational health that tends to emphasise the adverse effects of work on health and of ill health on capacity for work. It is perhaps time to add a third factor—“wellness”—to acknowledge that in favourable circumstances work contributes to good health (health gain), and healthier workers to better performance (work gain).

The Finnish concept of “maintenance of work ability” refers to a set of measures designed to assist workers to achieve a high level of work capacity in a changing job market over a working

Aims of occupational health services, formulated by the World Health Organization (WHO) and International Labour Organisation (ILO)

Occupational health should aim at: the promotion and maintenance of the highest degree of physical, mental, and social wellbeing of workers in all occupations; the prevention among workers of departures from health caused by their working conditions; the protection of workers in their employment from risks resulting from factors adverse to health; the placing and maintenance of the worker in an occupational environment adapted to his physiological and psychological capabilities; and, to summarise, the adaptation of work to man and of each man to his job

Joint ILO/WHO Committee on Occupational Health First Session (1950) and revised 12th Session (1995)

Mission statement for an occupational health department

“To support and ensure that the company health and safety community assists company management fulfil its responsibilities for employees’ health and safety by promoting their physical, mental and social wellbeing, a safe, healthy environment and safe and healthy products”

Macdonald EB. Audit and quality in occupational health. *Occup Med* 1992;42:7-11

Occupational health functions

- Evaluating the effect of work on health, whether through sudden injury or through long term exposure to agents with latent effects on health, and the prevention of occupational disease through techniques that include health surveillance, ergonomics, and effective human resource management systems
- Assessing the effect of health on work, bearing in mind that good occupational health practice should address the fitness of the task for the worker, not the fitness of the worker for the task alone
- Rehabilitation and recovery programmes
- Helping the disabled to secure and retain work
- Managing work related aspects of illness with potentially multifactorial causes (for example, musculoskeletal disorders, coronary heart disease) and helping workers to make informed choices regarding lifestyle issues

Occupational Health Advisory Committee, 2000

Occupational health services can help an employer

- Comply with legal responsibilities
 - Identify hazards and quantify health risks at work
 - Implement controls for health risks at work
 - Confirm the adequacy of controls through health surveillance
 - Select and place workers according to health criteria for particular jobs
 - Support employees with a disability
 - Ensure fitness for work
 - Manage work related disorders
 - Control sickness absence and advise on ill-health retirement
 - Develop policies relating to health and safety
 - Promote health among workers
 - Provide training and education in health aspects of employment
 - Organise adequate first aid arrangements
 - Reduce legal liability
 - Design new work processes
 - Provide travel health services for work related travel or postings overseas
-

lifetime. Its application has been found to reduce sickness absence rates and early ill-health retirement.

Occupational health services are in a good position to promote work ability maintenance by:

- Actions directed towards the improvement of employees' physical and mental health, and social wellbeing (by advising the client)
- Actions directed towards competence building, better control of work, encouragement, and motivation (by advising the managers)
- Actions directed to developing the work environment, work processes, and work community that are safe and healthy (by advising the employer).

A work ability index (WAI) has been developed consisting of a questionnaire (translated into many languages) which allows workers to rate their own work ability, track it over the years, and use the score distribution to act as an early warning of decline and guide interventions to improve matters.

The function of occupational health services is to minimise both work and health deficits while maximising health and work gains. To achieve these aims an occupational health service needs:

- to perform a health protection role
- to liaise with treating health professionals
- to undertake active work rehabilitation
- to engage in workplace health promotion and support national health screening programmes
- to provide advisory function to management and workers anticipating the benefits and losses that may arise from changes to work or work practices
- importantly, to monitor its own activities so that meaningful data accrue.

Provision of occupational health

Statutory provision of occupational health is the norm in many European countries, including France, Spain, the Netherlands, Belgium, Portugal, Germany, Denmark, and Greece. Italy provides occupational and environmental health services within the national health service. In the United Kingdom there is no regulation that requires the provision of occupational health services by employers, although all NHS employees should have access to an accredited specialist in occupational medicine.

The NHS is now being encouraged to make its occupational health services available on a commercial basis to small and medium sized enterprises that may not otherwise have access to occupational health. It is, however, more usual for firms to contract private occupational health provision, or to employ occupational health staff.

Employers can seek advice from the Employment Medical Advisory Service of the HSE, but they will usually be directed towards suitable sources of occupational health provision. To implement health and safety legislation effectively, an employer may need the support of a health professional—for example, to perform health surveillance under the Management of Health and Safety at Work Regulations 1999. It might also be prudent to take the advice of an independent health professional at several stages of the employment process, to ensure compliance with disability discrimination legislation and to support other risk management initiatives for the organisation.

The fact that so few private companies use occupational health services is perhaps indicative of their failure to manage certain risks. The HSE promotes a five step process of risk assessment for hazard identification and risk reduction.

Use of health professionals at work

- The following information is contained in research* carried out in 1992†
- In total, 8% of private sector establishments use health professionals to treat or advise about health problems at work. "Health professionals" includes physicians, nurses, and other professions allied to medicine (whether or not they have specialist occupational health (OH) qualification), occupational hygienists, health and safety consultants, and other practitioners with specific OH knowledge or qualifications
- The use of health professionals varies substantially by size of company, with over two thirds (68%) of large employers using professionals, compared with 5% of employers with less than 25 employees. In the private sector, use is highest in manufacturing (14%). The high level of use of health professionals in the public sector means that overall almost half the total workforce are employed by organisations using health professionals

*HSE Contract Research Report 57/1993 on Occupational Health Provision at Work

†There is no more recent data of a comparable nature available

A 2002 survey of UK occupational health provision commissioned by the Health and Safety Executive (HSE) found that among a sample of private companies:

- 15% received services comprising hazard identification, risk management, and provision of occupational health and safety information
- 3% received the above plus modification of workplace activities, training, measurement of workplace hazards, and monitoring of trends (mainly larger companies)
- Health was secondary to safety
- Services were mainly provided by private doctors and nurses
- There was rarely a health and safety budget
- Small and medium sized enterprises (SMEs) were generally happy with the occupational health and safety situation within their company

The Health and Safety Executive's five steps to risk assessment

Step 1: Look for the hazards

Step 2: Decide who might be harmed and how

Step 3: Evaluate the risks and decide whether the existing precautions are adequate or whether more should be done

Step 4: Record your findings

Step 5: Review your assessment and revise it if necessary

Access to Medical Reports Act 1988

The Act established a right of access by individuals to reports relating to themselves provided by medical practitioners for employment or insurance purposes and to make provision for related matters. The Act gives patients certain rights. The patient may:

- Refuse to allow a medical report from their treating doctor
 - Allow the report to be sent unseen
 - See the report during the six month period after it was written
 - See the report before it is sent to the employer (a 21 day period is allowed)
 - Ask their doctor to change any part of the report which they consider to be wrong or misleading before consenting to its release
 - Append their own comments
 - Refuse to let the doctor send the report
-

Health and safety risk management has tended to focus on accidents, yet the cost to employers of workplace injuries and work related illness is estimated (based on the UK Labour Force 1995-6 Survey) to be about £2.5 billion a year (at 1995-6 prices)—about £0.9 billion for injuries and £1.6 billion for illness. Figures from the US Bureau of Labor Statistics report 5 650 100 cases of non-fatal injury or illness in private industry in 2000, with 1 664 000 cases involving days away from work.

Communication

Before any important employment decisions are made, it is in the interests of all parties to gain a full understanding of the facts pertaining to an employee's medical situation. In these circumstances it may be necessary for the occupational health service to request information from the employee's treating doctor. Sometimes information that is not known to the treating doctor is available to the occupational health service. For example, screening procedures may have found a healthcare worker to be infected with hepatitis B virus; health surveillance may have found that a paint sprayer may develop occupational asthma. In such circumstances it is important for the treating doctor to be made aware of these diagnoses with the agreement of the employee.

Communication between an employer and an employee's treating doctor is usually initiated by the occupational health service requesting information from the doctor. Occasionally a request may come directly from a manager or personnel department. The request should be accompanied by appropriate authorisation to disclose medical details to an employer or their medical representative. In the United Kingdom this is under the provisions of the Access to Medical Reports Act 1988.

When asked to provide a report, the corresponding doctor must establish whether the report is intended to go to a doctor retained by the company or to a lay person, such as the employee's manager. A lay person may not fully understand medical jargon, and misinterpretation could give rise to unnecessary concern, to the detriment of the employee.

Reports received by an occupational health department are held in medical confidence, unless the employee has disclosed these or specifically requested that they are disclosed to the employer. The work related implications can be explained to management with advice based on a knowledge of the working environment. It is in everyone's interest (patients, family doctors, hospital doctors, employers, occupational physicians, society as a whole) to get patients back to work as safely and quickly as possible but to prevent their premature return. Rapid and accurate communication is the answer, but the biggest delay occurs when treating doctors fail to answer requests for information from the occupational health service. Delays often cause difficulty to patients, sometimes including financial loss resulting from the inability to work or perform overtime, pending decisions on fitness for work.

Opinions on the part of the treating doctor regarding fitness to work may be unhelpful when these have not been specifically asked for, particularly if the patient is aware of the opinion. For example, a family doctor may consider a "process worker" who is undergoing investigation for syncope as fit to work. The safety of the individual and others in the workplace may be at risk if the doctor is not aware of the duties entailed—for example, working alone in a control room, wearing breathing apparatus, and so on. Doctors may create legal liabilities for themselves in providing opinions when they are

Occupational health reports (The Association of National Health Occupational Physicians, 1996—see Further reading)

Occupational health reports to management must be in writing and include the following:

- (a) Details (not clinical details, but information on functional limitations) of any disabilities which may temporarily or permanently affect the ability of the employee to undertake his or her full range of contracted work duties
- (b) An estimate of the likely duration of absence or disability
- (c) Fitness to undertake the full range of duties, or a limited range of his or her contracted work
- (d) Whether and when any further review would be appropriate
- (e) Whether an application for retirement on grounds of ill health could be supported (this requires an understanding of the criteria applicable to the scheme)

It is essential that an employee is fully aware of the advice that is being sent to management and the implications of this advice. The employee should be provided with a copy of the advice.

This letter to a manager from a doctor acting as medical adviser to the company contains too many medical terms

Dear Harry,

I saw Mr ... He was well until 19 ..., when he had a coronary thrombosis. He made a good recovery from that until about 19 ..., when he began to complain of constant ache in his legs, which was worse on exercise. He now has persistent ache in both legs and an exercise limitation of about 200 yards. He recently had an episode of right-sided hemianopia, in which the outside half of the vision in the right eye disappears due to vascular disease of the eye. This is related to his generalised vascular disease as instanced by his coronary thrombosis and by his leg pains. He also complained recently of some shortness of breath and when I examined him I noticed that his heart beat was irregular. This man has quite severe generalised vascular disease and his life expectancy is not good. However, the only problem affecting his ability to work presently is the difficulty in focusing, due to his recent eye problem. This will hopefully improve sufficiently for him to be able to undertake his work in the office, provided no further disaster occurs. I would hope that he can resume employment in three to four weeks. However, as I said previously, the prognosis here is extremely poor. I hope this is of some assistance to you in organising your plans.

Yours sincerely,

Letter is written by a specialist to support a patient's application for a job in a remote tropical location. Knowledge of the medical facilities and the risks of disease in an immunosuppressed person must be considered

Dear Dr ...

I am writing in support of Ms J's application to work abroad. In 19 ... Ms J had a right leg DVT which was treated with warfarin but one month later she had a pulmonary embolus. Eight months after this, in January, she had an acute illness with fever and a vasculitic rash. A diagnosis of SLE was made and she was treated with prednisolone. In June she had an epileptiform seizure due to cerebral SLE. Glomerulonephritis was diagnosed on renal biopsy in July. The changes were consistent with SLE. She was treated with azathioprine in addition to the prednisolone. She then developed hypertension.

The current situation is that she has heavy proteinuria, indicating active glomerulonephritis; however, she seems clinically well. Her treatment is prednisolone 10 mg daily, azathioprine 100 mg daily, bendrofluazide 5 mg daily, propranolol 320 mg daily, and prazosin, 10 mg twice daily. She will need to continue on long term immunosuppressants but the short term outlook is good, although her renal function is likely to deteriorate in the longer term. Given her fortitude with illness I am sure she would make an excellent field worker for the ... project.

not aware of all relevant information and are without sufficient expertise.

The issue of payment for reports can also cause difficulties, and, ideally, fees should be agreed beforehand. Generally speaking, a higher fee is appropriate if the reporting doctor has been asked for an opinion on matters such as fitness for work; simply reporting on a previous diagnosis, and current and proposed treatment does not require exercising of specific judgement. As a matter of good practice and professional courtesy, payments to medical colleagues should be made promptly on the receipt of a report.

Having assessed the individual, the occupational physician may advise restriction of specific duties—for example, for a nursing care assistant with resolving back strain—that they can return to work under the restriction that no manual handling of patients nor of loads greater than 10 kg is undertaken. This still allows the nursing care assistant to perform a wide range of useful functions: assisting with food preparation and feeding, personal care tasks, checking supplies, and social interaction with clients. It is the skill of the manager to accommodate such advice.

A telephone conversation between the treating doctor and the occupational health department may help clarify the options in managing a return to work. Also, under disability discrimination legislation, there may be a duty on the employer to make a “reasonable accommodation” to facilitate work.

In the rare event of a complete disagreement between the occupational physician and the family doctor or specialist on an individual’s fitness for work, legal authorities tend towards the occupational physician’s opinion. They regard the occupational physician as being in fuller possession of all the facts, both clinical and relating to the actual work to be done, and therefore in a better position to make a balanced and independent judgement.

Ethics and confidentiality

Some doctors are wary of releasing medical details to occupational health professionals, believing that medical confidentiality may be compromised and information given to the employer. This should never happen. All communication between occupational health services and other doctors is held in strict medical confidence. Communication by occupational health services to managers is generally made in broad terms without revealing specific medical details. From a medical report indicating that an employee has angina on exertion, the occupational physician may inform the manager that “Mr. X has a medical condition that prevents him from working in the loading bay and performing other heavy manual work. He should be fit for his other duties as a senior storesman and will be kept under regular review.”

It is unnecessary for a manager to be aware of specific medical details, but sometimes it is helpful, with the patient’s agreement, for fellow workers to be aware of a medical condition such as epilepsy so that appropriate help can be given (or unhelpful actions avoided).

Some doctors also believe that occupational health services usually act in the interests of the employer, rather than the employee/patient. To behave in such a way is contrary to the ethics of occupational health practice, but this misconception still inhibits useful communication between the specialties. In fact, occupational health physicians and nurses act as independent and objective advisors to the individual *and* to the organisation, hopefully to their mutual benefit.

A “Mushroom worker”—without specific details the circumstances of work may not be obvious from the job title alone

General practitioners and hospital specialists may not be aware of the hazards associated with certain jobs: “blowing down” equipment with an air line, a poor practice that creates airborne dust and its attendant hazards

Cramped working conditions with ergonomic difficulties

Positive patch tests to acrylates in a worker who glued lead flashing onto window units. She had developed an allergic contact dermatitis affecting the hands. In such a situation, two way communication can be beneficial to the patient—a patient may see their general practitioner for hand dermatitis, and liaison with the occupational health department may help identify the cause

Ill-health retirement

Sometimes medical conditions will preclude a return to work because of permanent incapacity for a particular job. Information will often be requested in order to support ill-health retirement, or it may be necessary to explain why an employee's job is to be terminated because of incapacity (where a person has not attended work for an excessive period because of sickness absence, but recovery of fitness is envisaged), the latter being a managerial decision. The pension fund's grounds for ill-health retirement may be explicit and leave little room for clinical opinion, or may be quite open. There is potential for disagreement between the occupational physician and other medical advisers, particularly if restricted duties or redeployment are viable propositions. Ideally, views should be discussed openly and an equitable decision made.

The interface between occupational health and other healthcare providers should therefore be open and two way, initiated either by primary care and hospital services or by occupational health services whenever discussion of patient care in relation to employment could be advantageous.

Audit and monitoring

It is important that occupational health practitioners critically evaluate their practice and, through application of the iterative audit cycle, improve the quality, effectiveness, and efficiency of their service. Audit is conventionally divided into structure (resources), process (procedures), and outcome (results). The use of audit should not be confined to clinical matters, and the inclusion of occupational health practitioners from other disciplines—for example, occupational hygiene or safety, will contribute to better services for all.

For a service to report on its activities in a meaningful way there needs to be in place a basic dataset that allows comparison between time periods, different employee groups, or operational divisions. Data that may be appropriate include new appointments, review appointments, health surveillance activity, immunisations, referral reason, type of clinician (doctor or nurse), and diagnosis. This information is invaluable for presentation to management to show changes in activity or areas for which increased funding is needed when making a business case. It will also be useful when discussing issues from the perspective of occupational health in organisational meetings such as health and safety meetings, risk management, and when compiling an annual report or business plan. These data are ideally compiled in a computerised database, either bespoke or a commercially available occupational health software package.

Research

Research is an essential occupational health function. It is only through testing hypotheses that we can advance our knowledge of occupational disease causation, the effectiveness of screening programmes, the benefits of workplace health promotion, quantification of occupational risk, establishment of exposure levels, and the economic impact of occupational injuries and ill health.

Occupational health practitioners may also be faced with ethical difficulties in this field. For example, an organisation may not wish to publicise adverse information about its products or activities. If private companies or national bodies

The audit cycle

Information technology and occupational health

When implementing an occupational health computer system consider:

- The information required from the system and therefore the data entry fields that will be needed
- Data security, in the context of confidentiality and back up in the event of system failure (there are advantages of having the computer server in the organisation's IT department)
- Whether the system is to be "stand alone," networked within a department, or over multiple sites
- Compatibility with other organisational systems—for example, personnel or payroll for downloads of starters and leavers, incident reporting systems, sickness absence recording
- Production of reports and database queries
- Maintenance of data quality—that is, that the information recorded accurately represents the information presented
- The use of coding systems if comparisons with other occupational health services may be useful in the future, perhaps for audit, benchmarking, or research.

Practitioners also need to ensure that they meet professional requirements for continuing development. These responsibilities are usually set by professional bodies and it is important that employers recognise that continuing professional development is a necessary component of ongoing competence

An exposure chamber for respiratory challenge studies. The subject is seated inside the metal chamber and gas or vapour is passed through a laminar flow wall into the chamber, inside which spirometry can be performed

are concerned with or participate in research, their influence on what is finally published and intellectual property rights should be formally agreed at the outset. Too often there is reluctance for employers, unions, charities, and government bodies to fund occupational health research. Each seems to feel that the responsibility belongs to one of the other parties. It therefore behoves occupational health practitioners to participate in or act as advocates for occupational health research activities.

The box showing the use of health professionals at work is adapted from the report and recommendations on improving access to Occupational Health Support, Occupational Health Advisory Committee, 2000.

3 Investigating the workplace

Keith T Palmer, David Coggon

Investigation of the workplace is as central to the practice of occupational medicine as clinical assessment is of the individual patient. It is an essential step in the control of occupational hazards to health. Moreover, by visiting a place of work, a doctor can understand better the demands of a job, and thus give better advice on fitness for employment. Investigations may be prompted in various circumstances.

Direct inspection and the walk through survey

One method of investigation is direct inspection of the workplace. Inspections often take the form of a structured “walk through” survey, although more narrowly targeted approaches may sometimes be appropriate.

Planning

Industrial processes are often complex, and hazards are plentiful. How should a walk through survey be conducted? The arrangements and context are important. The initial visit should be by appointment. Arrangements should be checked before visiting, as a planned visit saves time.

The survey should be structured, but the precise way it is organised is less important and at least three approaches are commonly adopted.

- *Following a process from start to finish*—from raw materials coming in to finished goods going out. What hazards occur at each stage? How should they be controlled? Do the controls actually work? Focusing the assessment on the process helps with basic understanding of the work and its requirements.
- *Auditing a single category of activity or hazard* (such as dusty or noisy procedures or manual handling) wherever it occurs within the organisation. Does the control policy work everywhere, or are there special problems or poor compliance in certain groups of workers or sites? This approach is useful for introducing and monitoring new policies.
- *Detailed inspection site by site*—What are the hazards in this particular site? How are they handled? The inspection moves on only when the geographical unit of interest has been thoroughly inspected. This site focused approach is often appreciated by shop stewards and workers’ representatives with local ownership of the problem. They may accompany the inspection and often give insight into working practices and problems not apparent during the visit.

Circumstances that may prompt investigation of a workplace

- Initial assessment when first taking over care of a workforce or advising an employer
- Introduction of new processes or materials that could be hazardous
- New research indicating that a process or substance is more hazardous than was previously believed
- An occurrence of illness or injury in the workforce that suggests an uncontrolled hazard
- A need to advise on the suitability of work for an employee who is ill or disabled
- Routine review

When planning a walk through survey an unannounced snap inspection may be revealing, but is practicable only for a health and safety professional who has an established relationship of trust with the employer

Arranging a walk through survey

- Visit by appointment (at least to begin with)
- Check whether you will:
 - be accompanied by someone with responsibilities for safety
 - see someone who can explain the process
 - have a chance to see representative activities
- Look at documentation on health and safety, such as data sheets, risk assessments, safety policy, accident book
- Do some preliminary research: identify sorts of hazard likely to be encountered and legal standards that are likely to apply
- If visiting because of an individual’s complaint, discuss it first with complainant

A hazard represents a potential to cause harm. A risk represents the likelihood of harm. In risk assessment the hazard is put in its correct context

What to cover in a walk through survey

After listing the hazards, it is important to consider who might be exposed and in which jobs, how likely this is under the prevailing circumstances of the work (including any precautions followed), the magnitude of the expected exposures, and their likely impact on health (that is, the risks to health). The aim is to determine whether risks are acceptable, taking into account both the likelihood of an adverse outcome and its seriousness, or whether further control measures are required and, if so, what these should be.

As prevention is better than cure, can the hazard be avoided altogether, or can a safer alternative be used instead? Otherwise, can the process or materials be modified to minimise the problem at source? Can the process be enclosed, or operated remotely? Can fumes be extracted close to the point at which they are generated (local exhaust ventilation)?

Have these ideas been considered before issuing ear defenders, facemasks or other control measures that rely on workers' compliance ("Do not smoke," "Do not chew your fingernails," "Lift as I tell you to")? A realistic strategy should always place more reliance on control of risk at source than on employees' personal behaviour and discipline.

Health and safety professionals use checklists to ensure that all the major types of hazard are considered and to ensure that the control options are fully explored. They seek to verify that these options have been considered in an orderly hierarchy

Simple checklist of control measures

Option	Key questions to ask	Possible controls*
Avoidance or substitution	Does the material have to be used or will a less noxious material do the job?	Try using a safer material if one exists
Material modification	Can the physical or chemical nature of the material be altered?	Is it supplied as granules or paste rather than powder? Can it be used wet?
Process modification	Can equipment, layout, or procedure be adapted to reduce risk?	Can it be enclosed? Can the dust be extracted? If material is poured, tipped, or sieved, can the drop height be lowered?
Work methods	Can safer ways be found to conduct the work? Can it be supervised or monitored? Do workers comply with methods?	Avoid dry sweeping (it creates dust clouds). Be careful with spills. Segregate the work; conduct it out of hours
Personal protective equipment	Have all other options been considered first? Is equipment adequate for purpose? Will workers wear it?	Provision of mask, visor, respirator, or breathing apparatus suitable for intended use

*A dust hazard is used as an example. See also Verma DK, et al. *Occup Environ Med* 2002;59:205-13.

What the survey may find

The purpose of the walk through survey is to be constructively critical. When good practices are discovered these should be warmly acknowledged. Faulty ones arise from ignorance as often as from cutting corners.

In certain workplaces that we have visited, expensive equipment provided to extract noxious fumes from the workers' breathing zone was switched off because of the draught, or directed over an ashtray to extract cigarette smoke rather than the fumes, or obstructed by bags of components and Christmas decorations.

Local exhaust ventilation may be visibly ineffective: the fan may be broken, the tubing disconnected, the direction of air flow across rather than away from the workers' breathing zone. Protective gloves may have holes or be internally contaminated; the rubber seals of ear defenders may be perished with age; and so on. Poor housekeeping may cause health hazards. There may be no system of audit to check that items of control equipment are maintained and effective. Simple commonsense observations, made and recorded systematically, will go a long way towards preventing ill health at work.

The walk through survey may prompt improvements directly or highlight a need for further investigation, such as workplace measurements or a health survey.

Workplace inspection aids understanding of the job demands and risks. This stonemason is exposed to hand transmitted vibration, noise, and silicaceous dust

This industrial process (scabbling) generates a lot of dust. Formal measurements showed that respirable dust and silica levels were several times in excess of those advocated in British standards. The highest exposure arose during sweeping up

Formal assessment of exposures

More formal measurement of exposure may be required if an important hazard exists and the risk is not clearly trivial. Often a specialised technique or sampling strategy will be needed, directed by an occupational hygienist. The UK Health and Safety Executive publishes guidance on methods of measurement and acceptable exposure levels for some physical hazards, such as noise and vibration, and many airborne chemical hazards. In some cases legal standards exist. For some chemicals absorbed through the skin or lungs, exposure can also be assessed by blood or urine tests, and biological action levels have been proposed.

Action after a workplace assessment

The aim in assessing a workplace should be to draw conclusions about the prevailing risks and the adequacy of the controls. But if this is to have a lasting benefit the results must be communicated to senior managers who have the authority to set, fund, and oversee policies in the workplace. A written report is advisable, but a verbal presentation, perhaps at a meeting of the organisation's safety committee, may have more impact, as may a short illustrated slide show. Feedback on the findings of a workplace health survey can make important contributions to the promotion of change and a safer working environment.

Some exposure standards for airborne chemicals

- The UK Health and Safety Executive publishes an annual list of exposure standards (EH40) and also advice on measuring strategies (EH42) and techniques (various EH publications)
 - The listed chemicals generally fall into one of two categories. Occupational exposure standards (OES) are prescribed when a level can be specified below which long term exposure is thought not to present a risk to health. In other cases, where the safe level is less certain, a maximum exposure limit (MEL) is specified. This must not be exceeded, and there is a requirement to minimise exposure as far below the MEL as is reasonably practicable
 - Other international exposure limits include the threshold limit values (TLVs) published by the American Conference of Governmental Industrial Hygienists (ACGIH) (see <http://www.acgih.org>)
-

The worker is exposed to noise during grinding. He should be wearing ear defenders

Frayed electrical cable and homemade plug discovered at a work site

Investigating new occupational hazards

As well as inspecting workplaces to identify and control known hazards, health and safety professionals should be alert to the possibility of previously unrecognised occupational hazards. Suspicions may be aroused in various circumstances. The demonstration and characterisation of new hazards requires scientific research, often using epidemiological methods. The most frequent types of investigation include cohort studies, case-control studies, and cross sectional surveys.

An advantage of epidemiology is that it provides direct information about patterns of disease and levels of risk in humans. However, because of the practical and ethical constraints on research in people, it also has limitations that must be taken into account when results are interpreted. Epidemiological findings should therefore be evaluated in the context of knowledge from other relevant scientific disciplines such as experimental toxicology, biomechanics, and psychology.

Commonly used epidemiological methods

Cohort studies

People exposed to a known or suspected hazard are identified, and their subsequent disease experience is compared with that of a control group who have not been exposed or have been exposed at a lower level. Cohort studies generally provide the most reliable estimates of risk from occupational hazards, but need to be large if the health outcome of interest is rare

Case-control studies

People who have developed a disease are identified, and their earlier exposure to known or suspected causes is compared with that of controls who do not have the disease. Case-control studies are often quicker and more economical to conduct than cohort studies, especially for the investigation of rarer diseases. However, risk estimates tend to be less accurate, particularly if exposures are ascertained from subjects' recall

Cross sectional surveys

A sample of people are assessed over a short period of time to establish their disease experience and exposures. The prevalence of disease is then compared in people with different patterns of exposure. This method is best suited to the investigation of disorders that do not lead people to modify their exposures (which might occur because associated disability makes them unfit for certain types of work). Where a disease causes people to leave a workforce, cross sectional surveys may seriously underestimate the risks associated with exposure

Assessment of disease clusters

One starting point for investigation of a workplace may be the observation of a disease cluster. A disease cluster is an excess incidence in a defined population, such as a workforce, over a relatively short period (less than a day for acute complaints such as diarrhoea to several years for cancer).

Apparent clusters are not uncommon in occupational populations, and investigation sometimes leads to the recognition of new hazards. For example, on the one hand, the link between nickel refining and nasal cancer was first discovered when two cases occurred at the same factory within a year. On the other hand, excessive investigation of random clusters wastes resources. The extent to which a cluster is investigated depends on the level of suspicion of an underlying hazard and the anxiety that it is generating in the workforce. A staged approach is recommended.

Reasons for suspecting an occupational hazard

- Parallels with known hazards—for example, use of a substance that has a similar chemical structure to a known toxin
 - Demonstration that a substance or agent has potentially adverse biological activity *in vitro*—for example, mutagenicity in bacteria
 - Demonstration that a substance or agent causes toxicity in experimental animals
 - Observation of sentinel cases or clusters of disease
-

Interpretation of epidemiological findings

In evaluating epidemiological results, consideration must be given to the following factors:

Bias

A systematic tendency to overestimate or underestimate an outcome measure because of a deficiency in the design or execution of a study. For example, in a case-control study assessing exposures by questioning participants, affected persons might tend to recall exposures better than controls (because they are more motivated). The effect would be to spuriously exaggerate any association between exposure and disease

Chance

The people included in a study may be unrepresentative simply by chance, leading to errors in outcome measures. The scope for such errors can be quantified statistically through calculation of confidence intervals. Generally, the larger the sample of people studied, the lower the potential for chance error

Confounding

This occurs when a hazard under study is associated with another factor that independently influences the risk of disease. For example, an occupational group might have high rates of lung cancer not because of the chemical with which they worked, but because they smoked more heavily than the average person (that is, exposure to the chemical was associated with heavier smoking)

A cluster of wheezing and rhinitis occurred on this prawn processing line. High pressure hoses (used to free the prawns from the shells) had created aerosols containing crustacean protein

Is there a true cluster?

The first step is to specify the disease and time period of interest and to confirm the diagnoses of the index cases that prompted concern. Sometimes no further action is needed. Of three cases of brain cancer, two might turn out to be secondary tumours from different primary sites. If suspicion remains, it is worth searching for further cases. Often, the number of identified cases is clearly excessive, but if there is doubt, crude comparison with routinely collected statistics such as of cancer registration or mortality should establish whether the cluster really is remarkable.

Further steps

If a raised incidence is confirmed, the next step is to find out what the affected workers have in common. Do they work in the same job or building, and do they share exposure to the same substances? If so, what is known about the risks associated with their shared activities and exposures? This information may come from published reports or manufacturers' data sheets. Scientific articles should also be searched to identify known and suspected causes of the disease of interest. Could any of these be responsible for the cluster?

Getting help

At this stage the cause of the cluster may have been identified, or suspicions sufficiently allayed to rule out further investigation. If concerns remain it may be necessary to carry out a more formal epidemiological investigation to assess more precisely the size of the cluster and its relation to work. Help with such studies can often be obtained from academic departments of occupational medicine. Also, patients may need to be referred to specialist centres for investigations such as dermatological patch testing or bronchial challenge.

Hazards controlled

Over the years, investigation of workplaces has made a major contribution to public health through the identification and control of occupational hazards, and improved placement and rehabilitation of workers with illness or disability. Although some types of investigation need special technical expertise, all health and safety professionals should be familiar with the principles, and capable of inspecting and forming a preliminary assessment of working environments.

Stages in investigating occupational clusters of disease

1. Specify disease and time period of interest. Confirm diagnoses of index cases
 2. Search for further cases. Is the observed number of cases excessive?
 3. What do affected workers have in common? Do their shared exposures carry known or suspected risks?
 4. What is known about the causes of the disease?
 5. Further investigation: epidemiology and clinical investigation
-

Some important occupational hazards that have been identified and controlled through investigation of workplaces

Hazard	Control measures
• Bladder cancer from aromatic amines in dyestuffs and rubber industries	• Substitution of the chemicals with non-carcinogenic alternatives
• Lung cancer and mesothelioma from asbestos	• Substitution by less hazardous materials such as manmade mineral fibres; dust control and personal protective equipment in asbestos removal
• Coal workers' pneumoconiosis from dust in mines	• Dust suppression by water spraying
• Occupational deafness from exposure to noise	• Substitution or enclosure of noisy processes; exclusion zones; personal protective equipment

4 Fitness for work

William Davies

Assessments of fitness for work can be important for job applicants, employees, and employers. Unfitness because of an acute illness is normally self evident and uncontentious, but assessing other cases may not be straightforward and can have serious financial and legal implications for those concerned. Commercial viability, efficiency, and legal responsibilities lie behind the fitness standards required by employers, and it may be legitimate to discriminate against people with medical conditions on these grounds. Unnecessary discrimination, however, is counterproductive and may be costly if legislation is breached. The Disability Discrimination Act 1995 makes it unlawful for employers of 15 or more staff (all employers from 2004) to discriminate without justification against those with disability as defined by the Act. The Employment Rights Act 1996 requires procedural standards and fairness before any decision to dismiss an employee. Fortunately, balancing these often complex socioeconomic and legal issues to achieve a sustainable decision on fitness is not primarily a medical responsibility. Doctors do, however, have responsibilities to assess the relevant facts competently and to assist with the decision making process.

Basic principles and responsibilities

Staying on track

This chapter deals with assessing fitness for “identified employment.” To avoid confusion with related issues, the following points should be noted at the outset:

- Fitness for work in relation to ill health retirement benefits will depend on the specific provisions of the pension scheme. Pivotal issues that frequently arise are the interpretations that should be given to incapacity and to permanence, and whether fitness relates to current employment or all work. General guidance has been issued and specific guidelines for all UK public sector schemes should now be available following the recommendations of a HM Treasury report in 2000
- The Disability Discrimination Act 1995 has encouraged good medical practice in assessing and deciding on fitness for work by requiring individual and competent assessments, and by obliging employers to be more accommodating to those covered by the legislation
- Key health and safety concepts—hazard, risk, negligible risk, and competence—apply to assessing fitness for work and should be clearly understood
- Rehabilitation back to work and an emphasis on capability rather than limitations are now central themes of legislation, guidance, and government policies on health and safety and occupational health.

Medical responsibilities

Doctors’ responsibilities vary according to their role. General practitioners and hospital doctors acting as certifying medical practitioners have direct responsibilities to their patients to provide statutory evidence of advice given about fitness for the patient’s regular occupation. Such doctors also have an obligation to provide related information to a medical officer working for the Department for Work and Pensions.

Implications of fitness assessments

- Security of employment
 - Rejection at recruitment
 - Justifiable or unfair discrimination
 - Retirement because of ill health
 - Termination of contract
 - Claim for disability discrimination
 - Claim for unfair dismissal
 - Employment tribunals
 - Medical appeal
 - Civil litigation for personal injury
 - Criminal prosecution for breach of health and safety legislation
 - Professional liability
 - Pension entitlements
 - Benefit claims
-

Basic principles and responsibilities—when fitness assessments may be required

- Before employment, placement, or redeployment
 - Routine surveillance in safety critical jobs
 - During or after sickness absence
 - To identify adjustment needs
 - When attendance or performance issues arise
 - If health and safety concerns arise
 - To examine ill health retirement issues
 - If required by statute
 - Benefit assessment—for example, the “own occupation test” administered by the Department for Work and Pensions (DWP)
-

The personal capability assessment is the medical assessment used to determine if a person is eligible for state incapacity benefit. It does not consider fitness for a specific type of employment but assesses general functional ability in relation to everyday physical and mental activities. Decision makers within the Department for Work and Pensions who apply the test will take advice from a specially trained doctor approved for the purpose by the Secretary of State

Medical responsibilities

General and hospital practitioners

To patient

- Act in patient's best health interests
- Provide advice on fitness for regular occupation
- Consider clinical management that would support employment wherever clinically reasonable
- Provide patient with statutory forms (for example, Med 3) recording the advice given

To Department for Work and Pensions (DWP)

- Supply on request relevant clinical information to a medical officer

To society and the general public

- In certain circumstances public interest will override any duty to the individual patient or employer—for example, a surgeon infected with hepatitis B who continues to work in a way that puts patients at risk

Detailed advice for general and hospital practitioners on DWP issues is available in the guide IB204 (March 2000) and from regional Medical Services Centres

Occupational health practitioners

To patient

- Act in patient's best health interests
- Consider clinical management that would support employment wherever clinically reasonable

To employer

- Assess functional ability and occupational risks
- Make recommendations on fitness in accordance with valid predetermined standards
- Provide information and advice that enables management to make an informed decision on compatibility of subject with employer's requirements and legal responsibilities

Detailed advice on medical responsibilities of occupational health practitioners is available in *Fitness for Work. The Medical Aspects* or from accredited specialists in occupational medicine

Occupational health practitioners have direct responsibilities to the employee or job applicant and the employer. Both groups have a responsibility to society.

These groups may take different approaches but have important common ground. If patients, employees, and job applicants are to be treated fairly, every medical opinion on their fitness for a job should be based on a competent assessment of relevant factors, and should satisfy the same basic criteria. Patients' interests will be best served when there is clear understanding, due consultation, and, as far as possible, agreement between doctors.

Key principles in practice

The first principle in the table opposite establishes three basic criteria for fitness: attendance and performance, health and safety risk to others, and health and safety risk to self. In this context, "without risk" reflects a fundamental ethical concept of occupational medicine that limits medical discretion. Doctors should not presume to decide for others that risks are acceptable; employers must take this responsibility, and they require medical advice and information on the nature and extent of risk to make informed decisions.

The second principle means that an appraisal of the subject's medical condition and functional ability, together with a review of the relevant occupational considerations, should provide an empirical assessment of ability and risk. This assessment may be judged against the required fitness criteria to determine what the outcome should be.

The third, fourth, and fifth principles point to the potential there may be for preventing or controlling risk, and for accommodating the needs of people with disabilities or medical conditions. Such measures may justify a conditional recommendation of fitness.

The sixth principle means that technically all decisions on fitness rest with the employer. This is because the employer determines what is required of the employment and ultimately carries responsibility for the risks.

Framework for assessing fitness for work

The terms fitness and incapacity are open to interpretation, and responsibilities for assessing and deciding on fitness issues span medical and management disciplines. A systematic

Key principles of assessing fitness for work

1. The primary purpose of the medical assessment of fitness to work is to ensure that the subject is fit to perform the task required effectively and without risk to the subject's or others' health and safety
 2. The subject's fitness should be interpreted in functional terms and in the context of the job requirements
 3. Employers have a duty to ensure, so far as is reasonably practicable, the health, safety, and welfare of all their employees and others who may be affected (Health and Safety at Work etc. Act 1974)
 4. Legal duties of reasonable adjustment and non-discrimination in employment are imposed by the Disability Discrimination Act 1995
 5. Good employment practice involves due consideration of the needs of all job applicants and employees with disabilities or medical conditions (Employment Rights Act 1996)
 6. It is ultimately the employer's responsibility to set the objectives for attendance and performance, and to ensure compliance with the law on health and safety and employment
-

Framework for assessing fitness for work

Stage 1—Workplace assessment of ability and risk

Step 1: Assess medical condition and functional capacity

Step 2: Consider occupational factors

Step 3: Explore enabling options

Stage 2—Relate Stage 1 findings to fitness criteria

Step 4: Identify any attendance or performance limitations

Step 5: Identify nature and extent of any risks to others

Step 6: Identify nature and extent of any risks to self

Stage 3—Report on outcome in suitable terms

Step 7: Confirm fitness or unfitness

Step 8: Present assessment conclusions if 7 not possible

Step 9: Provide supplementary advice to 8 if appropriate

approach is required to ensure consistency and to avoid confusion of roles.

The framework is based on the key principles and relevant legal provisions. There are three stages and up to nine logical steps. In simple cases where no medical conditions apply, steps 1, 2, and 7 should suffice. In other cases, seven, eight, or all nine steps may be required.

Reporting the outcome

When the parameters of the fitness criteria are defined and the assessment clearly satisfies or fails to satisfy the employer's requirements and responsibilities, a confirmation of fitness or unfitness can be made (see green columns in the desktop aid on page 23).

When the parameters of the fitness criteria are uncertain (when the employer's requirements and responsibilities cannot be predetermined or presumed) the conclusions of the assessment should be made clear to the employer. In addition, an opinion on the reasonableness of any enabling options identified or the case for employment or continued employment may be given as supplementary advice (see red columns in desktop aid).

It should be noted, however, that supplementary advice offered under step 9 above relates to management rather than medical issues, and should be qualified accordingly. All reports should comply with professional standards on disclosure and consent.

Assessment of ability and risk

Medical functional appraisal

Doctors should always have a basic knowledge of the job's demands and working environment before undertaking a medical functional appraisal so that the extent and emphasis of the appraisal may be tailored accordingly. Any medical conditions that could pose a risk to the subject's or others' health and safety, or that could affect attendance and performance, should be identified and evaluated.

A suitably constructed questionnaire is the simplest form of assessment; for pre-employment screening, a questionnaire or health declaration will be sufficient to permit medical clearance in many categories of employment. Some occupations have statutory standards (for example, in the United Kingdom, there are statutory medical standards for seafarers), and appraisals must include measuring necessary factors. Others have standards set by authoritative recommendations or guidance (for example, the Health Advisory Committee of the UK Offshore Operators Association has drawn up guidelines on the medical standards for offshore work).

If no guidance exists, doctors must judge how extensive the assessment should be by taking account of the nature of any medical conditions identified, the type of work, and the reasons for management's request for medical advice.

Occupational considerations

In straightforward cases a medical functional appraisal and the doctor's existing knowledge of the job demands and working environment may be sufficient for a confirmation of fitness. However, a closer look at occupational factors is often needed to determine the precise requirements of the job, the subject's real abilities in a working environment, the nature of any hazards, and the probability of harm occurring (the actual risk in the workplace).

Medical functional appraisal

History and examination

- Pre-employment questionnaire or health declaration
- Health interview, occupationally relevant direct questions
- Physical examination focusing on job requirements

Functionally specific questionnaires

- Respiratory (MRC questionnaire)
- Pre-audiometry

Consultation and research

- Details from general practitioner and medical specialist, under Access to Medical Reports Act 1988 or non-UK equivalent
- Details from other specialists such as psychologists or audiologists
- Advice or second opinion from specialist occupational physician
- Advice or second opinion from independent specialists such as cardiologists or neurologists
- Clinical guidelines and evidenced based reviews
- Texts, journals, and research

Work related tests and investigations

Perceptual tests

- Snellen chart: special visual standards may be required for certain occupations such as aircraft pilots, seafarers, and vocational drivers
- Colour vision tests such as Ishihara plates or City University test, or matching tests, may be necessary if normal colour vision is essential—for example, for some jobs in transport, navigation, and the armed services
- Voice tests
- Audiometry: occupations such as the armed services, police, and fire service may have specific standards

Functional tests

- Lung function tests (for example, UK regulations require fire service employees to have their respiratory parameters measured before employment)
- Dynamic or static strength tests
- Physical endurance and aerobic capacity (for example, the fire service or commercial divers)
- Step test
- Bicycle ergometer

Diagnostic (health on work)

- Exercise electrocardiography: needed—for example, for vocational drivers and offshore workers
- Drug and alcohol tests may be a requirement in certain safety critical industries

Diagnostic (work on health)

- Haematology, biochemistry, and urine analysis: UK commercial divers will have full blood count and haemoglobin S assessed before employment
 - Radiographs: long bone radiographs are a requirement before employment for saturation diving in the United Kingdom
-

- A subject may be able to show satisfactory ability in a job simulation exercise despite a physical impairment that might have affected fitness—for example, a work related test of manual dexterity for an assembly line worker with some functional loss resulting from a hand injury
- In teaching, health care, and many other occupations, the perceived hazards of epilepsy are often found to be negligible when the potential for harm to others is properly assessed
- If diabetes is well controlled, the risk of injury from hypoglycaemia may be found to be very remote when the true frequency and duration of hazardous situations are taken into account.

Enabling options

A subject's potential fitness often depends on intervention. There may be unexplored treatments that can be provided. Rehabilitative support may be needed to achieve or speed recovery. Employers can make reasonable adjustments, temporary or permanent, to meet the needs of people with medical conditions. Prevention and control measures can reduce or eliminate health and safety risks that would otherwise prohibit a recommendation of fitness.

- Unexplored treatments that are often identified during assessments include physiotherapy, anxiety management, and psychotherapy
- A tailored, stepwise rehabilitative programme can make the prospect of returning to work after serious illness less daunting and may be vital for recovery from anxiety, depression, occupational stress, and other demotivating conditions
- Modifying a job specification may allow a recommendation of fitness with minimal inconvenience to the employer (for example, removing the requirement to undertake occasional lifting for an arthritic subject)
- Substituting a sensitising or irritant product may, with other sensible precautions, enable an employee with asthma or eczema to continue working as—for example, a paint sprayer or cleaner.

These measures may be applicable under the Health and Safety at Work etc. Act 1974. The Disability Discrimination Act 1995 may also require reasonable adjustments to be made. Even if intervention is not obligatory, employers may recognise the benefits of positive action. Doctors should therefore always bear these options in mind, as it may be possible to give a conditional recommendation of fitness that the employer would be willing to accommodate.

Fitness criteria in difficult cases

This approach should produce a reliable opinion in most cases, but further steps may be needed if the criteria for fitness for work are uncertain. In a fitness assessment this may occur with one, two, or all three of the criteria. Dealing with the issues in turn is advisable.

Attendance and performance

The possible impact of a medical condition on a subject's ability to meet required levels of attendance and performance is a major source of employers' requests for medical opinion. When asked by an employer about an employee's performance and attendance capabilities, the doctor's responsibility is to give the most accurate opinion that the circumstances allow. Conclusions and advice should be as positive as possible but without misrepresenting the facts, and should be discussed with the subject. This should help motivation and may improve recovery.

Occupational considerations

Ability in the workplace—consider actual effect of physical or medical condition on performance

- Confirm job requirements such as perception, mobility, strength, and endurance
- Ask employee what the work entails
- Review job description or inspect worksite
- Perform field tests of specific abilities or structured job simulation exercises
- Consider trial of employment with feedback from management

Nature of hazards—consider interaction of occupational factors and medical condition

- Harm from:
 - demands (heart attack, back strain, prolapsed disc, repetitive strain injury)
 - exposures (asthma, dermatitis, hearing loss)
 - situations (seizure, trauma, accidents)
 - infections (food handling, surgical procedures)
- How much harm is likely (temporary, permanent, minor, major, fatal)?
- Who may be affected (self, colleagues, clients, public)?

Extent of risk—focus on facts and avoid presumption

- Question employee on relevant details
 - Obtain management report on material facts
 - Examine documentation such as exposure records, accident reports, etc.
 - Observe work, workplace, and working practices
 - Identify frequencies and duration of hazardous exposures or situations
 - Request technical data from hygienist, ergonomist, etc. if required
 - Review relevant literature, journals, and research
-

Enabling options

Unexplored treatments

- Drug treatment or surgery
- Physiotherapy or occupational therapy
- Counselling or psychotherapy

Rehabilitative measures

- Graded resumption of responsibilities
- Refamiliarisation training
- Temporary reduction of workload
- Management appraisal or progress reports
- Scheduled or self requested medical reviews

Reasonable adjustments

- Modification of duties or working hours
- Redeployment to existing vacancy
- Modifying or providing equipment
- Time off for rehabilitation or treatment
- Providing supervision

Risk prevention and control

- Elimination or substitution of hazard
 - Implementation of methods to reduce worker exposure to hazards
 - Personal protection or immunisation
 - Information, instruction, and training
 - Health and medical surveillance
-

- Employers do not like open ended statements such as “Unfit; review in three months;” they prefer uncertainties to be expressed as probabilities: “Mr Smith has been incapacitated but is progressing well and is likely to become fit to return to work within four weeks”
- The doctor should may need to ask management for an appraisal of capabilities before making definitive conclusions on the relevance of medical factors: “I will therefore require a management report on her progress after week 6 of the rehabilitation programme”
- In cases of prolonged sickness absence, the doctor should not be pressured into recommending ill health retirement for doubtful reasons: “Mr Green is likely to remain unfit for the foreseeable future, but there are not sufficient grounds for ill health retirement under the pensions scheme.”

If social or motivational factors are evident, discuss these with the subject, and advise management accordingly: “Mrs Jones’ incapacitation is due to family commitments that are likely to continue for the foreseeable future. She realises that her employment could be at risk and would welcome an opportunity to discuss her situation with management.”

Health and safety risk to others

Employers have a legal duty to ensure the health and safety of employees and the public. In principle, the doctor identifies hazards and quantifies any risks; management decides on a subject’s fitness on the basis of the medical conclusions and advice. In practice, however, doctors confirm fitness when there is no risk, and unfitness if there are clearly unacceptable risks. For the many cases that lie in between, there may be confusion as to whether it is a management or medical responsibility to decide on fitness. A pragmatic approach is suggested.

For negligible risk, the doctor may advise that the subject be considered fit provided that the judgement of negligible risk is made objectively, is based on a competent risk assessment, and that the employer applies all reasonably practicable precautions.

For greater than negligible risk, the doctor should define the type of hazard and extent of risk as clearly as possible to enable management to make an informed decision.

Advice from a specialist occupational physician may be required to confirm the competence of the risk assessment or to assist management on acceptability.

Health and safety risk to self

The principles of assessing risk to others applies here, but medical advice can go further. In some cases employment may pose a risk of ill health but the employer is satisfied that everything possible has been done to prevent or reduce risks (for example, the risk of relapse in a teacher with a history of work related anxiety depressive disorder). To advise that in such cases the subject should always be deemed unfit because of a risk of work related illness is unrealistic. The benefits of employment for the subject, and possibly their employer, may considerably outweigh the risks. On the other hand, there could be issues of liability for both employer and doctor if the risks are overlooked.

The parameters of the fitness criteria may be uncertain when:

- Attendance or performance limitations resulting from a medical condition are identified, but the employer’s willingness to accommodate them cannot be prejudged
 - Health and safety risks to others exist, but they seem remote enough to ignore
 - Health and safety risks to self are identified, but they do not seem to justify a recommendation of unfitness.
-

Reasonable adjustments under the Disability Discrimination Act (DDA) 1995 (see chapter 5)

- Reasonable adjustments are essentially any steps relating to arrangements and premises that are reasonable for an employer to take in all the circumstances to prevent the disabled person being at a disadvantage. Many of the enabling options listed above fall within this definition
 - The DDA Code of Practice expands on examples given in the Act and provides guidance on the reasonableness of adjustments (Paragraphs 4.12-4.48)
 - A comprehensive series of practical briefing guides on the DDA is published by the Employers Forum on Disability, Nutmeg House, 60 Gainsford Street, London SE1 2NY
-

Data sources for standards of fitness (see Further reading)

Government departments

Department for Education and Skills for teachers

Statute

Seafarers: Merchant Navy Shipping (Medical examination) Regulations 1983. Revised in 1998 [Merchant shipping notice MSN 1712(M)]

The autonomy of the subject must be reconciled with the needs and responsibilities of the employer. Legal precedent does not provide clear guidance on how this should be done; the issues are complex and the implications serious. A rational basis for providing helpful medical advice includes a full discussion of the prognosis with the subject to determine where the balance of benefits and risks lies

- If the subject thinks the benefits outweigh the risks and the doctor agrees, advice should be given in support of employment, provided that the assessment and the judgement of balance between benefit and risk have been competently undertaken
- If the subject thinks the benefits outweigh the risks but the doctor cannot agree, consider seeking a second opinion from a specialist occupational physician before providing management with definitive advice
- If the subject thinks the risks outweigh the benefits and the doctor agrees, early retirement should be considered
- If the subject thinks the risks outweigh the benefits when the hazard and risk seem disproportionately low, then motivational factors (such as a common law claim or ill health retirement incentives) may be relevant. If so, the doctor should proceed cautiously and consider obtaining a second opinion from a specialist occupational physician.

The conclusions should be presented to management in context, indicating the nature of the hazard, the extent of risk, and strength of medical consensus. This will enable the employer to discharge his or her responsibility in a complex area with the benefit of such medical support as the circumstances allow.

Definitive opinion

The conclusions, recommendations, and advice outlined above are valid only for the specific fitness criterion considered. In each case, the outcomes of all three criteria should be consolidated to provide an all embracing definitive report. The desktop aid includes a synopsis of the outcomes commonly encountered and may be adapted as a classification guide for audit purposes.

Health and safety risk to self

<p>K No risk to self</p> <p style="text-align: center;"><i>Confirm fit</i></p>	<p>L Risk identified but preventable</p> <p>Identify and pursue relevant enabling options such as treatment, rehabilitation, reasonable adjustment, or risk prevention</p> <p><i>Report conclusions and advise fit (subject to specified conditions)</i></p>	<p>M Risks identified which subject thinks are outweighed by benefits</p> <p><i>If doctor agrees</i>—Ensure assessment and judgment of balance between risk and benefit have been competently undertaken (if unsure seek advice*) <i>If doctor disagrees</i>—Consider obtaining second opinion before advising</p> <p><i>Report conclusions with supplementary advice as appropriate</i></p>	<p>N Risks identified which subject thinks outweigh benefits</p> <p><i>If doctor agrees</i>—Consider early retirement <i>If doctor disagrees</i>—If risks seem disproportionately low consider relevance of motivational factors (such as common law claim or ill health retirement incentives) If present proceed cautiously and consider obtaining second opinion*</p> <p><i>Report conclusions with supplementary advice as appropriate</i></p>	<p>O Risk to self clearly unacceptable and likely to remain so</p> <p>Help subject come to terms with implications such as ill health retirement, termination of contract, redeployment (if available), or rejection (at pre-employment stage)</p> <p><i>Confirm likely to remain unfit</i></p>
---	---	---	---	--

Definitive opinion

The confirmations, conclusions, and advice outlined above are valid only for the specific fitness criterion addressed. In each case the outcomes of all three criteria should be consolidated to provide an all embracing definitive report

*Advice and second opinions should be obtained from doctors with training and expertise to provide proper assistance. Specialist qualifications for occupational physicians in the UK (MFOM, FFOM) are awarded by the Faculty of Occupational Medicine of the Royal College of Physicians.

5 Legal aspects

Martyn Davidson

Society has become increasingly litigious in recent years, and the modern “blame culture” has encouraged a tendency to look for fault whenever there is harm. In all areas of medicine this has led to increased awareness of the legal process, and occasionally defensive medicine. Employment law and rights based legislation following European Union initiatives have expanded as a result of enlightened social policies, extension of a single European market, and environmental protection. Because employment and rights based legislation affect the worker and the workplace, the occupational health (OH) practitioner needs to understand the legal provisions and the framework in which they operate.

Health and safety legislation aims to prevent the workforce being injured or made ill by their work. Employers have considerable duties, including duties relating to the general public, and the role of the OH practitioner is to advise on steps to achieve compliance. An understanding of the principles is essential, and these are covered here with reference predominantly to English law. Employees also have corresponding duties to take “reasonable care” for their own safety and that of others, and to cooperate with appropriate procedures.

The OH practitioner will become involved in employment law when medical advice is needed, and it is essential that the basics are understood.

Ethics

The position of the OH professional

Physicians are primarily bound by the codes of their profession and in the United Kingdom they are accountable to the General Medical Council for their behaviour. For OH nurses the corresponding body is the Nursing and Midwifery Council. Difficulties sometimes arise because the OH practitioner is often an employee of the company requesting advice. The company may feel that the practitioner’s contract of employment overrides professional codes. This is not so, and employers cannot insist on contractual terms that would require a physician or nurse to breach professional codes. If such terms existed, they would be difficult, if not impossible, to enforce.

Confidentiality

The duty of confidentiality applies as it does to any physician or nurse. This includes the safeguarding of all medical information, records, and results. The legal basis of the duty of confidentiality remains unclear, however, and the duty is ultimately relative rather than absolute. Material should be regarded as confidential if it has been obtained in circumstances which would indicate that this was the intention. Circumstances can arise in any medical specialty in which disclosure may be necessary; in such cases the clinician will be expected to justify his or her action, before a court if necessary.

OH practitioners may sometimes feel that they are not in a traditional nurse/doctor-patient relationship when they are acting on behalf of a third party. This might be the case with respect to a job applicant whom an OH practitioner sees in order to advise the employing company. Offers of employment are usually conditional upon “medical clearance”—is the

The legal framework defining the duty towards the health of the workforce was established in the 19th century. Although prompted by humanitarian concerns, these legal developments were the pragmatic result of the concerns of industry—the toll of premature death and disability threatened the supply of healthy workers required to increase productivity. Major responsibilities of occupational health physicians

Professional ethical obligations

- Provide a good standard of practice and care
- Keep up to date and maintain performance
- Respect confidentiality and maintain trust
- Maintain good communications

General Medical Council. *Good medical practice*. London: GMC, 2001
See also: Faculty of Occupational Medicine. *Good medical practice for occupational physicians*. 2001

Guidance

- Health assessments
- Advice on absence
- Confidentiality
- Health records
- Relationships with others

See: The Occupational Health Committee. *The occupational physician*. London: BMA, 2001

The OH physician must exercise professional skill and judgement in giving advice, and there is an ethical duty to inform the applicant of any abnormality uncovered by the process; however, the contractual duty lies with the prospective employer

applicant fit, in medical terms, for the duties of the post? The degree and extent of the duty upon the OH physician has been explored in two leading English cases.

Medical reports

When the OH practitioner is asked to provide advice on an individual's health for employment purposes, they should obtain written consent before releasing their opinion. This is correct ethical practice.

Because the OH practitioner is not usually the clinician caring for that individual, the Access to Medical Reports Act 1988 will not generally apply. It will apply, however, if the OH practitioner seeks further information from any other specialist or general practitioner who has been providing such care. The provisions of the Data Protection Act 1998 apply to obtaining, use, and retention of any personal information, including OH records.

Health and safety law

Statutory duties upon the employer

Health and safety

The Health and Safety at Work etc. Act (HSWA) 1974 is the main statute covering the general responsibilities of the employer. It covers others who might be affected by workplace activities—contractors, visitors, and the general public. The workplace must be safe and well maintained, with safe systems and organisation of work. Equipment and tools must be suitable and well maintained. Ensuring that employees behave safely is also down to the employer, who has the responsibility for supervision. Supervisory staff must be demonstrably competent. This duty is only limited when the employee might be considered to be “on a frolic of his own,” as the courts have termed it.

The underlying principle of the statutory framework is that those who generate risk as a consequence of work activities have a duty to protect the health and safety of anyone who might be affected by those risks. Occasionally the duty is absolute but more commonly the extent of the duty is “as far as reasonably practicable.” This allows the employer to balance the degree of risk against the difficulty and cost of reducing it. A small employer with modest resources may therefore argue that it could not go so far in risk reduction as a multinational company, for instance.

A great deal of more recent legislation, driven largely by directives from the European Commission, has focused on particular areas.

The general move has been away from the prescriptive approach and towards a duty on the employer (and the self employed) to assess risks arising from work activities. The employer must then identify and institute preventive actions on the basis of their assessment.

Reporting injuries and disease

Fatal and major injuries, those resulting in three or more days lost from work, and certain occupational diseases must be reported to the Health and Safety Executive (HSE), as per the Reporting of Injuries, Diseases and Dangerous Occurrences Regulations 1995 (RIDDOR). For a disease to be reported, the disease must be listed in the regulations, the affected employee must be involved in a relevant task or activity, and there must be a written diagnosis from a doctor. Under-reporting is considerable—the patient or treating doctor may not realise that the condition is work related, employers have little incentive to report, or the patient may fear for their job and therefore not wish to agree to disclosure.

Duty of care at pre-employment

Baker v Kaye (1997)

Mr Baker, applying for a job as International Sales Director, attended for pre-employment assessment by Dr Kaye. During the assessment, Dr Kaye elicited a history of significant alcohol consumption, supported subsequently by abnormal liver enzymes. Mr Baker had already resigned from his existing post, and when Dr Kaye advised the new employer that he did not consider Mr Baker fit for employment, Mr Baker sued for loss of the new post. The court in this case held that the OH physician owed a duty of care to the prospective employee, as well as to the employer, but as Dr Kaye had taken reasonable care in making the assessment, he was found not to be negligent

Kapfunde v Abbey National plc (1998)

However, the Court of Appeal, in *Kapfunde v Abbey National plc (1998)*, disagreed with the decision in the case above.

Mrs Kapfunde, who suffered from sickle cell disease, applied for a job at the Abbey National. Dr Daniel, advising Abbey National, reported that the applicant's medical history and previous absence record indicated that she was likely to have an above average sickness record. Mrs Kapfunde was not considered for the job, and subsequently sued Abbey National, arguing that Dr Daniel had been negligent. The Court, in judging Dr Daniel not negligent (because she had exercised reasonable skill and care in reaching her decision), added that neither did she owe a duty of care to Mrs Kapfunde

Modern domestic legislation since 1988 based on risk assessment

More than 20 European directives have produced a large number of specific regulations, notably the “Framework” Directive for the Introduction of Measures to Encourage Improvements in Safety of Health of Workers, which was enacted into UK law by the Management of Health and Safety at Work Regulations 1992 (updated in 1999), and together with its five “daughter” directives forms the “six pack” (marked *).

- Management of Health and Safety at Work Regulations 1992 (now MHSWR 1999)*
- Workplace (Health, Safety, and Welfare) Regulations 1992*
- Provision and Use of Work Equipment Regulations 1992*
- Personal Protective Equipment Regulations 1992*
- Display Screen Equipment Regulations 1992*
- Manual Handling Operations Regulations 1992*
- Working Time Regulations 1998

Many of these are accompanied by an approved code of practice or guidance notes. These are not legally binding in their own right. However, they bring detail to the statute, and guidance on how compliance may be achieved. An employer would have to justify a diversion from their recommendations

Information on potential health risks must be given to the workforce, with suitable instruction and training on control measures. Sometimes medical surveillance may also be specified

Failure to comply

Despite the extensive legislation to prevent them, work related injuries and illness still occur. In these cases, the legal system has two distinct roles: to punish the negligent employer, and to compensate the injured employee.

Prosecution

The enforcing authorities. The HSE is responsible for enforcement activities in most workplaces, including factories, farms, hospitals, schools, railways, mines, nuclear installations, and also driving as part of work. The exceptions are—for example, retail and finance, where responsibility lies with local authorities. The Health and Safety Commission and the HSE were established by the HSWA 1974. The HSE includes the Employment Medical Advisory Service, which comprises doctors and nurses who are OH specialists and who have the full powers of inspectors.

The law. Breach of the HSWA is subject to criminal sanctions. Prosecutions (most are undertaken by the HSE in the Magistrates' and Crown Courts) will generally result in a fine.

Manslaughter. After a fatal accident, the HSE will defer to the police. The Crown Prosecution Service may then bring a case for manslaughter. However, prosecution is rarely successful. The difficulty is that a "company" is not an individual and therefore not capable of a crime of this nature.

Manslaughter

An unsuccessful case

A total of 188 people died when the Herald of Free Enterprise capsized at Zeebrugge in 1987. The case against P&O showed failures within the management and with several individuals on the vessel. However, no single person was found sufficiently at fault for the charge to apply

A successful case

Peter Kite, the managing director of Oil Ltd, received a custodial sentence after four teenagers drowned during a canoeing trip in Lyme Bay in 1993. Kite ran the small company and was found to be the "controlling mind." There was a history of his ignoring warnings about safety and he clearly failed to adhere to accepted standards. The company was also found guilty of manslaughter and fined £60 000

Current thinking

Reform of this area has been considered since the 1996 Law Commission Report. This recommended new offences of corporate killing and individual offences of reckless killing and killing by gross carelessness. However, legislation has not been forthcoming. In May 1998 Simon Jones, aged 24, died on his first day at work at Shoreham Dockyard; the resulting unsuccessful action provoked further outcry. In 2000-1, 26 cases were referred by the Health and Safety Executive to the Crown Prosecution Service for consideration of manslaughter charges; six are proceeding. Since 1992, 162 referrals have led to 45 prosecutions and 10 convictions. Five individuals have received prison sentences

Compensation

An employee who suffers from a work related illness or injury has two possible routes to seek compensation. Firstly, they may claim from the government if they have a "prescribed disease" via the Industrial Injuries Benefit Scheme. Secondly, and entirely separately, they may claim against the employer via a personal injury claim in the civil court.

Prescribed diseases. The Industrial Injuries Scheme administered by the Department of Work and Pensions "prescribes" a number of occupational illnesses for compensation. To qualify for compensation, the applicant must have the prescribed

Main powers of enforcement authorities

Health and Safety Executive

- Enters and inspects workplaces
- Issues improvement or prohibition notices (immediate or deferred)
- Prosecutes

Employment Medical Advisory Service

- Gives advice on health and safety issues to employers and employees
- Investigates complaints or concerns about health, or after a report under Reporting of Injuries, Diseases, and Dangerous Occurrences Regulations 1995
- Has the same legal powers as inspectors (where the Health and Safety Executive is the reporting authority)
- Appoints doctors for health surveillance required by regulations (Ionizing Radiation Regulations 2000, Control of Lead at Work Regulations 1998, Diving at Work Regulations 1997)

Criminal law and enforcement activities

UK criminal law

- Arises from statute and is a punitive system for offences against society as a whole
- Acts of parliament and regulations made thereunder provide the "rules" by which employers are expected to abide
- Case law—the court's decisions in specific cases—provides guidance on the interpretation of these rules
- Decisions made in higher courts are binding upon lower courts
- The burden of proof in criminal cases is "beyond reasonable doubt;" a higher standard than that applying in civil claims "on the balance of probabilities"

Health and Safety Executive (2000-1) Activities

- 11,058 enforcement notices (70% in manufacturing and construction)
- 6673 improvement notices
- 2077 prosecutions, resulting in 1493 convictions (72%)
- Average penalty £6250

Local authorities (1999-2000)

- 4850 improvement notices
- 1250 prohibition notices
- 412 prosecutions, resulting in 358 convictions (87%)
- Average fine £4595

Zeebrugge ferry disaster. Reproduced with permission from Rex Features

disease, and must also have worked in an occupation recognised to carry a risk of that particular disease. The amount of the payment depends on the degree of disability, as assessed by an adjudication officer.

Civil claims. A claim through the civil courts is a means of compensating one person for damage arising from another's action or inaction. Most claims are brought under the tort of negligence. The employer is held to have a broad, general duty of care to avoid harm to its employees. This is part of the common law (where there is no guiding statute law, but is developed over time by decisions of the judiciary).

The employee must argue that the employer failed in their duty of care to safeguard the worker's health. The applicant employee must show that:

- (a) The employer owed the worker a duty of care
- (b) The employer negligently breached that duty
- (c) The employee suffered damage as a result of that breach.

The level of proof is the "balance of probabilities."

Employees with illnesses that may be occupationally related but are not prescribed can only pursue this route.

Large damages paid in compensation may seem impressive when reported in the media, but the adversarial system as presently practised has its problems, and the impact of new civil procedure rules introduced in 1999 in an attempt to improve the present system (on the basis of the Woolf reports on access to justice) is not yet clear. Furthermore, if state compensation is paid for an industrial disease before the personal injury claim, this may be clawed back from awarded damages in excess of £2500.

Another option in the civil courts is an action for breach of statutory duty. The HSWA expressly excludes any such civil action in sections 2-8, although some regulations made under the HSWA do support such an action. Current plans are to remove the existing civil liability exclusion from the Management of Health and Safety at Work Regulations 1999.

Employment law

Legislation

A considerable body of both European and domestic legislation exists in this area. The Employment Rights Act 1996 (ERA) consolidated employees' rights into a single statute. Other primary and subordinate legislation relates to issues of discrimination, pay, and sick pay and are supported by various influential codes of practice, such as those produced by the Advisory, Conciliation and Arbitration Service.

Complaints in this area are heard by employment tribunals, which were established so that employment disputes can be settled rapidly and without the expense of going to court. The employment tribunal comprises three members, including an experienced lawyer as the chair. Appeals are referred first to the Employment Appeal Tribunal, and ultimately to the Appeal Court.

Dismissal

The Employment Rights Act gives employees the right not to be unfairly dismissed. In general, one year's continuous employment is required before a complaint for unfair dismissal can be brought. Some types of unfair dismissal, notably certain grounds relating to discrimination or health and safety, require no such qualifying period—this might be the case if an employee were dismissed because he or she raised the issue of hazardous working conditions.

How diseases become prescribed

Thirty-nine conditions are listed in four categories; those caused by:

- A Physical agents (for example, occupational deafness)
- B Biological agents (for example, viral hepatitis)
- C Chemical agents (for example, angiosarcoma of the liver)
- D Those of a miscellaneous nature (for example, occupational dermatitis)

The list is similar to those diseases reportable under the Reporting of Injuries, Diseases and Dangerous Occurrences Regulations 1995. The Industrial Injuries Advisory Council advises on the addition of new prescribed diseases. Its criteria are narrow: the disease must be a recognised risk in a particular occupation and not to the general population, and the causal link between exposure and disease must be well established. This process may take some time

- Vibration white finger (now hand arm vibration syndrome) was considered four times between 1954 and 1985, when it was prescribed
- Occupational deafness was considered in 1961 and prescribed in 1975

Common law duty of care

The depth and breadth of the employer's duty of care has been developed over the years by landmark cases. The concept of the "reasonable and prudent employer, taking positive thought for the safety of his workers in the light of what he knows or ought to know" was clarified by Judge Swanwick in 1968

The duty is greater if the employee has a known vulnerability. This is known as the "eggshell skull" rule, after a 1901 case. A better example is that of *Paris v Stepney Borough Council* (1951). Mr Paris, a bus fitter with sight in only one eye, lost the sight in the other eye after entry of a metallic foreign body. The Council was negligent in not providing Mr Paris with eye protection, though, given that the risk of an accident was slight, they were not obliged to provide this for others in their workforce

Exactly when an employer should be aware of a particular health risk in the workplace is inevitably contentious, particularly in relation to claims for occupational illness. Courts may decide on a "date of knowledge," after which no employer could reasonably claim ignorance. This date will often relate to government guidance or other influential advice. For instance, in the case of noise induced hearing loss, the year 1963 became the watershed, after a Ministry of Labour pamphlet in that year

Areas of interest in civil litigation

Work related stress (WRS)

The 1995 case of *Walker v Northumberland County Council* attracted considerable attention. Mr Walker was an area social services officer. He had a heavy caseload, and frequently requested help. After five months' absence for a "nervous breakdown," he returned to a backlog of work, and the promised assistance did not materialise. After a second breakdown, he sued his employer. The Council was held not to be liable for his first breakdown as they were not aware that he was susceptible to stress. However, it was liable for the second breakdown. The risk was foreseeable and preventable, and there was a duty not to cause Mr Walker psychiatric injury. Damages were £175 000

However, successful actions for WRS are few and far between, and the burden of proof on the employee remains considerable. In February 2002 the Court of Appeal overturned three awards (*Hatton v Sutherland and others*) of almost £200 000. It set down 16 guidelines that it considered relevant, and which will aid both courts and employers. These include the following:

- The employer is entitled to assume that the employee can deal with the normal pressures of the job unless there is a known vulnerability
- No occupations should be regarded as intrinsically dangerous
- If the only alternative would be to dismiss or demote the employee, the employer would not be in breach of duty if the employee willingly continues in the job

The hurdle for applicants under this heading remains high and, if anything, this judgement will make a claim for WRS more difficult

Dismissal occurs when the contract of employment is terminated by the employer, when a fixed term contract expires and is not renewed, or when an employee terminates the contract as a result of the employers' conduct. The five potentially fair reasons for dismissal are given in the box.

Absence from work may generate grounds for dismissal and, if absence is attributed to ill health, OH advice will be required. It is important to differentiate between long term absence and recurrent short term absenteeism.

Long term absence—This may give rise to fair dismissal on the grounds of capability, which includes both ill health and incompetence. The employer is expected to gather enough information to assess the situation fully and to decide on a reasonable course of action. This should include consultation with the employee and will often include a medical opinion. The employer might consider alternative work, although it is under no statutory duty to do so (unless the case falls under the disability discrimination legislation, vide infra). The employer cannot know details of the illness because of confidentiality, but is entitled to ask when the employee might recover, whether the employee will be capable of returning to their former job and, if not, the likely restrictions on capability.

The final decision on employment is a management rather than a medical decision, with the physician in an advisory role. It is important to appreciate that the cause of ill health is irrelevant to the fairness of the dismissal, even if the current employment is likely to have been the cause.

Attendance—The problem of recurrent short term absenteeism may be approached rather differently. Employers may view this as an attendance issue and are entitled to expect a certain level of reliability from employees. The genuineness of the illness is not relevant, as an employer may ultimately fairly dismiss on the grounds of either capability or "some other substantial reason." However, the employer should investigate fully and act in line with its absence policy, giving due warning to the employee that attendance is expected to improve. It is good practice (although not essential, depending on the case) to take medical advice as to whether poor attendance is because of an important underlying medical condition. (If there is, the case might more properly be dealt with as a capability problem.)

Disability discrimination

The employment provisions of the Disability Discrimination Act 1995 came into force on 2 December 1996, with duties on the employer to accommodate disabled people, whether existing employees or job applicants. It is unlawful to discriminate—that is, to treat anyone with a disability less favourably for reasons relating to the disability. There is a duty to make "reasonable adjustments" to allow the disabled person to work. However, the Act can allow the employer to justify discriminatory treatment.

Awards for complaints under the Disability Discrimination Act have no upper limit; the stakes are therefore potentially high. Employment tribunals have sometimes had difficulty dealing with the medical issues, as they do not normally use medical experts. Experience of this legislation has clarified and confused in almost equal measure.

Reasons for fair dismissal

1. Relating to capability ("skill, aptitude, health, or any other physical or mental quality") or qualifications ("any degree, diploma, or other academic, technical, or professional qualification")
2. Relating to conduct (behaviour at, or sometimes outside, the workplace)
3. Redundancy
4. If employee cannot continue to work without breach of statutory duty (such as after loss of driving licence)
5. Some other substantial reason (SOSR) sufficient to justify dismissal

In February 2002 the compensatory award for unfair dismissal was limited to £52 600. The burden of proof is said to be neutral, although the employer is required to show that the dismissal was not unfair. An employment tribunal will judge the circumstances of the case—including elements such as the size, resources, consistency of behaviour, and procedural correctness of the employer—in deciding reasonableness

The Disability Discrimination Act (DDA) and some definitions

Disability—"a physical or mental impairment causing a substantial and long term adverse effect on the ability to carry out normal day to day activities"

- A physical impairment is not defined in the legislation, but is likely to encompass any "organic or bodily detriment," including severe disfigurements (facial scars or burns), but excluding deliberately acquired disfigurements (tattoos or body piercings)
- A mental impairment is any clinically well recognised condition (that is, one recognised by a responsible body of medical opinion), and must be beyond a reaction that could be described as a normal human reaction
- A substantial adverse effect is defined as one that is more than minor or trivial
- Normal day to day activities are:
 - Mobility
 - Manual dexterity
 - Physical co-ordination
 - Continence
 - Ability to lift, carry, or otherwise move everyday objects
 - Speech, hearing, or eyesight
 - Memory or ability to concentrate, learn, or understand
 - Perception of the risk of physical danger
- Long term implies an impairment that has lasted 12 months or more, is likely to last 12 months or more, or is terminal

Certain specific conditions (for instance, nicotine or alcohol dependence) are excluded from the Disability Discrimination Act. Controlled or corrected, progressive, and recurring conditions may be included

Reasonable adjustments to allow the disabled to work

- Accessible and equitable recruitment processes
- Modifications to equipment
- Changes to job design and work environment
- Resources and cost are relevant

Justification

- The failure to adjust must be both material to the circumstances of the case and substantial
- Stricter than "reasonable"
- Requires hard evidence

The Disability Discrimination Act does not currently apply to organisations with fewer than 15 employees, but this exemption will be removed from October 2004. The provisions of the Act are also likely to be extended to include the emergency services, and other medical conditions. The justification provision will be removed

Outcomes of the Disability Discrimination Act

5662 cases brought up to March 2000 (England and Wales)—23% successful

Medical conditions

- 21% back or neck conditions
- 16% hand or arm conditions
- 14% depression or anxiety

Legal issues

- 34% concerned failure to transfer to suitable alternative work
- 26% sought to justify on the basis of the amount of sick leave
- 51% required medical evidence

Awards

Total compensation in 1999: £369 297

Average: £9981 per award

Maximum award in 2001: £278 800

Disabled person at work with appropriate aids such as a voice recognition dictation system linked to a laptop computer for an employee no longer able to type rapidly. The photograph was produced by Mr D Griffiths, with the subject's permission

Future developments

Many other areas may come to have relevance to the work of the OH practitioner, two of which are considered below.

Human rights

The Human Rights Act 1998 came into force in October 2000, bringing the European Convention on Human Rights into UK law. It makes no explicit reference to HSWA. However, under the right to privacy it may foreseeably impinge on areas such as drug testing and surveillance. The lack of legal aid for employment tribunals (in England and Wales) and the fairness of the employment tribunal system may generate debate under the provisions for the right to a fair trial.

Rehabilitation

In contrast to the numerous duties to prevent ill health or injury, there is currently no requirement to rehabilitate back to the workplace. This has a huge cost: in 2000, 2.29 million people claimed incapacity benefit, and employers paid out £750 million in compensation under employer's liability insurance schemes. The United Kingdom has a poor record; a Swedish worker has an almost 50% chance of returning to work after an injury, whereas in the United Kingdom the figure is only 15%. Employers may have to develop a policy in this area as in all other health and safety fields. The Departments of Health, and of Work and Pensions are working on a pilot initiative to encourage early return to work, with its effectiveness evaluated by the National Centre for Social Research.

Frequent questions for the OH practitioner in relation to the Disability Discrimination Act

- **Is the condition covered?** In practice, employment tribunals have been hesitant to exclude a condition even when there is considerable scientific debate about the exact nature of the diagnosis (for example, chronic fatigue syndrome)
 - **Does the Act apply?** This is a legal decision, and judgement rests with the employment tribunals. The OH practitioner can advise, and the employer make its own judgement, but the employment tribunal is the final arbiter
 - **Is treatment unequal?** The "comparator" against which the disabled person should be considered must be an able bodied individual; not one who has another condition but does not fall under the Act
 - **Have accommodations been considered?** The employer must make genuine efforts to accommodate the disabled individual. The guidance that accompanies the Act must be followed closely
 - **Is unequal treatment justified?** Less favourable treatment may currently be justified, but the employer must make a properly constructed argument with evidence to support its case
 - **What happens if health and safety may be compromised?** The employer has a difficult balancing act under these circumstances. However, provided the employer has undertaken a proper risk assessment and subsequently generated a rational policy, then the tribunal cannot disregard the policy on the basis of a differing medical view. It is vital, though, that the employer acts on competent advice backed up by good evidence
 - **May the disabled person assume a risk to their own health?** In other words, at what threshold does paternalism on the part of the employer take over from the well informed view of the individual? Current case law suggests that when there is a significant risk to health, the employer has the right (or even duty) to exclude the employee from that work activity

6 Back pain

Malcolm IV Jayson

The number of working days lost as a result of back problems has increased dramatically in recent years. Over 80 million days were lost because of registered disability in 1994, but the total estimate, including short spells, is probably in the order of 150 million—four times more than 30 years ago. This increase does not reflect an increased incidence of back problems, which has changed little over the period, but it is probably because of an altered reaction to the problem, with increases in sick certification and state benefit, perhaps reflecting patients' and doctors' expectations, concerns by employers, and social and medicolegal pressures. There is, however, recent UK evidence to suggest that the peak in this rise of back pain incapacity is now past and claims for benefit are now falling. Whether the disability has simply been reclassified as "stress" (which is rising) is uncertain.

The costs of back pain are huge. Recent estimates suggest that the overall cost to the UK economy is about £6 billion a year. Improved management and better outcomes would lead to major financial and medical benefits.

Who gets back pain?

The problem affects workers of all ages. It usually starts between the late teens and the 40s, with the peak prevalence in 45-60 year olds and little difference between the sexes. The prevalence of back disability is increased in people performing heavy manual work, smokers, and those in non-managerial positions. Clearly these factors interact in many patients. It is often difficult to determine whether heavy manual work has caused or aggravated a back problem or whether a worker cannot do the job because of back pain. Obesity and tallness are also associated with back problems. Postural abnormalities do not predict back problems, except possibly gross discrepancies in leg length.

Psychological factors are important. Psychological distress in a population without back pain predicts the development of back pain. In the Boeing aircraft factory, workers who did not enjoy their jobs had a greatly increased risk of reporting back injury.

Causes of back pain

The major causes of back pain are mechanical strains and sprains, lumbar spondylosis, herniated intervertebral disc, and spinal stenosis. In many cases it is not possible to make a specific mechanical diagnosis. Such problems are commonly called non-specific back pain. Non-mechanical causes of back pain include inflammatory disorders such as ankylosing spondylitis and infections, primary and secondary neoplasms, and metabolic bone disorders such as osteoporosis. The patient's clinical characteristics and a general health screen will exclude systemic disease.

Pre-employment screening

There is no evidence that physical build, flexibility of spine movements, or other physical characteristics are of any value in predicting the development of back problems, and they should not be used for screening purposes. In particular, lumbar radiographs are not helpful in identifying people liable to develop back pain at work.

A detailed medical and occupational history is required for all employees, and an assessment of their fitness to do the job.

Changes in sickness and invalidity benefit for back pain since 1955

Heavy repetitive manual work increases the risk of back problems

The physical state of the spine determines how well it functions, and use and injury of the back will alter its structure. This interrelation between structure and function is central to understanding many back problems related to work

The principal risk factor for back pain is a history of back pain. Those who have had back problems in the past are likely to experience further episodes in the future

The most useful single item of information in predicting potential back problems is a history of back pain, particularly if it is recent and severe enough to cause absence from work.

Preventing back injuries

Manual handling is commonly associated with strains and sprains of the back and resultant disability. *Manual handling. Guidance on regulations* lists measures that employers should take to reduce the risk of problems. These include:

- Avoiding hazardous manual handling operations as far as is reasonably possible (lifting aids may be appropriate)
- Making an appropriate assessment of any hazardous manual handling operations that cannot be avoided
- Reducing the risks of injuries from these operations as far as is reasonably possible.

Weight limits

In Britain no limits for weights that may be lifted have been stated. This is because setting a weight limit is a fallacious approach as so much depends on the individual and the circumstances of any procedure. When a load is moved away from the trunk the level of stress on the lower back increases. As a rough guide, holding a load at arms' length imposes five times the stress experienced with the same load held close to the trunk. Moreover, the further away the load is from the trunk the less easy it is to control, adding to the problems.

Guidelines to loads that may be lifted are necessarily crude, given the wide range of individual physical capabilities even among fit and healthy people. There are no truly safe loads. Present guidelines do no more than identify when manual lifting and lowering operations may not need a detailed risk assessment. If the handler's hands enter more than one of the box zones during the operation, the smallest weight figures apply. Where the handler's hands are close to a boundary an intermediate weight may be chosen. Where lifting or lowering with the hands beyond the box zones is unavoidable, a more detailed assessment should always be made.

Lifting techniques

The technique for lifting is important. Simple ergonomic principles will protect the back against excessive strains. A poor posture increases the risk of injury. Examples include stooping and twisting while weight bearing, carrying loads in an asymmetric fashion, moving loads excessive distances, and excessive pushing and pulling. Repeated or prolonged physical effort may carry additional risk. Many episodes of back pain develop after sudden or unanticipated movements such as a stumble on the stairs or an unexpected twist.

Wherever manual handling occurs employers should consider the risks of injury and how to reduce them by reviewing the task required, the load carried, the working environment, and individual capability. Redesigning the job and providing mechanical assistance may be appropriate, and individual workers should be trained in safe manual handling.

Diagnosis and prognosis

Diagnostic triage

On simple clinical grounds, patients with acute back problems can be triaged into simple backache, nerve root pain, and possible serious spinal conditions. Simple back pain will be managed by an occupational health physician or general practitioner. Nerve root pain will initially be dealt with by a general practitioner in a similar way to simple backache, although at a slower pace, providing there is no major or

Excessive loading—simple mechanical aids can eliminate this

Reduction in handling capacity as hands move away from trunk

Guide to loads that may be lifted in various positions, assuming that the load is easily grasped with both hands

Principles of lifting and carrying a load

progressive motor weakness. However, early referral to a specialist may be required. Patients with possible serious spinal conditions require urgent referral, and emergency referral is needed for those with widespread or progressive neurological changes.

Prognosis

Most patients have simple backache. The exact condition and source of the pain are rarely identifiable, but the principles of management are now well established. Nearly all episodes of acute back pain resolve rapidly. Most patients return to work within a few days, and 90% return within six weeks. Some patients, however, develop chronic back pain, and this small proportion with prolonged disability is responsible for most of the costs associated with back injuries.

With longer time off work, the chances of ever getting back to work decrease rapidly. Only 25% of those off work for a year and 10% of those off work for two years will return to productive employment.

Investigations

Routine radiographs of the lumbar spine should be avoided. Apparent degenerative changes are common and correlate poorly with symptoms: they are better considered as age related changes. Radiographs are necessary when there is the question of possible serious spinal conditions, but a negative result does not exclude infection or tumour.

Imaging with computed tomography or magnetic resonance imaging is of no value for simple backache. These techniques also often display age related changes that correlate poorly with symptoms. The presence of these changes does not influence management.

Management

Simple backache

The early management of acute back pain is important. Much of the traditional management of back pain seems to promote chronicity. In view of the increasing toll of back disability, the Clinical Standards Advisory Group of the UK Departments of Health has published guidelines on managing back problems. These emphasise the importance of maintaining physical activity and minimising the period off work.

Indications for emergency referral

- Difficulty with micturition
- Loss of anal sphincter tone or faecal incontinence
- Saddle anaesthesia about anus, perineum, or genitals
- Widespread (more than one nerve root) or progressive motor weakness in legs or disturbed gait

Characteristics of simple backache

- Onset generally at ages 20-55 years
- Pain in lumbosacral region, buttocks, and thighs
- Pain is mechanical in nature—varies with physical activity and with time
- Patient is well
- Prognosis is good—90% of patients recover from acute attack in six weeks

Characteristics of nerve root pain

- Unilateral leg pain worse than back pain
- Pain generally radiates to foot or toes
- Numbness and paraesthesia in same distribution
- Signs of nerve irritation—reduced straight leg raise which reproduces leg pain
- Motor, sensory, or reflex change—limited to one nerve foot
- Prognosis reasonable—50% of patients recover from acute attack in six weeks

Red flags suggesting possible serious spinal pathology

- Age at onset <20 or >55 years
- Violent trauma—such as fall from height, or road traffic accident
- Constant, progressive, non-mechanical pain
- Thoracic pain
- History of cancer
- Use of systemic corticosteroids
- Misuse of drugs, infection with HIV
- Patient systematically unwell
- Weight loss
- Persisting severe restriction of lumbar flexion
- Widespread neurological signs
- Structural deformity

The natural course of simple backache is spontaneous resolution within a short time. Treatment is directed at relief of symptoms, a minimum period of rest, physical activity, and a rapid return to work.

Pain relief is with simple analgesics such as paracetamol or non-steroidal anti-inflammatory drugs. Narcotics should be avoided if possible, and never used for more than two weeks.

Rest is prescribed only if essential. Bed rest should be limited to three days as longer periods increase the duration of disability.

Early activity is encouraged. Patients should be reassured that exercise promotes recovery. The particular type of exercise is less important. There may be some increase in pain, but the patient should be reassured that hurt does not mean harm, and that those who exercise have fewer recurrences, take less time off work, and require less healthcare in the future.

Physical therapy should be arranged if symptoms last for more than a few days. This may include manipulation, exercises, and encouraging physical activity. Other techniques such as short wave diathermy, infrared treatment, ice packs, ultrasonography, massage, and traction provide only transient symptomatic benefit, but may enable patients to exercise and mobilise more rapidly. Some factories employ therapists so that physical therapy is available early in the work environment. This approach seems promising in promoting quick recovery and reducing risks of chronicity.

Persistent back pain

By six weeks, most patients will have recovered and be back at work. A detailed review is required for those with persistent problems. These patients should undergo a biopsychosocial assessment. There are particular risk factors for chronicity and for back pain and more prolonged disability, and their early identification will help in planning treatment.

Biological assessment includes reviewing the diagnostic triage, seeking evidence of nerve root problems or possible serious spinal conditions with appropriate referral. At this stage, measurement of the erythrocyte sedimentation rate, and radiographs, are indicated.

Psychological assessment should include the patient's attitudes and beliefs about pain. Many patients will not attempt to regain mobility because of unjustified fears about the risks of activity and work. Patients may have psychological distress and depressive symptoms, and develop characteristics of abnormal illness behaviour.

Social assessment includes patients' relationships with their families (who may reinforce the patient's disability), and work problems related to the physical demands of the job, job satisfaction, compensation, and medicolegal issues.

Referral

When a patient with simple backache does not return to work within three months, specialist referral is required to provide a second opinion about the diagnosis, to arrange investigations, and to advise on management, reassurance, multidisciplinary rehabilitation, and pain management. If pain in the back is referred to the buttocks or thighs the appropriate speciality is rheumatology, pain management, or rehabilitation medicine. For nerve root pain, the patient should be referred to orthopaedics or neurosurgery.

Psychological and social factors are increasingly recognised as important, and a multidisciplinary rehabilitation programme is likely to be effective. This may include incremental exercise and physical reconditioning, behavioural medicine, and encouragement to return to work.

Risk factors for back pain becoming chronic

- History of low back pain
 - Previous time off work because of back pain
 - Radicular pain, possibly with reduced straight leg raise and neurological signs
 - Poor physical fitness
 - Poor general health
 - Smoking
 - Psychological distress and depression
 - Disproportionate pain behaviour
 - Low job satisfaction
 - Personal problems—alcohol intake, marital, financial problems
 - Medicolegal proceedings

Work modification

Early return to work should be a priority because the physical and psychological consequences of inactivity and unemployment contribute to further dysfunction. Although patients should be encouraged to exercise, some are not capable of undertaking heavy manual work. Careful ergonomic assessment is necessary to avoid excessive stresses on the back. In particular, care should be taken to minimise tasks that require bending, lifting, and twisting. Light work—such as reception or inspection duties that require sitting, standing, and walking but avoid long periods in any one position—may be appropriate. At this point a coordinated approach with an Occupational Health Department is likely to be very helpful.

The figure showing changes in sickness and invalidity benefit for back pain since 1955 is adapted from a report of the Clinical Standards Advisory Group. *Back pain*. London: HMSO, 1994. The figures showing reduction in handling capacity as hands move away from trunk, guide to loads that may be lifted in various positions, and the principles of lifting and carrying a load are all adapted from *Manual handling. 7 Upper limb disorders

Mats Hagberg

Improved management of patients with work related neck and arm disorders can reduce the number of working days lost and the incidence of work related illness. A patient's quality of life and potential economic loss is largely dependent on the medical consultation.

The consultation

Every patient who seeks medical attention for neck and arm problems is entitled to a thorough medical examination. It is important for the patient—even when the disorder is non-specific—to get a clear message from the treating physician as to whether progressive disease is present, and for the physician to get the patient to engage with and have control over their rehabilitation and return to work.

The assessment of work related musculoskeletal disorders consists of a clinical examination, an exposure history, a workplace assessment, and suitable further tests.

History

The type, onset, and localisation of symptoms should be explored in detail. The use of a manikin ("bodymapping") to let the patient mark the type and location of pain has good reliability. It is important to distinguish between nociceptive and neurogenic pain. Nociceptive pain usually originates from peripheral pain receptors reacting to mechanical or chemical stimuli. Muscle pain can be regarded as nociceptive. Neurogenic pain is caused by a dysfunction in the nervous system. Accompanying sensory disturbances are common, and they can be caused by entrapment of nerves. Neurogenic pain may follow the sensory distribution of a nerve, whereas nociceptive pain is usually more diffuse and does not correspond to a single nerve distribution. Examples of questions to be asked are: "Does the pain radiate?" "Where to?" Diffuse symptoms may indicate musculoskeletal referred pain, whereas pain radiating towards specific dermatomes suggests a cervical root lesion (radiculopathy). For each single symptom the character, quality, distribution, intensity, frequency, and duration should be described. Information should be elicited about the relation between symptoms and posture, about movements and loading during occupational activity, and the relationship of symptoms to recreational activities and rest.

Special efforts should be made to identify red flags. Examples of red flags are weight loss and severe pain in the mornings. This may indicate a severe systemic disease, endocrine disorder, infection or malignancy. The family and medical history, and questions about morning stiffness and signs of inflammatory activity (joint swellings) may suggest a rheumatoid disorder.

Work and exposure history

A person's job title usually supplies insufficient information to determine whether the disorder is work related and whether the patient can return to their job. The actual work task has to be described in terms of what the patient produces, work posture, repetition, material handling, and work organisation. Any history of sudden events of high energy transfers (formerly termed "accidents") that could have resulted in clinical or subclinical injury should be explored.

Characteristics of non-specific musculoskeletal pain in neck, arm, and hand

History

- Pain and stiffness gradually increase during work and are worst at the end of the working day and week
- Pain localised to cervical spine and the angle between the neck and shoulder or to the upper part of forearm
- Usually no radiation of pain
- Symptoms are improved by heat and worsened by cold draughts

Signs

- Tenderness over neck and shoulder muscles or tenderness over forearm extensor muscles
- Reduced range of active movement of cervical spine (normal passive movement)
- No neurological deficits

Differential diagnosis

- Tendonitis
 - Nerve entrapments
 - Systemic diseases
-

Management of work related neck and arm disorders

Clinical management

- Non-steroidal anti-inflammatory drugs can reduce pain and inflammation
- Acupuncture can reduce pain
- Corticosteroids—a single subacromial injection of corticosteroid mixed with local anaesthetic may cure shoulder tendonitis. For tennis elbow and carpal tunnel syndrome, corticosteroids should be used by specialists only
- Heparin (15 000 IU/day in a single intravenous dose) given for 3-4 days is an effective treatment for acute crepitating peritendinitis
- Surgery—surgical division of the carpal ligament is the first choice of treatment for carpal tunnel syndrome. For chronic severe shoulder tendonitis, surgical removal of the lateral part of the acromion may relieve pain at night
- Splints—whether splints should be used to treat early hand and wrist tendonitis and carpal tunnel syndrome is still debated

Modifications to working environment

- Job analysis—to assess work relatedness of a patient's symptoms it is necessary to evaluate working posture, repetition, force and handling of loads, psychological and social factors, and static posture or task invariability
 - Job design—job enlargement can reduce the duration and frequency of awkward postures and load handling. Job enrichment reduces poor work content and task invariability. Layout of workplace and technical aids should be improved
 - Technique training—ergonomists and supervisors can improve working technique to reduce stressors of postures, motion, and load handling
 - Rests and breaks should be organised to allow recovery
-

For a better assessment of exposure, the patient should be encouraged to bring photographs of their station, products, and tools. Direct observation of the task at the worksite is valuable and can also be used as the basis for suggestions about job redesign and return to work policies during rehabilitation. Direct evaluation can also be enhanced by video recording.

Clinical examination

The physical examination should include the following steps: (1) inspection; (2) testing for range of motion; (3) testing for muscle contraction, pain, and muscle strength; (4) palpation of muscle tendons and insertions; and (5) specific tests. The physician must have a diagnostic strategy to identify and rule out systemic diseases. As a general rule when tests are used for screening or to rule out disease, the test with the highest sensitivity is preferred. When tests are used to confirm or rule in disease, the test with the highest specificity is preferred. Serial (multiple) tests with results that are all normal tend to rule out disease convincingly; serial tests with results that are all abnormal tend to confirm disease convincingly. Several textbooks cover the physical examination of the musculoskeletal system.

Further investigations

Blood tests such as sedimentation rate and rheumatoid factor can be used to rule out general inflammatory disorders. Imaging tests such as radiographs, ultrasound, and magnetic resonance imaging to detect morphological changes should be done if there are red flags present. Radiographic findings such as spinal degeneration, cervical ribs, etc. should be interpreted with caution because they may be normal physiological findings unrelated to back, neck, or arm symptoms. Patients who are told that their radiograph shows that their back or cervical spine is “worn out” may be resistant to rehabilitation. Even advanced magnetic resonance imaging of the spine may show severe degenerative changes that are not related to the patient’s symptoms. A patient may deduce from the radiographic findings that they have a progressive disease and thereby become “medicalised.” This may, in turn, influence their participation in active rehabilitation and impair the process of returning to work.

Common work related musculoskeletal disorders may constitute a disturbance of sensory neural processing. In the future both neurosensory testing—for example, vibratory perception threshold—and biochemical markers, may become a part of clinical musculoskeletal assessment.

Classification of disease (ICD-10)

The terminology of common musculoskeletal disorders is confusing. The use of terms such as repetitive strain injury (RSI) and cumulative trauma disorder (CTD) should be avoided. The evidence base is often weak or non-existent for these terms. In industrial settings ergonomics may modify the symptoms and signs of disorders and diseases. In a task involving repetitive arm elevation, signs of both tendonitis and non-specific disorders may be present, which are probably related to both concurrent strain on rotator cuff tendons and static strain on neck and shoulder muscles. The occurrence of musculoskeletal symptoms and clinical signs in working and mixed populations has been described. If the different musculoskeletal symptoms and signs do not wholly comply with the criteria for a disease, the recommendation is to choose an ICD label that focuses on the symptoms rather than on the disease. An example of this for non-specific neck and shoulder

Principles of managing hand and arm pain in keyboard operators

- Exclude clear pathological causes such as carpal tunnel syndrome
 - Explore psychological profile, including attitudes to work, and support from management and colleagues
 - Reassure patient that the condition will improve and is likely to resolve
 - Keep the patient physically active and at work. Both aerobic and strength training will reduce pain and increase performance
 - If necessary reduce keyboard work
 - Liaise with patient’s workplace—if possible, with an occupational physician or nurse
 - Consider variation of work tasks, reduced work intensity, encouraging short breaks from keyboard work, or job rotation
 - Ensure that workstation ergonomics have been evaluated and are satisfactory and that the patient has been taught to use the equipment properly and has the right glasses
 - Monitor patient’s progress with regular follow up
 - When symptoms have subsided advise gradual increase in normal activities
 - Exercise may improve blood flow and reduce pain. Strength training may reduce pain and increase performance. Heat application may be worth trying
 - Advice from an experienced physiotherapist may assist in rehabilitation
 - Those few patients who do not respond to this multidisciplinary management may be at risk of developing chronic symptoms. Revisit the biopsychosocial aspects
 - Consider specialist referral (for example, to an occupational physician, rheumatologist, or pain or rehabilitation specialist)
 - In extreme cases where long term disablement seems likely, retraining may be necessary. Voice activated software is now widely available
-

No consensus accepted criteria exist for most ICD-10 (international classification of diseases, 10th revision) musculoskeletal related diagnoses for manual work. When considering the criteria for different musculoskeletal disorders it is reasonable to look first at proposed criteria for surveillance, and epidemiological studies

pain with or without radiation to the forearm would be the label “cervicobrachial syndrome M53.1” (ICD-10, nerve root entrapment is excluded).

Risk factors

Multiple factors

Certain occupations are associated with a high risk for neck and arm pain. Some risk factors can be identified, but the interaction between different risk factors is not understood, and there are not enough data yet to set accurate limits for disease effects. It is important to recognise that personal characteristics and other environmental and sociocultural factors usually play a role in these disorders. A patient with neck pain may be exposed to an awkward posture at work but also to social stress at home: both factors contribute to sustained contraction of the trapezius muscles, inducing pain and stiffness. The cause of a work related disorder can sometimes be attributed to a specific exposure in a job, but there is often simultaneous exposure to several different factors. Individual factors must also be considered when assessing the history of a patient with a work related disorder, and when redesigning a job before such a patient returns to work.

Awkward postures

Working with hands at or above shoulder level counts as an awkward posture and may be one determinant of rotator cuff tendonitis. Awkward postures may cause mechanical trauma or compression, reducing blood flow and tissue nutrition.

The pathogenesis of rotator cuff tendonitis is mainly impingement—compression of the rotator cuff tendons when they are forced under the coracoacromial arch during elevation of the arm. The supraspinatus tendon is forced under the anterior edge of the acromion, causing both a compression that impairs blood circulation through the tendon and mechanical friction to the tendon. Reduced blood flow because of static muscle contraction may contribute to degeneration of the rotator cuff tendons.

Abduction and forward flexion of more than 30° may also constitute a risk factor because the pressure induced within the supraspinatus muscle will exceed 30 mm Hg, impairing blood flow. The vessels to the supraspinatus tendon run through the muscle, and so raised intramuscular pressure can affect the tendon vasculature.

Static postures (task invariability)

It used to be argued that to prevent work related musculoskeletal disorders it was necessary to minimise the load that workers were exposed to. This concept has led to the creation of jobs with low external load, but some of these are still not ideal because poor work content usually leads to a job with invariable tasks, resulting in constrained postures and a low static load for the neck and arms. Ergonomists now try to design jobs that are not only physically variable but also psychologically variable and stimulating.

The health problems caused by task invariability may result from prolonged static contraction of the trapezius muscle during work or daily activity, resulting in an overload of type I muscle fibres, explaining the neck pain. At a low level of muscle contraction, the low threshold motor units (type I fibres) operate. A low static contraction during work may result in a recruitment pattern in which only the type I muscle fibres are used, causing selective fatigue of motor units and damage to the type I fibres. Biopsies of the trapezius muscle from patients with work related trapezius myalgia show enlarged

Risk factors for work related neck and arm disorders

- Working posture
 - Awkward postures or task invariability
 - Static postures
- Repetitive motion
- Force—handling loads or tools
- Psychological and social factors
 - Work organisation
 - Stress
- Working environment

Poultry dressing involves forceful and repetitive manipulation in cold conditions—ergonomic assessment is essential

Impingement of the supraspinatus tendon against the surface of the anterior part of the acromion when the arm is raised to shoulder height. Pressure and mechanical friction are centred on the tendon (thick black arrows)

type I fibres and a reduced ratio of type I fibre areas to capillary areas. Strength training improves the performance of the type 2 fibres and there is reduced perceived exertion during work in patients with non-specific neck pain.

Another pain hypothesis is a relative shortage of energy in the muscle cells. When the energy demand in the muscle fibre is excessive, pain can result. The postural pain syndrome associated with sagging shoulders is a type of cervicobrachial pain that may be caused by prolonged stretching of the trapezius muscle or the brachial plexus. In cervical brachial pain syndromes, pain may be triggered by a pain locus in muscles, tendons, joint capsules, ligaments, or vessels. Nociceptors (pain receptors) in these loci may be the origin not only of the neck and shoulder pain but also of the referred pain to the arm and hand. The nociceptive pain may trigger a chronic pain syndrome that can affect the sympathetic nervous system. A possible pathogenic mechanism is that a small injury caused by a strain or a microrupture during some activity (work or leisure time) does not recover properly. Pain receptors induce a pathway of signals to the central nervous system by increasing the susceptibility to stimuli. The neurological response to normal activity is perceived as pain, and a chronic pain syndrome is the result. The predominant clinical symptom is activity related pain. Stiffness and severe pain at extreme postures are also common. The patient affected by chronic pain must be recognised as soon as possible for proper treatment and rehabilitation, preferably in a pain clinic.

Awkward and static postures are common in players of musical instruments. Pain in the neck and arm have been related to gripping an instrument in an awkward posture. Pain in the left shoulder and arm in professional violinists can be the result of static holding of the violin with the left arm.

Neck flexion while working at a visual display terminal may be associated with non-specific shoulder symptoms. A prospective study showed that a non-optimal sight angle with the head overextended was related to neck symptoms, and extreme radial deviation of the hands was related to hand and arm disorders. An exposure-response relation has been found for neck pain and angle of neck flexion in keyboard operators: neck pain was more prevalent among operators who flex their necks more acutely. Incorrect glasses or the need for glasses when working at a visual display terminal may result in neck and shoulder pain, by affecting posture and because of muscle activity in the trapezius muscle caused by a reflex mechanism of oculomotor strain during sustained visual work at short distances.

The development of non-keyboard input devices, such as the computer mouse, has resulted in new postures that may cause a combination of symptoms from the wrist to the shoulder. Work tasks of long duration with a flexed and, to some extent, extended wrist have been reported as risk factors for carpal tunnel syndrome.

Repetition motion

Repetitive motions of the shoulder may constitute a risk for rotator cuff tendonitis. An experimental study showed that women performing repetitive forward flexions of the shoulder developed shoulder tendonitis. Clinical signs of tendonitis were present up to two weeks after the experiments. Repetitive motions by industrial assembly workers (truck making, meat packing, and circuit board assembly) have been associated with the development of shoulder tendonitis, lateral epicondylitis, and tendonitis at the wrist (de Quervain's disease). Excentric exertion with injury of the extensor carpi radialis brevis muscle is one mechanical model for the pathogenesis of lateral epicondylitis.

Intramuscular pressure in the supraspinatus muscle at different angles of abduction and forward flexion

Differential recruitment of muscle fibres with different levels of contraction. At low level static contraction, only type I muscle fibres may be recruited, leading to their selective fatigue and damage

Association between neck flexion and pain and stiffness in the neck

Repetitive motion, being a causal factor for tendonitis, is consistent with the high risk of shoulder tendonitis in competitive swimmers, and epicondylitis in tennis players.

Force—handling load or tools

Only a few studies have investigated the effect of handling loads on neck and arm symptoms. Handling heavy loads seems to be associated with osteoarthritis and cervical spondylosis. Low frequency vibration exposure of high magnitude is associated with osteoarthritis of the elbow, wrist, and acromioclavicular joints, and symptoms in the elbow and shoulder. Impacts, jerks, and blows with high energy transfer to the hands at low frequency might have the potential to result in musculoskeletal disorders, considering the general model for injuries. Furthermore, the observed associations with vibration exposure and musculoskeletal disorders might result from the strong dynamic and static joint loading and the repetitive hand and arm motions required in tasks where handheld machines are used.

Psychological and social factors

Psychological and social factors are generally more strongly associated with back pain than with shoulder pain. Furthermore, the association is stronger for non-specific pain than for pain with a specific diagnosis. This means that a diagnosis of general cervicobrachial pain may be more strongly related to psychological and social factors than are carpal tunnel syndrome or shoulder tendonitis. Highly demanding work and poor work content (repetitive tasks with short cycles) have been identified as risk factors for neck and shoulder pain. Psychological factors and personality type may be determinants of muscle tension and the development of myofascial pain.

Piece work is associated with neck and arm disorders when compared with work paid by the hour. This may be because of an increased work pace in addition to high psychological demand and low control in the work situation. Management style, in terms of social support to employees, is claimed to be associated with increased reporting of neck and shoulder symptoms. Social support from management obviously affects turnover of workers, and sick leave.

Psychological stress and burnout are associated with depression. Depressive moods are associated with musculoskeletal pain. It is likely that both psychological stress and chronic musculoskeletal pain can cause depressive moods. When assessing a patient with chronic musculoskeletal pain, a psychological evaluation and identification of possible affective disorders should be done. Treatment of depression can reduce musculoskeletal pain and facilitate return to work.

Individual susceptibility

Individuals may have increased vulnerability to injury because of disease, genetic factors, or lack of fitness. This individual susceptibility may result in a lower threshold for given exposures to cause work related musculoskeletal disorders. Additionally, the exposure may trigger symptoms earlier and at an unusual location because of localised vulnerability in a person who has preclinical systemic disease. As examples, a worker exposed to repetitive flexion in the shoulder developed tendonitis one year before developing rheumatoid arthritis. An electrician exposed to repetitive power grips and vibration developed symptoms and signs of carpal tunnel syndrome: at surgery these were found to be caused by amyloidosis. For work related musculoskeletal disorders individual factors usually have a low magnitude of risk compared with relevant ergonomic factors.

Outward rotation of the shoulder and ulnar deviation of the wrist may be found with use of a computer mouse (yellow) and keyboard (blue)

Work related musculoskeletal disorders found in blue collar and white collar workers

Shoulder pain

Blue collar workers—assembly workers

- Usually shoulder tendonitis due to working with hands above shoulder height
- Repetitive forward flexions

White collar workers—keyboard operators

- Usually non-specific cervicobrachial pain, which may be caused by task invariability leading to static tension of trapezius muscle

Hand and wrist pain

Blue collar workers—assembly workers

- Repetitive power grips may cause repetitive strain of extensor tendons and tendonitis
- Carpal tunnel syndrome may also be related to repetitive power grips

White collar workers—keyboard operators

- Intensive keying may cause repetitive strain of extensor tendons and tendonitis
- Carpal tunnel syndrome may also be related to intensive keying

Individual susceptibility to musculoskeletal disorders

Age

- For most musculoskeletal disorders, risk increases with age

Sex

- Among both the general population and industrial workers, women have a higher incidence of carpal tunnel syndrome and muscular pain in the neck and shoulder than men
- Whether this is due to genetic factors or to different exposures at work and at home is not clear

Anatomical differences or malformations

- A rough surface and the sharp edge of the intertubercular sulcus on the humeral head increases wear on the tendon of the long head of biceps muscle, which may make a person more prone to biceps tendonitis
- A cervical rib is a common cause of neurogenic thoracic outlet syndrome: a repetitive task may be the occupational exposure that triggers clinical disease
- Width of the carpal tunnel has been proposed as a risk factor for carpal tunnel syndrome, but there is no consensus

8 Work related stress

Tom Cox

It is clear from large scale surveys of working people, and of those who have recently worked, that stress is currently one of the two main work related challenges to health. (The other is musculoskeletal disorders.) It is therefore not surprising that a plethora of guidance on work stress is available from government bodies, the social partners, and professional and scientific organisations, and it is unlikely that any individual or organisation could successfully claim ignorance of the topic or a lack of basic knowledge.

What is and what is not stress?

Stress is not an illness; neither is it a meaningful descriptive term to apply to a situation such as a domestic scenario or a workplace, although they might be described as “stressful” or containing “stressors.”

Stress is an emotional state that is very real for many people, and poses a major threat to the quality of their lives and to their health. Although that experience is rooted in the way the person sees and thinks about their world, it is essentially *emotional* in nature, normally involving a mixture of negative feelings, such as unpleasant arousal, apprehension, shame, guilt, or anger. It is not necessarily trivial.

Why do people experience stress?

Stress is the emotional state that results from someone’s perceptions of an imbalance between the demands (pressures) on them, and their ability to cope with those demands. The control they have over related events and the support that they receive in coping are very important factors in this equation. Demands can be internally (self) generated as well as externally imposed, and a person’s needs and expectations can be important in their experience of stress.

Classically, people at risk experience events that place demands on them with which they cannot cope. Their inability to cope may be because of lack of relevant knowledge or skill. They feel out of control and without support. Under these circumstances, they are more likely to experience stress and show the commonly associated patterns of cognitive, behavioural, and physiological change. Interestingly, although some of these changes may represent attempts at coping, others may be detrimental to coping. It is easy to see how a vicious cycle can quickly become established in that the person’s ability to cope may be degraded by their experience of stress.

The correlates of stress

The experience of stress alters the way people think, feel, and behave. Many of the changes that occur are modest and potentially reversible, although detrimental to the person’s quality of life at the time. Other changes may be more enduring, and have substantial consequences for health.

Behavioural changes may include increases in health risk behaviour, such as smoking and drinking, and decreases in health positive behaviour, such as exercise and relaxation. Many behavioural changes represent attempts to cope with the

Myths and facts

“Work related stress is not a serious problem”

Wrong—in the United Kingdom, as many as one in five people report themselves to be suffering from high levels of work related stress. That’s around 5 million workers. An estimated half a million individuals report experiencing stress at a level they believe has made them ill. The cost to Britain’s economy is estimated at **6.7 million working days lost per year**. It costs society between **about £3.7 billion and £3.8 billion**

Health and Safety Executive

The Ad hoc Group on Work Stress of the European Commission offered the following definition of work stress

Work stress is the emotional reaction to aversive and noxious aspects of organisations, work, and the work environment. It is a state characterised by extremes of arousal, and by discomfort and distress. It is often characterised by feelings of being out of control and helplessness. Stress can arise as a result of exposure to both physical and psychosocial hazards and may, in turn, affect not only psychological, physical, and social health, but also availability for work and work performance

Stress can occur through work. It may be experienced as a result of exposure to a wide range of work related hazards and, in practice, often coexists with adverse influences operating outside the workplace

Some factors affecting individual susceptibility to stress

- Individual constitution
 - Lifestyle and work style
 - Coping mechanisms
 - Emotional stability
 - Previous experiences
 - Expectation
 - Self confidence
-

emotional experience of stress—for example, by drinking more. However, this type of coping can easily become a secondary source of stress and ill health if sustained.

Evidence shows that cognitive stress is associated with poor decision making, impaired concentration, reduced attention span, impaired memory, and confusion. People who report “being stressed” also tend to admit to “not being able to think straight.” Social behaviour and interpersonal relations may also be affected, possibly reflecting these and other psychological changes such as exhaustion and increased irritability.

The effects of stress are thought to contribute to a range of disorders as wide as cancer, heart disease, musculoskeletal conditions, skin disease, gastrointestinal disorders, and sexual problems. The evidence is strongest for links between certain types of prolonged stress and ischaemic heart disease, hypertension, and mental illness. Evidence also suggests that stress plays a part in the aetiology, course, and outcome (recovery from disability) of musculoskeletal disorders. Most of the evidence for such links is epidemiological. The pathophysiological mechanisms are not clear—perhaps the effects are direct (chemical mediators, effects on immunity) or indirect (the results of secondary, damaging behaviour).

It is likely that what is bad for the individual employee is also bad for their organisation. Organisational concerns associated with work related stress include high absenteeism, increased staff turnover, low job satisfaction, low morale, poor organisational commitment, poor performance and productivity, possible increased accident and near miss rates, and, in some cases, an increase in employee and client complaints and litigation.

Causes of stress at work

“Psychosocial and organisational” hazards refer to those aspects of the design and management of work and of its social and organisational contexts that are known to contribute to employee stress—so, to a lesser extent, do “physical” hazards such as noise and extremes of temperature. There is a reasonable consensus on the nature of the psychosocial and organisational hazards, and they have been divided into nine broad categories.

Managing stress at work

Work stress can be managed from two different perspectives: the individual and the organisational. The occupational health practitioner has a role to play in each approach.

Education, treatment, and rehabilitation: the individual

Much of little value has been written about individual stress management, and many weird and wonderful treatments are offered commercially. A healthy scepticism is warranted here as few of these treatments are based in scientific knowledge and even fewer have been evaluated.

Three strategies that might help the individual experiencing stress through work are: further education and training in relevant work or life skills, short term treatment for any medical condition, and managed rehabilitation to a normal pattern of working life.

Without doubt, the most effective form of stress management training is through a proper analysis of training needs in relation to the person’s job; lifestyle counselling can also be valuable. Fundamental problems in the demands-ability balance may need to be examined. At the same time, reducing health risk behaviour and strengthening health positive

Some possible self reported symptoms of work stress

- Anxiety about work, continually agitated
 - Continual complaints of unreasonable or unrelenting work demands
 - Deep exhaustion
 - Disturbed sleep and daytime tiredness
 - Expressed dislike of work or work colleagues and low job satisfaction
 - Feelings of being out of control or helpless
 - Feelings of lack of support and care from others
 - Forgetfulness
 - Inability to concentrate, continually distracted
 - Inability to think straight
 - Irritability, being short tempered
 - Loss of sexual interest, or impaired sexual performance
 - Loss of the “big picture:” unable to get events into perspective
 - Repeated absences from work
-

Psychosocial and organisational hazards: a taxonomy

Content of work

- **Task content:** lack of variety or short work cycles, fragmented or meaningless work, underuse of skills, high uncertainty
- **Workload and workspace:** work overload or underload, lack of control over pacing, time pressure
- **Work schedule:** shift working, inflexible work schedules, unpredictable, long or unsociable hours
- **Control:** low participation in decision making, lack of control over work

Context to work

- **Organisational culture and function:** poor communication, low levels of support for problem solving and personal development, lack of definition of organisational objectives
- **Role in organisation:** role ambiguity and role conflict, responsibility for people
- **Career development:** career stagnation and uncertainty, under or over promotion, poor pay, job insecurity, low social value to work
- **Interpersonal relations at work:** social or physical isolation, poor relations with superiors, interpersonal conflict, and lack of social support
- **Home-work interface:** conflicting demands of work and home, poor support at home, dual career problems

Adapted from Cox (1993)

Work related factors and ill health: the Whitehall II Study

This research concentrated on how the design of work affected people’s mental well being and related health outcomes. The key findings were as follows:

- Having little say in how the work is done is associated with poor mental health in men and a higher risk of alcohol dependence in women
 - Work requiring a fast pace and the need to resolve conflicting priorities is associated with a higher risk of psychiatric disorder in both sexes, and poor physical fitness or illness in men
 - A combination of putting high effort into work and poor recognition of employees’ effort by managers is associated with increased risk of alcohol dependence in men, poor mental health in both sexes, and poor physical fitness or illness in women
 - A lack of understanding and support from managers and colleagues at work is associated with higher risk of psychiatric disorder. Good social support at work, particularly from managers for their staff, has a protective effect
 - Aspects of poor work design is also associated with employees taking more sickness absence
-

Causes of stress and possible solutions

Poor management culture

Examples of good management are when:

- An organisation is committed to promoting the wellbeing of employees through good management practice
- The people who work in the organisation are valued and respected
- They receive support from the organisation if they wish to raise problems affecting their work

Poor relations

Examples of good relations are when:

- There is good communication between employer and employees, so that the employees understand what is expected, and the employer reacts to any problems experienced by the employees
- Employees are not bullied or harassed, and policies are in place to manage this

Role uncertainty

People understand their role when:

- They know why they are undertaking the work and how this fits in with the organisation's wider aims and objectives
- Jobs are clearly defined to avoid confusion

Too many demands

Demands are at the right level when:

- Staff are able to cope with the volume and complexity of the work
- The work is scheduled sensibly so that there is enough time to do allocated tasks; shift work systems are agreed with employees or their representatives; people are not expected to work long hours over an extended period

Poor management of change

Good change management includes when the organisation:

- Communicates to employees the reason why change is essential
- Has a clear understanding of what it wants change to achieve
- Has a timetable for implementing change, which includes realistic first steps
- Ensures a supportive climate for employees

Lack of control

People feel in control when:

- They are given a say in how they do their work
- The amount of control they have is balanced against the demands placed on them

Lack of training and support, and failure to take account of individual factors

Examples of good practice:

- Employees receive suitable and sufficient training to do their jobs
 - Employees receive support from their immediate line management, even when things go wrong
 - The organisation encourages people to share their concerns about health and safety and, in particular, work related stress
 - The individual is fair to the employer—they discuss their concerns and work towards agreed solutions
-

behaviour such as exercise and relaxation may both improve the person's psychological and physical health, and offer a distraction from their problems.

If the person is affected by anxiety, depression, or some other stress induced illness, then that should be treated in the conventional way, possibly with drugs or psychological treatments, but always appropriately combined with education and rehabilitation. Managed rehabilitation is critical to the success of any treatment for work stress, and necessarily entails a dialogue between the occupational health practitioner and line management.

Prevention and an appropriate response: the organisation

Employers have a duty of care under common law to take reasonable and practicable steps to protect their employees' safety and health at work. This duty clearly extends to psychological as well as physical health, and to psychosocial and organisational as well as physical hazards. It is clear that an employer's failure to consider stress seriously can result in legal challenge. Employers also have duties under statutory health and safety law. Such law has evolved to prevent harm to employees through work, whereas common law allows for financial redress when harm has occurred. These two bodies of law are complementary, as are the duties they impose.

The occupational health practitioner can advise employers on two issues: prevention through risk management, and provision of employee support systems.

According to guidance from the Health and Safety Executive in the United Kingdom and the European Commission, work stress is to be treated as a health and safety issue and dealt with in organisations through the application of a risk management approach (essentially systematic problem solving). Organisations will need to include methods of assessing the risk from exposure to psychosocial and organisational hazards in their routine assessments and develop ways of reducing such risks if necessary. Methods to do this are

Expectations of a person experiencing stress through work

- Timely and appropriate support from both management and occupational health
 - A professional and sensitive approach
 - Help in solving the problem at source: moderating work pressures, providing education and training, increasing control over work events, and improving support
 - Advice, if necessary, on lifestyle
 - Short term treatment for any associated medical problems
 - Active management of rehabilitation to work
-

available, and occupational health practitioners have a major role to play both as expert advisers and organisational champions.

The successful provision of employee support (to deal with stress) depends on three things: a broad based and competent system, an accessible system, and an integrated system. Most large organisations provide good employee support in theory, but fail themselves and their employees in practice because the overall system is fragmented, often competitive for resources, and territorial, and lacks internal collaboration at the case level. Much can be achieved by bringing existing systems together, by training staff in relation to work stress, and by marketing what is available within the organisation.

The box containing information on psychosocial and organisational hazards is adapted from Cox 1993. The box containing causes of stress and possible solutions is adapted from Health and Safety Executive. *Work related factors and ill health: the Whitehall II study*. 9 Mental health at work

Rachel Jenkins

Introduction

Mental illness affects about a tenth of all adults at any one time—about 450 million people worldwide. Lifetime prevalence is much higher. Mental disorders now account for about 12% of the global burden of disease and this is expected to rise to 15% by the year 2020. Neuropsychiatric conditions account for 30% of all years lived with disability.

Mental disorders and substance abuse are important issues in the workplace, partly because they are so common in the general adult population and partly because increasing rates of employment in many countries mean that the less able are entering the workforce. Mental ill health at work seems to be rising and in the United Kingdom at least, it has overtaken musculoskeletal disorders as the main cause of absence from work, long term sickness, and retirement on medical grounds. Whatever the cause of mental disorders, they have consequences for work performance and economic productivity. Appropriately tailored work is generally beneficial for people suffering mental illness, and the workplace can be an important setting for mental health promotion and the prevention of illness.

Positive mental health is not just the absence of mental disorder but has been defined as a positive sense of wellbeing, implying the presence of self esteem; optimism; a sense of mastery and coherence; the ability to initiate, develop, and sustain mutually satisfying personal relationships; and the ability to cope with adversity (resilience). Factors such as these enhance a person's capacity to contribute to family and other social networks, the local community, and society at large. They are also qualities that may be expected to influence work performance.

The spectrum of mental health problems

Mental disorder is common in the adult population of the United Kingdom, as elsewhere in Europe and the rest of the world.

Those who are unemployed have higher rates of mental illness than people in employment, partly because of the socially stressful aspects of unemployment and partly because people with mental illness experience more difficulty in finding and maintaining work.

Rates of mental illness in employed and unemployed, Great Britain 2000

	Working full time	Working part time	Unemployed	Inactive
	Rate per thousand (se)			
Neurosis (per thousand in past week)	136 (7)	161 (11)	196 (30)	270 (12)
Probable psychosis (per thousand in past year)	1 (1)	6 (2)	–	17 (3)
Alcohol dependence (per thousand in past 6 months)	94 (5)	53 (8)	146 (25)	67 (7)
Drug dependence (per thousand in past year)	40 (4)	32 (6)	137 (23)	40 (6)

The spectrum of mental health disorders

Disorder	Rough prevalence
Psychological distress usually connected with various life situations, events, and problems	Most of us from time to time
Common mental disorders (depression, anxiety disorders in adults, and emotional and conduct disorders in children)	10-20% of adults in general population but 40-50% in highly vulnerable populations; 30% of primary care attenders; 10% of children in general population
Severe mental disorders with disturbances in perception, beliefs, and thought processes (psychoses)	0.5% of general population
Substance abuse disorders (excess consumption and dependency on alcohol, drugs, and tobacco)	Highly country specific; 5% and above, increasing
Eating disorders	1-5%; mostly women
Abnormal personality traits that are handicapping to the individual and/or others	Not known; existing studies suggest 5%
Progressive organic diseases of the brain (dementia)	Senile dementia: 5% of over 65s and 20% of over 80s (hence the demographic time bomb)
Tropical organic dementias	Situation specific
AIDS dementia	A growing problem in countries where people with AIDS live long enough to develop it
Toxic organic brain syndromes	Industry specific (mercury, lead, carbon monoxide) or environmental

Prevalence of psychiatric disorders per 1000 population in adults aged 16-64 years in Great Britain 2000

	Women	Men	All adults
	Rate per thousand in past week (se)		
Mixed anxiety and depressive disorders	112 (6)	72 (5)	92 (4)
Generalised anxiety disorder	48 (3)	46 (4)	47 (3)
Depressive episode	30 (3)	26 (3)	28 (2)
Phobias	24 (2)	15 (2)	19 (2)
Obsessive-compulsive disorder	15 (2)	10 (2)	12 (1)
Panic disorder	7 (1)	8 (2)	7 (1)
Any neurotic disorder	202 (8)	144 (7)	173 (6)
	Rate per thousand in past year (se)		
Probable psychosis	5 (1)	6 (1)	6 (1)
Drug dependence	24 (3)	60 (5)	42 (3)
	Rate per thousand in past 6 months (se)		
Alcohol dependence	32 (3)	130 (6)	81 (4)

The prevalence of mental disorders in the workplace

Study	Number studied	Population	Instrument	Male	Female	Total prevalence per 1000
Fraser R, 1947	3000	Light and medium engineering workers	Medical assessment	283	360	300

Causes and consequences of mental disorder

Causes

The causation of mental disorder is multifactorial, being half genetic and half environmental for psychoses but largely environmental for the non-psychotic disorders.

Some disorders have a genetic basis, especially the major psychoses. Malnutrition can be a direct cause, whether in childhood or as an adult (for example, pellagra). Rarely, endocrine disorders such as myxedema may be causative. Occupational and environmental causes include infection (for example, encephalitis), the toxic effects of exposures at work (for example, mercury poisoning), and trauma (head injury).

Psychological factors—for example, poor coping skills and persistently low self esteem—also contribute. Such routine adverse life events as bereavement or job loss can lead to at least temporary mental disorder in the vulnerable. Unusually distressing or life threatening events may predispose towards the development of post-traumatic stress disorder. Such mechanisms are exacerbated by inadequate social support networks. Chronic social adversity (unemployment, poverty, illiteracy, child labour, violence, and war) is also often responsible, especially among underprivileged people.

Longitudinal studies have shown that unemployment, redundancy, or even the threat of redundancy cause mental illness, although naturally, employees who are already mentally ill are more likely to lose their jobs—either voluntarily or involuntarily. Given what is known about the mean rates of illness in the population as a whole and a higher rate in the unemployed, one would expect to find comparatively lower rates of illness in people at work. However, those studies that have been done in particular groups of workers have shown quite high rates of mental illness. It has been suggested,

Risk factors associated with common mental disorders: odds ratio (OR) of sociodemographic correlates of revised clinical interview schedule (CIS-R) score of 12 or more; *p < 0.05 **p < 0.01

	Adjusted odds ratio	95% confidence interval
Sex

Urban	1.16*	1.01 to 1.34

however, that some bias may have occurred in studying working populations that were chosen because they are perceived to be particularly stress prone. The table on page 46 shows the strength of some of these risk factors in relation to mental illness in the United Kingdom.

The clinical interview schedule is a semistructured standardised clinical interview for use in epidemiological studies in the community, primary care, and workplace settings. It was originally devised to be used by mental health researchers, but has since been revised for use by lay interviewers with no mental health training.

Consequences

The development of mental illness is often followed by a series of psychosocial problems. Physical illness may occur, partly as a result of self destructive behaviour. Suicide is now the tenth leading cause of death worldwide. A descent in the social order is common, and with this comes poverty and secondary effects on social relationships, especially family ones. These potential developments are paralleled by effects on working life—for example, loss of job status or unemployment. The employer incurs the costs of sickness absence, impaired productivity, and increased devotion of time to human resources issues. The table shows the high level of social disability associated with mental disorder, both psychotic and non-psychotic.

The role of the employer

Whether or not a person's illness is contributed to by work, their workplace bears the consequences of the illness in terms of reduced productivity, sickness absence, labour turnover, accidents, and so on. It should be in the employer's interest to provide a good working environment, supportive if necessary, and to enlist some kind of occupational health service to detect and, sometimes, to help rehabilitate people with mental disorders in collaboration with other health and social agencies. In fact, such is the negative attitude of employers towards potential employees with such an illness that, far from offering support, they usually attempt instead to exclude. Mental disorders that have a substantial impact on everyday life are regarded as disabilities in the United Kingdom, and employers are forbidden to discriminate unreasonably against such people when offering employment. Instead, adjustments to working life must be entertained.

Less serious disorders that have little influence on everyday life, and drug and alcohol dependence, which are not covered by the Disability Discrimination Act, may nevertheless cause immense problems for employers and fellow employees. Mental disorders can be screened for but, rather like back pain, the lifetime prevalence is so high that excluding candidates with a history of mental disorder will simply reduce the potential workforce to unmanageable levels. Certain conditions, if declared, do probably render applicants potentially unfit for certain occupations: psychotic illness, personality disorder, and substance abuse for the caring professions; personality disorder and dependency disorders in safety sensitive jobs.

The role of Government

To support a successful economy and to make an appropriate contribution to the prevention of discrimination against people with mental illness, government agencies and other national bodies may need to take action on environmental conditions at work; access to employment, including sheltered employment for those who need it; opportunities for employment rehabilitation; the promotion of workplace mental health

Difficulties in activities of daily living in household samples

	% with any difficulties	N
People assessed as having ...		
Suicidal thoughts in the past week	59	45
Probable psychosis in the past year	58	54
Neurosis in the past week	41	1376
None of the above	13	5919

Mental disorder is already prevalent within the workplace. Working conditions are known to have a considerable influence on mental health. Therefore, to minimise the damage from this source to both employees and employers, the most sensible course would seem to be for employers to institute mental health policies as part of their human resources framework

Workplace mental health policy

A workplace mental health policy is agreed between employers, employees, and their representatives—for example, trade unions, and includes:

- A statement that the organisation is committed to a course of action which might include
 - increased understanding of causes of mental health problems in the workforce
 - action to combat workplace stressors and helping staff to manage their stress
 - action to manage mental health problems effectively through early recognition and appropriate management
 - action to manage the return to work of those who have suffered mental health problems to ensure their skills are not lost to the enterprise
- Commitment to a healthy workforce, placing a huge value on both physical and mental health
- Acknowledging that mental health problems may have many causes, including stressors in the workplace and in the outside world
- Listing factors that may lead to increased stress levels in the organisation (customised, based on discussion with staff and needs assessment)
- Recognising that domestic factors (such as housing, family problems, and bereavement) may add to levels of stress experienced by employees

policies; and the provision of occupational health for the workforce. This is especially important now that many governments encourage the return to work of those who have suffered mental health problems, as well as those recovering from physical illness as part of “welfare to work” schemes. In times of full employment this may well increase the proportion of those at work who are psychiatrically vulnerable.

The role of schools in supporting subsequent occupational health initiatives

Besides their primary educational role, schools are important settings for mental health promotion. They can teach children important life skills aimed at reducing acute and chronic social stressors and enhancing social supports, all of which have a direct influence on mental health, and which may be expected to influence subsequent mental health in adult working life. Thus, employers as a body have an interest in encouraging mental health promotion in schools in the same way that they encourage mathematical and literacy skills, as well as physical health. Such mental health promotion should include teaching of coping skills, citizenship skills, exam skills and techniques, stress management, achieving potential in relationships and working situations, recognising and combating bullying, learning to say no to risky behaviours, and education about parenting and child rearing in collaboration with a health education and addiction programme.

The role of health professionals

Health professionals, including occupational health professionals, need to be adept at detecting and assessing mental health problems in the workplace. Managers may suspect mental health problems but they cannot be expected to diagnose or assess them, and they need help from health professionals in understanding and managing them. An occupational physician should be able to take an adequate psychiatric history, identify any possible physical agents responsible or stressors (in or out of work), and then perform a mental state examination to complete a risk assessment.

An occupational health professional’s most important and unique contributions to helping manage people at work who have had or are experiencing mental health problems are to try to reduce stigma and discrimination, foster an understanding among managers and work colleagues, and advise on adjustments to the workplace when employees decompensate or when they return after a period off work because of mental illness.

The high rate of suicidal thoughts in people with depression means that teaching good assessment and management techniques to health and social care professionals should be a priority, as should national and local action to minimise environmental risk factors for suicide.

Common mental disorders that may present in the workplace

Mixed anxiety or depression

Mixed anxiety or depression is the commonest disorder seen in occupational settings. People with this disorder may present with one or more physical symptoms—for example, various pains, poor sleep, and fatigue, accompanied by a variety of psychological symptoms. It is a prime cause of absence from

Many schools now teach children “values”—respect for others’, feelings, acceptance of differences in race, religion, etc. This can be established equally well in a workplace with a set of “company values” that go beyond the usually facile “mission statement”

Mental state examination

- *Appearance and behaviour*—Grooming, hostility, restlessness, pupils, alcohol smell
 - *Communication*—Rapid, sparse, confused
 - *Mood*—Low or high, feelings of self worth, hopelessness, concentration, biological aspects (sleep, energy levels, appetite, libido), suicidal ideation
 - *Thoughts*—Thought formation, thought content
 - *Perceptions*—Hallucinations, etc.
 - *Cognitive aspects*—Orientation, short term memory, knowledge of current affairs, neurological deficits
 - *Insight*—Individual aware they are ill? Prepared to be treated?
-

Diagnostic features of mixed anxiety and depression

- Low or sad mood
 - Loss of interest or pleasure
 - Prominent anxiety or worry
 - Multiple associated symptoms
 - Disturbed sleep
 - Tremor
 - Fatigue or loss of energy
 - Palpitations
 - Poor concentration
 - Dizziness
 - Disrupted appetite
 - Suicidal thoughts and acts
 - Dry mouth
 - Loss of libido
 - Tension and restlessness
 - Irritability
-

work “due to stress.” Together with related states, it contributes considerably to the disability accompanying musculoskeletal disorders, especially back pain, and to fatigue states.

Depression

Depression is common, with a lifetime prevalence in the United States of 17% for a major episode. The sufferer may present with physical symptoms, irritability, anxiety or insomnia, worries about social problems such as financial or marital difficulties, increased drug or alcohol use, or (in a new mother) constant worries about her baby or fear of harming the baby. Some groups are at higher risk—for example, those who have recently given birth or had a stroke, and those with physical disorders such as Parkinson’s disease or multiple sclerosis.

Differential diagnosis

The differential diagnosis includes acute psychotic disorder if hallucinations or delusions are present; bipolar disorder if there is a history of manic episodes; poisoning or substance misuse if heavy alcohol or drug use has occurred; and chronic mixed anxiety-depression. Some medications may produce symptoms of depression (for example, β blockers, other antihypertensives, H₂ blockers, oral contraceptives, corticosteroids). Unexplained somatic symptoms, anxiety, or alcohol or drug disorders may coexist with depression.

Alcohol and drug misuse

Employees (or employers) with alcohol problems may present with depression, nervousness, insomnia, physical conditions such as peptic ulcer, gastritis, liver disease, hypertension, accidents or injuries, poor memory or concentration, and evidence of self neglect (for example, poor hygiene). They may be people in whom treatment for depression has failed. Patients may also have legal and social problems resulting from alcohol—for example, marital problems, domestic violence, child abuse, or missed work. Signs of alcohol withdrawal may be present—for example, sweating, tremors, morning sickness, hallucinations, and seizures. Those with alcohol problems often deny or are unaware of their problems, and it may be others who request professional help.

Management by the occupational health department

Employees may be referred with a suspicion of an alcohol problem or the possibility may be raised at the first interview. Assessment may be aided by simple well validated screening questionnaires such as the CAGE questionnaire and, for less excessive but still harmful drinking, the alcohol use disorders identification test (AUDIT) questionnaire.

The assessment should be conducted in a straightforward non-judgmental way and cover drinking pattern, amount, type, circumstances, and duration, as well as symptoms; convictions for drink driving should be specifically asked about. Laboratory tests may help diagnosis but have a limited use in isolation. They can help in patient education and in monitoring alcohol reduction, as can a drink diary.

Managing alcohol problems at work

This is best done in the context of an alcohol and drugs policy at work, which will always include a ban on the use of illegal drugs at work but which may have a variable attitude to alcohol at work, perhaps allowing alcohol to individuals whose jobs are not safety sensitive, for social occasions, or after the working day is over, etc. Whatever the policy, it needs to be signed up to

Diagnostic features of depression

- Low or sad mood
 - Loss of interest or pleasure
 - At least four of the following:
 - disturbed sleep
 - disturbed appetite
 - guilt or low self worth
 - pessimism or hopelessness about future
 - decreased libido
 - diurnal mood variation
 - poor concentration
 - suicidal thoughts or acts
 - loss of self confidence
 - fatigue or loss of energy
 - agitation or slowing of movement or speech
 - Symptoms of anxiety or nervousness are also frequently present
-

Essential information about depression for patient, family, work colleagues, and managers

- Depression is a common illness and effective treatments are available
- Depression is not weakness or laziness
- Depression can affect a person’s ability to cope

Information leaflets or audiotapes can be used to reinforce the information

Alcohol dependency

The presence of three or more of the following suggests alcohol dependency

- Strong desire or compulsion to use alcohol
- Difficulty controlling alcohol use
- Withdrawal (anxiety, tremors, sweating, hallucinations) when drinking has ceased
- Tolerance—drinking large amounts of alcohol without appearing intoxicated
- Continued alcohol use despite harmful consequences

Presentation of alcohol problems at work

- Poor attendance—frequent sickness absence, certified or uncertified—may be regular—for example, after weekends or breaks
 - Lateness for work
 - Poor performance—mistakes, slowness, poor judgement, frequent mishaps
 - Prolonged lunch hours, afternoon sleepiness
 - Poor personal hygiene, scruffiness, smelling of alcohol
 - Irrational or noisy behaviour, inappropriate comments, irritability
 - Frequent disappearances during the day
 - Signs of violence—cuts and bruises
 - Dishonesty or deviousness
 - Frequent sickness absence because of gastrointestinal upsets
-

by management and workers' representatives. If there is an Occupational Health Department or some kind of welfare service, then referrals by managers or individuals themselves for alcohol related problems should be possible, and the condition treated initially as a health problem, and only when there is refusal or inability to stop or reduce drinking to reasonable levels are disciplinary procedures invoked. Time off work as sick leave may be required. Referral to a general practitioner or alcohol misuse specialist will be necessary. Compliance with undertakings can be managed by an occupational health department, using random testing if required. The same process can be used for employees who use illegal drugs, although the very illegality of the drugs can lead to disciplinary measures much more quickly.

Both alcohol and drug abuse are chronic conditions, and any employer or Occupational Health Service has to realise the high probability of relapse, although research shows that rehabilitation is more likely to be successful when the problem is dealt with in a work context when the individual is threatened with potential job loss. Early recognition, assessment, and active management of the situation also help.

Alcohol and drug abuse is a serious problem for society and is clearly increasing in incidence; it is also a huge problem for employers. The yearly cost to industry of alcohol misuse has been estimated at about £3 billion in the United Kingdom through accidents, reduced productivity, and absenteeism. Hangovers alone have been estimated to cost industry £50-100 million.

Drugs of abuse other than alcohol can have serious effects on performance, probity, and so on. Testing for drugs at pre-employment or randomly is practised in some safety sensitive industries. The testing has to be done using proper chain of custody techniques and in the context of an agreed drugs policy, which may or may not allow for rehabilitation while still employed. Employers and occupational health professionals who undertake coercive testing for drugs of abuse must ask themselves whether by instituting this programme they are trying to exclude "undesirables" from this workplace or to identify those who, while under the influence of drugs, may present a safety or security risk? This issue raises concerns about human rights.

Women's issues

Women, by virtue of their increased exposure to acute life events, chronic social stresses, lower social status and income, and smaller social networks, are often particularly vulnerable to common mental disorders. This is reflected, hardly surprisingly, in higher rates of sickness absence because of psychological causes. Disorders associated with menstruation, pregnancy, and childbirth are additional disorders specific to women. New mothers often feel pressured to return to work early after childbirth, and one of the most important preventive actions that can be taken in the mental health arena is to recognise postnatal illness and ensure adequate and prompt treatment.

Eating disorders

An eating disorder may be declared at a pre-employment screening. The two main types, anorexia and bulimia, of which the latter is more common, occur mainly in young women. An individual may present with binge eating and extreme weight control measures such as self induced vomiting, and excessive use of diet pills and laxatives, usually covert. In the case of employees, management may ask occupational health professionals for help because of concerns about an

CAGE questionnaire

Four questions:

- Have you ever felt you ought to **Cut** down on your drinking?
- Have people **Annoyed** you by criticising your drinking?
- Have you ever felt bad or **Guilty** about your drinking?
- Have you ever had a drink first thing in the morning to steady your nerves or get rid of a hangover ("**Eye-opener**")?

Over 90% of dependent drinkers answer "yes" to two or more of these questions

Alcohol use disorders identification test (AUDIT)

See Saunders JB, Aasland OG, Babor TF, de la Fuente JR, Grant M. Development of the alcohol disorders identification test (AUDIT): WHO collaborative project on early detection of persons with harmful alcohol consumption. *Addiction* 1993;88:791-803

Management of alcohol dependence

Essential information for employees, managers, and families

- Alcohol dependence is an illness with serious consequences
- Ceasing or reducing alcohol use brings mental and physical benefits
- Drinking during pregnancy may harm the baby
- For people with alcohol dependence, physical complications of alcohol abuse or psychiatric disorder, abstinence from alcohol is the preferred goal
- In some cases of harmful alcohol use without dependence, or where the individual is unwilling to quit, controlled or reduced drinking is a reasonable goal
- Relapses are common. Controlling or stopping drinking often requires several attempts. Outcome depends on the motivation and confidence of the patient

Advice and support to patient and family

- Discuss costs and benefits of drinking from individual's perspective
- Give feedback about health risks, including the results of gamma glutaryl transferase and mean corpuscular volume measurements
- Emphasise *personal responsibility* for change and give clear advice
- Consider targeted counselling

For patients willing to stop now

- Set a definite day to quit
 - Discuss symptoms and management of alcohol withdrawal (may require time off or even hospitalisation)
 - Discuss strategies to avoid or cope with high risk situations (for example, how to face stressful events without alcohol, ways to respond to friends or colleagues who still drink)
 - Help identify colleagues, friends, and family who will support ceasing alcohol use
 - Discuss support after withdrawal
 - Mention self help organisations such as Alcoholics Anonymous, which are often helpful
-

Concern has arisen that a history of such disorders makes candidates unsuitable for caring professions such as nursing or school teaching, but this is not necessarily the case. In this context, attention should be paid to any accompanying behavioural disorders including self harm—for example, and personality disorders, rather than uncomplicated eating disorders

individual's weight loss. Both anorexia and bulimia may present as physical disorders (for example, seizures or cardiac arrhythmias) that may have employment consequences and need treatment. Bulimia is, in general, a much more transitory condition with a better record of successful treatment. Anorexia nervosa is often more chronic and intractable and may involve prolonged sickness absence because of hospitalisation.

Bipolar disorder

Patients may present with a period of depression, mania, or excitement, or referral may be made by others because of the individual's lack of insight.

The diagnostic features of bipolar disorder are given in the box. Periods of either mania or depression may predominate. Episodes may alternate often or may be separated by periods of normal mood. In severe cases, patients may have hallucinations (hearing voices or seeing visions) or delusions (strange or illogical beliefs) during periods of mania or depression. The differential diagnosis includes poisoning or drug or alcohol misuse, which may cause similar symptoms.

Individuals often enter the hypomanic state rapidly, with danger to themselves and to others at work, especially if their job is safety sensitive. Some kind of early warning system should be instituted by the Occupational Health Department with the individual's consent and the cooperation of managers or sympathetic work colleagues.

High risk occupations

Certain occupations are at high risk for work related mental illness (and, incidentally, for fatigue states). These include occupations such as teaching, nursing, and the police force where there is a need for emotional commitment in the personal problems of other people and where there are considerable staff shortages, high demand, and poor locus of control.

Certain occupations are also at high risk for suicide. These include vets, doctors, dentists, pharmacists, and farmers—they have greater access to the means of suicide and better knowledge about effective methods of suicide, as well as being in demanding occupations.

Health professionals lead stressful lives, and epidemiological studies have confirmed the high levels of depression and anxiety in healthcare staff, indicating the need to address the support of this key group.

Employers are becoming increasingly worried—mainly for legal reasons—about the effect of demanding work on the mental health of vulnerable employees. This is a contentious area with little in the way of legal precedent but one where advice is frequently asked of occupational health professionals. Careful psychological assessment, knowledge of the job stressors, and a traditional risk assessment approach offer the best way forward. Attempts have been made, using a partially evidence based approach, to define health standards, including medical criteria, for entry into certain demanding professions—the armed forces, medicine, nursing, teaching, and civil emergency services. This can be helpful.

The potential for violence and bullying at work has also concerned employers, but such behaviour does not in fact usually emanate from those with mental illness but from those with problematic personality types or drug and alcohol problems.

Diagnostic features of bipolar disorder

Periods of mania characterised by

- Increased energy and activity
- Elevated mood or irritability
- Rapid speech
- Loss of inhibitions
- Decreased need for sleep
- Increased importance of self
- Persistent distraction

Periods of depression characterised by

- Low or sad mood
 - Loss of interest or pleasure
 - Disturbed sleep
 - Guilt or low self worth
 - Fatigue or loss of energy
 - Poor concentration
 - Disturbed appetite
 - Suicidal thoughts or acts
-

ABC of Occupational and Environmental Medicine

The third area of concern is safety. The potential problems with psychotic or dementing employees and employees who misuse drugs or alcohol will be obvious. The assessment of less serious mental disorders and their relation to safety is a job for the occupational physician using a similar approach to that described for assessing those entering demanding jobs. Psychotropic medication often affects cognition, especially at the beginning of treatment; drowsiness and lack of concentration are common and should be anticipated.

Mental ill health at work is likely to become the dominant occupational health issue of the future. There is enormous scope for research and enormous need for public education and the destigmatisation of mental illness.

The table showing the prevalence of psychiatric disorders and the table showing rates of mental illness employed and unemployed are adapted from ONS survey of psychiatric morbidity among adults living in private households. London: HMSO, 2000. The table showing the prevalence of mental disorders in the workplace is adapted from Jenkins R. Public policy and environment. In: Gelder M, ed. *Oxford textbook of psychiatry*. 10 Human factors

Deborah Lucas

The term “human factors” is often invoked after an accident, whether a minor incident in the workplace or a major disaster entailing significant loss of life. In many respects “human factors” is regarded by the layman as being synonymous with “human failure”—an unavoidable aspect of the human condition. Although there is a long list of major accidents across all hazardous industrial sectors where human failures were causal factors, this is not to imply that human errors are inevitable. Research over the past 20 years has shown much about the origins of different types of error and the best means of reducing their occurrence. However, the loss of life in disasters such as the Clapham Junction rail crash in 1988, the Southall and Ladbroke Grove train crashes in 1997 and 1999, respectively, and the sinking of the Herald of Free Enterprise in 1987 are high in the British public’s mind. All of these disasters had human factors as a cause: a maintenance worker not disconnecting a wire, a train driver passing a red danger signal, and a bosun failing to close the bow doors of a ferry. The nuclear industry faced up to the issue of human factors after Three Mile Island in 1979 and the Chernobyl accident in 1986. The oil sector recognised the issue after the Piper Alpha tragedy in 1988. The aviation, rail, and marine transportation sectors are all actively considering the issue of human factors. Proper consideration of human factors is a key ingredient of effective health and safety management in all industrial sectors.

Modern health care is also a complex and, at times, high risk activity where adverse events are inevitable. However, a substantial proportion of adverse events results from preventable human failure by medical staff. Adverse events occur in about 10% of admissions to hospital in the United Kingdom—a rate of 850 000 adverse events a year. In the United Kingdom, 400 people die or are seriously injured every year in adverse events involving medical devices. Hospital acquired infections are estimated to cost the NHS nearly £1 billion every year, but about 15% of such infections may be avoidable. In the United States it is estimated that between 44 000 and 98 000 people die annually because of medical errors. Yet health care is not unique. There are many parallels with other high risk sectors, which have been examining the need to reduce human failures in complex systems for over two decades.

Definition

Human factors are often described as the thread that runs through all the key health and safety management issues, and numerous definitions of human factors and the related term ergonomics exist. The definition given by the UK Health and Safety Executive is “Human factors refer to environmental, organisational and job factors, and human and individual characteristics, which influence behaviour at work in a way that can affect health and safety.” Key elements have been identified by psychologists and ergonomists after an incident or accident, and in the military field human factors programmes explicitly consider six aspects or domains during the design or procurement of a system. These domains have been found to be useful in other industrial contexts.

“Human error” is often cited immediately after a disaster

Examples of human failures in medicine

- A patient is inadvertently given a drug that they are known to be allergic to
- A clinician misreads the results of a test
- A child receives an adult dose of a toxic drug
- A patient is given medicine that has a similar sounding name to that prescribed
- A toxic drug is administered by the wrong route—for example, intrathecally
- A heart attack is not diagnosed by emergency room staff in an older patient with ambiguous symptoms

Common errors relating to drugs

- Unavailable drug information (for example, lack of up to date warnings)
 - Miscommunication of drug orders (for example, through poor handwriting, confusion between drugs with similar names, misuse of zeros and decimal points, confusion between milligrams and micrograms)
 - Incomplete patient information (such as not knowing about other medicines they are taking)
 - Lack of suitable labelling when a drug is repackaged into smaller units
 - Workplace factors that distract medical staff from their immediate tasks (such as poor lighting, heat, noise, and interruptions)
-

Human factors considered in the development of military systems

Domain	Issue	Issues to consider
Staffing	How many people are needed to operate and maintain the system?	Workload Job descriptions Staffing levels Team organisation
Personnel	What human characteristics, including aptitudes and experience, are needed to operate and maintain the system?	Selection and recruitment Career development Required qualifications, competences, and experience Specific characteristics
Training	What is the best way to develop and maintain the required knowledge, skills, and abilities to operate and maintain the system?	Training needs analysis Documentation Assessment Team training Skill maintenance and update
Human factors engineering	How can human factors be built into the system design to optimise human performance?	Equipment design Workstation design Workplace layout User interface design Maintenance access
Health hazards	What are the short term and long term health hazards from operation of the system?	Minimising exposure to health hazards such as toxic materials, electricity, musculoskeletal injury, noise and vibration, extremes of temperature
System safety	How can safety risks that humans might cause when operating or maintaining the system be avoided?	Sources of human errors Effects of misuse of equipment Abnormal and emergency situations

Human failure

Research across industries has shown much about the types of human failure and the underlying psychological mechanisms. A key distinction can be made between unintended human errors and deliberate rule violations. However, even deliberate violations can result from system pressures such as shortage of time because of a lack of staff, or the correct equipment not being available. In high hazard industries it is no longer acceptable to attribute a safety incident just to a “human error” with the assumption that this was somehow beyond the control of managers and safety management systems. A detailed

Classification of the types of human failure

Typical causes of human failures in accidents

Job factors

- Illogical design of equipment and instruments
- Constant disturbances and interruptions
- Missing or unclear instructions
- High workload
- Noisy and unpleasant working conditions

Individual attributes

- Low skill and competence levels
- Tired staff
- Bored or disheartened staff
- Individual medical or fitness problems

Organisational aspects

- High work pressure because of poor work planning
- Poor health and safety culture
- One way communications (messages sent but no checks to ensure they are received or are appropriate)
- Lack of safety systems and barriers
- Inadequate responses to previous incidents

Causes of incidents in a department of surgery

investigation into the causes of incidents involving human failure will show a number of immediate and underlying causes and contributing factors. Many of these will be problems with organisational systems rather than with the individual member of staff.

Control measures

There is no “magic bullet” for the problems of human fallibility. However, thoughtful, multifaceted approaches can reduce the probability of human failures leading to serious consequences. In medicine, knowledge and tools to enhance patient safety are emerging, and much can be learnt from other industries, particularly the high hazard sectors such as the nuclear industry, aviation, and transportation.

Designing for people

Many sources of human error can be removed through effective design of equipment and procedures. Such “error tolerant” designs consider the tasks that the equipment is intended for and the errors the user may make. To give an example, in the early days of automatic teller machines, the user’s bank card was returned to them by the machine *after* their cash had been issued. Banks found that many people took their money but forgot to take their card. This error was prevented by returning the card before the cash appeared.

Consideration of human factors is an important aspect of overall design and equipment procurement, and should be considered early in the design process. If left too late, then complicated procedures, added warnings, and requests for the user to “take care” can be the unfortunate result. Compliance with instructions and procedures differs according to the situation, the risks, the element of personal choice, and the probability of being detected. Written warnings are usually noticed, read less often, and complied with infrequently.

Poorly designed equipment can directly influence the chance of human errors occurring. For example, the layout of controls and displays can influence safety if switches are placed so that they can inadvertently be knocked on or off, if controls are poorly identified and can be selected by mistake, or when critical displays are not in the user’s normal field of view. The controls of different equipment may not be compatible: for example, a switch in the up position may be “on” in one

Case study: reducing errors in the administration of intravenous heparin

The intravenous administration of heparin (an anticoagulant) is a complex procedure, and this drug has been the subject of serious drug errors. A US hospital wanted to reduce errors in the administration of heparin in cardiac care units. They developed a form that combined the ordering and recording of the use of heparin. In addition, they improved communication with the hospital laboratory, converted all heparin protocols to pharmacy managed protocols, introduced pre-typed heparin orders and the double-checking of pump programming, and encouraged the use of low molecular weight heparin instead of standard heparin. These control measures were claimed to have reduced drug errors by 66%

“Human beings make mistakes because the systems, tasks, and processes they work in are poorly designed”

Dr Lucian Leape, testifying to the US President’s Commission on Consumer Protection and Quality in Health Care

Examples of ergonomic criteria for procuring equipment

- Does the equipment suit the body size of all users?
- Can users see and hear all they need to easily?
- Is it easy to understand the information displayed?
- Would the equipment cause discomfort if used for any length of time?
- Is it easy to learn how to use the equipment? Are instructions and any warning signs clear? Is the language used appropriate for the users?
- What errors may occur? Can these be detected easily, and corrected?
- Is the equipment compatible with other systems in use?
- Can users reach controls easily?
- Can users move safely between operating positions?
- Is the equipment too noisy, does it vibrate too much, is it paced too fast?

Compliance rates in different situations

Arrangement of controls on a lathe and the “ideal” operator, who should have the following dimensions—4 feet 6 inches tall, shoulders 2 feet across, and an 8 foot arm span!

case but “off” in another. Alarm systems may be designed so that high priority alarms are not clearly differentiated and are thus easily missed.

Designing tasks, equipment, and workplaces to suit the users can prevent or reduce human errors and thus reduce accidents and ill health. A key message is that effective use of ergonomics will make work safer and more productive.

Sleep and human performance

Although it is often feasible to prevent human failures by the effective design of jobs and equipment, in other situations human performance problems may arise as the result of fatigue, shiftwork, poor communications, lack of experience, or inadequate risk perception. These aspects all need to be managed effectively to reduce the potential risks. One of the most commonly cited problems is lack of sleep for staff carrying out safety critical tasks. The decision to launch the Challenger space shuttle was partly attributed to the effects of fatigue on the decision making team. The rail crash at Selby in the United Kingdom in 2001 occurred because a car driver fell asleep and drove onto a railway line.

A significant proportion of road traffic accidents occur between 2 am and 5 am and are attributed to drivers falling asleep at the wheel. As we are not a nocturnal species, this is the time when our biological clock programmes us to sleep. Such circadian rhythms are hard to adjust to, even when working regular night shifts. Many people work shift systems, do night work, or work very extended hours including significant levels of overtime. Such working patterns can have adverse effects on their health as well as being associated with poorer performance on tasks that need attention or sustained vigilance, decision making, or high levels of skill. Sleep is a powerful biological need, and night work or certain shift systems can disrupt both the quantity and the quality of sleep. Sleeping during the day is never as satisfactory as sleeping at night. Sleep loss of just a few hours over a few days can lead to a build up of a sleep debt and reduced performance, but the person may not be aware of this.

A large body of research on shiftwork exists, but often the findings are not put into practice. Working patterns are usually seen as matters to be negotiated between employees and the employer, and additional overtime can be perceived as a financial advantage, and not as a potential health and safety issue. However, in high hazard industries awareness of the relation between sleepiness and accidents is growing.

Organisational influences

A number of factors within an organisation are associated with good safety performance. These affect not only human factors issues but also the “safety culture” of the organisation. A “culture” means shared attitudes, beliefs, and ways of behaving. An effective culture will be shown through good ways of informing and consulting all staff, recognition that everyone has a role to play in safety, visible commitment by managers to involving all staff, cooperation between members of the workforce, open two way communications, and high quality of training. The organisation that continually improves its own methods, and learns from mistakes (including accidents and “near misses”) will tend to have a better safety performance than one that blames individuals for “being careless” when accidents happen.

The relationship between sleepiness and accidents: best practice approaches to managing the problem

- Plan shift rosters to take biological rhythms into account
 - Set limits for maximum hours of duty and time needed for recovery afterwards
 - Educate shift workers on sleep routines, nutrition, and exercise
 - Make environmental changes to the workplace including lighting, temperature, and comfort level, which can all influence alertness
 - Plan safety critical tasks to avoid night shifts
 - Provide medical advice for shift workers
 - Recognise the possibility of true sleep disorders (sleep apnoea, narcolepsy) and referral for investigation and treatment
-

High hazard industries are becoming increasingly aware of the importance of proper consideration of human factors

The Herald of Free Enterprise sank because no effective system was in place to ensure the bow doors were closed

Key principles

Human factors is a broad concept that can be seen as too complex or difficult to do anything about. However, there are five key principles to be remembered, and these are ones that many regulatory bodies are promoting:

- Recognise that people do not make mistakes because of “carelessness” and accept that even the most experienced members of staff are vulnerable to unintentional errors.
- Learn from adverse events including “near misses.” Understand that usually there will be no single cause of an incident but a number of causes and contributing factors.
- Anticipate the influences on human performance. Key themes will include time pressure, experience, staffing levels, fatigue, and risk communications.
- Defend against paths to failure. In particular, appreciate the role of designing equipment and systems that are error tolerant.
- Encourage a “culture of safety.”

11 Physical agents

Ron McCaig

The use of the term “physical agents” is not always clear. Sometimes it is taken to mean dusts and fibres whose effects are determined by their physical properties as well as their chemical composition. However, the term usually refers either to those agents that impart energy to the body by physical means (for example, the effects of radiation, heat, or noise and vibration), or to the effects of environments that differ in their physical characteristics from that existing at ground level on dry land (for example, found in diving and compressed air work, at altitude, and in flight).

The body offers some protection against physical agents experienced in the normal environment, such as heat and radiation—for example, by the physiological changes of heat acclimatisation or, at a cellular level, the operation of DNA repair mechanisms. Such mechanisms are limited in their effectiveness and can be overwhelmed if challenged by an exposure of sufficient magnitude. Even in artificial environments, such as work in compressed air tunnelling or high accelerations in flight, it is possible that a certain amount of physiological adaptation can take place. For example, the incidence of decompression illness often reduces after the first few days of exposure of a work force tunnelling in compressed air—an effect that is thought to be a form of acclimatisation—and some G tolerance can develop with physical fitness training.

Many physical agents have a threshold of exposure below which the body is unlikely to be harmed. Beyond that, it is necessary to restrict exposures, often by administrative controls such as limiting the duration of exposure (as in work rest schedules in the heat), providing shielding or protective clothing and equipment, or limiting the potential for harm by procedures such as staged decompression. Exposures must be carefully managed as some physical agents can kill within quite short periods.

Before exposure to hot, cold, or hyperbaric environments it is important to ensure that individuals have no predisposition to suffer from the effects of the environment. Fitness standards may be available, published by a variety of agencies. For ionising radiation it is important to know that individuals are medically fit for the type of work that they are expected to perform. (They may need to wear protective equipment—for example.)

Heat

Regulation of the central (core) body temperature is an essential physiological function—core temperature must be within the range 36–38°C for the body to perform efficiently. In the face of heat gain from the environment or as a result of exercise, the body defends the core temperature by vasodilatation (increasing skin blood flow) and by sweating.

If heat gain is greater than heat loss by the evaporation of sweat, convective cooling, and thermal radiation, then the body stores heat. As it does so, the temperature of the brain and central organs (such as the liver)—the core temperature—increases and this threatens the survival of the individual. Eventually external cooling must be provided to prevent death. Heat hyperpyrexia (heat stroke) is the most serious effect of exposure to heat. It is generally characterised by a body

The effects of physical agents have been well studied, and for many of these exposure criteria are now established at an international level. Fatalities are only likely to occur where established safety procedures are broken

Authorities that set exposure standards for physical agents

- International Standards Organisation (ISO)
 - American Conference of Governmental Industrial Hygienists (ACGIH)
 - International Commission on Radiological Protection (ICRP)
 - International Commission on Non-Ionising Radiation Protection (ICNIRP)
 - Other national, transnational, and international authorities
-

The principles of managing work in hot environments

- An assessment of the risk should be undertaken and ways sought to reduce the environmental heat load, paying attention to humidity and radiant heat, as well as air temperature
 - Individuals should be screened for medical conditions that may predispose to heat illness, and should be physically fit, well hydrated, and ideally below 40 years of age
 - Work-rest regimes should be established from published standards and adhered to, with regular opportunities taken for the worker to cool down
 - Workers should be educated about heat illnesses, and first aid facilities should be available
 - In planning work, the state of acclimatisation of the workers and the resistance to heat loss provided by their clothing has to be taken into account
-

Heat acclimatisation increases the magnitude of these responses. Any factor that impairs either the circulation or the ability to sweat will compromise thermoregulation

temperature of 40–41°C, an altered level of consciousness, and a hot dry skin resulting from failure of the sweating mechanism. These features are not invariable, however, so treatment should not be delayed if heat stroke is suspected.

Heat exhaustion results from a combination of thermal and cardiovascular strain. The individual is tired and may stumble, and has a rapid pulse and respiration rate. The condition may develop into heat stroke if not treated by rest, cooling, and fluids. Other effects are heat syncope (fainting), heat oedema, (often in the unacclimatised), heat cramps, and heat rash (prickly heat). Working in high temperatures can also result in fatigue and an increased risk of accidents.

Workers in fire and rescue services may be exposed to extreme heat in an unpredictable manner. Their safety depends on proper selection, training, and monitoring of the duration of exposure. Personal heat stress monitors are not yet widely available, but their use in these circumstances may confer some benefit.

Cold

In cold conditions the problem is to balance heat produced by physical activity with heat lost to the environment. The rate of heat loss depends on the insulation of the clothing and the external climate, including air temperature and wind velocity. The windchill index (derived in units of kcal/m²/hour) relates to the risk of freezing of superficial tissues, and this, or the related chilling temperature (expressed in °C), is quite widely used as a measure of the discomfort of cold conditions.

The insulation of clothing may be impaired by moisture in the form of condensed sweat or by precipitation. Protection is generally easier in cold dry environments such as mountains or arctic regions than in cold wet conditions. The protection of individuals who are active in cold wet environments, and who need waterproof external garments, is only partly solved by the introduction of “breathable” fabrics. A particular problem occurs in those environments where there is a risk of immersion in cold water, with resulting catastrophic loss of insulation. Where this risk can be anticipated—for example, in helicopter flights over water, protective immersion suits should be used.

Large numbers of workers are employed indoors in conditions of moderate to severe cold, mostly in food preparation and storage. Only a few people are exposed to cold in scientific and testing laboratories. Cold stores can operate at temperatures as low as –30°C. Workers in cold stores must be provided with proper insulated clothing, and they must have regular breaks in warm conditions. A major problem in severe cold, indoors or outside, is to keep the hands and feet warm. The necessary insulation is bulky, which is less of a problem for footwear than for hand wear. Mitts provide better thermal protection than gloves, but limit dexterity.

Indoors, in moderately cold conditions—that is, temperatures below 15°C, it may also be hard to maintain comfort of the extremities, and exposure to draughts can be particularly troublesome. Limited evidence indicates that workers regularly exposed to cold conditions such as these may have worse than average general health.

Serious hypothermia should not occur in occupational settings. If there is a risk, people should not work alone, should have good communications with others, and should be trained in first aid management of the effects of cold. Hypothermia is treated by slow rewarming using the individual’s own metabolism, and copious insulation, possibly supplemented by body heat from another person.

Groups of people at risk from heat illness

- Unacclimatised workers in the tropics
 - Workers in hot industries who have had a break from exposure
 - Workers with an intercurrent illness
 - Workers in the emergency services—for example, fire or mines rescue
 - People undertaking very heavy physical activity—for example, military recruits
 - People working even moderately hard at normal temperatures in all enveloping protective clothing—for example, fire crews dealing with chemical spills
 - Older people and the very young when ambient temperatures are raised for prolonged periods
-

The wet bulb globe temperature

- The wet bulb globe temperature (WBGT) index is an index of heat stress. It is derived from the natural wet bulb temperature (WB), the dry bulb temperature (DB), and the globe temperature (GT) (a measure of radiant heating) in the ratio:

$$WBGT = 0.7WB + 0.2GT + 0.1DB$$
 - The WBGT index is measured using a “Christmas tree” array of thermometers, or purpose built electronic sensors and integrating apparatus
 - The index was originally derived to protect troops exercising outdoors by relating environmental conditions to the risk of heat illness. It has since been developed and used extensively in industry and is the basis for International Standard 7243 and guidance by the ACGIH. These documents give upper boundaries of WBGT value for continuous and intermittent work of different intensities. Other standards apply in relation to thermal comfort—for example, ISO 7730
-

Heat stroke

Heat stroke is a medical emergency. The body temperature should be lowered by tepid sponging and fanning with cool air.

Intravenous fluids may be necessary. The following may predispose to heat exhaustion and heat stroke:

- Obesity
 - Lack of fitness
 - Age 50 years or more
 - Drug or alcohol abuse
 - History of heat illness
 - Drug treatment (for example, antihistamines, tricyclic antidepressants, or antipsychotics)
 - Pre-existing disease of cardiovascular system, skin, gastrointestinal tract, or renal system
-

Frostbite in an outdoor worker

The peripheral effects of cold are frost nip, frost bite, and non-freezing cold injury. Frost nip appears as a white area on the skin, and in frost bite the appearance is of marbled white frozen tissue that is anaesthetic to touch. Treatment is by slow rewarming, often using body heat. Non-freezing cold injury often does not manifest until exposure to cold ceases, and it results in warm painful swollen extremities, usually the feet. Chilblains are a minor form of cold injury.

Ionising radiation

Ionising radiation displaces electrons from their normal orbits around the nucleus of the atom. The resulting ionisation alters the nature of biological molecules, especially DNA, resulting in gene mutation or cell death. α Small particles are relatively large and easily stopped. β Small particles are small and can penetrate up to a centimetre in tissue. Neutrons are smaller than α particles but are much more penetrating. γ Small radiation and x rays are packets of energy transmitted as electromagnetic radiation, and are highly penetrating.

External irradiation is that arising from a source—either a radiation generator, such as an x ray machine, or a radioactive substance—that is separate from the body. The irradiation ceases when the generator is switched off or the source is moved away or shielded. The body can be *contaminated* by particles of radioactive material that lie on the skin externally or are incorporated into the tissues, resulting in *internal* irradiation. The latter will persist as long as the radioactive material is in the body. Alpha emitters such as plutonium are particularly harmful sources of internal irradiation.

Large doses of ionising radiation cause death by damage to the brain, gut, and haemopoietic system. Such exposures only occur in the event of accidents or deliberate release in nuclear warfare. Lower doses can damage the skin or the lens of the eye. This may occur if sources are mishandled or exposures are prolonged—for example, in industrial radiography or interventional radiography. The *direct* effects of radiation are considered to have a dose threshold for their occurrence, and the severity of the effect is related to the dose received.

The *stochastic* effects of radiation (including the induction of cancer and hereditary effects) do not have a threshold, and the likelihood of the effect is related to the dose. Risk estimates for the stochastic effects of radiation have been derived from epidemiological studies (cancer) and animal studies (hereditary effects). The most important epidemiological data are from the Life Span Study of survivors of the atom bombs used in 1945. The risk estimates are published by a number of bodies of which the ICRP is the most influential. The ICRP also publishes dose limits derived from the risk estimates, and these are the basis of the statutory dose limits applied in many countries. Risk estimates and dose limits are regularly updated as the underlying science develops.

Workers who are substantially exposed to ionising radiation are subject to regular medical surveillance. This is to ensure that they are fit for their proposed work with radiation—for example, the need to work with unsealed sources or to use respiratory protective equipment. They are also subject to dose monitoring. Exposure to ionising radiation should be as low as reasonably practicable (ALARP) by the provision of appropriate controls, including shielding and reduction of exposure time. As legislative controls have been tightened, so the typical exposure to ionising radiation of workers has fallen. In the United Kingdom, average annual occupational doses are 1-2 millisieverts per year (about the same as background radiation).

Conditions that preclude work in moderate to severe cold

- History of ischaemic heart disease
 - Peripheral vascular disease
 - Hypertension or Raynaud's phenomenon
 - Asthma
 - Metabolic disorders
 - Sickle cell disease
 - Arthritis
-

Doses and units of radiation

- Absorbed dose—the energy of ionising radiation a body absorbs, measured in gray
 - Dose equivalent—an adjustment of the absorbed dose, using a quality factor for the type of radiation involved, to take account of the effectiveness of the different types of radiations in harming biological systems; measured in sieverts
 - Effective dose—an integrated index of the risk of harm, derived by multiplying the dose equivalent for each of the major tissues by a weighting factor based on the tissue's sensitivity to harm by radiation. The weighted values are summed. The unit is the sievert
-

The probabilities of harm from exposure to ionising radiation derived by the ICRP

Values are expressed as percentage risk per sievert dose received (the values in the table are multiplied by 10^{-2}Sv^{-1} to give the actual risk)

	Whole population	Working population
Fatal cancers	5	4
Hereditary disorders	1	0.6
Total risk	6	4.6

The ICRP recommends an effective dose limit of 20 mSv (averaged over a defined five year period) for workers, and 1 mSv per year for the public. Limits are also set for exposure of the eye lens, the skin, and the hands and feet. The dose limit for the fetus is the same as the public dose limit of 1 mSv a year

Studies of large cohorts of workers occupationally exposed to radiation consistently show a healthy worker effect. Nevertheless, cases of cancer of types known to be produced by ionising radiation do occur in these populations, sometimes with a slight excess. Individuals may be compensated for such disease on the basis of presumption of origin or probability of causation.

Electromagnetic fields

Electromagnetic fields with wavelengths shorter than 0.1 mm—that is, ultraviolet and below, contain insufficient energy to break molecular bonds and so do not result in ionisation. This “non-ionising radiation” does, however, have other frequency dependent effects on biological tissues. Broad divisions of this radiation include microwave and radio frequency radiation, as well as extremely low frequency, which includes the frequencies of power distribution.

At high frequencies—for example, microwaves used in communication systems—the main effect is tissue heating, a phenomenon made use of in the microwave oven. This effect is quantified by the specific absorption rate of energy into the body, and in most situations there are unlikely to be ill effects. This might not be the case where the individual is also working hard, or is exposed to a hot environment. At lower frequencies the effects of electric and magnetic fields are considered separately. Exposure to magnetic fields can set up circulating currents within the body, which have the potential to interfere with physiological processes if sufficiently great. For example, muscle activation could potentially occur during magnetic resonance imaging. Low frequency electric fields do not penetrate the body, but can generate charges on the body surface.

Other recognised but rarer effects include the phenomenon of microwave hearing. Some people hear repeated clicks when exposed to pulsed sources of electromagnetic fields, usually radars. A visual illusion of flickering lights (magnetophosphenes) can be produced when the retina is exposed to intense magnetic fields. Exposure standards, which reflect the frequency dependence of effects, have been derived to protect against the established effects of electromagnetic fields.

Since the late 1970s there has been increasing public concern about exposure to electromagnetic fields. This was prompted by epidemiological studies of the association between childhood cancer and residential exposure to magnetic fields. In 2001 the International Agency for Research on Cancer concluded that there was limited evidence that residential magnetic fields increase the risk of childhood leukaemia, resulting in a classification of “2B” “possibly carcinogenic” for extremely low frequency magnetic fields. It is thought that any risk relates to those exposed to fields at or above 0.4 microtesla, which are relatively large. The UK Childhood Cancer Study (UKCCS), the world’s largest case control study on the causes of childhood cancer, found no evidence to support the association between residential magnetic field exposure and childhood leukaemia or other cancers. Any real effects must be very small in magnitude.

Public concern also extends to the possible effects of exposure to electromagnetic fields from mobile phone hand sets and base stations. In the United Kingdom an independent expert group was commissioned to study the evidence in relation to mobile phone technology. This group concluded that exposure to radio frequency radiation below the ICNIRP guidelines did not adversely affect population health, but in

Typical magnetic and electrical fields

Typical magnetic fields

- Natural fields—70 microtesla (static)
- Mains power—200 nanotesla (if not close to power lines), 20 microtesla (beneath power lines)
- Electric trains—50 microtesla
- Cathode ray tubes—700 nanotesla (alternating)

Typical electric fields

- Natural fields—200 V/m (static)
 - Mains power—100 V/m (in homes), 10 kV/m (under large power lines)
 - Electric trains—300 V/m
 - Cathode ray tubes—10 V/m (alternating), 15 kV/m (static)
-

ICNIRP 1998 Exposure guidelines to time varying electric and magnetic fields

- These specify basic restrictions in terms of current density for the head and trunk, whole body and localised specific absorption rates, and power density
 - Reference levels below which the basic restrictions are unlikely to be exceeded are specified in terms of electric field strength (E), magnetic field strength (H), magnetic flux density (B), and power density (S). These are given separately for occupational exposure and for the general public, with lower values for the latter. Reference levels are also given for contact currents from conductive objects and for induced current in any limb
-

Exposure from mobile phones and base stations

- Public exposures from base stations are low; typical power densities have been measured as 1 mW/m², with maximum power densities of 10 mW/m²
 - For comparison, the ICNIRP public exposure guidelines are a power density of 4.5 W/m² at 900 MHz and 9 W/m² at 1.8 GHz
 - Power densities can exceed guidelines very close to the antenna, and for this reason public access to these antennae has to be controlled
 - Hand sets can generate power densities of up to 200 W/m², but the resulting fields inside the body are appreciably less than those measured externally
-

Units for electromagnetic fields

- Electric field strength (E)—volts per metre
 - Magnetic field strength (H)—amps per metre
 - Power density (S) (vector product of E and H)—watts per square metre
 - Magnetic flux density (B)—Tesla (1 Tesla is about equal to 10 000 Gauss)
-

view of other biological evidence it concluded that it was not possible to say that exposures below current guidelines were totally without potential adverse health effects. The group therefore advocated a precautionary approach in the use of this technology—for example,, suggesting that the use of mobile phones by children for non-essential calls should be discouraged.

There is no evidence that exposure to electromagnetic fields from the use of display screen equipment has any harmful effects.

Optical radiations

Optical radiation comprises ultraviolet, visible, and infrared radiation, which have wavelengths between 100 nm and 1 mm. Their harmful effects are largely restricted to the skin and the eye. Ultraviolet radiation is implicated in non-melanoma and melanoma cancers. Outdoor workers—for example, farmers and the deck crews of ships—have an increased risk of non-melanoma cancer. Fortunately this is usually curable. As a sensible precaution, all those who work outdoors should avoid overexposure of the bare skin to sunlight and sunburn in order to reduce their risk of melanoma cancer. Some evidence suggests that exposure to ultraviolet radiation can impair the function of the immune system.

Ultraviolet radiation is responsible for the painful symptoms of arc eye (photokeratoconjunctivitis), which occurs some hours after exposure to a bright source of ultraviolet radiation such as a welding arc. Often, bystanders who are adventitiously exposed get this condition.

Infrared radiation can cause thermal damage to the skin and eyes, both of which are easily protected, the latter with appropriate goggles. In developed countries occupational cataract from exposure to infrared radiation is largely of historical interest, given proper protection. In developing countries, however, cataracts may occur as a result of overexposure to infrared radiation, possibly exacerbated by episodes of dehydration.

Sources of optical radiation where the light waves are in phase (for example, from lasers) can cause serious thermal damage to the retina, and skin burns. Engineering and administrative controls and personal protection are needed to prevent damage where high powered lasers are in use. Routine eye examination is not appropriate for laser workers, although a baseline assessment of visual acuity is useful to identify the functionally monocular individual, for whom a greater duty of care exists.

If unusual skin symptoms are reported in workers exposed to optical radiation the possibility of photosensitisation should be considered, as can occur with exposure to plant products—for example, psoralens released in parsley cutting. Photosensitisation can also occur from certain drugs. If workers complain of “sunburn” from working in the vicinity of ultraviolet sources such as insect killing lamps, it is important to check that the bulbs have the correct frequency spectrum.

Altered ambient pressure

Compressed air is used in civil engineering to stabilise the ground and to remove water from workings. Alternative methods of doing so are available, and should always be considered before opting to use compressed air. The effects of hyperbaric exposure in diving and compressed air work are different. Surface diving usually entails short exposures to high pressures, whereas compressed air work generally entails

Possible effects of optical radiation on the eye

- Ultraviolet C/B—arc eye
 - Ultraviolet B—pigmentation of lens
 - Ultraviolet A—retinal damage in aphakia
 - Visible—accelerated ageing (high power sources), burns of retina (lasers)
 - Infrared—corneal burns, usually prevented by blink reflex, cataract, retinal burns, from infrared A sources including lasers
-

Wavelengths of optical radiation

- Ultraviolet C (UVC)—100-280 nm
 - Ultraviolet B (UVB)—280-315 nm
 - Ultraviolet A (UVA)—315-400 nm
 - Visible—400-760 nm
 - Infrared—760 nm – 1 mm
-

The most potent sources of optical radiation are those in which the light waves are coherent or in phase, typically coming from laser sources

Working at pressure

- Atmospheric pressure is 14.7 psi
 - 1 atmosphere, 1 bar, 10 m (or 33 feet) of sea water, are broadly equivalent pressures
 - Absolute pressure is that of the working environment added to atmospheric pressure
 - Decompression illness is very rare at pressures below 1.7 bar absolute. There is no risk from slight elevations of pressure such as in clean rooms
 - Typical pressures experienced in civil engineering works are in the range 2-3.5 bar absolute
 - Saturation diving techniques become necessary at depths below 50 m, 6 bar absolute
-

prolonged exposures at relatively low pressures. In diving, the physical effort required for the task may be limited, often using only the arms, whereas heavy manual work may be undertaken in compressed air work.

One effect that differs little in either situation is barotrauma—damage to an air containing organ by pressure exerted across a structure, typically in the ear or respiratory tract. Individuals exposed to raised pressures must be able to equalise such pressures—for example, by steady exhalation, during ascent from diving. The risk of barotrauma is minimised by excluding individuals with upper respiratory tract infections and by careful control of the rate of change of pressure during compression and decompression.

Decompression illness and osteonecrosis

More serious health effects are decompression illness and osteonecrosis. Under pressure, inert gas (principally nitrogen) dissolves in the tissues. When the pressure is reduced, this gas will come out of solution and form bubbles, in much the same way that bubbles form when pressure on carbonated drinks is released. These bubbles in turn cause effects which, if they are in the circulation or central nervous system, can be life threatening.

Decompression illness occurs in two types: pain only (previously type 1), in which symptoms occur in the skin (niggles) or around joints (bends), and serious (previously type 2), in which symptoms can occur in the circulation or nervous system. Symptoms can arise from gas bubbles in the pulmonary or coronary circulations (for example, the chokes), or from damage to the brain or spinal cord (for example, the staggers). Serious decompression illness can be life threatening.

To reduce the potential for bubble formation during decompression, pressure is reduced in a controlled, staged manner, the details of which depend on the duration and pressure of the preceding hyperbaric exposure. At its simplest this can be achieved by a series of timed stops at specified depths during ascent to the surface.

Decompression regimens inevitably entail a compromise between the long times needed for nitrogen to evolve from the tissues and the practical constraints arising from keeping a group of workers (in the case of civil engineering work) in the decompression chamber for long periods. The decompression chamber is an airlock between the working chamber and the external environment. Workers remain seated, resting, while the ambient pressure is reduced in a controlled fashion over one or more hours. Breathing oxygen during decompression helps to remove nitrogen from the body and shortens decompression times. As exposures increase in terms of both depth and time, longer decompression periods are required. At some of the higher pressures encountered in diving, the only practical approach is to adopt saturation methods, where individuals live and work under pressure for long periods, avoiding the need to decompress between working exposures.

With careful control of decompression and oxygen breathing, the incidence of decompression illness in offshore diving work has been kept very low. Further advances are needed in civil engineering work, where oxygen decompression is not yet always routine.

When decompression illness occurs it should always be treated by therapeutic recompression, as such events increase the risk of osteonecrosis. This serious complication of hyperbaric work results from compromise of the blood flow within bone structures. A section of normal bone dies and is replaced by softer material. If this occurs below the surface of a joint, such as the hip joint, there is a real risk of the joint surface collapsing, resulting in permanent disability.

Guidance on exposures, and international standards

- ICNIRP. Guidelines for limiting exposure to time-varying electric, magnetic, and electromagnetic fields (up to 300 GHz). *Health Phys* 1998;74:494-522
- ICRP. 1990 *Recommendations of the international commission on radiological protection*. Annals of the ICRP 21,1-3. Oxford: Pergamon Press, 1991
- International Standards Organisation. *Hot environments—estimation of the heat stress on working man, based on the WBGT index (wet bulb globe temperature)*. Geneva: ISO, 1989 (ISO 7243)
- International Standards Organisation. *Moderate thermal environments—determination of the PMV and PPD indices and specification of the conditions for thermal comfort*. Geneva: ISO, 1993 (ISO 7730)
- International Standards Organisation. *Ergonomics of the thermal environment—Medical supervision of individuals exposed to extreme hot or cold thermal environments*. Geneva: ISO, 2001 (ISO 12894)

Risk factors for osteonecrosis are not clearly established. It can occur after one "bad" decompression but is normally seen only after higher pressure exposures. Risk factors in compressed air work include the number of hyperbaric exposures and the number of episodes of decompression illness.

Barotrauma and decompression illness may occur in aviation environments. They are most likely to occur if an aircraft pressurisation system fails at an altitude above 20 000 feet, after a high altitude ejection, or after flight at altitude in an unpressurised aircraft. The risks can be minimised by breathing 100% oxygen (denitrogenation) before flights or training exposures in an altitude chamber carrying a risk of decompression illness. Osteonecrosis after decompression in aviation is exceedingly rare.

Living and working at altitude

Living and working at altitude carries different risks—namely, acute mountain sickness, high altitude pulmonary oedema (HAPE), and high altitude cerebral oedema (HACE). Symptoms of acute mountain sickness can occur at altitudes of 2500 m, with the prevalence reaching 40% at altitudes over 4000 m. The symptoms include headache, nausea and vomiting, sleep disturbance, and muscle weakness, and are thought to arise from a mild oedema of the lungs, the splanchnic circulation, and the brain. The condition is treated by descent to a lower altitude. Breathing oxygen, and taking acetazolamide and dexamethasone can also help. The main preventive measure is to limit the rate of ascent to altitude. Unlike acute mountain sickness, both high altitude pulmonary oedema and high altitude cerebral oedema are life threatening. The former is treated by descent and the use of oxygen.

People who live at high altitude show physiological adaptations to their environment, although even these may fail with time. Chronic mountain sickness (Monge's disease) is a loss of tolerance to hypoxia, which occurs particularly in middle aged men. It results in an erythropoiesis, with the haematocrit rising as high as 80%. Clinical effects include cyanosis, dyspnoea, cough, palpitations, and headache. The condition can only be alleviated by moving to a lower altitude.

Acceleration

Exposure to sustained acceleration is experienced on fairground rides (2-3 G) or in flight, and then only significantly in aerobatic or military flying. Radial acceleration occurs during banked turns. When the head is to the inside of the turn the acceleration is positive in the "z" axis. With the head on the outside of the turn the acceleration is negative in the same axis. Positive G increases the hydrostatic weight of the column of blood above the heart, reducing arterial pressure and perfusion of the retina and the brain. Negative G has the opposite effect, increasing arterial pressure and resulting in engorgement of the head and neck

Protection from positive G is provided by posture, keeping the body nearer the horizontal plane than the vertical, by lifting the legs up and lowering the backrest. Valsalva type manoeuvres are used slightly in anticipation of acceleration to increase the pressure in the arterial system, and protective anti-G suits are routinely worn by military pilots. These prevent pooling of blood in the peripheries and limit the descent of the heart and diaphragm under acceleration

Effects of positive headwards acceleration

- 3-4 G—darkening of visual fields
- 3.5-4.5 G—loss of peripheral vision
- 5-6 G—loss of consciousness

If the rate of onset of acceleration is high, loss of consciousness will be the first symptom

12 Noise and vibration

Paul Litchfield

Sound is generated when a vibrating source transmits energy to the surrounding air, creating small changes in pressure. If the frequency of the sound produced lies between about 20 and 16000 Hz it may be perceived by the hearing mechanism and is classed as being “audible.” Sound levels are measured in decibels (dB), a logarithmic unit in which the faintest sound detectable by the human ear is set at 0 and the level doubles for every 3 dB. In assessing audible sound it is conventional to use a weighted scale that filters the actual pressure level in specified octave bands by an agreed amount to resemble the response of the ear over those frequencies. The most commonly used weighting is the “A” network, and resultant units are expressed as dB(A). Noise is simply unwanted sound.

The body is also susceptible to non-acoustic vibration transmitted by direct contact with oscillating surfaces. As with sound, frequency is important: vibration below 2 Hz and above 1500 Hz is not thought to be harmful; motion between 5 Hz and 20 Hz is considered potentially most damaging. Vibration can be measured in various ways, but is normally expressed as acceleration in metres per second squared (m/s^2) averaged over the three axes. As vibration at frequencies below 2 Hz and above 1500 Hz is not thought to cause damage, weighting is applied to measurements of vibration magnitude to allow for this frequency dependence of the risk of harm.

Health effects of noise

The principal hazard from noise is impairment of hearing. This may be confined to a reversible alteration in hearing levels, known as temporary threshold shift, which resolves spontaneously in the quiet. It may last from a few minutes to months depending on the noise level encountered. If exposure to high noise levels is sustained for a prolonged period a permanent shift can occur, termed noise induced hearing loss. Short bursts of very high intensity sound (such as an explosion or gunfire), known as impulse noise, can also cause additional harm to the ear by rupturing the tympanic membrane or even disrupting the ossicles.

There has been considerable interest in recent years in the non-auditory effects of noise. Comprehensive literature reviews

Non-auditory health and physiological effects of noise

- *Cardiovascular effects:* in laboratory studies, noise has been shown to produce increases in diastolic blood pressure. However, there is no clear evidence that long term exposure to noise is a risk factor for hypertension
- Some studies suggested an association between noise exposure or noise annoyance and the frequency of *psychiatric symptoms* but these findings have been questioned in later studies. There is some evidence that noise sensitivity is an indicator of vulnerability to minor psychiatric disorder, and that annoyance responses are stronger among individuals with psychiatric disorders
- The effect of noise on *performance* is complex. Some research found no clear evidence of effects at noise levels below 95 dB, whereas other research suggests that performance may be affected at much lower levels
- *Fatigue, headaches, and irritability* have been found to be over-represented in groups exposed to noise, but methodological flaws in study design have made valid conclusions difficult

The human ear is more sensitive to certain frequencies, and in order to approximate the response of the ear it is possible to suppress certain frequencies and boost others in the electronic circuitry of sound level meters. This technique is known as “weighting,” and the most commonly quoted weighting network is the A weighting

Vibration is usually measured in three orthogonal directions at the interfaces between the body and the vibrating surface

Range of instruments for measuring noise and vibration levels

have been published, but much of the evidence remains weak or equivocal.

Noise induced hearing loss

Noise induced hearing loss is caused by damage to the cilia on the basilar membrane in the organ of Corti in the inner ear. This damage is progressive and irreversible and results in loss of both absolute sensitivity of the ear and in frequency selectivity. Characteristically, loss is initially predominant in the higher frequencies (3-6 kHz) and classically, a depression at 4 kHz may be seen on audiometry. With continuing exposure hearing loss extends to both higher and lower frequencies and is frequently superimposed on the effects of age related hearing loss, also known as presbycusis.

The development of noise induced hearing loss is insidious, and deafness may be considerable by the time an individual seeks assistance. Initially those affected describe difficulty in hearing conversations against a noisy background. Because consonants have a higher frequency than vowels, they are more difficult for a person with noise deafness to recognise, with resultant degradation of discrimination of speech. Hearing loss is frequently associated with tinnitus, which may be more disabling than deafness. On examination, the tympanic membranes usually seem normal, but testing with a tuning fork shows a sensorineural deafness. Industrial noise usually gives rise to bilateral hearing loss but specific activities, such as use of firearms, may produce unilateral deafness depending on the location of the noise source in relation to the ears. Audiometry shows a hearing loss that is predominantly high frequency, although in severe cases lower frequencies are affected. This latter case produces far greater disability because of the impact on the speech range (0.5-2.0 kHz).

Noise induced hearing loss is common. Data from the UK National Household Survey indicate that in excess of 130000 people have hearing problems arising from noise at work, and the Occupational Safety and Health Administration estimates that there are 10 million people with similar hearing problems in the United States. Manufacturing industry has been the source of most cases in the past, but noise levels can be high for those working in many other sectors including construction, transport, and the armed forces. More recently, concern has been raised in relation to call centre operatives, but any potential problems seem to relate to extraneous noises received through headsets (acoustic shock) rather than to ambient noise levels.

Risk management

Noise induced hearing loss is a preventable condition and, as with any hazard, the first step is to assess the risk. As a general guide, noise levels are likely to be hazardous if communication without shouting is difficult at a distance of two metres. If there is reason to believe that there may be a problem then noise levels should be measured by a competent person. The risk of developing noise induced hearing loss is a function of both the level of noise exposure and its duration. Noise levels are therefore often expressed as daily personal noise exposure (L_{EP,d}), which averages the dose over an eight hour working day. L_{EP,d} action levels of 85 dB(A) and 90 dB(A) have been set in both the United States and European Union, above which certain control measures are mandatory. However, at the time of writing, negotiations are far advanced in Europe for a new Noise Directive, which will replace the existing directive (86/188/EC, implemented in the United Kingdom by the Noise at Work Regulations 1989) with tougher legislation that will reduce the action levels to 80 dB(A) and 85 dB(A), and introduce a limit value on exposure of 87 dB(A).

The best means of hazard control is elimination, and machinery noise can often be reduced substantially by better

Audiogram showing noise induced hearing loss with classical depression at 4 kHz

Noise induced hearing loss in the United Kingdom (adapted from Health and Safety Executive statistics 2000-1)

- UK Health and Safety Executive statistics are obtained from a variety of sources, including the occupational physicians reporting activities (OPRA), occupational surveillance scheme for audiologists (OSSA), and industrial injuries scheme (prescribed diseases)
- The industry groups with the highest annual average incidence rates of new cases qualifying for benefit were extraction, energy, and water supply (7.9 cases per 100 000 employees), manufacturing (3.9), and construction (2.3) (based on 1999 and 2000 data). Of cases qualifying for benefit, 11% were in shipbuilding, repair, or breaking, and 9% were in the coal mining industry. Of new cases qualifying for benefit in 2000, 52% were in the occupational group of metal machinery and related trades workers
- Noise induced hearing loss is not reportable under the Reporting of Injuries, Diseases and Dangerous Occurrence Regulations 1995 (RIDDOR)

	Number of cases (OSSA/OPRA, estimated for 2000)
Sensorineural hearing loss	627
Tinnitus	161
Balance problems	5
Tympanic disorder	3
Other problems	1
Total	797 (648 individuals)
Prescribed diseases*	226

*To qualify for benefit, there must be at least 50 dB of hearing loss. The degree of disability is calculated from the hearing loss in such a way that 50 dB in both ears equates to 20% disability. Under current guidelines, a worker must have been employed for at least 10 years in specified noisy occupations. Of the almost 2000 disallowed claims in 1998, 800 claimants had 35-49 dB hearing loss

Differential diagnosis of noise induced hearing loss

- Conductive—Wax, acute otitis media, chronic otitis media, otosclerosis, tympanic membrane injury, barotrauma, ossicular dislocation
- Sensorineural—Presbycusis, congenital (maternal rubella, hereditary, perinatal anoxia), infective (measles, mumps, meningitis), vascular (haemorrhage, spasm or thrombosis of cochlear vessels), traumatic (head injury), toxic (streptomycin, neomycin, carbon monoxide, carbon disulphide), Meniere's disease, late otosclerosis, acoustic nerve tumours (usually unilateral)

Main requirements of the UK Noise at Work Regulations 1989

Action required where L EP,d* is likely to be:	<85 dB(A)	85 dB(A) First action level	90 dB(A) Second action level†
Employers' duties			
<i>General duty to reduce risk</i>			
Risk of hearing damage to be reduced to the lowest level reasonably practicable*	√	√	√
<i>Assessment of noise exposure</i>			
• Noise assessments to be made by a competent person		√	√
• Record of assessments to be kept until a new one is made		√	√
<i>Noise reduction</i>			
Reduce exposure to noise as far as is reasonably practicable by means other than ear protectors			√
<i>Provision of information to workers</i>			
• Provide adequate information, instruction, and training about risks to hearing, what employees should do to minimise risk, how they can obtain ear protectors (if they are exposed to an L EP,d between 85 and 90 dB(A)), and their obligations under the Regulations		√	√
• Mark ear protection zones with safety signs, so far as reasonably practicable			√
<i>Ear protectors</i>			
Ensure so far as is practicable that protectors are:			
• Provided to employees exposed to an L EP,d of 85 dB(A) or above and less than 90 dB(A), who ask for them		√	
• Provided to all exposed above the second action level			√
• Maintained and repaired		√	√
• Properly used by all exposed			√
Ensure so far as reasonably practicable that all who go into a marked ear protection zone use ear protectors			√‡
<i>Maintenance and use of noise control equipment</i>			
Ensure so far as is practicable that:			
• All equipment provided under the Regulations is used, except for the ear protectors provided between first action level and second action level	√	√	√
Ensure all equipment is maintained	√	√	√
Employees' duties			
<i>Use of equipment; so far as is practicable:</i>			
• Use ear protectors	√	√	√
• Use any other protective equipment	√	√	√
• Report any defects discovered to employer	√	√	√
Machine makers' and suppliers' duties			
<i>Provision of information</i>			
Provide information on the noise likely to be generated	In theory if equipment provided to comply with*	√	√

*The dB(A) action levels are values of daily personal noise exposure L EP,d.

†All the actions indicated at 90 dB(A) are also required where the peak sound pressure is at or above 200 pascals.

‡This requirement applies to all who enter the zones, even if they do not stay long enough to receive an exposure of 90 dB(A) L EP,d.

design and maintenance. Damping and enclosure of vibrating machinery can greatly reduce exposure, or people can be provided with well insulated noise refuges in otherwise noisy environments. As a last resort, people can be issued with hearing protection: ear muffs (which completely cover the ear), ear plugs (which are inserted into the auditory canal), or semi-inserts (which cover the entrance to the ear canal).

It is important to ensure not only that any ear protection offered provides adequate noise attenuation but also that it does not interfere with any other protective equipment required, and that those using it understand that even short periods of non-use will greatly reduce the protective value.

Health surveillance

Health surveillance (including audiometry), although not a legal requirement, can provide a useful adjunct to risk management and is considered good practice where the second action level (see table) is exceeded. Hearing conservation

Noise hazard sign to indicate that use of hearing protection is mandatory and standard design of ear muffs

programmes will normally include a structured interview to gather relevant health data. This should cover relevant medical history based on the differential diagnosis for noise induced hearing loss, and a history of previous noise exposure such as previous employment in noisy industries, service in the armed forces, and leisure pursuits such as shooting or regular clubbing. The ear canal and tympanic membrane should be examined. Personal protective equipment should be inspected, and workers reminded of its correct use. Audiometric testing should be undertaken in a soundproof booth, and the screening results should be fully discussed, with onward referral if required.

Such programmes aim to identify at an early stage individuals particularly susceptible to noise damage, and to reinforce hazard information together with the use of control measures. The UK Health and Safety Executive has produced comprehensive guidelines on the conduct of audiometric testing programmes, including a helpful categorisation scheme that provides a template for the management of individuals according to the degree of hearing loss identified. The five categories within the scheme and the suggested action for each, and a chart of age related hearing loss at low and high frequencies are given in the two tables.

Classification of audiograms into warning and referral levels

Age in years	Sum of hearing levels			
	0.5, 1, 2 kHz		3, 4, 6 kHz	
	Warning level	Referral level	Warning level	Referral level
20-24	45	60	45	75
25-29	45	66	45	87
30-34	45	72	45	99
35-39	48	78	54	111
40-44	51	84	60	123
45-49	54	90	66	135
50-54	57	90	75	144
55-59	60	90	87	144
60-64	65	90	100	144
65	70	90	115	144

The Health and Safety Executive categorisation scheme

Category	Symptom	Suggested action
1	Rapid change in hearing threshold has occurred (that is, a change in the sum of the hearing levels for either the low or high frequencies of 30 dB, compared with the previous audiogram, or 45 dB if the period between the tests is more than three years). This change may be due to noise exposure or disease	Referral
2	This is usually related to medical factors. Unilateral hearing loss is not normally noise induced and may indicate auditory nerve disease. Unilateral hearing loss is considered to exist if the difference in the sums of the hearing levels between the two ears exceeds 45 dB for the low frequencies, or 60 dB for the high frequencies	Referral
3	Results show a pattern that could suggest significant noise inducing hearing loss (that is, where the sum of either the low or high frequencies, or both, in either ear, exceeds the value given for the appropriate age band)	Referral
4	Hearing has deteriorated beyond the level that might be accounted for by age alone, but not to the extent that medical referral is required	Warning. Formally notify the employee of the presence of hearing damage. Employee to understand that they have suffered some hearing loss; it is essential that they comply with the employer's hearing conservation measures. Assess rate of progression of hearing loss
5	Within normal limits	None, but assess rate of progression of hearing loss

Health effects of vibration

Vibration and noise often emanate from the same source. Vibration may reach the body through a number of pathways, but consideration of adverse health effects centres on whole body vibration and hand arm vibration. As with noise, the risk of harm is a function of both the magnitude of exposure and of its duration: "doses" are therefore adjusted to a standard reference period of eight hours to allow comparison, and this figure is termed A(8). Measuring vibration is complex and should only be undertaken by those with specialist training.

Whole body vibration

Interest in the effects of whole body vibration stems from the middle of the 20th century when mechanisation, particularly of transport, became more prevalent. Vibration is transmitted either from a machine platform through the feet, or from a

Use of a vibrating tool for road breaking

seat through the buttocks. Exposure is most likely to occur with vehicle use and this includes road, off road, rail, air, and maritime use: it is estimated that as many as 9 million people in the United Kingdom are regularly exposed to whole body vibration. The disorders reported in groups exposed in this way include gastric problems, vestibular dysfunction, circulatory changes, menstrual disturbance, and psychological effects. However, the main problem associated with whole body vibration is back pain, and the UK Health and Safety Executive estimates that up to 21 000 cases may be caused by exposure, with a further 13 500-31 500 cases of exacerbation of a pre-existing condition. The evidence base for a causal link between whole body vibration and back pain nevertheless remains weak, and has recently been comprehensively reviewed.

Hand arm vibration

Vibration may be transmitted to the hands and arms by the use of hand held power tools, hand guided machinery, or by holding materials being processed by machines. Exposure is particularly common in agriculture, construction (particularly scabbling), mining, engineering, forestry, public utilities, and shipbuilding. It is estimated that about 1 million people in the United Kingdom are exposed to potentially harmful levels of hand arm vibration in their work, and as many as 300 000 may have developed adverse health effects as a result.

The health effects of exposure to hand arm vibration have been recognised for many years and have been ascribed a variety of labels. There is now general consensus on the use of the term “hand arm vibration syndrome” to describe the vascular (sometimes also known as vibration white finger), neurological, and musculoskeletal symptoms that can result. Acute vibration exposure causes vasoconstriction of the blood vessels supplying the fingers and, if prolonged, it may damage the endothelium and stimulate smooth muscle proliferation so that the lumen of the vessels gradually narrows. Damage also occurs to the peripheral nerves, with acute oedema and chronic demyelination. Muscular weakness in the hand is common, carpal tunnel syndrome is recognised in some cases, and there is evidence to indicate that premature osteoarthritis of the wrist and elbow may occur. The precise relation between these elements of the syndrome remains a matter for debate, but there is no doubt that the vascular and neurological components can occur separately.

In the early stages of vibration injury the only symptom may be a tingling in the fingers, most noticeable at the end of the working day. This may be associated with a loss of sensation and periodic blanching of the tips of the fingers when exposed to cold. As the condition progresses the blanching extends to the root of the fingers, although the thumbs are rarely affected. In more severe cases there is considerable pain, with a loss of grip strength and dexterity, and attacks may occur even in warm surroundings. Rarely the condition can progress to the extent that circulation is permanently impaired and the fingers become cyanosed—exceptionally, cases of vibration induced gangrene have been reported.

Risk management

Assessment of risk is based on the type of vibrating equipment employed and its pattern of use. In the United Kingdom the action level for introducing preventative measures is if exposure regularly exceeds an A(8) of 2.8 m/s^2 (dominant axis). It is important to recognise that this is not a “safe” level: some individuals are likely to develop hand arm vibrations with prolonged use even if this threshold is not exceeded. A new European Vibration Directive has recently been adapted (to be transferred into UK law in 2005), which sets a limit value

Vibration induced disorders in the United Kingdom

- A UK survey on behalf of the Health and Safety Executive gave an estimate for the national prevalence estimate of vibration white finger (VWF) of 288 000
- The industry with the highest annual average rate of new assessments of disability at 1% in 1999-2000 was extraction, energy, and water supply, because of the relatively high number of claims made by current or former coal miners. Of the new assessments made in other industries, 3% were in shipbuilding, repair, or breaking; 5% were in other manufacturing industry; and 4% in construction
- In 1999-2000, coal mining accounted for 46% of cases for carpal tunnel syndrome, construction for 12%, and shipbuilding, repair, or breaking for 4%

	No of cases*
Raynaud's phenomenon or hand arm vibration or vibration white finger	935
<i>RIDDOR† (2000-1 provisional)</i>	
Carpal tunnel syndrome	119
Hand arm vibration	905
<i>Prescribed diseases (1999-2000)</i>	
Vibration white finger	3212
Carpal tunnel syndrome	475

*Musculoskeletal occupational surveillance scheme (MOSS), reporting by rheumatologists or occupational physicians reporting activities (OPRA), estimated for 2000.

Differential diagnosis

Vascular conditions

- Connective tissue disease—scleroderma, mixed connective tissue disease, systemic lupus erythematosus, rheumatoid arthritis, dermatomyositis, polyarteritis nodosa, Sjogren's disease
- Traumatic—after injury or surgery, hand transmitted vibration, frostbite, thoracic outlet syndrome
- Arterial disease—thromboangitis obliterans, thromboembolism, arteriosclerosis
- Toxins and drugs—vinyl chloride, ergot, β blockers, clonidine
- Dysglobulinaemia—cryoglobulinaemia
- Neurogenic—poliomyelitis, syringomyelia, hemiplegia

Neurological conditions

- Peripheral nerve entrapment—carpal tunnel syndrome, ulnar nerve entrapment at elbow or wrist, thoracic outlet syndrome
- Central nervous system disorders—compression myelopathy (spondylosis or spinal cord tumor), subacute combined degeneration of the cord, multiple sclerosis
- Peripheral neuropathy—diabetic, alcoholic, toxic (for example, organophosphates, thallium, acrylamide, carbon disulphide, *n*-hexane, methyl butyl ketone, diethyl thiocarbamate, lead)
- Drug induced (for example, chloramphenicol, isoniazid, streptomycin, polymyxin, ethambutol, nitrofurantoin, metronidazole, gold, indomethacin, vincristine, perhexiline, phenytoin)

on exposure of 5 m/s^2 (sum of three axes) and an action value of 2.5 m/s^2 (sum of three axes).

Manufacturers of vibrating tools may be able to provide useful data on levels under standard conditions, but care must be taken because actual levels in field use can differ substantially from those generated in a controlled environment. Similarly, field measurements can vary widely depending on mode of use and the materials being worked. In practice it is therefore usual to institute a preventive programme wherever there is prolonged use of tools likely to be hazardous.

Prevention programmes aim to eliminate or substitute the hazardous process where possible. Where this is not possible, the procurement of low vibration machinery, fitting of vibration reducing adaptations (such as vibration reducing handles), regular maintenance and re-engineering of processes to avoid the need for prolonged tight gripping of high vibration parts will reduce exposure. Keeping the hands and body warm helps to maintain a good blood supply to the fingers and thereby reduces the risk of injury. Vibration reducing gloves are available but their efficacy is limited. A key element in a preventive programme is the provision of training and information about the hazard and the means of reducing risk.

Health surveillance

Health surveillance aims to identify those who develop early symptoms so that progression can be avoided and it is appropriate if exposure levels are likely to trigger a prevention programme. Pre-employment screening is helpful in identifying individuals with conditions such as Raynaud’s disease that are a contraindication to work with vibrating tools, in establishing baseline measurements, and in educating workers about measures to minimise risk—not least the avoidance of smoking. It is good practice to repeat the assessment for newly exposed workers to identify those who may be particularly susceptible. Thereafter, annual review is recommended, with any symptoms being reported to a designated person as soon as they occur.

Assessment should comprise a structured history and relevant clinical examination that will identify early hand arm vibration syndrome and assist with differential diagnosis, as a number of constitutional conditions give rise to similar symptoms. Guidelines from the UK Health and Safety Executive (see Further reading) give a sample questionnaire and guidance on tests that may be helpful for examination. Various methods of grading signs and symptoms have been devised and those of Taylor and Pelmear, and Griffin have been widely used. However, the most commonly used system of classification for hand arm vibration syndrome is currently the Stockholm Workshop scale, which grades the vascular and sensorineural components by severity. This scale, and the speed of progression along it, can helpfully be used to guide the management of affected workers. No effective treatment is available for this condition: management relies on adjustments to work, and limitation of vibration exposure. Cessation of vibration exposure may well compromise an individual’s continuing employment, and great care is therefore required before making any such recommendation. A number of additional test measurements (detailed Lindsell CJ and Griffin MJ, 1988) can be carried out by specialist centres to help confirm the degree of incapacity, and referral should be considered in such circumstances.

The photographs showing the range of instruments for measuring noise and vibration and showing a vibrating tool for road breaking are courtesy of Castle Instruments. The figure showing how vibration is measured is adapted from HS(G)88.

Vibration induced gangrene

Stockholm workshop classification

Vascular component		
Stage	Grade	Description
0		No attacks
1V	Mild	Occasional attacks affecting only the tips of one or more fingers
2V	Moderate	Occasional attacks affecting distal and middle (rarely also proximal) phalanges of one or more fingers
3V	Severe	Frequent attacks affecting all phalanges of most fingers
4V	Very severe	As in stage 3 with trophic changes in the fingertips

Sensorineural component	
Stage	Description
0SN	Vibration-exposed but no symptoms
1SN	Intermittent numbness with or without tingling
2SN	Intermittent or persistent numbness, reduced sensory perception
3SN	Intermittent or persistent numbness, reduced tactile discrimination or manipulative dexterity or both

Results of cold provocation showing an abnormal response as found in vascular damage from hand arm vibration syndrome

13 Respiratory diseases

Ira Madan

The pattern of occupational lung disease is changing in industrialised countries. A reduction in manufacturing industries and stricter health and safety legislation during the past 50 years have resulted in a sharp decline in the incidence of silicosis, asbestosis, and other pneumoconioses. Asthma is now the most common occupational respiratory disorder in these countries. By contrast, the traditional occupational lung diseases are commonly seen in developing countries, and occupational asthma is reported less often. However, the true prevalence of asthma attributable to occupation in these countries remains unknown.

Since 1989, the understanding of the epidemiology of occupational lung disease in the United Kingdom has been greatly enhanced by the Surveillance of Work related and Occupational Respiratory Disease (SWORD) and Occupational Physicians Reporting Activity (OPRA) projects. Occupational and respiratory physicians systematically report new cases of occupational lung diseases, together with the suspected agent, industry, and occupation. The projects have provided an estimate of the incidence and pattern of occupational lung disease in the United Kingdom.

Occupational asthma

Occupational asthma is a disease characterised by variable airflow limitation and airway hyper-responsiveness caused by specific agents inhaled in the workplace. It does not include activation of pre-existing asthma or airway hyper-responsiveness induced by non-toxic irritants or physical stimuli such as cold air.

Two types of occupational asthma are recognised: immunological asthma appears after a latent period of occupational exposure; non-immunological occupational asthma develops without a period of latency and is associated with exposure to high concentrations of irritants. This latter type is referred to as reactive airways disease and is discussed separately. To date, more than 250 agents capable of causing immunological occupational asthma have been reported. In some jobs, such as hairdressing and farming, workers are exposed to many potential sensitisers and sensitisation may occur through interaction of several agents.

Substances that induce occupational asthma are classified as either high (>5kDa) or low molecular weight allergens. High molecular weight substances are usually protein derived allergens such as natural rubber latex and flour. It is thought that some low molecular weight chemicals, such as diisocyanates, act as haptens and combine with a body protein to form a complete antigen.

Atopic individuals seem to be at increased risk of developing occupational asthma from some agents that induce specific immunoglobulin E (IgE)—for example, rat urinary proteins, and protease enzymes derived from *Bacillus subtilis* (detergent workers). However, atopic workers who are exposed to other agents—for example, isocyanates and plicatic acid (Western red cedar) seem to be at no more risk than non-atopic workers. Tobacco smokers are at greater risk of developing asthma after occupational exposure to several agents such as platinum salts, acid anhydride, and green coffee bean; the mechanism of this modifying effect is unknown.

Estimated number of cases of work related and occupational respiratory disease reported to SWORD/OPRA by diagnostic category, 1998-2000

Diagnostic category	1998	1999	2000
Benign pleural disease	625	1243	1080
Asthma	807	1129	797
Malignant mesothelioma	701	1018	964
Pneumoconiosis	225	320	292
Other diagnosis	187	239	218
Inhalation accidents	178	154	119
Bronchitis/emphysema	58	29	144
Lung cancer	112	81	126
Infectious disease	87	63	77
Allergic alveolitis	29	42	37
Total number of diagnoses	3009	4418	3854
Total number of individuals*	2934	4298	3787

*Individuals may have more than one diagnosis.

Top eight suspected causative agents for occupational asthma cases reported to SWORD/OPRA 1998-2000

Farmers are at particular risk of developing occupational asthma because they are often exposed simultaneously to an array of potential sensitisers, such as animal derived allergens, arthropods, moulds, plants, and fungicides

Tobacco smoking and atopy are common among the working population. If these risk factors are found at pre-employment assessment the individual should not automatically be excluded from working with a respiratory sensitiser

Diagnosis

Between 5% and 10% of adult asthma is attributable to occupational factors. A detailed history of past and present occupational exposures is therefore essential in the assessment of a patient with adult onset asthma. Coughing at work or at the end of a shift is often the first symptom and precedes wheezing. Concurrent nasal congestion, lacrimation, and conjunctivitis may be associated with exposure to high molecular weight substances. The symptoms generally improve at weekends and holidays, but at advanced stages the respiratory symptoms may persist. Where possible, advice should be sought from the patient's employer's occupational health service, as they will have information on the substances that the employee is exposed to and will know if other workers have developed similar respiratory symptoms.

Investigations

Patients should record the best of three measurements of peak expiratory flow made every two hours from waking to sleeping over a period of one month (charts are available from Clement Clarke International Limited). Ideally, this period should include one or two weeks away from work. A drop in peak expiratory flow or substantial diurnal variability on working days but not on days away from work supports a diagnosis of occupational asthma. If there is any doubt, the patient should be referred to a specialist centre for further investigation.

A bronchial provocation test (inhalation test) with the suspected agent may be required to give the patient advice about future employment. The test may precipitate severe bronchospasm, so the procedure must be undertaken in a specialist hospital unit with inpatient facilities. The individual is exposed to the suspected sensitiser in circumstances that most closely resemble their exposure at work. Forced expiratory volume in one second (FEV₁), forced vital capacity, and responsiveness to histamine or methacholine are measured serially and then compared with serial measurements taken during a control challenge test performed on a separate day. An increase in airway hyper-responsiveness, particularly a late response, caused by the putative agent in concentrations that occur at work is taken as evidence of an allergic response. Although bronchial provocation testing is considered the gold standard test for the diagnosis of occupational asthma, false negatives can arise if the testing is conducted with the wrong material or if the concentration of the suspected agent is too low.

Management

Treatment of acute occupational asthma is the same as for asthma generally, but it is important to remove the sensitised individual from exposure to the substance causing their asthma, as subsequent exposure to even minimal quantities of the sensitising agent may precipitate severe bronchospasm. If their job entails working with the causative agent, relocation to another area will need to be considered. The employer's occupational physician will be able to advise on suitable areas for redeployment and will be in a position to liaise with the employee's manager. The employer should review their statutory risk assessments and control measures in the area

Examples of high and low molecular weight substances that may cause occupational asthma

Chemicals (low molecular weight)	Occupational group at risk/industrial use
Toluene di-isocyanate	Car or coach paint spray
Colophony (pine resin)	Electronics industry
Complex platinum salts	Platinum refinery workers
Proteins (high molecular weight)	
Flour or grain	Bakers
Rodent urinary proteins	Laboratory workers
Salmon proteins	Fish processing plant workers
Natural rubber latex	Healthcare professionals

Self recorded peak expiratory flow measurements showing a classic pattern of occupational asthma

Specialist investigation of occupational asthma

- Identification of atopy: skin prick tests with common allergens—for example, grass pollen, *Dermatophagoides pteronyssinus*, and cat fur
- Skin prick tests with specific extracts of putative sensitising agent
- Serology: radioallergosorbent tests (RAST) to identify specific IgE antibody
- Bronchial provocation test with the suspected causative agent

A worker who develops occupational asthma should avoid further exposure to the causative agent. As this often means relocation or loss of current employment, it is essential that the specific cause is identified accurately

where the affected employee was working to prevent other workers being similarly affected.

Reactive airways disease

Exposure to gases

Although fatalities from exposure to gases in the workplace are now rare in industrialised countries, inhalation accidents still occur relatively often. Accidental inhalation of gas (most commonly chlorine), fume, or vapour with irritant properties can lead to reactive airways disease. Frequently, individuals complain of a burning sensation in their nose and throat within minutes of exposure. The symptoms of asthma develop within 24 hours. The airway irritability usually resolves spontaneously but can persist indefinitely, and it may be provoked by a range of irritants or other provoking factors—for example, cold. The key to preventing the syndrome is good health and safety management.

On a wider scale, industrial accidents involving the release of a toxic irritant gas may cause pulmonary injury or even death in the surrounding population. The release of methylisocyanate from the Union Carbide pesticide plant in Bhopal, India, in 1984 resulted in many deaths from acute pulmonary oedema. Survivors still have chronic respiratory ill health.

Byssinosis

The symptoms of byssinosis occur as a result of hypersensitive airways and an acute reduction in FEV1 in susceptible individuals when they are exposed to dusts of cotton, sisal, hemp, or flax. It occurs most commonly in cotton mill workers and is probably a response to inhaled organic contaminants of the cotton boll, such as cotton bract (leaves at the base of the cotton flower that become hard and brittle during harvesting and comprise a major constituent of cotton dust in the mill). Smokers are at increased risk of developing the disease, but the pathogenic mechanisms underlying the disease remain obscure.

Characteristically, individuals experience acute dyspnoea with cough and chest tightness on the first day of the working week, three to four hours after the start of a work shift. The symptoms improve on subsequent working days, despite continued exposure to the sensitising agent. As the disease progresses the symptoms recur on subsequent days of the week, and eventually even occur at weekends and during holidays. Exposure of textile workers to cotton and flax dust per se does not seem to cause a significant loss of lung function. However, if the subset of workers who develop byssinosis are not removed from further exposure, they go on to develop long term respiratory impairment and subsequently have an excess risk of mortality from respiratory disease.

Pneumoconiosis

Pneumoconiosis is the generic term for the inhalation of mineral dust and the resultant diffuse, usually fibrotic, reaction in the acinar part of the lung. The term excludes asthma, neoplasia, and emphysema.

Silicosis is the commonest type of pneumoconiosis worldwide. It is caused by inhalation of crystalline silicon dioxide, and may affect people working in quarrying, mining, stone cutting and polishing, sandblasting, and fettling. Silicosis

Diagnostic criteria for reactive airways disease syndrome

- History of inhalation of gas, fume, or vapour with irritant properties
 - Rapid onset of asthma like symptoms after exposure
 - Bronchial hyper-responsiveness on methcholine challenge test
 - Individual previously free from respiratory symptoms
-

The Bhopal disaster in India highlighted the need for rapid access to expert advice in the event of a chemical disaster

Harvested cotton consists of leaves, bracts, stems, bacteria, fungi, and other contaminants. Steaming or washing it before processing can reduce the biological activity of cotton

Chest radiograph of quarry worker showing extensive simple silicosis

occurs in several different forms depending on the level and duration of exposure.

Simple nodular silicosis is the most common form, and is similar clinically and radiographically to coal worker's pneumoconiosis. Chronic silicosis presents with increasing dyspnoea over several years and chest radiography shows upper lobe fibrosis or calcified nodules. Acute silicosis results from a brief but heavy exposure: patients become intensely breathless and may die within months. Chest radiographs show an appearance resembling pulmonary oedema. Accelerated silicosis occurs as the result of less heavy exposure and presents as slowly progressive dyspnoea caused by upper lobe fibrosis.

Coal worker's pneumoconiosis is caused by inhalation of coal dust, which is a complex mixture of coal, kaolin, mica, silica, and other minerals. Simple coal worker's pneumoconiosis usually produces no symptoms or physical signs apart from exertional dyspnoea. The diagnosis is made by a history of exposure and the presence of characteristic opacities on chest radiographs. A small proportion of individuals with simple coal worker's pneumoconiosis go on to develop progressive massive fibrosis which, when sufficiently advanced, causes dyspnoea, cor pulmonale, and ultimately death. Coal worker's pneumoconiosis is disappearing in developed countries as mines close and working conditions improve; however, it remains widespread in China and India.

Silicotic nodule

Classification of radiographs for pneumoconiosis is based on the 1980 International Labour Office (ILO) system. This is a method of describing the pattern and severity of the change in groups of workers. The classification has been used worldwide for epidemiological research, surveillance, and medical checks of dust exposed workers

Chronic obstructive pulmonary disease and mining

The relationship between occupational exposure to coal dust and loss of ventilatory function is well established. However, after accounting for the effects of smoking and dust exposure, some miners still develop a severe decline in FEV1; the reasons for this are not fully understood. In the United Kingdom, chronic obstructive pulmonary disease due to coal dust is a prescribed industrial disease in those who have worked underground for at least 20 years and whose FEV1 is at least 1 litre below the predicted value.

Coal miners' pneumoconiosis

Asbestos related diseases

Exposure to asbestos causes several separate pleuropulmonary disorders, including pleural plaques, diffuse thickening of the pleura, benign pleural effusions, asbestosis, bronchial cancer, and malignant mesothelioma. Bronchial cancer and malignant mesothelioma are discussed in chapter 15.

Asbestosis is a diffuse interstitial pulmonary fibrosis caused by exposure to fibres of asbestos, and its diagnosis is aided by obtaining a history of regular exposure to any form of airborne asbestos. The presence of calcified pleural plaques on a chest radiograph indicates exposure to asbestos and helps to distinguish the condition from other causes of pulmonary fibrosis. Once the diagnosis is made, workers should be removed from further exposure. As there may be a synergistic effect between smoking and asbestosis in the development of lung cancer, workers should be encouraged to stop smoking.

Extrinsic allergic alveolitis

Extrinsic allergic alveolitis is a granulomatous inflammatory reaction caused by an immunological response to certain inhaled organic dusts and some low molecular weight chemicals. Farmer's lung and bird fancier's lung remain the most prevalent forms of the disease.

Occupational groups at greatest risk of developing asbestos related diseases

- Carpenters and electricians
- Builders
- Gas fitters
- Roofers
- Demolition workers
- Shipyard and rail workers
- Insulation workers
- Asbestos factory workers

Blue asbestos fibres (left); white asbestos fibres (right)

Acute extrinsic allergic alveolitis usually occurs after exposure to a high concentration of the causative agent. After a sensitising period, which may vary from weeks to years, the individual develops flu-like symptoms after exposure to the sensitising antigen. Prolonged illness may be associated with considerable weight loss, but symptoms usually improve within 48 hours of removal from the causative agent.

Chronic extrinsic allergic alveolitis is caused either by chronic exposure to low doses of the causative antigen, or as a consequence of repeated attacks of acute alveolitis over many years. It results in irreversible pulmonary fibrosis, and the dominant symptom is exertional dyspnoea. Weight loss may be considerable but other systemic symptoms are usually absent.

Diagnosis principally depends on a history of relevant exposure and on identification of a potential sensitising agent at home or at work. Inspiratory crackles may be heard on examination of the chest, and chest radiography in acute extrinsic allergic alveolitis may show a ground glass pattern or micronodular shadows. In chronic extrinsic allergic alveolitis lung shrinkage in the upper lobes is usually apparent. The diagnosis is confirmed by detailed pulmonary investigations and the demonstration of precipitating antibodies (precipitins) to the causal antigen in the serum.

Some causes of extrinsic allergic alveolitis

Disease	Source of antigen	Antigen
Farmer's lung	Mouldy hay and straw	<i>Micropolyspora faeni</i> <i>Thermoactinomyces vulgaris</i>
Bird fancier's lung	Bird excreta and bloom	Bird serum proteins
Bagassosis	Mouldy sugar cane	<i>Thermoactinomyces sacchari</i>
Ventilation pneumonitis	Contaminated air conditioning systems	<i>Thermophilic actinomyces</i>
Malt worker's lung	Mouldy barley	<i>Aspergillus clavatus</i>
Mushroom worker's lung	Spores released during spawning	<i>Thermophilic actinomyces</i>
Cheese washers' lung	Mould dust	<i>Penicillium casei</i>
Animal handler's lung	Dander, dried rodent urine	Serum and urine proteins
Chemical extrinsic allergic alveolitis	Polyurethane foam manufacture and spray painting	Toluene (TDI) and diphenylmethane di-isocyanate (MDI)

Farmers and pigeon fanciers often deny a relation between causative exposure and symptoms for fear of compromising their livelihood or hobby

Characteristic abnormalities of lung function in extrinsic allergic alveolitis

- Total lung capacity—reduced
- Residual volume—reduced
- Vital capacity—reduced
- Forced expiratory volume in one second (FEV1)—reduced
- FEV1/forced vital capacity—normal or increased
- Transfer factor for carbon monoxide—reduced*
- Gas transfer coefficient—reduced

14 Occupational infections

Dipti Patel

The pattern of infectious hazards at work changes constantly. Occupational infections, although not common, can be serious and easy to miss unless there is a high index of suspicion combined with an understanding of infectious disease. Furthermore, infections that are predominantly of historic interest in the developed world continue to pose a considerable problem in the developing world, and the changing pattern of travel means that those who visit or work overseas remain exposed. Drug resistance, the resurgence of certain diseases, and the emergence of new or previously unrecognised organisms further complicate matters, as does an increasing number of immunocompromised individuals. A detailed occupational history is therefore essential, as this will often point to the diagnosis of unusual illnesses caused by infectious hazards.

Occupational infections may be work specific or may be common in the general population, but they occur more often in those with occupational exposure. Like all occupational diseases, they are mostly preventable.

Healthcare workers are at risk acquiring infections from human sources such as bloodborne viruses

The traditional model of infectious disease causation

The epidemiological triangle

- An external agent—the organism that produces the infection
 - A susceptible host—attributes that influence an individual's susceptibility or response to the agent—for example, age, sex, lifestyle
 - Environmental factors that bring the host and agent together—factors that affect the agent and opportunity for exposure—for example, climate, physical surrounding, occupation, crowding
-

Basic concepts in infectious disease

- The *infectivity* of an agent is the proportion of exposed people who become infected (attack rate)
- The *pathogenicity* is the proportion of people exposed who develop clinical disease
- The *virulence* is the proportion of people with clinical disease who become severely ill or die
- The *infectious dose* is the number of organisms that are necessary to produce infection in the host, and this will vary according to the route of transmission and susceptibility of the host

Occurrence

- An infectious disease is *endemic* if there is a persistent low to moderate level of occurrence
- It is *sporadic* if the pattern of occurrence is irregular with occasional cases
- When the level of disease rises above the expected level for a period of time, it is referred to as an *epidemic*
- An *outbreak* is two or more cases of illness that are considered to be linked in time and place

Reservoir

This is any person, animal, arthropod, soil, etc. in which the infectious agent normally resides

Mode of transmission

This is the mechanism by which an infectious agent is spread from source or reservoir to a susceptible person—that is, direct (touching, biting, eating, droplet spread during sneezing, etc.), indirect (inanimate objects, fomites, vector borne) transmission, or airborne spread (dissemination of microbial aerosol to a suitable port of entry, usually the respiratory tract)

Main occupational groups at risk of infection

The three main categories of occupational infections are zoonoses, infections from human sources, and infections from environmental sources

Zoonotic infections

About 300 000 workers are at risk in the United Kingdom. Zoonotic infections include anthrax, leptospirosis, Q fever, Lyme disease, orf, and psittacosis. Workers at risk:

- Farmers and other agricultural workers
- Veterinary surgeons
- Poultry workers
- Butchers and fishmongers
- Abattoir workers and slaughtermen
- Forestry workers
- Researchers and laboratory workers—that is, animal handlers
- Sewage workers
- Tanners
- Military staff
- Overseas workers

Infections from human sources

About 2 million people are employed in the health service sector in the United Kingdom. Infections in this category include tuberculosis, erythema infectiosum, scabies, bloodborne viruses, and rubella. Workers at risk:

- Healthcare workers
- Social care workers
- Sewage workers
- Laboratory workers
- Overseas workers
- Archaeologists (during exhumations)

Infections from environmental sources

Examples include legionellosis and tetanus. Workers at risk:

- Construction workers
 - Archaeologists
 - Engineering workers
 - Military staff
 - Overseas workers
-

The European Union has introduced the Biological Agents Directive (ongoing with updates since 1993), which is designed to ensure that the risk to workers from biological agents in the workplace is prevented or adequately controlled. In the United Kingdom this directive has been implemented via the Control of Substances Hazardous to Health (COSHH) Regulations 2002

Assessment of health risks of an infectious hazard, and its prevention or control should include:

- Details of the hazard group the agent belongs to
- The diseases it may cause
- How the agent is transmitted
- The likelihood of exposure and consequent disease (including the identification of those who may be particularly susceptible—for example, asplenic individuals, those with generalised immune deficiency, pregnant staff), taking into account the epidemiology of the infection within the workplace
- Whether exposure to the hazard can be prevented
- Control measures that may be necessary
- Monitoring procedures
- Need for health surveillance, which may include assessment of worker's immunity before and after immunisation

Hazard classification

In the United Kingdom biological agents are classified into four hazard groups according to their ability to cause infection

- *Group 1*—unlikely to cause human disease—for example, *Bacillus subtilis*
- *Group 2*—can cause human disease and may be a hazard to employees; it is unlikely to spread to the community, and there is usually effective prophylaxis or treatment available—for example, *Borrelia burgdorferi*
- *Group 3*—can cause severe human disease and may be a serious hazard to employees; it may spread to the community, but there is usually effective prophylaxis or treatment available—for example, *Bacillus anthracis*
- *Group 4*—causes severe human disease and is a serious hazard to employees; it is likely to spread to the community and there is usually no effective prophylaxis or treatment available—for example, *Ebola virus*

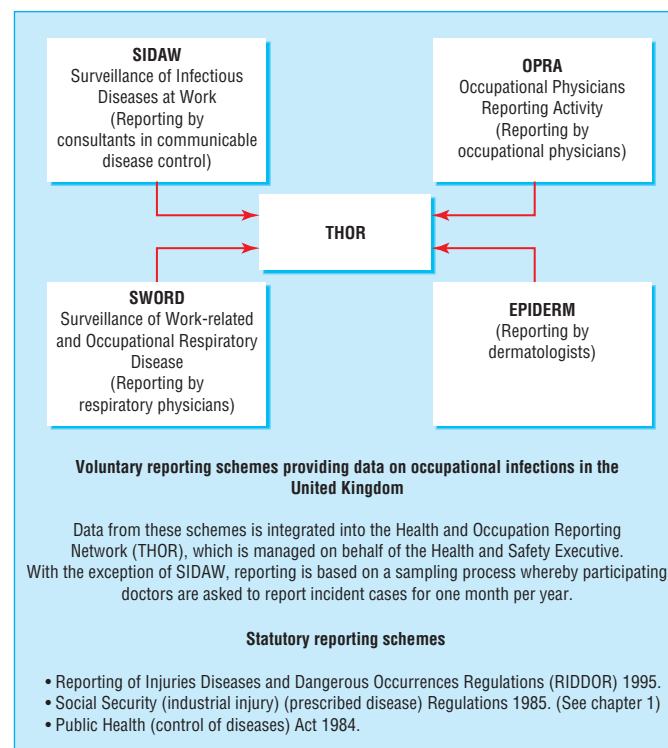

When a biological agent does not have an approved classification, the COSHH Regulations 2002 contain guidance on how biological agents should be classified. If in doubt, a higher classification should be assigned

Epidemiology

As with all occupational ill health statistics, no single source of information provides comprehensive data on occupationally acquired infections. In the United Kingdom, the principal data sources, although useful, underestimate the true incidence of occupational infections.

Data from UK reporting schemes. The industry with the highest estimated rates of infection per 100 000 workers per year for 1998-2000 was health and social care, followed by fishing, and agriculture and forestry. Diarrhoeal illnesses were the most frequently reported conditions

Disease	No of cases of infectious disease SIDAW 2000 (estimated)
Diarrhoeal illness	367
Hepatitis	–
Legionellosis	4
Leptospirosis	7
Ornithosis	4
Pulmonary tuberculosis	4
Q fever	–
Other (for example, scabies)	175
SIDAW total	561
SWORD/OPRA 2000	77
EPIDERM/OPRA 2000	88
RIDDOR (2000-1 provisional)	93
	Anthrax (1), chlamydiosis (2), hepatitis (4), legionellosis (14), leptospirosis (12), Lyme disease (3), Q fever (1), tuberculosis (15), others (41)
Prescribed diseases (1999-2000)	7
	Leptospirosis (1), tuberculosis (4), viral hepatitis (2)

Main information sources for occupational infections in the United Kingdom

Typical painless blister of Orff

Zoonoses

These are infections that are naturally transmissible from vertebrate animals to man. The World Health Organization estimates that there are over 200 zoonoses worldwide, and around 40 occur in the United Kingdom.

Protection of workers exposed to zoonotic infections relies on a number of control measures

Control of the disease in the animal reservoir

- Stock certification and vaccination (for example, anthrax or brucellosis)
- Quarantine measures (for example, for psittacine birds)
- Infection free feeds (for example, *Salmonella* free feed for poultry)
- Avoidance of contamination of animal drinking water
- Test and slaughter policies (for example, for bovine tuberculosis)
- Good standards of hygiene in stock housing
- Regular stock health checks by vets
- Meat inspection

Safe work practices

- Safe handling of animals or animal products (for all zoonotic infections)
- Safe disposal of carcasses and animal waste (for example, hydatid disease)
- Avoidance of equipment likely to cause cuts, abrasions, and grazes

NB

For protection of laboratory workers advice on control measures has been provided by the Advisory Group on Dangerous Pathogens

(Adapted from Health and Safety information sheet "Common zoonoses in agriculture")

Strict personal hygiene

- Covering existing wounds with waterproof dressings before work
- Prompt cleaning of any cuts or grazes that occur while handling animals
- Regular and correct hand washing, and avoidance of contact between unwashed hands and the mouth, eyes, or face

Personal protective equipment

- Waterproof aprons or parturition gowns
- Obstetric gauntlets for lambing or calving
- Face protection if there is a risk of splashing from urine or placental fluids
- Plastic or synthetic rubber gloves for oral or rectal examinations
- Gloves, overalls, and face protection for slaughtering animals or dressing carcasses
- Chainmail gloves for butchers

Other measures

- Immunisation of at risk worker (anthrax, Q fever)
- Provision of health warning cards (leptospirosis)

Anthrax

Also known as malignant pustule, Woolsorter's disease, and Ragpicker's disease, anthrax is a notifiable disease, a prescribed disease, and RIDDOR 1995 reportable. It is an acute infection caused by *Bacillus anthracis* (a spore forming Gram positive bacterium), and the normal animal reservoirs are grazing mammals such as sheep, cattle, and goats. Human anthrax is primarily an occupational hazard for workers who process hides, hair, wool, bone, and bone products, but it also occurs in vets and agricultural workers who handle infected animals. It is rare in the United Kingdom (only three cases of anthrax were reported in England and Wales between 1998 and 2001), occurring in those who work directly or indirectly with infected animal products from epizootic areas. Most cases of anthrax occur in Africa, the Middle East, and the former Soviet Union.

Cutaneous anthrax accounts for 95-8% of cases, and occurs when the organism enters a cut or an abrasion. After an incubation period of one to seven days, a small papule develops at this site. Over 24-48 hours, it enlarges, eventually forming a characteristic black ulcer (eschar). If not treated, cutaneous anthrax may progress to bacteraemia, meningitis, and death.

Pulmonary and gastrointestinal anthrax occur infrequently, and are the result of inhalation and ingestion of anthrax spores, respectively. In pulmonary anthrax (Woolsorter's disease) non-specific upper respiratory tract symptoms follow an incubation period of one to six days. Rapid deterioration in respiratory function and death generally follow unless treatment is started promptly. Gastrointestinal anthrax is characterised by severe abdominal pain, watery or bloody diarrhoea, and vomiting. Progression to bacteraemia is usually two to three days. Case fatality in both these forms of anthrax is high.

Most naturally occurring strains of anthrax are susceptible to penicillin, although doxycycline and ciprofloxacin have been used recently. Immunisation is also available for at risk workers, and oral antibiotics (ciprofloxacin and doxycycline) have been used as prophylaxis for individuals exposed to anthrax spores.

Leptospirosis

Leptospirosis is also known as Weil's disease, canicola fever, haemorrhagic jaundice, mud fever and swineherd disease. It is a notifiable disease, prescribed disease, and RIDDOR 1995 reportable. Leptospirosis is a rare cause of septicaemia caused by pathogenic leptospire belonging to the genus

Patient with cutaneous anthrax

Anthrax has recently received attention because of its potential for use in bioterrorism. Other potential bioterrorism organisms include:

Organism (disease)	Potential source	Ability to cause disease
<i>Brucella</i> (Brucellosis)	Aerosol or food	High
<i>Clostridium botulinum</i> toxin (Botulism)	Food, water, or aerosol	High
<i>Coxiella burnetii</i> (Q fever)	Aerosol or food supply	High
<i>Variola virus</i> (Smallpox)	Aerosol	High
<i>Vibrio cholerae</i> (Cholera)	Food, water, or aerosol	Low

Leptospira interrogans (*Li*). The genus has over 200 serovars; of most importance in humans are *Li hardjo* (cattle associated leptospirosis), *Li icterohaemorrhagiae* (Weil's disease), and *Li canicola*. The principal animal reservoirs are cattle, rats, and dogs, respectively.

The distribution of human disease depends on the local prevalence of animal infection and local environmental conditions. At risk occupational groups include agricultural workers, farmers, vets, miners, abattoir workers, and sewer and canal workers. In 2001 there were 25 notified cases of leptospirosis in England and Wales (predominantly caused by *Li hardjo*).

Leptospirosis is usually acquired by direct contact with infected animals or their urine, contaminated soil, food, or water (a hazard for those indulging in watersports). The incubation period is usually five to 14 days, and symptoms, which are not serotype specific, typically consist of fever, flu-like symptoms, headache, myalgia, photophobia, and conjunctival injection. In severe cases (often associated with *Li icterohaemorrhagiae*) haemorrhage into skin and mucous membranes, vomiting, jaundice, and hepatorenal failure may occur.

Mild infection is often self limiting, but penicillin, erythromycin, and doxycycline are all effective treatments. For more severe disease, intensive and specialised therapy is necessary.

Immunisation of animals is possible for certain serovars, and in some countries (Japan, Italy, Spain) immunisation of at risk workers against certain serovars is available. In the United Kingdom, workers who may be exposed to leptospirae usually carry an alert card provided by their employer to warn their doctors should they develop such symptoms.

Transmissible spongiform encephalopathies (TSEs)

Prion disease

These are a group of progressive and fatal neurological disorders occurring in humans and certain animal species. TSEs are thought to be caused by infectious proteins (prions) that are unusually resistant to conventional chemical and physical decontamination. They do not seem to be highly infectious and, with the exception of scrapie, do not seem to spread through casual contact.

Bovine spongiform encephalopathy (BSE) was first recognised in British cattle in 1986. Its origin is still uncertain, but it probably originated in the early 1970s, developing into an epidemic because of changing practices in rendering cattle offal to produce animal protein in the form of meat and bonemeal, which was included in compound cattle feed. This resulted in the recycling and wide distribution of BSE. In 1996, a previously unrecognised form of Creutzfeldt-Jakob disease (CJD) occurring in younger patients (range 14-53 years, mean 28 years), with a different symptom profile and different postmortem changes in the brain tissue, was identified in the United Kingdom.

The Government's Spongiform Encephalopathy Advisory Committee concluded that the most likely explanation for the emergence of this variant CJD (vCJD) was that it had been transmitted to humans through exposure to BSE as a result of consumption of contaminated bovine food products.

A major concern now is the risk of transmission in a healthcare setting. Although there have been no reported cases of nosocomial transmission of vCJD, an expert group has been established by the UK government to advise on prevention and management of possible exposures.

Farm workers are at increased risk of catching animal borne diseases

Transmissible spongiform encephalopathies (TSEs)

Human TSEs

- Creutzfeldt-Jakob disease (CJD)
- Variant CJD (vCJD)
- Gerstmann Sträussler Scheinker syndrome
- Kuru
- Fatal familial insomnia

Animal TSEs

- Scrapie (sheep and goats)
 - Bovine spongiform encephalopathy (BSE) (cattle)
 - Transmissible mink encephalopathy (farmed mink)
 - Chronic wasting disease (deer)
 - Feline spongiform encephalopathy (domestic cats and captive exotic felines)
 - Spongiform encephalopathy (captive exotic ungulates)
-

A number of measures have been taken to minimise disease transmission among animals and humans, and although there is no clear evidence of occupational risk, advice on safe working practices has been provided by the Advisory Committee on Dangerous Pathogens. Those potentially at risk include workers in abattoirs, slaughterhouses and rendering plants; farmers; neurosurgeons; pathologists; and mortuary technicians

The incubation period of vCJD is unknown, but is likely to be several years. The infectious dose is also unknown, and is likely to be dependent on the route of exposure. However, by February 2002, a total of 114 individuals throughout the United Kingdom (106 dead and 8 alive) were considered to have had definite or probable vCJD. There is currently no evidence to link any cases of vCJD with surgical procedures or with transmission by blood, but the possibility cannot be ruled out.

It is already current practice to dispose of instruments used on anyone showing symptoms of vCJD. A problem, however, occurs in those who have presymptomatic disease; precautions to avoid this theoretical risk of transmission are therefore essential. Any assessment of risk of transmission from instruments must consider a wide range of scenarios, and precautionary measures should be taken against risks that might occur, even if the level of risk is not known. The key message in reducing any risk of vCJD transmission is the rigorous implementation of washing, decontamination, and general hygiene procedures.

In January 2001, a recommendation that single use instruments were used for tonsillectomy and adenoidectomy surgery was made. This recommendation was withdrawn in December 2001 because adverse incidents (mainly haemorrhage, but also one death) were reported after the introduction of single use instruments. It was felt that on balance, the single use instruments represented an actual risk to patients, whereas the concerns regarding vCJD transmission were only theoretical. Further information is available at <http://www.open.gov.uk/doh/coinh.htm>.

Infections from human sources

These infections are of most relevance to healthcare workers. They are important because healthcare workers are at high risk of acquiring infections occupationally and they are also a potential source of infection to their patients, particularly those who are immunologically impaired.

Bloodborne viruses

Occupational exposure to blood or body fluids poses a small risk of transmission of bloodborne pathogens. Those presenting the greatest crossinfection hazard are HIV, and hepatitis B and hepatitis C viruses. Although healthcare staff are at greatest risk, other occupational groups (for example, police officers) may also be exposed.

The risk of infection depends on the type and severity of the exposure, the infectivity of the source patient, the immune status of the exposed healthcare worker, and the availability of treatment after exposure.

Prevention entails minimising exposure to blood or body fluids, and consists of strict infection control, adherence to universal precautions, immunisation against hepatitis B, and prompt management of any occupational exposure.

Healthcare workers infected with bloodborne viruses can potentially transmit infection to their patients, and although the risk is small, guidelines exist in many countries to reduce this risk further. In the United Kingdom, all healthcare workers who perform exposure prone procedures are required to provide evidence that they are immune to hepatitis B as a result of immunisation, or that they are not HBe antigen (HBeAg) positive. Because of transmissions of HBV associated with codon 28 precore mutations, those who are HB surface antigen positive, but HBeAg negative, must now be tested for hepatitis B virus DNA; they may perform exposure prone work provided that their HB viral load is below 10^3 genome equivalents per millilitre, and this is subject to annual testing.

Although it is likely that most of the UK population has been exposed to BSE, the true number of individuals who have been infected is not known

Reasons that vCJD might be spread from person to person in healthcare settings

- Classical CJD has been transmitted from person to person by a range of medical procedures including surgery, grafts or transplants, and treatment with pituitary extracts, and about 1% of classical CJD cases in the past are considered to have been iatrogenic
- Abnormal prion protein has been shown in the lymphoreticular tissue (tonsils, spleen, and lymph nodes) of patients with established vCJD
- Abnormal prion protein has been shown in the appendix of a patient who subsequently developed vCJD
- Although, to date, the transmissible agent has not been shown in blood, it is possible that abnormal prion protein, at concentrations not detectable with current techniques, may be associated with circulating B lymphocytes and with other cells of the immune and circulatory systems
- Abnormal prion protein has been shown to be highly tenacious and may not be inactivated by conventional sterilisation and decontamination procedures

Exposure prone procedures are invasive procedures where there is risk that injury to the worker may result in the exposure of a patient's open tissues to the blood of the worker. These include procedures where a healthcare worker's gloved hand may be in contact with sharp instruments or tissues inside a patient's open body cavity, wound, or confined anatomical space where the hands may not be completely visible at all times

Risk of transmission of bloodborne viruses

High risk body fluids

- Cerebrospinal fluid
- Peritoneal, pleural, pericardial fluid
- Synovial fluid
- Amniotic fluid
- Breast milk
- Vaginal secretions
- Semen
- Saliva associated with dentistry
- All visibly blood stained fluid
- Unfixed organs or tissues

Estimated risk of seroconversion after percutaneous exposure

HIV: 0.32% (based on data of 6202 healthcare workers). Risk of mucous membrane exposure is 0.09%, and there have been no transmissions associated with exposure of intact skin. In the United Kingdom there have to date (March 2002) been five definite occupationally acquired transmissions of HIV. Worldwide by 1999, 102 definite and 217 possible cases of occupationally acquired HIV had been reported

The risk of percutaneous exposure is increased if the injury is deep, the device is visibly blood stained, the injury is from a needle placed in artery or vein, or the source patient has terminal HIV infection

Post-exposure prophylaxis (PEP)

HIV

Most countries now recommend a four week course of zidovudine with lamivudine, and many recommend the addition of a protease inhibitor. The choice of drugs, doses, route of administration, and the length of PEP are somewhat empirical. However, because most studies indicate a time limited response to PEP, the need for timely and early therapy is vital. In the United Kingdom, HIV PEP generally consists of zidovudine and lamivudine (Combivir) with nelfinavir, indinavir, or soft gel saquinavir (March 2002)

Hepatitis B virus

Hepatitis B virus immunoglobulin (HBIG) is available for passive protection and is normally used in combination with hepatitis B vaccine to confer passive-active immunity to susceptible individuals after exposure. The post-exposure efficacy of combination HBIG and hepatitis B vaccine has not been evaluated in the occupational setting, but increased efficacy (85-95%) has been observed perinatally. Although HBIG may not completely inhibit virus multiplication, it may prevent severe illness and the development of a chronic carrier state

Individuals who, as a result of testing, are found to be hepatitis C RNA positive should not perform exposure prone procedures. However, hepatitis C infected workers who have been successfully treated with antiviral therapy and remain hepatitis C virus RNA negative six months after finishing treatment should be able to resume exposure prone procedures or start professional training for a career that relies on the performance of exposure prone procedures.

HIV testing is not compulsory for healthcare workers in the United Kingdom and many other countries. In the United Kingdom, professional regulatory bodies state that workers who may have been exposed to HIV have an ethical responsibility to be tested. If found to be HIV infected, exposure prone work is prohibited. The UK Department of Health is currently reviewing their policy.

Tuberculosis

Tuberculosis is a notifiable disease, a prescribed disease, and RIDDOR 1995 reportable.

Mycobacterium tuberculosis continues to be the leading cause of adult death from any single infectious agent worldwide.

Low risk body fluids (unless visibly bloodstained)

- Urine
- Faeces
- Vomit

Significant exposures

- Percutaneous injury
- Exposure of broken skin
- Exposure of mucous membrane

Hepatitis C virus: 1.8%

Hepatitis B virus: 37-66% from HBeAg positive source; 23-37% from HBsAg positive source
Effective immunisation is available for hepatitis B virus and 80-90% of individuals mount an adequate response

Hepatitis C virus

No effective PEP exists. Recommendations for post-exposure management are therefore intended to achieve early identification of infection, with appropriate specialist referral. Although consistent data are lacking, one uncontrolled trial has shown a substantially better response rate of early treatment using interferon compared with treatment of patients with chronic disease

Recent UK guidance for hepatitis C

- Healthcare workers who carry out exposure prone procedures and already know themselves to be infected with hepatitis C should be tested for hepatitis C virus RNA (if not already done)
 - All healthcare professionals intending to undertake professional training for a career that relies on the performance of exposure prone procedures should be tested for hepatitis C infection
 - Those who perform exposure prone procedures and believe that they may have been exposed to hepatitis C should seek and follow confidential and professional advice on whether they should be tested for hepatitis C
-

Bloodborne viruses and risk to patients

HIV

- In the United Kingdom, the Expert Advisory Group on AIDS (EAGA) provides guidance on look-back procedures for HIV. As UK studies of over 30 000 patients after look-back exercises have shown no evidence of transmission of HIV to patients, it is likely that look-back procedures for HIV in the United Kingdom will stop
- Two incidents of transmission from a healthcare worker to a patient have been reported: a Florida dentist who infected six patients, and a French orthopaedic surgeon who infected one patient
- Dr Patrick Ngosa, an HIV positive obstetrician, was removed from the UK General Medical Council's Register in 1997 when it was discovered that he had refused to have an HIV test and continued to perform exposure prone procedures after learning that a former sexual partner was HIV positive. A total of 1750 women on whom he had operated were sent letters informing them that there was a possibility that they had been exposed to HIV

Hepatitis B virus

- A number of look-back studies involving surgical staff from 1975 to 1990 have identified transmission risks of 0.9-20%
- The most recent look-back exercise for hepatitis B virus in the United Kingdom was in 2001. About 350 patients were contacted in Fife, when infection in two patients was traced back to one healthcare worker
- A surgeon infected with hepatitis B (Dr Gaud) who lied about his infectivity was convicted and jailed for the common law charge of "public nuisance" after knowingly operating on patients and putting them at risk of infection

Hepatitis C virus

- In the United Kingdom there have been five patient notification exercises after investigations of hospital acquired hepatitis C infection. Since 1994 there have been 15 documented transmissions of hepatitis C virus to patients from infected healthcare workers during exposure prone procedures
-

The emergence of multidrug resistant tuberculosis (MDRTB), with its high case fatality, its prolonged sputum positivity (and consequently, high transmission risk), and its complex treatment has re-emphasised the importance of tuberculosis control.

Tuberculosis remains a hazard in the healthcare setting, and incidence in healthcare workers parallels (but is higher than) that in the community; a study in the mid-1990s found about a twofold increased risk of tuberculosis among healthcare workers in England and Wales. Healthcare workers should therefore be protected against infection, and measures should be taken to detect tuberculosis in new or existing staff in order to protect their patients and colleagues. Protection begins at pre-employment, and continues with strict infection control measures for nursing infected patients.

In the United Kingdom, protection of healthcare workers should follow the guidelines produced by the Joint Tuberculosis Committee of the British Thoracic Society.

Adults with non-pulmonary tuberculosis can usually be nursed on general wards, but those with pulmonary tuberculosis should initially be admitted to a single room vented to the open air until their sputum status is known. Those with smear positive sputum should be managed as infectious. In the case of known or suspected MDRTB, particular care must be taken, and patients should be admitted to a negative pressure single isolation room until MDRTB is excluded or until sputum smears have been negative on three consecutive occasions over 14 days.

Outbreaks of MDRTB in the United States and Europe have emphasised the importance of control. These outbreaks have occurred predominantly in institutional settings (prisons, residential homes, and hospitals) and have mainly been in HIV infected patients. Contributory factors in these outbreaks included lapses in respiratory isolation, inadequate ventilation in isolation rooms, and "immunocompromised convergence" (the assembling of immunocompromised HIV infected patients in institutions).

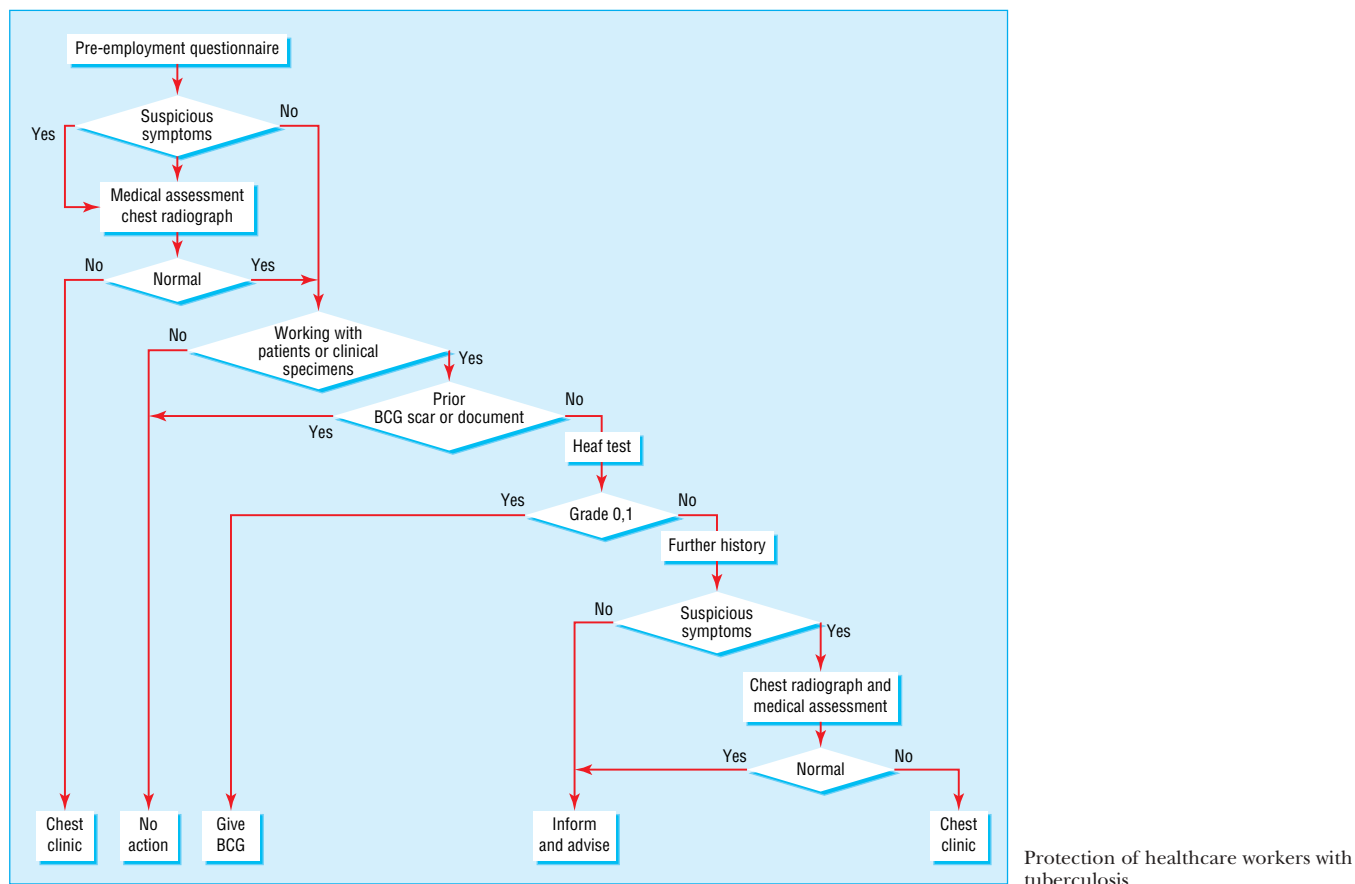

Multidrug resistant tuberculosis (MDRTB)

MDRTB is tuberculosis resistant to at least isoniazid and rifampicin

Effective control of MDRTB requires a multidisciplinary approach involving the hospital infection control team, microbiologist, tuberculosis physician, consultant in communicable disease control, engineers, and occupational health

- Visitors to patients with known or suspected MDRTB should be kept to a minimum
- The number of healthcare workers exposed to MDRTB patients should be kept as low as possible
- All who enter the rooms of MDRTB patients should wear suitable particulate masks that filter down to particles of 1 micron in diameter
- Staff should wear masks during aerosol generating procedures, such as sputum induction, bronchoscopy, and pentamidine therapy. These procedures should only be performed in suitably ventilated facilities
- Individuals who have not been checked for immunity to tuberculosis, or those with a negative skin test who have not received BCG vaccination should avoid contact with MDRTB patients, as should those who are immunocompromised

The decision to discontinue strict isolation and infection control procedures should only be made after discussion between the clinician with responsibility for the patient, the hospital infection control team, occupational health, and a consultant in communicable diseases

When a patient or member of staff is found to have tuberculosis, infection control and occupational health staff have to assess the need for contact tracing. In the United Kingdom, most staff are not considered to be at special risk and should be reassured and advised to report any suspicious symptoms. Those who are immunocompromised, have undertaken mouth to mouth resuscitation, prolonged high dependency care, or repeated chest physiotherapy without appropriate protection should be regarded as close contacts and followed up according to national guidelines. Similar precautions should be taken if the index case is highly infectious.

Chickenpox

Chickenpox is a systemic viral infection resulting from primary infection with varicella zoster virus. It is highly infectious and transmitted directly by personal contact or droplet spread, and indirectly through fomites. Shingles (herpes zoster) is a reactivation of dormant virus in the posterior root ganglion and can be a source of infection generally by contact with the skin lesions, but occasionally by the respiratory route in immunocompromised individuals.

Primary infection in adults can be severe, resulting in a higher frequency of complications such as pneumonia, encephalitis, and hepatitis, but its main importance is the risk to non-immune pregnant women and the immunosuppressed.

Although the prevalence of seropositivity for varicella zoster virus in healthcare workers in temperate climates is high (90-98%), nosocomial exposure to the virus is a major occupational health problem requiring non-immune healthcare workers to be excluded from patient contact from day 8 to 21 after a substantial exposure. A live attenuated vaccine is now available in many parts of the world.

Complications of varicella zoster virus

- Severe disease due to fulminating varicella pneumonia is more likely in adults, especially pregnant women, and smokers
- Pregnant women are at greatest risk late in second or early third trimester
- In the immunocompromised and neonates, disseminated or haemorrhagic varicella is more likely
- The risk to fetus and neonate from maternal infection relates to gestation at time of infection
 - *First 20 weeks*—congenital varicella syndrome (limb hypoplasia, microcephaly, hydrocephalus, cataracts, growth retardation, and skin scarring)
 - *Second and third trimester*—herpes zoster in otherwise healthy infant
 - *A week before to a week after delivery*—severe and even fatal disease in the neonate (particularly premature babies)
- Human varicella zoster immunoglobulin (VZIG) is available and can be given for post-exposure prophylaxis in individuals who fulfill the following conditions:
 - a clinical condition that increases risk of varicella infection
 - no antibodies to varicella zoster virus
 - substantial exposure to chickenpox or herpes zoster
- A substantial exposure to varicella zoster virus depends on:
 - the type of infection in the index case—for example, the risk of acquiring infection from an immunocompetent individual with non-exposed shingles is remote
 - the timing of the exposure in relation to onset of rash in the index case—the critical time for chickenpox or disseminated zoster is 48 hours before the onset of rash until crusting of lesions for varicella zoster virus, and day of onset of rash until crusting in localised zoster
 - closeness and duration of contact—contact in same room >15 minutes, or face to face contact
- The recommendation that VZIG is used for exposed non-immune pregnant women during the first 20 weeks of pregnancy is based on biological plausibility. No evidence exists showing that the risk of congenital varicella syndrome is reduced
- VZIG is not recommended for healthy healthcare workers, but in the United States, varicella vaccine is recommended for use in susceptible individuals after exposure; data from hospital and community settings suggest that it is effective in preventing illness or modifying severity if used within three days of exposure

Other infections

Other infections worth mentioning include skin infection in engineers associated with the re-use of cutting oils (which can lead to oil mists being contaminated with bacteria and fungi), pseudomonas otitis externa in deep sea divers who use saturation techniques, and legionellosis (which can occasionally be occupationally acquired). Finally, travel associated infections are becoming an important cause of occupationally acquired disease with the increase in international business travel and overseas workers (see *ABC of Healthy Travel*).

Legionellosis (Legionnaire's disease, Pontiac fever)

This infection is RIDDOR 1995 reportable. It is an acute bacterial infection caused by a Gram negative bacillus belonging to the genus *Legionella*. Two clinical presentations are recognised: Legionnaire's disease and Pontiac fever, and the majority of infections are due to *L. pneumophila*. The bacillus is an ubiquitous aquatic organism that thrives in warm environments (25-45°C, but preferably at 30-40°C), and is often isolated from natural habitats (rivers, creeks, hot springs) and from artificial equipment where the temperature is maintained at levels favouring bacterial proliferation.

Transmission of infection is from inhalation of contaminated aerosols, and both Legionnaire's disease and Pontiac fever present initially with non-specific flu-like symptoms. Pontiac fever occurs after an incubation period of 4 to 66 hours, and is a self limiting non-pneumonic form of the infection. By contrast, the incubation period for Legionnaire's disease is two to ten days. Initial symptoms of fever, malaise, anorexia, and myalgia are followed by progression to pneumonia and associated multisystem involvement, with diarrhoea, vomiting, confusion, and renal failure. Case fatality can range from 5% to 15%, but may be higher in outbreaks.

Treatment generally consists of erythromycin (although rifampicin may be used as an adjunct). If infection is confirmed, local public health authorities need to be notified as contacts may need to be identified, and the source of infection needs to be established and appropriately controlled.

Conclusion

The extent of occupationally acquired infections is unknown, but it is likely that they are extremely common, particularly mild infections in agricultural and healthcare workers. Preventing infection is an important aspect of occupational health practice as it will impact favourably on communicable disease in the general population. Similarly, the control of communicable disease in both the general (and animal) population will decrease the risk to certain occupational groups.

The table showing Data from UK reporting schemes depicting the industries with the highest estimated rates of infection is adapted from Health and Safety Executive Statistics 2000-1. The figures showing the protection of workers with tuberculosis are adapted from the guidelines of the Joint Tuberculosis Committee of the British Thoracic Society. Control and prevention of tuberculosis in the United Kingdom: code of practice 2000. <http://www.brit-thoracic.org.uk>

Legionnaire's disease

- Travel abroad is a major risk factor for Legionnaire's disease in the United Kingdom, with nearly 50% of cases being contracted abroad
 - About 15% of UK cases are linked to local outbreaks (caused by wet cooling systems or hot water systems), and roughly 2% are hospital acquired. Many cases are sporadic, or from an unidentified source
 - Hospital outbreaks in particular have high case fatalities
 - The highest risk of infection occurs with water systems leading to the aerosolisation of water that is stored at temperatures of 25-45°C. This includes:
 - wet cooling systems (for example, cooling towers and evaporative condensers)
 - hot water systems (especially showers)
 - whirlpool spas
 - indoor and outdoor fountain and sprinkler systems
 - humidifiers
 - respiratory therapy systems
 - industrial grinders
 - Prevention of infection relies on ensuring that equipment and systems are kept as clean as possible, and disinfected regularly. Where possible, water temperatures should be kept above 50°C or below 20°C. Use of biocides may also need to be considered. In the United Kingdom, the Health and Safety Executive provides guidance on the prevention and control of legionellosis

15 Occupational cancers

John Hobson

The first report of cancer caused by occupational exposure was in 1775 by Percival Pott, a British surgeon who described scrotal cancer in boy chimney sweeps. A century later, in 1895, Rehn, a German surgeon working in Frankfurt, treated a cluster of three cases of bladder cancer in workers at a local factory producing aniline dyestuffs from coal tar.

Occupational cancer is any malignancy wholly or partly caused by exposures at the workplace or in occupation. Such exposure may be because of a particular chemical (such as β -naphthylamine), a physical agent (such as ionising radiation), a fibre like asbestos, a biological agent (such as hepatitis B virus), or an industrial process in which the specific carcinogen may elude precise definition (such as coke production).

Overall it is estimated that 4% of all cancers are caused by occupation (range 2-8%), but for bladder cancer this may be as high as 20%. In the working population as many as one in five cancers may be attributable to exposure in the workplace. In England and Wales at least 3000 men die each year from potentially preventable malignancies.

The International Agency for Research on Cancer (IARC) was set up to identify carcinogenic hazards to humans. To date, 874 chemicals, groups of chemicals, complex mixtures, occupational exposures, cultural habits, and biological and physical agents have been evaluated. The findings have been published in 79 monographs and eight supplements.

Mechanisms of cancer

Cancer is a genetic disorder of somatic cells and can be triggered by the genotoxic action of carcinogens. There are five or six independent stages of carcinogenesis, each of which is rate limiting. The best available model is colorectal cancer, which requires seven independent genetic events. The three key stages are initiation (by a mutagen), promotion (where development of tumours is enhanced by other stimuli to cell proliferation such as lung fibrosis), and progression (development of malignant tumours from benign neoplasms).

Mutations in tumour suppressor genes (for example, *p53*) are particularly important, and half of all cancers contain *p53* mutations, of which there are 6000 possible point mutations. Several environmental and occupational carcinogens are linked to *p53* mutations—for example, ultraviolet light and skin cancer, and tobacco and oral cancer. Other factors linked with *p53* include alcohol, vinyl chloride, and asbestos.

Most carcinogens are genotoxic (DNA reactive) and cause mutation. There is no threshold below which they are not carcinogenic and therefore exposure levels are set at acceptable levels. Tests for genotoxicity such as Ames and fluorescent in situ hybridization (FISH) are now well established. The Ames test is the most widely used procedure for assessing the mutagenicity of chemicals. The relative mutagenic potency of an agent is indicated by the number of bacterial colonies growing on a plate containing the toxic agent relative to those growing on a plate containing normal medium. FISH is used to assess chromosomal abnormalities.

Epigenetic carcinogens (also known as non-genotoxic or cocarcinogens) act more directly on the cell itself, through

Foundry workers may be exposed to a complex mixture of carcinogenic agents in fumes

Of all the occupationally related diseases, cancer evokes particular concern and strong emotions, because of the opportunity afforded for attribution, blame, and compensation. However, occupational cancers also have unique potential for prevention

International Agency for Research on Cancer (IARC) classifications to date

Group		Number
1	Carcinogenic	87
2A	Probably carcinogenic	63
2B	Possibly carcinogenic	233
3	Unclassifiable as to carcinogenicity in humans	490
4	Probably not carcinogenic to humans	1 (caprolactam)

hormonal imbalances, immunological effects, or promoter activity, to cause abnormal cell proliferation and chromosomal aberrations that affect gene expression. These carcinogens have a threshold dose for carcinogenicity and it is possible to set exposure levels. There is probably a minimal threshold dose as well as a clear dose-response relation influencing the occurrence of cancers. For example, all workers involved in distilling β -naphthylamine eventually developed tumours of the urothelial tract, whereas only 4% of rubber mill workers who were exposed to β -naphthylamine (a contaminating antioxidant (at 0.25%) used in making tyres and inner tubes) developed bladder cancer over a 30 year follow up.

Polymorphisms are different responses to the same factor such as a drug. Slow acetylators who are heavy smokers are 1.5 times more likely to get bladder cancer if exposed to carcinogens. Certain polymorphisms increase the risk of mesothelioma 7.8 times. It will be possible in the future to rapidly and cheaply test individuals for polymorphisms and genotypes.

Thick walled mesothelioma of pleura with haemorrhagic cavitation in a former insulation worker

Sites of cancers

Carcinogens are organotropic. In the United Kingdom the most commonly affected sites are the lung (mesothelium) (75%), bladder (10%), and skin (1%). Other sites affected are the haemopoietic system, nasal cavities, larynx, and liver.

Natural course of cancers

Occupationally related cancers are characterised by a long latent period (that is, the time between first exposure to the causative agent and presentation of the tumour). This latency is not usually less than 10 to 15 years and can be much longer (40-50 years in the case of some asbestos related mesotheliomas): presentation can therefore be in retirement rather than while still at work. However, susceptibility to occupational carcinogens is greater when the exposure occurs at younger ages. An occupationally related tumour does not differ substantially, either pathologically or clinically, from its "naturally occurring" counterpart.

Recognition and diagnosis

For a group of workers, occupational cancer is evidenced by a clear excess of cancers over what would normally be expected. Some common malignancies that can be work related also have a well recognised and predominant aetiology related to other agents, diet, or lifestyle (for example, lung cancer from smoking). There are, however, some features that may help to distinguish occupational cancers from those not related to work.

History taking

Taking a patient's occupational history is paramount. It should be defined in detail and sequentially. For example, a holiday job in a factory that lasted only a few months could easily be overlooked, but it may have included delagging a boiler or handling sacks of asbestos waste.

Signal tumours

Several uncommon cancers are associated with particular occupations. Thus, an angiosarcoma of the liver may indicate past exposure to vinyl chloride monomer in the production of polyvinyl chloride, although there have been no cases in workers exposed since 1969. A worldwide registry of all exposed workers exists.

Diagnosis of work related cancer

- Detailed lifelong occupational history
 - Comparison with a checklist of recognised causal associations
 - Confirmation of requisite exposure
 - Search for additional clues: shift to a younger age, presence of signal tumours, other cases and "clusters," long latency, absence of anticipated aetiologies, unusual histology or site
-

Rubber workers in mill room

Age

A younger age at presentation with cancer may suggest an occupational influence. For example, a tumour of the urothelial tract presenting in anyone under the age of 50 years should always arouse suspicion.

Patients' information

Patients may speak of a "cluster" of cancer cases at work, or they may have worked in an industry or job for which a warning leaflet has been issued.

Prevention

Primary prevention seeks to prevent the onset of a disease. Secondary prevention aims to halt the progression of a disease once it is established. Tertiary prevention is concerned with the rehabilitation of people with an established disease to minimise residual disabilities and complications or improve the quality of life if the disease itself cannot be cured.

Cystoscopic view of papillary carcinoma of the bladder in a 47 year old rubber worker

Levels of prevention

	Stages			Outcomes		
	Health	Asymptomatic	Symptomatic	Disability	Recovery	Death
Intervention strategies	Health education, immunisation, environmental measures and social policy	Presymptomatic screening	Early diagnosis and prompt effective treatment	Rehabilitation		
Level of prevention	Primary	Secondary		Tertiary		

Adapted from Donaldson and Donaldson, 1999.

Primary prevention of occupationally related cancers depends essentially on educating employers and employees; firstly about recognising that there is a risk, and then about the practical steps that can be taken to eliminate or reduce exposure and to protect workers. Modern risk based legislation now directs these educational and practical measures.

Secondary prevention

Screening procedures may enable earlier diagnosis, but there is little evidence to suggest that most screening makes a difference to outcome. Screening is of proven benefit in cutaneous cancers of occupational origin, mainly because of the excellent prognosis afforded by treatment. Routine skin inspections should be initiated where there is exposure to known skin carcinogens. Routine urine cytology has been carried out in many industries where there has been previous exposure to known carcinogens. It is possibly of benefit but this has not been proven. β -Naphthylamine was withdrawn from use by 1950, but many former workers continue to participate in urine cytology screening programmes. Once commenced, surveillance should be lifelong. In the United Kingdom it is recommended workers exposed to 4,4-methylene-bis-(2-chloroaniline) (MbOCA) should have their urinary levels of MbOCA and its *N*-acetyl metabolites checked, but periodic urine cytology for those exposed remains controversial. Screening for lung and liver cancer is not of benefit.

Action for primary prevention of occupational cancers

- Recognition of presence of hazards and risks
- Education of management and workforce
- Elimination of exposure by substitution and automation
- Reduction of exposure by engineering controls (such as local exhaust ventilation and enclosure, changes in handling, and altering physical form in processing)
- Monitoring of exposure and maintaining plant
- Protection of workers with personal protective equipment
- Limiting access
- Provision of adequate facilities for showering, washing, and changing
- Legislative provisions

Criteria for screening

- Is the condition an important health problem?
- Is there a recognisable early stage?
- Is treatment more beneficial at an early stage than at a later stage?
- Is there a suitable test?
- Is the test acceptable to the population?
- Are there adequate facilities for diagnosis and treatment?
- What are the costs and benefits?
- Which subgroups should be screened?
- How often should screening take place?

Legislation and statutory compensation

Essential legislative provisions in the United Kingdom and the European Union are comprehensive. Ten types of cancer are prescribed diseases and are eligible for industrial injuries benefit. Some cancers are reportable under the Reporting of Injuries, Diseases, and Dangerous Occurrence Regulations 1995 (RIDDOR), although many occur in those who have retired. Most occupational cancers recorded or eligible for benefit are mesotheliomas. In 2000, 652 people received benefits in the United Kingdom for mesothelioma, which is less than half the number of deaths recorded as caused by this disease (1595 deaths in 1999). About 80 people with other occupational cancers receive benefits each year, these being split between bladder cancer and asbestos related lung cancer. Bladder cancers have slowly increased over the past decade, whereas lung cancers have decreased. The figure for asbestos related lung cancers substantially under-represents the true number.

Specific carcinogens

Metals and metalliferous compounds

Arsenic, beryllium, cadmium, chromium(VI), nickel, and iron are considered to be proven human carcinogens, either as the metal itself or as a derivative. The risk from iron is related only to mining the base ore and is caused by coincidental exposure to radon gas. In foundries, where there is concomitant exposure to several agents in a complex mix of emanating fume, the responsible agents are not clearly defined.

With all the metallic carcinogens, the lung is the main target organ, but other potential sites are shown in the table. The main occupational exposures occur in the mining, smelting, founding, and refining of these metals, and less commonly in secondary industrial use.

Aromatic amines

Aromatic amines are among the best known and most studied of chemical carcinogens. The bladder is the main target organ, but any site on the urothelial tract composed of transitional cell epithelium can be affected—that is, from the renal pelvis to the prostatic urethra. Tumours of the upper urothelial tract (renal pelvis or ureter) are very rare, and a cluster of these signal tumours usually heralds an underlying risk of occupational cancer. The carcinogenic potential of aromatic amines lies not in the parent compound but in a metabolite formed in the liver and excreted through the urinary system.

The occupations classically associated with risk from these chemicals were in the industries' manufacturing chemicals and dyestuffs. In the early 1950s an investigation of bladder cancers in workers in British chemical industries showed that individuals exposed to benzidine and 2-naphthylamine had a 30 times greater risk of developing bladder cancer than the general population. Occupational bladder cancer became a prescribed disease in 1953.

Antioxidants contaminated with β -Naphthylamine were used in the rubber and cable making industries until the end of 1949 (when they were universally withdrawn), and they caused an excess of bladder cancer. The level of contamination was only about 0.25%, yet it almost doubled the risk for the workforce so exposed. People who started work in the rubber industry after 1951 seem to have no excess risk.

There is now increasing evidence that some polycyclic aromatic hydrocarbons can act as urinary tract carcinogens.

Benefits and disadvantages of screening

Benefits

- Improved prognosis for some cases detected by screening
- Less radical treatment for some early cases
- Reassurance for those with negative test results

Disadvantages

- Longer morbidity for cases whose prognosis is unaltered
 - Over treatment of questionable abnormalities
 - False reassurance for those with false negative results
 - Anxiety and sometimes morbidity for those with false positive results
 - Unnecessary medical intervention for those with false positive results
 - Hazard of screening test
 - Resource costs: diversion of scarce resources to screening programme
-

Main legislative provisions in the United Kingdom

- Control of Substances Hazardous to Health (COSHH) Regulations 2002 and associated approved code of practice on the Control of Carcinogens
 - European Commission Carcinogens Directive (90/934/EEC)
 - Chemical Agents Directive (98/24/EC)
 - Chemicals (Hazard Information and Packaging) Regulations 1999 (CHIP)
 - Ionising Radiations Regulations (1999)
 - Control of Asbestos at Work Regulations (1998)
 - Reporting of Injuries, Diseases, and Dangerous Occurrences Regulations (RIDDOR) 1995
-

Metalliferous carcinogens

Agent	Target organ
Arsenic	Lung and skin
Beryllium	Lung
Cadmium	Lung, prostate gland
Chromium (hexavalent)	Lung
Nickel	Lung, nasal sinuses
Iron in:	
Haematite mining (radon)	Lung
Iron and steel founding	Lung, digestive tract

Aromatic amine carcinogens

Proved

- 4-Aminobiphenyl (xenylamine) and its nitro derivatives
- β -Naphthylamine
- Benzidine
- Auramine and magenta

Probable

- Polycyclic aromatic hydrocarbons

Possible

- The hardener MbOCA (4,4-methylene-bis-(2-chloroaniline))
-

This is reflected in excesses seen in aluminium refiners and in painters exposed to solvents.

Asbestos

Few natural materials used in industry have been the subject of more epidemiological and pathological research than the fibrous mineral, asbestos. Lung cancer because of asbestos was first reported in the 1930s and its association was confirmed in the 1950s. In 1960, Wagner and colleagues reported 33 cases of the "rare" tumour mesothelioma in workers exposed to asbestos in South Africa.

In asbestos workers who have developed asbestosis the risk of lung cancer is increased at least five times. For chrysotile there is a linear relationship between exposure and risk of lung cancer. Each additional fibre exposure (every ml a year) is equivalent to a 1% increase in the standardised mortality ratio.

Between 0.6% and 40% of lung cancers have been attributed to occupation, depending on place and time. Chlormethylesters, used in ion exchange resins, increase the risk of lung cancer 20 times and have a short latent period of 10-15 years. The type of cancer is small cell, also caused by uranium and beryllium (which also causes adenocarcinoma). Painters have a 30-100% increase in lung cancer. This may be caused by heavy metal salts or chromates, organic solvents, or exposure to silica and asbestos.

Over 40% of people with asbestosis die of lung cancer, and 10% die of mesothelioma. Mesotheliomas, which are predominantly of the pleura (ratio of 8:1 with peritoneum), have usually been growing for 10 to 12 years before becoming clinically evident. This latency can be very long—often 30 years and sometimes up to 50 years. However, median survival from the time of initial diagnosis is usually short—three to 12 months.

The amphibole fibres in crocidolite (blue asbestos) and amosite (brown asbestos) carry the greatest risk of causing mesothelioma, but the serpentine fibres in chrysotile (white asbestos) can also do so, especially if they contain tremolite. In about 90% of patients with mesothelioma, close questioning will usually show some earlier exposure to asbestos. The possible risk to neighbourhoods outside asbestos factories from discharged asbestos dust or contaminated clothing brought home should not be forgotten.

The annual number of deaths from mesothelioma has increased rapidly from 153 in 1968 to 1595 in 1999. The latest projections suggest that male deaths from mesothelioma may peak in about 2011, at about 1700 deaths every year. Occupations with the highest risk of mesothelioma for men include metal plate workers (including shipyard workers), vehicle body builders (including rail vehicles), plumbers and gas fitters, carpenters, and electricians.

Occupations causally associated with urothelial tract cancers

- Dyestuffs and pigment manufacture
 - Rubber workers (in tyre, tube, and cable making before 1950)
 - Textile dyeing and printing
 - Manufacture of some chemicals (such as 4,4-methylene-bis-(2-chloroaniline) (MbOCA))
 - Gas workers (in old vertical retort houses)
 - Laboratory and testing work (using chromogens)
 - Rodent controllers (formally using (alpha)-naphthylthiourea)
 - Painters
 - Leather workers
 - Manufacture of patent fuel (such as coke) and firelighters
 - Tar and pitch workers (roofing and road maintenance)
 - Aluminium refining
-

Asbestos related cancers

- Lung
 - Malignant mesothelioma—most commonly of pleura, occasionally peritoneal, and rarely of pericardium
 - Larynx
 - Possibly gastrointestinal tract
-

Smoking and asbestos

Asbestos	Tobacco	Lung cancer rate per 100 000
–	–	11
+	–	58
–	+	123
+	+	590

Smoking with concomitant exposure to asbestos greatly increases the risk of developing lung cancer: compared with non-smokers not exposed to asbestos, a smoker exposed to asbestos has a 75-100 times greater risk if exposure was sufficient to cause asbestosis, otherwise the risk is about 30-50 times higher. This multiplicative theory on effects of asbestos exposure and smoking, however, has recently been disputed

Blue asbestos

White asbestos

Asbestos legislation

Asbestos is controlled in the United Kingdom by three complementary sets of regulations:

- **The Asbestos (Licensing) Regulations** (amended 1998) require work with the most dangerous types of asbestos (coating, lagging, and asbestos insulating board) to be carried out only by contractors who have a licence issued by the Health and Safety Executive
- **The Control of Asbestos at Work Regulations** (amended 1998) lay down the practices that must be followed for all work with asbestos, including that which requires a licence. Employers must prevent the exposure of employees to asbestos or, where this is not reasonably practicable, reduce exposure to a level that is as low as possible
- **The Asbestos (Prohibitions) Regulations** (amended 1999) prohibit the importation into the United Kingdom, and the supply and use within Great Britain, of amphibole asbestos—crocidolite (blue) asbestos and amosite (brown) asbestos—and, since 1999, of chrysotile (white) asbestos

The supply and fitting of vehicle brake linings containing asbestos is prohibited in **The Road Vehicles (Brake Linings Safety) Regulations 1999**, and the European Union has amended the **Marketing and Use Directive (76/769/EEC)**, which prohibits the marketing and use of chrysotile asbestos throughout the EU after 1 January 2005, with one derogation for diaphragms for the chlor-alkali process

Forthcoming legislation will require employers to manage the risk from asbestos in non-domestic premises

The latest amendments to the Control of Asbestos at Work Regulations 1987 (which came into force in 1999) target workers who come across asbestos accidentally, such as electricians, plumbers, other maintenance workers, and demolition workers. The Amendment Regulations also tighten the law on control of exposure to asbestos by lowering the action level and the control limit for chrysotile

Mesothelioma extending through needle biopsy tract

Occupations involving exposure to asbestos

- Manufacture of asbestos products
- Thermal and fire insulation (lagging, delagging)
- Construction and demolition work
- Shipbuilding and repair (welders, metal plate workers)
- Building maintenance and repair
- Manufacture of gas masks (in second world war)
- Plumbers and gasfitters
- Vehicle body builders
- Electricians, carpenters, and upholsterers
- Armed forces (historical)

Tyndall beam photography showing asbestos fibres released by handling of asbestos boards (left), emphasising the need for proper protection when dealing with asbestos (right)

Ultraviolet radiation

Ultraviolet radiation from exposure to sunlight causes both melanotic and non-melanotic skin cancers (basal cell and squamous cell carcinomas), but an excess of skin cancers in outdoor workers is seen only in those with fair skin. Initial presentation may be that of solar keratoses or a premalignant state. Immunosuppression can increase the risk; other possible additive factors are trauma, heat, and chronic irritation or infection.

Premalignant melanosis (lentigo maligna) in a man who retired after a lifetime of working outdoors

Mineral oils

The classic epithelioma of the scrotum or groin caused by contact with mineral oil is rarely seen today, but these tumours can appear at other sites (such as arms and hands) if contamination with oil persists.

Other occupational carcinogens

Ionising radiation is a carcinogen at low doses (0.2 gray or a dose rate of 0.05 mSv per min). Cancer or hereditary defects are known as stochastic effects and can only be minimised. Cataract, sterility, and skin disorders are deterministic effects and can be prevented by keeping exposure below threshold. The recommended dose limit is 20 mSv a year averaged over five years for occupational exposures and 1 mSv for the public.

Epithelioma of groin caused by past exposure to mineral oil

Proven human carcinogens

Miscellaneous proved human carcinogens

Miscellaneous proved human carcinogens	Site of cancer
Aluminium production	Lung, bladder, skin
Benzene in petroleum associated industries	Haemopoietic
Bis-(chloromethyl)-ether in production of ion exchange resin	Lung
Benzene and leather dust in boot and shoe making and repair	Haemopoietic, nasal
Polycyclic aromatic hydrocarbons and aromatic amines in coal gasification and coke production	Lung, bladder, skin
Coal tars and pitch in roofing and road maintenance	Lung, bladder, skin
Ethylene oxide as medical steriliser and chemical intermediary	Lung, bladder, skin
Formaldehyde and hardwood dust in furniture and cabinet making	Nasal, paranasal
Isopropyl alcohol manufacture	Nasal, paranasal
Mineral and shale oils in engineering and metal machining, past exposure to mule spinning in cotton industry and jute processing	Skin, scrotum
Solvents and pigments in painting and decorating	Lung, bladder, stomach, oesophagus
Mists of strong inorganic acid (sulphuric acid) in acid pickling and soap making	Nasal, larynx
Radon in underground mines	Lung
Soots from chimney sweeping and flue maintenance	Lung, skin
Antineoplastic agents	Bladder, haemopoietic

Frieben documented the first case of skin cancer on the hand of an x ray tube factory worker in 1902. Cancer risk estimates on nuclear workers are still not conclusive, and the Gardener hypothesis that the children of radiation workers have an increased risk of leukaemia has not been supported. However, incidence may be increased in emergency workers. The epidemiological evidence from studies concerning airline crew who may receive the equivalent of 100 mSv over a 20 year period from cosmic radiation are inconclusive. No excess cancer has been reported among therapeutic or diagnostic radiologists.

All studies on electromagnetic radiation show inconsistencies and seldom indicate dose-response trends. This may mean that there is no association between electromagnetic fields and cancer, or that there is a risk but studies have not been able to show it. Particular aspects studied so far have been leukaemia, brain cancer, male breast cancer, electrical workers, and welders, but a broader research hypothesis is needed.

Studies of manmade mineral fibres have looked only at small exposures in terms of fibres and years of exposure. An increased risk of lung cancer was found in rock wool workers but it was not possible to conclude that it was caused by manmade mineral fibres. No risk was found in glass wool or glass filament workers. Five deaths from mesothelioma have

been found in various cohorts, but at least three of these workers may have previously been exposed to asbestos.

There is sufficient evidence for the carcinogenicity of inhaled crystalline silica in the form of quartz or cristobalite. Studies show the Bradford-Hill criteria of temporality, consistency, exposure-response gradients, and convergence with experimental and clinical evidence. Measures to prevent silicosis are likely to reduce lung cancer risk.

16 Occupational dermatoses

Ian R White

Skin disorders are among the most often encountered problems in the occupational health setting, and although there are many dermatoses that have occupational relevance, the overwhelming majority are dermatitic. In the United Kingdom, in the period 1998-2000, of the estimated 4540 workers each year with work related skin disease seen by specialist physicians, about 80% were diagnosed as having contact dermatitis. Occupations considered to be at greatest risk are hairdressers and barbers, grinding machine setters and operators, galvanisers, rubber process operatives, and printers.

Contact dermatitis

In current terminology the term “dermatitis” is used synonymously with “eczema” to describe inflammatory reactions in the skin with a spectrum of clinical and histopathological characteristics.

A dermatitis may be entirely endogenous (constitutional) or entirely exogenous (contact). The latter consists of irritant and allergic contact reactions. Commonly, a dermatitis has a multifactorial aetiology and may be aggravated by the presence of pathogens (for example, *Staphylococcus aureus*). Assessment of the relative importance (contribution) of the possible factors can be difficult and subjective. Atopic hand dermatitis and vesicular hand dermatitis are examples of endogenous conditions.

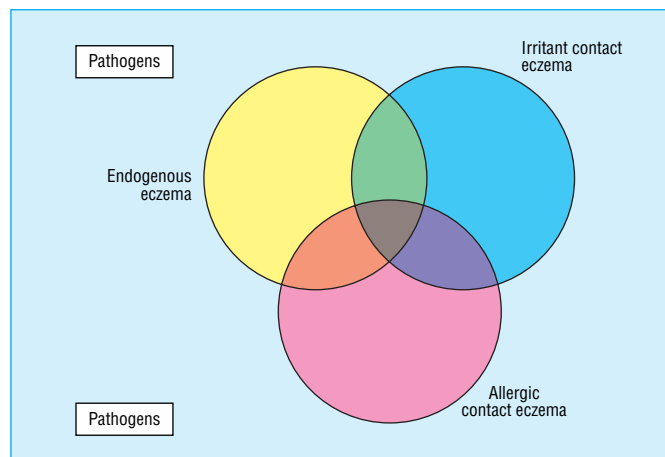

An occupational dermatitis is one where the inflammatory reaction is caused entirely by occupational contact factors or where such agents contribute to the reaction on a compromised skin—that is, they are partially responsible.

In most cases, an occupationally related dermatitis will affect the hands alone or there may be spread onto the forearms. Occasionally, the face may be the prime site of dermatitis (for example, with airborne agents); other sites may be affected.

Irritant contact dermatitis

This is initiated by direct chemical or physical damage to the skin. All individuals are susceptible to the development of an irritant contact dermatitis if exposure to the irritant (toxic) agent or agents is sufficient. It occurs particularly where the stratum corneum is thinnest. Hence, it is often seen in the finger webs and on the backs of the hands, rather than on the palms. Irritant contact dermatitis is of two principal types: acute and chronic. The former is caused by exposure to an agent(s) causing early impairment in stratum corneum function followed by an inflammatory reaction. The latter is caused by repeated exposure to the same or different factors, resulting in “cumulative” damage until an inflammatory reaction ensues and persists for a prolonged period, even after further exposure is stopped. Those with a history of atopic eczema, and especially atopic hand eczema, are at particular risk of developing chronic irritant contact dermatitis. Chronic irritant contact dermatitis is particularly seen in “wet work.”

Wet work, solvents, detergents, soluble coolants, vegetable juices, wet cement, low relative humidity, and occlusive gloves are all examples of common irritants.

Dermatitis may be endogenous or exogenous, or a combination of these, and may be aggravated by pathogens

Indications for occupational cause of dermatitis

- A dermatitis first occurred while employed
- There is a history of aggravation by work
- There may be, at least initially, improvement (or clearance) when not at work
- There is exposure to irritant factors or potential allergens
- Work is in an “at risk” occupation

Irritant contact dermatitis

Acute

- Severity of reaction depends on “dose” of irritant agent
- “Chapping” can be considered a minor form, with a “chemical burn” (for example, cement burn) being an extreme event.
- Intermediate eczematous reactions are common; minor reactions are very common
- May occur on the face—for example, low humidity occupational dermatosis, airborne irritant vapours
- Once the irritant factor(s) has been removed, resolution is usually spontaneous without important sequelae

Chronic

- A persistent dermatitis and the most common cause of continued disability from occupational skin disease
- Problem continues for long periods even with avoidance of aggravating factors
- Re-exposure to even minor irritant factors may cause a rapid flare
- Even after apparent healing there may be an indefinitely increased susceptibility to recurrence of a dermatitis after irritant exposure

Examples of common occupational allergens

- Biocides—for example, formaldehyde, methylidibromoglutaronitrile, methylchloroisothiazolinone
- Hairdressing chemicals—for example, *p*-phenylenediamine
- Chromate (leather, cement)
- Rubber accelerating chemicals—for example, thiurams, carbamates, mercaptobenzothiazole
- Epoxy resin monomers (plastics manufacturing, electrical manufacture)
- Plant allergens—for example, sesquiterpene lactones (horticulture)

Listing of ingredients

All cosmetic (skin care) products in Europe have full ingredient listing on the product packaging, with uniform nomenclature. Skin cleansers, barrier creams, and after work creams are legally cosmetic products. Labelling permits tracing of sources of exposure to allergens. However, there is a lack of meaningful ingredient labelling on other types of consumer and industrial products.

Lichenified and fissured eczema on hands of bricklayer resulting from chronic irritant dermatitis. Patch tests were negative, and he was not sensitive to chromate

Allergic contact dermatitis

This is a manifestation of a type IV (delayed) hypersensitivity reaction. An allergic contact dermatitis will develop at the site of skin contact with the allergen, but secondary spread may occur. Contaminated hands may spread the allergen to “non-exposed” sites. Trivial or occult contact with an allergen may result in the persistence of a dermatitis; some allergens are “ubiquitous.”

Presentation of an allergic reaction has two phases: induction and elicitation. Even with potent experimental allergens there is a minimum period of about 10 days from the first exposure to the immunological acquisition of hypersensitivity. The probability of developing hypersensitivity depends on the sensitising capacity of the chemical and exposure to it. Exposure is assessed in terms of dose every unit area applied to the skin. Most potential allergens on the consumer and industrial market have a low intrinsic allergenic potential, but there are important exceptions, including some biocides (preservatives). Contact allergens tend to be low molecular weight (< 600) and capable of forming covalent bonds with carrier proteins in the skin. It is not possible to determine an individual's susceptibility to the development of contact allergy. Hypersensitivity is specific to a particular molecule or to molecules bearing similar allergenic sites. Although hypersensitivity may be lost over a long time, once acquired it should be considered to last indefinitely.

Management of occupational dermatitis

- An understanding of the patient's job is essential. A job title is not sufficient for this understanding: the question to be asked is not “what do you do?” but “what do you actually do and how do you do it?” The title “engineer” carries a multiple of descriptions ranging from the desk bound professional to the lathe worker exposed to soluble coolants.

Development of acute (top) and chronic (bottom) irritant contact dermatitis

Relevance of contact allergens

- Current: exposure is causing dermatitis or is aggravating it
- Old: past history of exposure but no current exposure
- Don't know: unknown whether there is current exposure to the allergen or whether exposure is important to the dermatitis
- Exposure: must have occurred but no history of it

Sheeted eczema over the dorsal aspect of the hand and up to the forearm, resulting from allergic contact dermatitis to a carbamate accelerator in protective rubber gloves

From the job description, it will be possible to estimate sources of excessive contact with potentially irritant contact factors or allergens. The provision of material safety data sheets may be helpful in this evaluation, although the information that they contain is often superficial, generic, and is that required for regulatory requirements. A site visit to watch the worker working may be necessary.

- The history and anatomical distribution of the dermatitis may provide clues as to the aetiology.
- Irritant contact dermatitis may occur as “epidemics” in a workplace if hygiene has failed. Allergic contact dermatitis is usually sporadic in a workplace.
- The evaluation of irritant factors is always subjective. Evaluation of allergic contact factors is objective and provided only by diagnostic patch test investigations. Properly performed, patch tests will show the presence or absence of relevant allergens.
- Patch testing is the only method for the objective evaluation of a dermatitis; however, there are major pitfalls in the use of this essential tool, so adequate training and experience is necessary if it is to be used properly. The ability to assess relevance of allergens is central.
- A competent assessment requires all of the above followed by recommendations on reducing or stopping exposure to the offending agent(s) and similar ones.
- The diagnosis of an occupational dermatitis should describe thoroughly the nature of the condition with due regard to any endogenous or aggravating factors. A general practitioner’s entry in a medical record of “Works in a factory, contact dermatitis. 2/52” is inadequate as a description of an important disease process, and it can have profound implications on the patient’s concept of his problem and employment.
- Delays in diagnosis resulting in continued exposure to relevant irritants or allergens can adversely affect the prognosis.
- Early referral to an appropriate dermatology department is necessary for a comprehensive assessment of a suspected occupational dermatitis; improper assessment can have devastating effects on future employment prospects for the individual, with important medicolegal implications. If in doubt, the patient should be referred.

Rubber latex protein sensitivity

Of continuing concern is the immediate type 1 hypersensitivity reaction to proteins present in natural rubber latex used to make gloves and other items. This should be differentiated from irritant contact dermatitis and allergic contact dermatitis, which can also be attributed to chemical agents used in latex products, particularly gloves.

Prevalence and incidence of sensitivity to rubber latex proteins remain unquantified. The prevalence in the general population is thought to be less than 1%, but is likely to be higher within certain risk groups. A prevalence of 2.8-17% has been reported in healthcare workers, and in other occupations where workers are regularly exposed to rubber latex (hairdressers, greenhouse workers, housekeeping staff, and glove factory workers) the frequency of allergy has been reported as ranging from 5-11%.

At particular risk are people with spina bifida (prevalence reported to be 18-65%), atopic individuals, and individuals with certain food allergies (for example, to avocado, chestnut or banana, and kiwi fruit).

Rubber latex protein sensitivity can result in reactions including urticaria, rhinitis, and asthma. The latter is more

The primary prevention of occupational dermatitis is aimed at providing appropriate information and protection

- Awareness by employer and employee of the potential risks of exposure
 - Education on the necessity of good occupational hygiene precautions
 - Adequate provision of suitable and effective means of reducing exposure
 - Awareness of the limitations of personal protection devices
-

It is not possible to be definitive about aetiology from the distribution and morphology of a dermatitis on the hands. For example, vesicular hand dermatitis with a “classical” endogenous distribution may be mimicked by an allergic contact dermatitis to isothiazolinone biocides or chromate sensitivity. It is a major error to rely on patterns of hand dermatitis in making a diagnosis

Patch testing

- Properly performed requires expertise, time, and proper facilities
 - Difficult to undertake adequately in the workplace. There are no short cuts
 - Primarily a hospital based procedure
 - Should be performed only by those with appropriate training who can prescribe an appropriately comprehensive screen, know what not to test, know what to dilute for testing, can competently read the reactions, and can give authoritative advice after interpretation of the reactions
 - Anyone can patch test; few do it well. If you don’t know how to do it, don’t do it
-

Immediate contact reaction to latex proteins in examination gloves. Type 1 hypersensitivity reactions to latex proteins are of growing concern

common when starch powdered gloves have been used. In the healthcare setting, gloves made from rubber latex are likely to be the main cause of sensitisation in staff, as well as the main cause of symptoms in those who are allergic. Therefore, prevention includes clear policy regarding the type of glove used. If latex gloves are to be used, powdered rubber latex gloves should not be used, and extractable protein levels in latex gloves must be as low as possible, as should the level of allergenic protein residues. Staff with known sensitivity should be provided with non-latex alternatives.

A definitive demonstration of hypersensitivity can be made by skin prick testing with the water soluble proteins. Commercial preparations are available; the proteins can also be eluted from a suspect rubber item. Radioallergosorbent tests are less sensitive.

Other occupational dermatoses

- Contact urticaria—type I hypersensitivity reaction—for example, natural rubber latex protein
 - Chloracne (halogenacne)—acneiform eruption caused by certain halogenated aromatic hydrocarbons; a symptom of systemic absorption
 - Oil folliculitis (oil acne)—irritant effect of neat petroleum oils localised to hair follicles
 - Depigmentation (leukoderma)—caused by hydroquinone and phenol derivatives
 - Hyperpigmentation—caused by mineral oils, halogenated hydrocarbons, photodynamic actions of psoralenes and tar products
 - Skin cancer (see chapter 15)
 - Skin infections (see chapter 14)
-

17 Work, genetics, and reproduction

Nicola Cherry

The sequencing of the human genome, and the intense interest that accompanied this achievement, again raised issues surrounding the interaction of genetic and environmental exposures in causing disease. Even where exposures at work and in the environment have been clearly shown to be related to specific pathologies, and preventive measures initiated, the question of genetic susceptibility remains: why do only some of those exposed develop the disease? Understanding of such susceptibility will seldom exclude workers, but it may improve understanding of the mechanisms by which disease occurs, and suggest approaches to prevention or treatment.

There is also concern that occupational or environmental exposures may affect subsequent generations through changes to stem cells; by this means an infant born to such a parent may be at greater risk of disease even if exposure of the parent ceased long before the child was conceived. Evidence from human studies of occupational exposure affecting the genetic blueprint of the next generation is sparse and controversial, but pressing questions remain about whether such exposures can cause infertility, affect the outcome of pregnancy, or influence the development of the infant in later life.

In all these areas—genetic susceptibility, genetic alteration, and reproductive health—exposures in the working population may be of particular concern because exposures tend to be greater than in the general population, a large proportion of those exposed are of reproductive age, and any exposure effects that are found are, in principle, preventable. Environmental exposures to the general public (including the very young, and pregnant or nursing mothers) through contaminants in food, water, and air may also be suspected of affecting reproductive health. For example, even trace amounts of chemicals affecting the endocrine system of pregnant women may be responsible for the increased rate of testicular cancer seen in many societies.

Work and genetics

Why should occupational health professionals be concerned with the genetic make up of people in the workforce or who seek to join it? Firstly, in some, genetic inheritance, even in the absence of a specific occupational exposure, will lead to disease that will put at risk themselves, their fellow workers, or the general public. For example, a worker genetically programmed to develop Huntington's disease, if employed as a driver of a high speed train, may put the public at risk in the early stages of the disease before a diagnosis can be made that permits redeployment or retirement on medical grounds. Secondly, some genetic conditions render a person unable to tolerate work environments that can be tolerated by other workers. For example, deep sea diving may induce a crisis in a worker carrying the gene for sickle cell disease and, as a result, the worker and others may be put at peril. Thirdly, a particular genetic variant (or polymorphism) or a combination of variants may carry a risk of ill health if a worker is exposed to a chemical that is detoxified by the enzyme produced by the gene. The case of slow acetylators is a well known example. Where such a disease is a serious threat to quality of life or life

Genetic testing

- Can identify a predisposition to illness—for example, thalassaemia, Huntington's disease, sickle cell disease
- Could be used for genetic monitoring—for example, exposure to radiation or polycyclic aromatic hydrocarbons
- Has been used for estimation of fitness to work (exclusion or protection)—for example, exclusion of those with sickle cell trait from flying, diving and compressed air work, and exclusion of those with glucose-6-phosphate dehydrogenase deficiency from work involving naphthalene or trinitrotoluene, and cultivation or processing of broad beans
- Has been proposed as a way to:
 - predict the likelihood of common diseases (diabetes, schizophrenia—for example) that might raise sickness absence rates or medical costs to employers
 - identify resistant individuals (rapid acetylators—for example) who could, in theory, be exposed without harm to higher concentrations of toxic chemicals

Genetic testing or screening in an occupational context is clearly beset with problems of ethics, effectiveness, and practicality

Genetic information

- Is a unique identifier
 - Can be done on a small sample
 - Can be done covertly, without consent
 - Can be used for prediction
 - Is of interest to employers, insurance companies, and relatives
 - Has potential commercial value (patents)
 - Can outlast the source
 - Can define susceptible groups
 - Can be used for purposes other than those for which it was collected
-

Statement of the Nuffield Council on Bioethics 1993

Genetic screening of employees for increased occupational risks ought only to be contemplated where:

- (i) Strong evidence exists of a clear connection between the working environment and the development of the condition for which genetic testing can be conducted
 - (ii) The condition in question is one that seriously endangers the health of the employee or is one in which an affected employee is likely to present a serious danger to third parties
 - (iii) The condition is one for which the dangers cannot be eliminated or significantly reduced by reasonable measures taken by the employer to modify or respond to the environmental risks
-

itself, it may be tempting to consider introducing screening to monitor such workers and exclude them from exposure. The balance of opinion, however, is that such screening for genetic susceptibility is seldom, if ever, justified from either an ethical or a practical standpoint.

A further issue is whether the potential for a substance to cause mutation (and ultimately cancer) can be monitored through the formation of “adducts” when a chemical binds to DNA after exposure (for example, to polycyclic aromatic hydrocarbons) and can be measured in cells obtained from a routine blood sample. Those with the highest number of adducts may be thought to be at the greatest risk of developing cancer, either because their exposures have indeed been higher (perhaps because of poor environmental controls) or because a finding of a particularly high level of adducts may in itself be an indication of an inherent inability to detoxify a particular mutagen (or to repair damage when it occurs). Given the wide variation in adducts in the same individual measured on separate occasions and the uncertainty in interpreting such measures in assessing the risk of cancer in later years, the routine use of DNA adducts as exposure effect markers for individual workers may not be defensible. However, occupational health professionals need to understand the potential importance of such measures, as evidence of a relevant mechanism (that is, the formation of adducts) is already being used by the International Agency for Research on Cancer in the designation of chemicals as carcinogens (for example, ethylene oxide).

Genetic analysis may also have a place in the attribution of causality after disease has occurred. Mutations in the suppressor gene *p53* have been found in most types of cancer; in individual cases, it may be helpful to consider whether the mutation observed is one that occurs more often in tumours associated with one type of exposure, increasing the post facto probability that this is the exposure that was responsible. In epidemiological studies, where an excess of ill health is observed but the importance of exposure is uncertain, showing that those with a genetic susceptibility to the exposure are more likely to develop the disease may again shift the balance towards acceptance of causality.

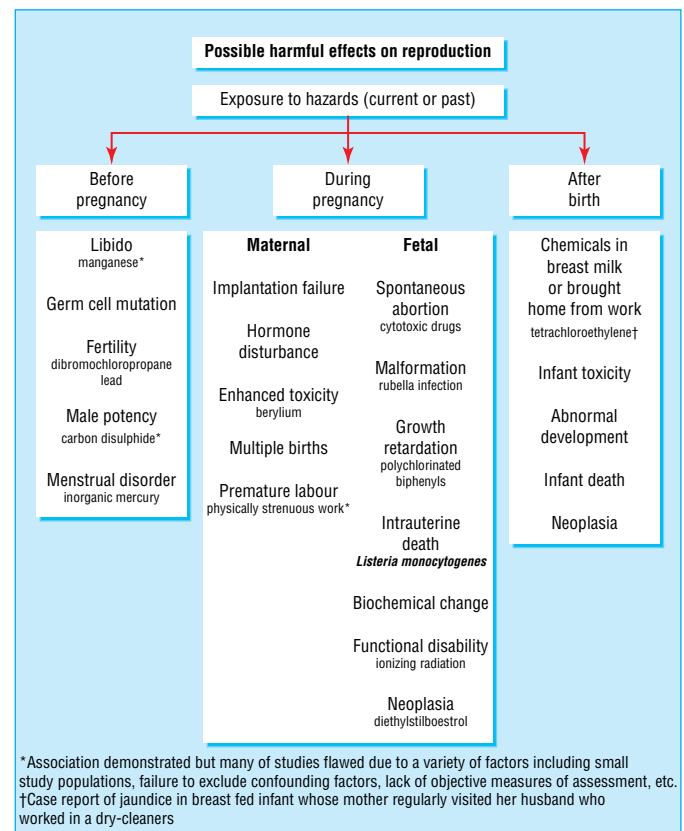

Genetics and reproduction

The time window for genetic damage in reproductive stem cells differs markedly between men and women. In women, ova that will be available for fertilisation in adulthood go through most phases of development while the fetus is in utero. The implication is that genetic changes to the ovum that will affect children born to the woman will be caused by exposures to the grandmother while she was pregnant. In practice, there is little evidence that this does occur (at least for occupational exposures). In men, by contrast, damage to stem cells that may affect the genetic complement of the resulting child can happen at any time, from in utero exposure to the point at which production of the sperm occurs. There is then a further three month window for adverse environmental effects as the sperm that will eventually fertilise the ovum moves through its final stages of development. Although the time period of opportunity for damage is much greater for men, and the protection from external influences is less stringent than in utero, the evidence of such effects from occupational exposure in humans is sparse.

Finally, environmental exposures in utero have been suspected to cause childhood cancers, although the best evidence for this again comes from pharmaceutical products—mothers’ use of diethylstilboestrol—for example,

Statement of the Human Genetics Advisory Committee 1995

- (i) An individual should not be required to take a genetic test for employment purposes—an individual’s “right not to know” their genetic constitution should be upheld
- (ii) An individual should not be required to disclose the results of a previous genetic test unless there is clear evidence that the information it provides is needed to assess either current ability to perform a job safely or susceptibility to harm from doing a certain job
- (iii) Employers should offer a genetic test (where available) if it is known that a specific working environment or practice, while meeting health and safety requirements, might pose specific risks to individuals with particular genetic variations. For certain jobs where issues of public safety arise, an employer should be able to refuse to employ a person who refuses to take a relevant genetic test
- (iv) Any genetic test used for employment purposes must be subject to assured levels of accuracy and reliability, reflecting best practice. We recommend that any use of genetic testing should be evidence based and consensual. Results of any tests undertaken should always be communicated to the person tested and professional advice should be available. Information about and resulting from the taking of any test should be treated in accordance with Data Protection principles
 Furthermore, test results should be carefully interpreted, taking account of how they might be affected by working conditions, and
- (v) If multiple genetic tests were to be performed simultaneously, then each test should meet the standards set out in (ii), (iii), and (iv)

Possible harmful effects on reproduction

was responsible for vaginal cancers in female offspring as they reached adolescence and beyond. It is likely that such somatic mutations are more common than those to stem cells, which would perpetuate genetically mediated disorders through the generations.

Work and reproductive health

Although the fertility of both men and women can be adversely affected by exposure to chemical compounds (particularly certain pesticides and solvents), metals, the physical environment (heat, radiation), and other factors at work, evidence suggests that the range of exposures with such adverse reproductive effects is fairly limited. Once the fertilised ovum is implanted and begins to develop, the risk seems much greater, with exposure to chemicals, infective agents, and radiation having the capacity to interrupt fetal development during the period of organogenesis (as happened with thalidomide), to interfere with the development of the nervous system (with effects on hearing or eyesight—for example, and possibly on rates of spina bifida), or to result in retardation (not evident at birth) in the infant as it develops. Importantly, there is good epidemiological evidence that heavy physical demands at work are related to fetal death and prematurity. Few occupational cohort studies have been able to follow the offspring of workers into childhood to determine subtle effects on development that may result from exposure in utero, but if community studies of environmental exposures are correct in their interpretation, similar effects of occupational exposure would be anticipated.

Environment and reproductive health

Many of the concerns about effects on the developing infant have arisen from interpretation of community studies of the relation between exposure to lead (from flaking paint or gasoline), household pesticides (used repeatedly in poor quality housing in hot climates), and neurotoxic substances (for example, organic mercury) from diet (fish, game) or water and infant development. Of particular interest in recent years has been the suggestion that endocrine modulators from water, diet (phytoestrogens such as soya), or exposures to—for example, plasticisers such as phthalates, have effects in utero on the male fetus, leading to congenital malformations (hypospadias), low sperm count, and testicular cancer. Results of research into such effects in humans are just becoming available and are not wholly supportive of this overarching hypothesis, but the impetus arising from this elegant synthesis has pushed environmental (and occupational) reproductive health into the focus of regulators throughout the western world.

The figure showing possible harmful effects on reproduction is adapted from Barlow SM, Dayan AD, Stabile IK. Workplace exposures and reproductive effects. In: Baxter PJ, Adams PH, Aw TC, *et al.*, eds. *Hunter's diseases of occupations*. London: Edward Arnold, 2000.

Agents associated with risk to male fertility

Chemical

- Carbaryl: abnormal sperm morphology
- Carbon disulphide: oligospermia, abnormal morphology
- Chlordecone: oligospermia, reduced sperm motility, abnormal sperm morphology
- Dibromochloropropane: oligospermia/azoospermia
- Lead: oligospermia, reduced sperm motility, abnormal sperm morphology

Physical

- Heat: oligospermia
- Ionising radiation: oligospermia or azoospermia

Biological

- Mumps: oligospermia or azoospermia
-

Some hazards associated with adverse pregnancy outcome

Chemical

- Anaesthetic gases: spontaneous abortion, growth retardation, intrauterine death*
- Organic solvents: spontaneous abortion*
- Lead: spontaneous abortion, intrauterine death, prematurity
- Polychlorinated biphenyls (PCBs): congenital PCB syndrome

Physical

- Ionising radiation: spontaneous abortion, growth retardation, malformation of central nervous system, childhood cancer
- Heavy physical demands, shift work, extremes of temperature: spontaneous abortion, prematurity, growth retardation, intrauterine death*

Biological

- Rubella: spontaneous abortion, intrauterine death, congenital rubella syndrome
- Varicella zoster infection: neonatal infection, congenital varicella syndrome
- Parvovirus B19: hydrops fetalis, fetal loss

*The epidemiological evidence is conflicting for some of these hazards

18 Pollution

Robert Maynard

Pollution of the air, soil, and water is a major problem in many parts of the world. In developed countries the worst excesses of industrial pollution are coming under control but have been replaced by pollutants generated by motor vehicles. In developing countries the rapid increase in industrialisation combined with the increased use of motor vehicles is producing conditions as bad, if not worse, than those seen in developed countries a century ago. Dense chemical smog is common in megacities such as Mexico City and São Paulo and is an increasing problem in many of the cities of China and India. Photochemical air pollution is a problem in the Mediterranean area; in fact, only the dense and damp smogs so characteristic of London until the 1950s seem to have disappeared. The combination of a damp, foggy climate and intensive use of soft coal in inefficient household fireplaces does not seem to have been repeated on such a scale elsewhere, although similar conditions may have occurred in Eastern European countries and in Istanbul. High concentrations of coal smoke and sulphur dioxide do occur in some Chinese cities, and forest fires have, over recent years, caused significant “haze” conditions in South East Asia.

Air pollution is not solely an outdoor problem: in many countries indoor pollution produced by the use of biomass as a fuel damages health, especially that of women and young children who may be exposed for much of a 24 hour day. The seemingly inevitable link between poverty and poor environmental conditions persists, and efforts to resolve this and instil a sense of environmental justice are only now beginning.

Air pollution is a major problem but so is pollution of water. Attention has been drawn to the contamination of drinking water with arsenic leached from soil in West Bengal. High levels of lead, nitrates, and pesticides have also been detected in drinking water in various countries. A recent problem in California has been the seepage of methyl *tert* butyl ether (MTBE) into drinking water: an ironic problem as MTBE was added to petrol as an oxygenating agent designed to reduce the production of air pollutants.

Air pollution

Air pollution is a worldwide problem. A recent publication by WHO estimated that of 17 major cities, nine had serious problems with suspended particulate matter—the WHO guideline was exceeded by more than a factor of two. The impact of air pollution on health is large: some three million deaths each year are attributed by WHO to air pollution. Of these, 2.8 million result from indoor exposure (1.9 million occurring in developing countries) and only 0.2 million occur as a result of outdoor exposure. Of these 0.2 million deaths, only 14 000 are thought to occur in developed countries. These figures are not easy to interpret. In the United Kingdom, airborne particles (PM_{10}) are thought to be associated with about 10 000 extra deaths every year. Those affected experience by far the greatest part of this exposure indoors. It is salutary to consider how much effort is put into controlling outdoor concentrations of air pollutants compared with indoor concentrations.

London street scene from 1923. The figure shows a classic London “smog”

Mixture of water vapour and smoke being emitted from an industrial site

Particulate air pollution

Until recently it was believed that airborne concentrations of particles in countries like the United Kingdom had fallen to such levels that effects on health had essentially disappeared. This is now known to be untrue.

An increase in PM₁₀ of 10 µg for every cubic metre is associated with about a 1% increase in deaths, although recent studies suggest that a lower percentage increase, perhaps 0.7%, might be more accurate. The effect on non-accidental hospital admissions is of the same degree. In a small country like the United Kingdom this leads to a large impact on health: 8100 deaths brought forward (all causes), and 10 500 hospital admissions (respiratory) either advanced in time (that is, the admission would have occurred but occurs earlier as a result of exposure to pollution) or caused de novo.

It has been argued that the extra deaths calculated in this way are merely deaths advanced by just a few days in those who are already seriously ill. This does not seem to be true, however: recent work by Schwartz has suggested that at least some of the deaths may be advanced by months. Studies in the United States have shown that living in a city with a comparatively high level of particles leads to a reduction in life expectancy.

Calculating the extent of the impact at an individual level is impossible because we do not know how many in a population are affected. If all people were affected equally, then at levels of particles found in the United Kingdom, the individual impact would be small, some days only. If, however (as is much more likely), the effect is unevenly distributed across the population, some would lose months, or even years, of life.

If this is the case in the relatively unpolluted United Kingdom then the effect in much more polluted developing countries must be large indeed. Predicting the size of the effect in developing countries is not easy as it will, in part, depend on the background prevalence of disease. Note that cardiovascular disease is increasing in some developing countries.

These calculations of the impact of particles on health have produced a revolution in thinking in inhalation toxicology. Some, being unable to understand the exact mechanism of effect, have argued that the associations are not causal. Others have, rather more usefully, set out to find the mechanism of effects, and research has flourished.

Ultrafine particles (less than 100 nm in diameter) have been suggested to play an important role. These particles contribute little to the mass concentration of the ambient aerosol but a great deal to its number concentration. The idea that the number of particles in every cubic metre of air may be more important than the mass per cubic metre has gained ground in recent years. More recently, the idea that total particle surface area per unit volume of air may be important has been discussed. If this is true then air quality standards dependent on mass measurements will need revision. The unusual and unexpected toxicological properties of ultrafine particles have been recently reviewed (see Further reading).

Photochemical air pollution

Concern about secondary pollutants generated from primary emitted pollutants by photochemical reactions began in Los Angeles in the late 1940s. Ozone is the best known photochemical air pollutant produced from nitrogen dioxide (see box) particles; other chemical species, including peroxy radicals derived from volatile organic compounds, are also important. Ozone is the classic example of a secondary air pollutant: essentially no ozone is emitted by sources of outdoor air pollution.

Ozone is a strong oxidising agent and at concentrations above 100 parts per billion (200 µg/m³) produces inflammation of

Electron micrograph of diesel particles. Individual particles are about 25 nm in diameter. Photograph kindly provided by Professor RJ Richards, Cardiff University

Modern epidemiological techniques employing time series analysis have shown that day to day variations in outdoor mass concentrations of particles are related to daily counts of events including deaths, hospital admissions, general practitioner consultations, and days of restricted activity

New trends in research on particulate air pollution

- Effects are not limited to the respiratory system; effects on the cardiovascular system are likely to be more important
 - Small particles (less than 2.5 µm in diameter) are likely to play an important role
 - The production of free radicals, perhaps as a result of metals acting as catalysts, is likely to be important
 - Changes in the control of the heart's beat to beat interval and in the production of clotting factors may be important
-

Ozone production reactions

It will be appreciated that as long as sunlight (represented by $h\nu$), oxygen, nitrogen dioxide, and peroxy radicals (RO₂, produced from volatile organic compounds emitted by motor vehicles) are present, ozone production will continue. The reactions stop at night and levels of ozone fall, to build up again the next day. Ozone is thus a problem in cities with heavy traffic and bright sunlight: Athens, Los Angeles, and Mexico City are examples. In the United Kingdom ozone is a greater problem in rural than in urban areas, the formative reactions taking place in polluted air masses drifting from the city to the countryside

the respiratory tract. This is reflected in a reduction in the forced expiratory volume in one second and peak expiratory flow rate. Pain on deep inspiration occurs and these effects lead, unsurprisingly, to a reduction in athletic performance. Interestingly, the effect is short lived, and daily exposure studies have shown that the effect is much reduced by about the fourth or fifth day. Epidemiological studies show that daily deaths and hospital admissions for asthma and other respiratory diseases are related to daily ozone concentrations. Discussion about a possible threshold of effect remains unresolved. If no threshold is assumed, the effects in the United Kingdom are large.

Combinations of air pollutants

Chemical air pollutants never occur alone. There is always a mixture, and it is likely that effects on health are caused by the mixture and might vary with the composition of that mixture. Separating out the more important pollutants has proved to be difficult, and recent studies have shown that the effects of one pollutant may be modified by co-pollutants. This seems to be the case in co-exposures to ozone and nitrogen dioxide. Much more work is needed in this area.

Carbon monoxide (a pollutant that is well known to produce lethal effects at high concentrations) has recently been shown by epidemiological studies to be associated with heart attacks and heart failure at current outdoor concentrations—a remarkable finding. Carbon monoxide may be acting as a marker for other pollutants in the ambient mixture, or at low concentrations it may have unexpected effects in sensitive subjects. Recent studies in volunteers who had angina have shown that carboxyhaemoglobin concentrations as low as 2% are associated with a reduction in “time to pain” on exercise.

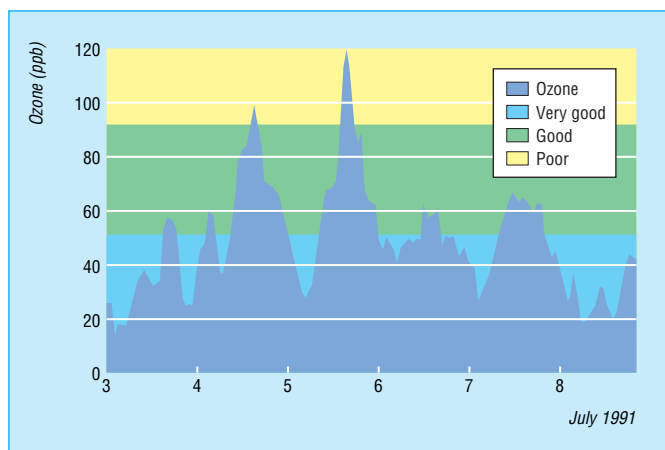

Carcinogenic air pollutants

Many well recognised human carcinogens occur in ambient air, both outdoors and, often to a greater extent, indoors. Studies in UK homes have shown—for example, that concentrations of benzene indoors may exceed those outdoors. Motor vehicles generate benzene, 1,3-butadiene, and polycyclic aromatic hydrocarbons. High levels of arsenic may occur near metal smelting works. These carcinogens are genotoxic and thus at all levels of exposure no guarantee of safety can be provided.

All estimates of increased risk of this sort are based on mathematical extrapolation from studies, in animals or man, of measured increases in risk on exposure to high concentrations. The process is unlikely to be precise and the accuracy of the predictions cannot be ascertained. This has led UK regulators to adopt a pragmatic approach and to set standards for ambient concentrations at levels at which the risk is judged to be very small and not to attempt quantification of the effects. Thus, in the case of benzene, a standard of five parts per billion (15.6 µg/m³) expressed as an annual average concentration has been adopted.

Indoor air pollution

All the pollutants discussed above, with the exception of ozone (which reacts rapidly with furnishings and fittings and disappears), occur indoors. Indoor concentrations are, in part, driven by outdoor sources as well as by specific indoor sources. Carbon monoxide and nitrogen dioxide may be produced by fires and by cooking—peak levels in kitchens can be higher than those commonly found outdoors. Recent work has led to concern about an association between nitrogen dioxide and respiratory infections, worsening of lung function in women with asthma, and increased sensitisation and response to allergens. Long term exposure to low levels of carbon

Daily variations in ozone concentrations.

Numbers of deaths and hospital admissions for respiratory diseases per year caused by ozone in both urban and rural areas of Great Britain (GB) during summer only

	GB, threshold (in parts per billion)	
	50	0
Deaths (all causes)	700	12 500
Hospital admissions for respiratory disease	500	9900

The WHO has published “unit risk factors” that allow the risk to be estimated (expressed as an increase in risk of getting a specified cancer as a result of lifetime exposure to a unit concentration of the carcinogen). For example, lifetime exposure to benzene of 17 µg/m³ is estimated to be associated with an increase of risk of 1 in 10 000. The unit risk at 1 µg/m³ is estimated as 6 × 10⁻⁶

monoxide that produce only mild symptoms may lead to lasting neurological effects.

Regulating indoor pollutant concentrations is difficult: fewer countries have produced standards for indoor air quality than for outdoor air quality. The need for regular maintenance of devices that can produce pollutants indoors, for smoke alarms, and for constant vigilance on the part of doctors dealing with potentially poisoned patients is obvious.

Water and soil pollution

In developed countries the quality of drinking water is often accepted unthinkingly as high: we assume that the water is safe to drink. In many countries, however, such an assumption may be unwise because of microbiological and chemical contamination. The former causes more disease than the latter but will not be considered here. Accidental contamination of water supplies occurs from time to time in all countries: in the United Kingdom the accidental contamination of water with aluminium sulphate in Camelford (Cornwall) in 1988 (see chapter 20) led to widespread complaints that are still the subject of investigation. The quality of water supplies is improving in many countries, but the rate of improvement is uneven. WHO reported that in the period 1990-4 the number of people without a satisfactory water supply increased in Africa, Latin America, and the Caribbean. In some countries, including developed countries such as the United Kingdom, concern has been expressed about the possible impacts on health of so called endocrine disrupting chemicals.

Conclusion

Pollution of air, soil, and water remains a problem in nearly all parts of the world. In developed countries air pollution tends to attract the greatest attention, and considerable efforts to control outdoor sources of air pollutants have been made. In developing countries both air and water pollution remain important problems, and a large effort will be needed before these are removed.

Compounds that are of proved concerns as water and soil pollutants

Arsenic

Arsenic is found in high concentrations in many countries including Argentina, Canada, Chile, China, Japan, Mexico, the Philippines, and the United States. The recent discovery of arsenic concentrations at 70 times the national standard of 0.05 mg/l in West Bengal has highlighted this pollutant. Poisoning via water leads to evidence of chronic toxicity including melanosis, hyperkeratosis, and skin cancer. In West Bengal 200 000 people are reported to be suffering from arsenical skin lesions

Nitrates

Nitrates leached from agricultural land may enter drinking water. The use of infant food prepared with such water can lead to poisoning, methaemoglobin being produced by interaction between nitrite ions (produced from nitrate ions) and haemoglobin. The reaction is an oxidative one (ferrous iron in haemoglobin being converted to ferric iron in methaemoglobin) but the exact mechanism is unclear. In very young children cyanosis may occur. In 15 European countries 0.5-10% of the population may be exposed to nitrate levels in excess of the WHO standard of 50 mg/l

Lead

Lead can be mobilised from pipes and solder joints, especially in areas with acidic water supplies ("soft water" areas). Lead is accumulated in the body and can damage the central nervous system. A number of studies have linked lead intake and a decreased intelligence quotient. Mercury and cadmium are examples of other metals that contaminate water supplies

Fluoride

Fluoride is added to water in some countries to provide protection against tooth decay: effective protection is provided at levels of 0.5-1.0 mg/l. The margin between protective and toxic effects is unfortunately narrow, and effects ranging from dental fluorosis (mottling of enamel) to skeletal fluorosis occur in some areas. High levels of fluoride are found in parts of the Middle East, Africa, and North and South America

19 Global issues

Tony Fletcher

Environmental effects on health can be direct, as in the effect of lead pollution on the development of children, or indirect—for example, the eventual health impacts of the loss of biodiversity among plant and animal species. Many widespread and global environmental issues impact on human health. A selection of important areas follow along with some of the policy instruments that seek to mitigate these global risks.

Carrying capacity

Man's activities of production and consumption affect not only our local environment but the environment of whole regions and the entire planet. Given the large scale of such activities in an increasingly globalised world, certain polluting or resource depleting activities that the carrying capacity of the local environment used to absorb now result in overload or contamination of global proportions. One of the best recognised examples in the 20th century has been the devastating effect of acid rain on natural ecosystems whose ability to absorb and eliminate sulphuric acid was overwhelmed.

The carrying capacity amounts to some 10 hectares for every person for the richest countries compared with only 2.5 hectares per person on a global average. Thus, on this and other measures there is not enough land to support the world's population at the level of consumption enjoyed by the most industrialised countries. Of course, there is no widespread enthusiasm to reduce levels of consumption. On the contrary, there are widespread aspirations to increase industrial production and employment and to reduce, or eliminate, poverty.

Various attempts have been made to estimate how many people can comfortably and sustainably live on this planet, based on some reasonable compromise between the (low) current average standard of living and the high average in the richest countries. Realistic estimates based on food production, water usage, energy consumption, and the integrated footprints fall mostly in the range of three to five billion people. With a world population of six billion and projected increases to at least 10 billion before any prospect of levelling off, the sustainable carrying capacity of the planet is already being exceeded.

Biodiversity

As pressure on land has increased in the past 100 years, the rate of extinction has accelerated. It is estimated that 20-50% of species present 100 years ago will have become extinct by 2100, with the rate of loss accelerating from now until then.

Many species are lost as biodiverse tropical rainforests are depleted by clearance and burning. This has practical consequences on human health by affecting food and drugs. Medicines have been identified and developed from tropical plants, and pharmacological possibilities for numerous species have not been explored. In the case of food, we have in the past relied on the cross breeding of food crops with wild strains to maintain productivity and resistance to pests, and will no doubt need to continue to do this, whatever achievements arise from genetic modification in laboratories.

Volcanic eruption, Montserrat—pollution on a grand scale and a social disaster

Silver mine—the social price paid for precious metal

The concept of *carrying capacity* for people derives from the *ecological footprint*: “the area of productive land and water required on a continuous basis to produce all the resources consumed, and to assimilate all the wastes produced”

The rate of loss of species is estimated to have increased from 10 000 a year in 1900 to some 50 000 a year in 2000

Arsenic in ground water

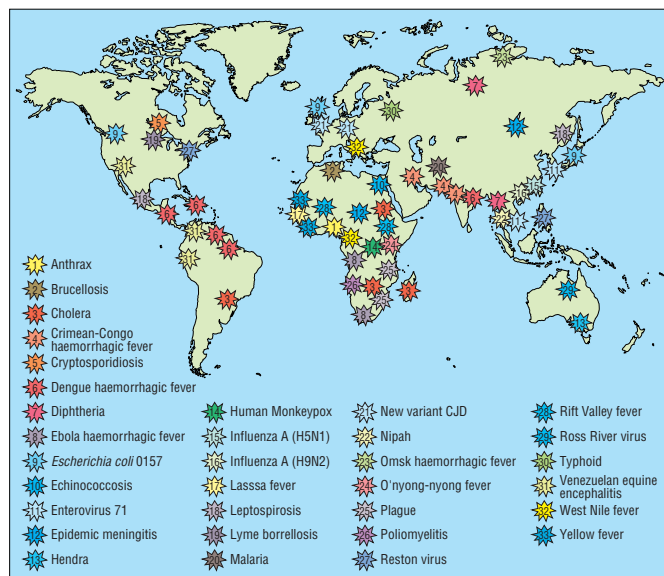

Arsenic is a widespread mineral in the Earth's crust and occurs at rather high concentrations in some ground waters that get exploited as sources of drinking water. In Europe few populations have been exposed and signs of arsenic toxicity, including melanosis and keratosis of the skin, peripheral neuropathy, and vascular and respiratory ill health, are rare. Consequently, attention has shifted to cancer risk, estimated by extrapolation from more exposed populations. Skin and internal cancers (bladder and lung in particular) have been clearly associated with higher levels of arsenic exposure and concern about risks at relatively low concentrations has prompted most countries to adopt a standard of 10 µg/l in drinking water. However, in some developing countries, most notably Bangladesh, it has recently been discovered that more than 20 million people are being exposed to over 50 µg/l and levels over 1000 µg/l have been found. Thus, many thousands of cases of arsenic poisoning have already occurred, and this is likely to be followed by many fatal cancers, especially if remediation measures are not put into place rapidly.

Global climate change

A significant upward trend in mean temperature is now in little doubt, and anthropogenic sources are substantially contributing, especially in relation to carbon dioxide. The Intergovernmental Panel on Climate Change (IPCC) in 2001 predicted an increase in 2-3°C over the course of the 21st century. The authoritative IPCC, among others, has highlighted a number of serious consequences if this were to happen. One consequence, the increase in frequency of extreme weather events, already seems to be underway. Melting of the polar ice caps, accompanied by a rise in sea levels, would lead to disastrous flooding of low lying coastal regions. Shifts in climate patterns would lead to changes in agricultural productivity and, given the time and investment it takes to adapt to such changes, most likely famine and conflict. The distribution of infectious diseases is expected to change, with malaria migrating north as temperatures rise. Other vector borne diseases threatening to spread include dengue fever, viral encephalitis, schistosomiasis, leishmaniasis, onchocerciasis, and yellow fever.

Stratospheric ozone depletion

Few have not heard of the ozone hole, with the accompanying increase in ground level exposure to ultraviolet radiation and the consequent increase of sunburn and skin cancer. Damage to the ozone layer is the result of chemical reactions between stratospheric ozone and certain chemicals, most notably the chlorofluorocarbons used as aerosol propellants and refrigerants. Although chlorofluorocarbons are inert at ground level temperatures, in the very cold stratospheric environment over the poles, sunlight breaks them down into reactive intermediates which in turn destroy the ozone present there. As the ozone is depleted, more harmful solar radiation gets through. In recognition of this problem, chlorofluorocarbons were banned under the Montreal Protocol of 1987. This was not implemented in every country, however, and in the meantime other ozone destroying chemicals have been identified. Because it takes some time for the ozone to build up again, ozone depletion is not expected to recover until the middle of the 21st century. Ground level ultraviolet light is predicted to rise by 12-15% relative to 1970s levels.

Unexpected outbreaks—examples of emerging and re-emerging infectious diseases, 1994-9

Emerging and re-emerging infectious diseases

Emerging infectious diseases are those that have been recently discovered, have increased in humans over the past two decades, or threaten to increase in the future

Re-emerging infections are infectious diseases which have increased (previously having diminished in incidence) because of ecological changes, public health decline, or development of drug resistance

Six major factors have contributed to their emergence or re-emergence:

1. Changes in human demography and behavior (for example, immunosuppression, aging population, migration, risky behaviours)
2. Advances in technology and changes in industry practices (for example, air conditioning cooling towers, changes in food processing, changes in rendering.)
3. Economic development and changes in land use patterns (encroachment on the tropical rainforests, conservation efforts, climate changes)
4. Dramatic increases in volume and speed of international travel and commerce of people, animals, and foodstuffs
5. Microbial adaptation and changes
6. Breakdown of public health capacity for infectious diseases

In most instances, the emergence of a specific agent results from a complex interaction of several factors

Examples of emerging and re-emerging infections include:

- HIV
- Legionnaire's disease
- Hantavirus
- E. Coli* O157
- Vancomycin resistant enterococci
- Severe acute respiratory syndrome (SARS)

Lead in the environment

Lead has multiple toxic health effects—haematological, renal, and neurological—although at typical levels of exposure in the environment, neuropsychological impacts are the main concern, especially for developing children. Aside from local contamination or pollution, exposure to lead has been quite widespread from dissolution into drinking water from lead piping, use of lead in paint in old houses, and airborne exposure from leaded petrol. In addition, people have been exposed via their food from the use of lead solder for sealing cans, although this has now been completely phased out.

However, the other sources still lead to exposure. Although the use of lead additive in petrol has virtually ceased, there is still much dust on roadsides from past use and this is resuspended or picked up by children; lead present in paint in older houses remains an important source as it is chipped off through normal wear and tear; again in older dwellings, lead pipes in the home or connecting with the main water supply can be a source, with solubility depending on the chemistry and pH of the water supply. Research into the effects of lead exposure on children's neurological development measures their intelligence quotient and emotional and behavioural development.

Polychlorinated biphenyls (PCBs)

PCBs, along with dioxins and chlorinated pesticides such as DDT, exhibit a particular persistence. They are not broken down in the environment and indeed are accumulated as they are taken up by plants, herbivores, and carnivores, with concentrations increasing at each level. Mass production of PCBs started in 1929 and expanded enormously until environmental damage was recognised in the 1960s. The first evidence of adverse health effect came in 1968 with the mass poisoning of Japanese who ate rice oil contaminated with PCBs. The resulting Yusho disease (named after the place where this incident took place), entailed disfiguring pigmentation of the skin, sweating, conjunctivitis, headaches, weakness, cough, and liver damage then later an increased incidence of cancer. For pregnant women, exposure led to malformed children. The effect of bioaccumulation on wildlife was subsequently established—for example, reduced fertility in various seabirds feeding on fish with accumulated PCBs. Production and use was, after some delay, reduced, with bans being introduced in the 1970s in Western Europe and the 1980s in Eastern Europe. Environmental levels of PCBs are slowly reducing again.

Transport and health

In recent years attention has been increasingly focused on the links between transport and health. The traditional dominant concern—death and injury from collision—has been extended to embrace transport related emissions. Pollution from industry and domestic fireplaces has fallen, but as a result of the phenomenal increase in mobility and car ownership, motor vehicles are now the main source of emissions in the United Kingdom (directly or through atmospheric reactions) of particulates, oxides of nitrogen, and ozone.

Added to these more obvious health risks are other concerns relating to quality of life and health—for example, trade-offs between different psychosocial impacts. Greater mobility has the potential to increase more distant social contacts and potentially to provide protection against

In children, a doubling of body lead burden 10–20 mcg/dl is associated with a deficit of 1–2 full scale IQ points

Lead smelter—the starting point of dissemination of a toxic metal

Smokestack industry—global relocation to the poorest countries

vulnerability to assault. Set against this is the community severance and loss of social networking and support within communities that is a consequence of busy roads passing through residential areas. Regular physical exercise is reduced if walking and cycling are cut in favour of car journeys; this has been shown dramatically in the case of children's journeys to school. Not only is this unhealthy per se, but it ingrains the habit of car dependence, leading to the cumulative effect of insufficient exercise.

Policy responses

This range of examples has been selected to illustrate the wide range of environmental impacts on health. Our choice of mode of transport has both local and global impacts. Our energy consumption has an impact via its contribution to global warming. Toxic chemicals in the environment may be local problems or bioaccumulating and thus contribute to very distant increases of risk. These may be natural as in the case of the arsenic contamination of drinking water, or manmade as in lead pollution.

In a parallel manner, the range of policy instruments for preventing adverse environmental impacts operates on various levels. At a global level international conventions play a major role, although the important and potentially expensive ones are the most difficult to get all parties to agree to and ratify. The Kyoto agreement on limiting climate change gases will remain in limbo as long as the major polluters refuse to ratify it.

Regulation at national and, for the European Union, European level is embodied in directives, regulations, and policies, such as, in the United Kingdom, NAAQS.

Local initiatives prompted by the meeting on the environment and development in Rio de Janeiro have become an important focus for both local authority initiatives and the involvement of civil society. The so-called La21, or Local Agenda 21, developed as an idea intended to catalyse local environmental initiatives.

Finally, industrial undertakings by their very size can have large environmental impacts, or make products with significant environmental impacts. Responsible corporate and product stewardship can be implemented to seek to reduce adverse environmental (or environmental health) impacts. This may be represented by adherence within the worksite to quality standards such as the Eco-Management and Audit Scheme or ISO 14000 environmental quality schemes, or the adoption of "cradle to grave" product stewardship initiatives, ensuring that raw materials such as wood are derived from sustainable sources, recycling is maximised, and products are designed so that they can be recycled.

Toxic waste

Many of the materials we use are useful yet have an inherent toxicity, or to produce them entails generating toxic waste, which in any case needs careful disposal to avoid or at least minimise human exposure. This has frequently not been the case, with a legacy of contaminated land or poorly documented waste sites in the United Kingdom, or waste being exported to other less well regulated countries. This latter practice has been somewhat restricted through international agreements such as the Basel Convention on the Control of Transboundary Movements of Hazardous Wastes and Their Disposal (1989), although not all countries are signatories to this convention.

20 Occupational and environmental disease of uncertain aetiology

Andy Slovak

Occupational and environmental conditions, by their nature, invite and create contention. This is particularly so where causality is uncertain. The diagram seeks to explain why this might be. Individual and group beliefs, behaviours, and so on, and their social modulation seem to play as substantial a part in the experience of symptoms as does exposure to the range of putative causal agents.

The issues of causality, attitude, and perception that affect approaches to these conditions are discussed first, before discussing specific syndromes. From a practical point of view, there is an obvious dichotomy between the support it is proper to give to patients and the more detached objectivity one would wish to bring to understanding their condition scientifically. This is particularly so when, as is often the case, health professionals are invited to make a commitment to a particular belief system related to the causality of the disease under discussion. At the same time, those health professionals are all members of the public and as such are susceptible to prevalent, popular, belief systems.

The box lists a selection of medical syndromes whose nature and aetiology are at present uncertain. They are an apparently disparate grouping, but as far as broader circumstances are concerned, they tend to reflect some common themes:

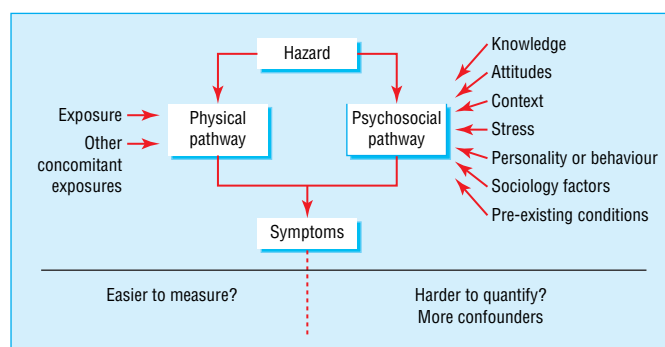

- Multifactoriality (both symptoms and putative causes)
- Lack of control (“involuntary” exposure)
- Marked variation in susceptibility
- Tendency to ascribe to external causes.

As such, there are resonances between these conditions and others considered elsewhere in this book or that are beyond its scope. These conditions include non-specific upper limb disorders, regional pain syndromes, fibromyalgia, and stress.

It is also perhaps worthwhile deconstructing the nature of the multifactoriality a little. In the cases of sick building syndromes, multiple chemical sensitivity, and war syndromes, the factors implicated are truly extensive and highly varied, whereas in situational syndromes (for example, after the Braer disaster and Camelford incidents) they are defined by the event, although still difficult to pinpoint. The debates about electromagnetic fields and nuclear installations are even more unusual because they are biphasic with more or less distinct occupational and environmental modes.

Landfill sites present another situational pattern, having a wide but segmented range of attributed, putative effects (in time and space), and an even wider range of possible hazards and attendant risks. In contrast to all of the foregoing, the putative causal agents cited for conditions attributed to sheep dipping are highly specific—namely, organophosphate pesticides. Acute effects are well known and well characterised, but the controversy continues as to how they might be implicated in longer term effects.

More dramatic examples are provided by disasters and their health consequences, which may vary according to factors other than easily measurable ones. The health deficit produced by the Chernobyl incident in 1986 has been, with the exception of

Medical syndromes with uncertain nature and aetiology

- Long term conditions claimed to be associated with proximity to electromagnetic fields (for example, power lines) and nuclear installations
- Gulf war syndromes
- Multiple chemical sensitivity
- Situational syndromes: the Braer disaster and the Camelford incident
- Sick building syndromes
- Conditions claimed to be associated with proximity to landfill sites
- Long term conditions claimed to be associated with pesticides used for sheep dipping

“Natural” disasters such as volcanic eruptions are less likely to have prolonged health effects (other than obvious immediate ones or secondary effects due to—for example, evacuation) than manmade disasters that usually last longer (food contamination), take time to come to light (bovine spongiform encephalopathy or variant Creutzfeldt-Jakob disease), can have a serious impact on Government or medical credibility, and create many cases of “illness” among the worried well

a few thousand cases of childhood thyroid cancer, wholly psychological and socioeconomic.

Electromagnetic fields and nuclear installations

Studies, mainly epidemiological, relating to power lines have been pursued for about 30 years and for nuclear installations, for about 20 years. Their conclusions are still hotly debated.

The suspect agent in the electrical sector has been electromagnetic fields. The issues of interest occupationally have been leukaemia and brain cancer in electrical workers. Environmental concerns have focused on childhood leukaemia and, to a lesser extent, other childhood cancers.

The outcomes of extensive, painstaking epidemiological work on electromagnetic fields in both the occupational and environmental sectors have been tantalising.

As an example, the table shows the amalgamated risk data from a number of recent Nordic studies of electromagnetic fields “exposure” and childhood leukaemia.

Numbers are sparse and exposure criteria poorly defined. This situation of finding difficulty in differentiating “effect from background noise” is typical of these sorts of long running debates. The rationale for continuing is nevertheless powerful because of the universality of exposure, the likelihood that exposure will increase in the future, and for reasons of risk perception. Studies on those occupationally exposed are even weaker.

With regard to nuclear installations, concerns have also centred around childhood leukaemia and other childhood cancers. In the United Kingdom the debate was initiated by a single television programme in 1983. The putative risk factor at that time was assumed to be installation discharges of radioactive materials. However, such discharges produce doses to the general public that are very small (by several orders of magnitude) when compared with those that might be expected to produce such effects according to robust scientific risk estimations.

Studies on electromagnetic fields have struggled to develop sufficient power to dispel the tentative concerns raised by other studies

In a letter to the *Lancet*, Ahlbom and colleagues reported: “Our results show that the three Nordic studies taken together support the hypothesis that exposure to magnetic fields of the type generated by transmission lines has some aetiological role in the development of leukaemia in children” (*Lancet* 1993;342:1295)

Amalgamated data from three principal Nordic studies concerning childhood cancer risk and proximity to power lines

Study	Leukaemia			Nervous system tumours			Lymphoma			Total		
	Cases	Relative risk	95% CI	Cases	Relative risk	95% CI	Cases	Relative risk	95% CI	Cases	Relative risk	95% CI
1	7	2.7	1.0 to 6.3	2	0.7	0.1 to 2.7	2	1.3	0.2 to 5.1	12	1.1	0.5 to 2.1
2	3	1.5	0.3 to 6.7	2	1.0	0.2 to 5.0	1	5.0	0.3 to 82.0	6	1.5	0.6 to 4.1
3	2	1.6	0.3 to 4.5	5	2.3	0.8 to 5.4	0	0.0	0.0 to 4.2	11	1.5	0.7 to 2.7
Total	13	2.1	1.1 to 4.1	9	1.5	0.7 to 3.2	3	1.0	0.3 to 3.7	29	1.3	0.9 to 2.1

* Data from Ahlbom et al. *Lancet* 1993; 342: 1295.

A period of intensive research (1983-90) failed to find much support for an environmental (discharge) hypothesis, and this theory was substantively supplanted in 1990 by an occupational hypothesis based on paternal preconceptional irradiation in radiation workers. Centred on the experience of workers living in Seascale, a village near Sellafield in Cumbria, the paternal preconceptional irradiation theory did not survive when tested elsewhere in Cumbria and more generally in the United Kingdom and other countries. More recently, excess childhood leukaemia rates have been attributed to population mixing in communities that have a high proportion of incomers, raising the possibility of a viral aetiology.

Even though the scientific plausibility has subsided, these matters can still polarise scientific opinion at the extremes of construct belief.

Gulf war syndromes

In 1992, after some months of preparation, a multinational army was engaged in a brief, one sided conflict against Iraq resulting in minimal military casualties to them. Subsequently there emerged among the veterans of some nations, particularly the United States and United Kingdom, a series of symptoms now collectively known as Gulf war syndromes. These have now been extensively studied in the surprisingly large numbers of personnel involved.

A number of separate or combined entities have been suggested as possible causes, and it is easy to draw up a list of 30 or 40 factors that might plausibly come into the frame. Some of these are listed in the box.

Epidemiological studies have looked for distinct Gulf war syndromes and what exposures or experiences might be associated with them. To date, the key observations are that there is no specific syndrome, but that war theatre veterans have discernibly stronger symptoms per person than military personnel who did not serve in the Gulf. There is an association between symptom frequency and complexity of inoculation programmes (where given). Mortality, morbidity, and reproductive outcomes have been unremarkable to date, although, of course, it is early days yet. The same caution that is applied to negative data must also be applied to early positive associations now beginning to be reported (for example, amyotrophic lateral sclerosis).

Those who remember the Vietnam war recall analogous later manifestations of complaints attributed to that experience and specifically to Agent Orange, a widely deployed defoliant. Recent retrospective research suggests that increased symptom frequency may be associated with conflict experience back to the mid-19th century. This subject is set to run for some time.

Multiple chemical sensitivity

Multiple chemical sensitivity is a difficult entity to position clinically. The range of symptoms observed within the scope of the condition are protean. They include chronic fatigue type syndromes, weakness, sleep disturbance, rashes, headache, chest tightness, and oppression, but these examples are far from a complete and arguable list.

It is accepted that multiple chemical sensitivity applies to a group of patients with a disabling condition with symptomatology whose severity seems to be lessened by restriction of exposure to the everyday environment, particularly by inhalation. It is inferred, therefore, that the aetiology or precipitation of the condition is derived from that environment. Underlying immunological and neurological mechanisms have been proposed but not substantiated. Diagnostic criteria are hard to define, as are objective investigative methods.

Braer and Camelford

The Braer oil tanker ran aground in Northern Scotland, releasing a cargo of light crude oil (1992-3). At Camelford in Cornwall in 1988, a specific agent, aluminium sulphate, was inadvertently introduced into the water supply. Both incidents resulted in immediate symptoms in local residents. Those associated with the Braer were primarily acute and upper

Some of the most popular possible causes of Gulf war syndromes

- Inoculation programmes
 - Prophylaxis against biological warfare agents
 - Depleted uranium
 - Insecticide spraying
 - Pyrolysis due to military action or “scorched earth” action
 - Involuntary dispersal of chemical or biological war agents due to military action
-

Gulf war soldiers in protective clothing

respiratory, whereas those in Camelford were more diffuse. The former did not persist; the latter did.

The persistence of a “malaise” syndrome, as at Camelford (for example, fatigue, joint pain, depression, memory loss) is a feature of a number of the conditions described in this chapter, and the contrast offered between the Braer and Camelford events may therefore be generally instructive. Toxicologically the circumstances were different, and indeed it is possible to argue that local exposures after the Braer disaster were minimal or non-existent because of vigorous weather dispersal of pollution.

Others have argued that the difference lay in contrasting approaches to the situation by the responsible public authorities. In a perhaps oversimplistic way, it has therefore been inferred that a strong social and sociopsychological modulation of response can be obtained in situational events by authoritative communication and action.

Aspects of societal action that have been perceived as positive in these circumstances are given in the box.

Aspects of societal action perceived as positive following situational disasters such as Braer and Camelford

- Timely communication of an action plan
 - Timely communication of hazard information
 - Effective dialogue with the population at risk
 - Feedback to the population at risk
-

Sick building syndrome

Originally seen and reported as primarily a respiratory occupational disease in the early 1980s, sick building syndrome has more recently seemed more protean and diffuse. Thus, a malaise syndrome similar to situational events was increasingly recognised in later studies; the incidence of complaint was found to be overlaid on quite high prevalence of such symptoms even in buildings not associated with sick building syndrome. Strong linkages to upper limb disorders and stress symptomatology have also been increasingly reported. It seems likely that these different functional ways of looking at syndromes may be taking different slices out of what is part of the same cake.

Landfills

The figure shows the geographical distribution of UK landfill sites and perhaps also the futility of “nimbyism.” (Nimby is an acronymic characterisation—“not in my back yard”—of resistance to the location of any undesired feature in a particular neighbourhood.)

A recent large UK study showed a small association (about 1%) between congenital abnormalities and proximity to a landfill site. It was unclear whether this finding should be seen as reassuring, given that the effect was small and “proximity” encompassed a majority of the UK population. Landfill and other “amenity” sites are particularly likely to be the subject of local symptomatic complaint and anecdotal reporting of cluster events (for example, cancers). Investigationally, the range of reported conditions and (usually) the lack of easily definable toxic exposure may result in unsatisfactory outcomes for all parties involved.

Organophosphate sheep dips

Organophosphates are well characterised neurotoxins that exert their effects acutely by inhibiting of the widespread neurotransmitter enzyme acetylcholinesterase. This toxic effect has been widely exploited in pesticide applications, as in sheep dips for parasitic infestations. The acute effects have also been widely seen in humans in occupational, domestic, and deliberate overexposures. A typical acute syndrome of stomach cramps, weakness, paralysis, and collapse is directly associated

Distribution of UK landfill sites

with measurable cholinesterase suppression in a traditional dose-response relation.

Two syndromes of longer duration have been attributed to long term effects of organophosphate exposure, mainly in sheep dippers who have high and repeated contact with these agents. One, known colloquially as “dipper’s flu,” is reported to come on some time after exposure, typically up to a day later. As the name indicates, the illness is described as “flu-like” in nature and duration. The other syndrome or syndrome set is reported to be truly chronic, and the syndrome range is typical of that described repeatedly in this chapter. At the anecdotal level, some preponderance of chronic fatigue and cognitive deficits is claimed.

Dipper’s flu has been subjected to objective field investigations of exposure and symptoms following dipping. Little difference was observed between symptoms of dippers and unexposed controls when symptoms were grouped (for example, cognitive, visual, flu-like). When symptoms were degrouped and analysed separately, some emerged as more common in dippers but these were not those of flu. Thus, despite quite extensive research, the findings continue to be inconclusive or perverse, and there is no clear dose or dose-surrogate relation. Complaints of neuropathy are more frequent in sheep dippers, especially those handling concentrate, who are also more prone to anxiety and depression. Again, no cause and effect relation has been established, and objective signs of damage have not been in evidence.

Puzzlingly, a plausible mechanism of action has not been found for the longer term or chronic effects attributed to organophosphate exposure. The long term effects are not associated with cholinesterase inhibition, the acute toxic mechanism, in any discernible or direct way. It is possible, speculatively, to postulate some “shadow” effect of cholinesterase inhibition, or some other unknown mechanism of the agent or some contaminant, but the investigations to date have been elusive and discouraging of the existence of such mechanisms.

Conclusion

The foregoing sections describe a substantive sample of occupationally and environmentally ascribed complaints of uncertain origins. Others of no less importance are noted here but have not otherwise been selected for discussion.

To a greater or lesser extent they posit scientific problems associated with differentiating between hazard (innate adverse characteristics) and risk (the likelihood of them happening). Ill understood by society, the difference between hazard and risk is, or seems to be, being marginalised in a society where such issues are now more dominantly subject to perception and the precautionary principle (where ultimately hazard equals risk). The natural course of issues of the type discussed in this chapter is often a cycle of initial concern, resistance, disturbance, investigation, assimilation, and exhaustion. This is shown in the figures, which examine the epidemiological time course of investigations into the nuclear installations issue discussed earlier, and soft tissue sarcoma associated with herbicide application, moving from the sentinel observation towards regression to the mean.

To resolve such issues effectively in the altered perceptual framework of the society in which they flourish probably needs some fundamental reordering of current “expert” and “authoritarian” approaches. The models that have been created to “understand” these issues, while dictated by common sense

Sheep dipping

Claims that long term effects of exposure to organophosphates leading to a variety of chronic syndromes remain unsubstantiated, both epidemiologically and toxicologically

Other environmental ascribed complaints

- Oestrogenic modulators in water and food chains
- Mercury dental amalgams
- Pesticides residues in foodchains

ABC of Occupational and Environmental Medicine

and observation, are themselves authoritarian rather than consensual.

A consensual approach (that is, a process widely accepted, understood, and supported) has been attempted in the United States in dealing, practically and scientifically, with a group known as “downwinders.” These were people exposed to downwind deposition of radioiodine released in north west United States in the 1940s. Features of the process are similar to those perceived to have prevented escalation of the Braer disaster but are more rigorously structured. The time, communications, and effort costs are large; the outcomes so far, imperfect.

If attribution and handling these problems in a public health context is difficult then so can be dealing with the “patients”/victims and the “worried well.”

Therapeutic handling of sufferers, regardless of the putative source of their illness, usually includes accepting that there is a problem, separating out cause, symptomatology, and illness behaviour, and treating the latter by psychological techniques—an approach similar to that adopted by pain therapists.

Appendix I

Features of some important occupational zoonoses

Disease and infectious agent	Main animal reservoir	Workers at risk	Features
Brucellosis Undulant fever <i>Brucella abortus</i> <i>B. melitensis</i> <i>B. suis</i> <i>B. canis</i> Prescribed disease RIDDOR reportable	Cattle Sheep and goats Pigs Dogs	Farmers Butchers Abattoir staff Vets	Distribution: Worldwide, especially North and East Africa, Middle East, and Latin America Mode of acquisition: Direct contact with infected animals, or ingestion of contaminated milk or dairy products Incubation period: Variable, usually 5-60 days Clinical features: Acute or insidious onset with intermittent fever, fatigue, arthralgia, and localised suppurative infection of organs. Splenomegaly and lymphadenopathy occurs in about 15% of cases. Neurological symptoms may occur acutely. In the chronic form symptoms include depression, fatigue, and arthritis Treatment: Doxycycline with rifampicin or streptomycin Immunisation possible for cattle, but not suitable for humans
Cryptosporidiosis <i>Cryptosporidium parvum</i>	Cattle Sheep and goats	Farmers Vets	Distribution: Worldwide Mode of acquisition: Faeco-oral; ingestion of oocysts excreted in human or animal faeces Incubation period: 1-12 days, oocysts (the infectious stage) appear in stool at onset of symptoms, and continue to be excreted in stool for several weeks after symptoms resolve. Oocysts may remain infective for up to 6 months in a moist environment Clinical features: Often infection is asymptomatic. Commonest symptom is diarrhoea, often associated with abdominal cramps. Most immunocompetent people will improve within 30 days. Immunocompromised individuals may have severe and protracted illness Treatment: Supportive
Escherichia coli O157 Notifiable	Cattle Sheep and goats Deer Horses	Farmers Healthcare staff	Distribution: Worldwide Mode of acquisition: Ingestion of contaminated food, direct contact with infected animals, direct person to person spread, and waterborne Incubation period: 1-9 days, haemolytic uraemic syndrome may follow after a further 5-10 days Clinical features: Asymptomatic, diarrhoeal illness, haemorrhagic colitis, haemolytic uraemic syndrome in up to 10% of infected patients (particularly in children), and thrombotic thrombocytopenic purpura. Infectious dose probably < 100 organisms, and case fatality 3-17% Treatment: Nil specific
Erysipeloid <i>Erysipelothrix rhusiopathiae</i>	Fish Wild or domestic animals	Fishermen Butchers Fish handlers Poultry workers Vets	Distribution: Worldwide Mode of acquisition: Direct contact with infected animal Clinical features: Localised cutaneous skin infection/cellulitis with violaceous tinge (fishmonger's finger). Occasionally fever, articular pain, rarely septicaemia and endocarditis. Usually self-limiting Treatment: Penicillin, cephalosporins, erythromycin, or tetracycline
Histoplasmosis <i>Histoplasma capsulatum</i>	Chicken Bats	Poultry workers	Distribution: Americas, Africa, East Asia, Australia—rare in temperate climates Mode of acquisition: Inhalation of airborne conidia Incubation period: Generally within 3-17 days Clinical features: (a) asymptomatic, (b) acute benign respiratory, (c) acute disseminated disease, (d) chronic disseminated disease, (e) chronic pulmonary disease Treatment: Itraconazole or ketoconazole for immunocompetent patients with indolent non-meningeal infection. Amphotericin for those with fulminant or severe infections
Hydatid disease (Tapeworms of genus <i>Echinococcus</i> <i>E. granulosus</i> and <i>E. multilocularis</i>) Prescribed disease RIDDOR reportable	Dogs Sheep— intermediate host Sylvatic hosts for <i>E. multilocularis</i>	Shepherds Farmers	Distribution: Worldwide except Antarctica Mode of acquisition: Hand to mouth transfer of eggs after association with infected dogs or through contaminated food, soil, water, or fomites Incubation period: Months to years Clinical features: Usually asymptomatic until cysts cause noticeable pressure effects; symptomology will depend on size and location of cysts. Eosinophilia common Treatment: Surgical resection of cysts combined with albendazole Alveolar hydatid disease (caused by <i>E. multilocularis</i>) is usually fatal if not treated

continued

Appendix I continued

Disease and infectious agent	Main animal reservoir	Workers at risk	Features
Listeriosis <i>Listeria monocytogenes</i>	Cattle, sheep, and other domestic and wild animals	Farmers Vets	Distribution: Worldwide Mode of acquisition: Mostly foodborne (soft cheeses, etc.), but also nosocomial, and direct contact with infected animals or aborted animal fetuses Incubation period: Variable, but 3-70 days. Infected individuals may shed organism in stool for several months Clinical features: General malaise or flu-like symptoms. In pregnant women infection may lead to abortion, intrauterine death, or neonatal sepsis. Immunocompromised individuals may suffer from meningoencephalitis Treatment: Amoxicillin and gentamicin
Lyme disease <i>Borrelia burgdorferi</i> RIDDOR reportable	Wild rodents Deer	Shepherds Farmers Foresters Outdoor work	Distribution: United States, Canada, Europe, former Soviet Union, China, Japan Mode of acquisition: Tickborne— <i>Ixodes scapularis</i> , <i>pacificus</i> , <i>ricinus</i> , and <i>persulcatus</i> Incubation period: Erythema migrans generally occurs within 7-10 days after tick bite, transmission of <i>B. burgdorferi</i> unlikely within 48 hours of tick attachment, therefore prompt removal of tick essential Clinical features: Initially erythema migrans (60-80%), associated lymphadenopathy, general malaise, and arthralgia. Aseptic meningitis, cranial nerve lesions, myopericarditis, AV block, cardiomegaly, and arthritis may occur up to 2 years after infection Treatment: Penicillin and tetracyclines Vaccine currently available in United States
Newcastle disease <i>Paramyxovirus</i>	Domesticated and wild birds	Poultry workers Pet shop staff Vets	Distribution: Rare in United Kingdom, occasional outbreaks in import quarantines Mode of acquisition: Direct contact with eyes or inhalation Clinical features: Mild systemic illness with conjunctivitis Treatment: Nil
Nipah virus <i>Paramyxovirus</i>	Natural hosts—possibly fruit bats Pigs	Pig farmers Abattoir staff	Distribution: South East Asia Mode of acquisition: Direct contact with infected blood, body fluids, or tissue Incubation period: 4-18 days Clinical features: Influenza type symptoms with severe headache, fever, respiratory symptoms, encephalitis. Death occurs in about 50% of those with symptoms Treatment: Supportive treatment; ribavirin has been used but effectiveness is uncertain Classified as a Hazard Group 4 agent
Orf <i>Parapoxvirus</i> Prescribed disease	Sheep and goats	Farm workers Abattoir staff Vets	Distribution: Worldwide Mode of acquisition: Direct contact with mucous membranes of infected animals Incubation period: 3-7 days Clinical features: Solitary maculopustular lesion surrounded by erythematous rim. Lesion dries, and crust detaches after 6-8 weeks with no persisting scar. With secondary bacterial infection, cellulitis and regional lymphadenitis occur Treatment: Nil
Psittacosis Avian chlamydiosis Ornithosis <i>Chlamydia Psittaci</i> Prescribed disease RIDDOR reportable	Waterfowl Pheasants Pigeons Psittacine birds	Poultry workers Pet shop staff Vets	Distribution: Worldwide Mode of acquisition: Inhalation of aerosols contaminated by infected avian faeces or fomites Incubation period: 1-4 weeks Clinical features: Fever, headache, myalgia, respiratory symptoms. (non-productive cough). Respiratory symptoms are often disproportionately mild when compared with chest x ray findings. Complications include encephalitis, myocarditis, and Stephens-Johnson syndrome Treatment: Tetracyclines or erythromycin
Ovine enzootic abortion Prescribed disease RIDDOR reportable	Sheep		Ovine strains can cause severe a septicaemic illness with intrauterine death in pregnant women. Maternal death due to disseminated intravascular coagulation may also occur. Women who are or may be pregnant should avoid exposure to sheep, particularly during lambing
Q Fever <i>Coxiella burnetii</i> Prescribed disease RIDDOR reportable	Sheep and goats Cattle Cats Dogs Wild rodents	Sheep workers Farmers Meat workers Dairy workers Abattoir staff Vets	Distribution: Worldwide Mode of acquisition: Inhalation of airborne organism, direct contact with infected animals or products Incubation period: 2-3 weeks Clinical features: Fever, retrobulbar headache, general malaise, atypical pneumonia. Occasionally, acute hepatitis. Chronic symptoms (months or years after original infection) resulting in endocarditis can occur on prosthetic or abnormal valves

continued

Appendix I continued

Disease and infectious agent	Main animal reservoir	Workers at risk	Features
Ringworm Various species of genera <i>Trichophyton</i> , <i>Microsporum</i> <i>Epidermophyton</i>	Dogs Cattle Cats	Vets Farmers	Treatment: Tetracyclines. Endocarditis will require specialist advice with combination therapy A vaccine is available in some countries for at-risk workers Distribution: Worldwide Mode of acquisition: Direct skin-to-skin contact Incubation period: Variable but usually 3-5 days for infection to become established and 2-3 weeks for symptoms to manifest Clinical features: Depends on site and causative agent, but <i>T. verrucosum</i> (from cattle) may produce large pustular lesions (kerions). Lesions on trunk or legs consist of prominent red margin with scaly central area Treatment: Mild infection responds to topical antifungals. Oral antifungals such as griseofulvin or terbinafine may be necessary when topical therapy fails
<i>Streptococcus suis</i> Prescribed disease RIDDOR reportable	Pigs	Pig workers Pork processors	Distribution: Worldwide Mode of acquisition: Direct contact with infected pigs or pork Clinical features: Primary skin infection with surrounding erythema and associated septicaemia and meningitis. Sequelae include ataxia and deafness in those with meningitis. Case fatality is extremely high in asplenic. Arthritis, pharyngitis, and diarrhoea may also occur Treatment: Penicillin
Toxoplasmosis <i>Toxoplasma gondii</i>	Cats	Farm workers Vets	Distribution: Worldwide Mode of acquisition: Ingestion of undercooked infected meat, contact with contaminated soil, contact with infected animals Incubation period: 5-20 days Clinical features: Mostly asymptomatic, but some have glandular fever type symptoms. Primary infection in pregnancy may result in fetal infection, abortion, intrauterine death, chorioretinitis, hepatomegaly, hydrocephalus, and mental retardation. Cerebral toxoplasmosis may occur particularly in the immunocompromised. Reactivation of latent infection may also occur Treatment: Not routine for uncomplicated acute infection in healthy immunocompetent adults. For toxoplasmic encephalitis a combination of pyrimethamine and sulphadiazine or pyrimethamine with clindamycin or clarithromycin, but expert advice should be sought. Spiramycin may reduce risk of transmission of maternal infection to fetus

Appendix II

Important occupationally acquired infections from human sources

Disease and infectious agent	Features
Measles <i>Paramyxovirus</i> Notifiable disease Immunisation available	<p>Distribution: Although the incidence decreased after introduction of vaccination. In the United Kingdom, due to unsubstantiated concerns regarding the combined measles, mumps, and rubella vaccine, immunisation rates have dropped and outbreaks are predicted</p> <p>Mode of acquisition: Airborne by droplet spread or direct contact with nose and throat secretions. Measles is one of the most highly communicable diseases</p> <p>Incubation period: 7-18 days. Communicability: 1 day before the prodromal period to 4 days after the appearance of rash</p> <p>Clinical features: Prodromal fever, conjunctivitis, coryza, and Koplik's spots on buccal mucosa. Red maculopapular facial rash starts on day 3-4, and then spreads to trunk and limbs. Complications include pneumonia and encephalitis. Subacute sclerosing panencephalitis is a rare late and fatal complication developing several years after initial infection</p> <p>The decrease in vaccine uptake in the United Kingdom will mean that non-immune healthcare workers are at high risk of nosocomial infection, but currently there is no consistent screening policy to identify those at risk. In the United States, all non-immune healthcare workers are identified at pre-employment and offered immunisation if non-immune</p> <p>Human normal immunoglobulin (HNIG) can be offered to those who are non-immune and have compromised immunity</p>
Meningococcal infection <i>Neisseria meningitidis</i> Notifiable disease Vaccines available against serogroups A, C, W135 and Y	<p>Distribution: Worldwide there are 13 serogroups; in Europe serogroups B and C predominate. About 10% of the population are asymptomatic carriers</p> <p>Mode of acquisition: Person-to-person through respiratory droplets and direct contact with nose and throat secretions. Infectivity is relatively low and transmission requires prolonged close contact</p> <p>Incubation period: 2-10 days. Communicability: Patients are generally not infectious within 24 hours of antibiotic treatment</p> <p>Clinical features: Symptoms of meningitis. The appearance of a petechial rash signifies septicaemia</p> <p>Healthcare personnel are rarely at risk therefore routine immunisation not indicated. Only intimate contact with infected patients—for example, mouth-to-mouth resuscitation would warrant antibiotic prophylaxis</p>
Fifth disease Erythema infectiosum <i>Parvovirus B19</i>	<p>Distribution: Worldwide, common in childhood</p> <p>Mode of acquisition: Person-to person by droplet spread. Rarely by contaminated blood products. It is highly infectious</p> <p>Incubation period: 4-20 days. Communicability: From 7 days before the appearance of rash until onset of rash. In aplastic crises, infectivity may last for up to a week after the rash appears. In the immunosuppressed with severe anaemia, infectivity may last for months or years</p> <p>Clinical features: Initially fever that lasts until rash appears. The rash is maculopapular and generally on the limbs. The cheeks often have a "slapped cheek" appearance. Illness is mild in immunocompetent individuals, although sometimes, persistent joint pain may occur. In those with haemoglobinopathies, transient aplastic crises may occur, and in the immunosuppressed, red cell aplasia and chronic anaemia may occur. Infection in the first 20 weeks of pregnancy can cause hydrops fetalis and fetal loss</p> <p>Pregnant women <21/40, immunocompromised individuals or those with haemoglobinopathies who have a significant contact with an infected healthcare worker in the 7 days before onset of rash will need further follow-up. In the case of immunocompromise the administration of intravenous immunoglobulin may be considered</p>
Rubella Notifiable disease Immunisation available	<p>Distribution: Rare in most countries in Western Europe due to vaccination programmes</p> <p>Mode of acquisition: Direct person-to-person contact by respiratory droplets</p> <p>Incubation period: 2-3 weeks</p> <p>Communicability: 1 week before onset of rash to about 4 days later</p> <p>Clinical features: Generally a mild fever with sore throat and conjunctivitis precedes a macular rash. Persistent joint infection occasionally occurs, but complete and rapid recovery usual. The main importance clinically is the risk of congenital rubella syndrome</p>
Scabies <i>Sarcoptes scabiei var. hominis</i>	<p>Distribution: Worldwide</p> <p>Mode of acquisition: Transfer of parasites by direct contact with infested skin</p> <p>Incubation period: There may be no sign of infection for 2-4 weeks after exposure, although re-exposure may result in rash within a few days</p> <p>Communicability: Remains infectious until it is treated</p> <p>Clinical features: Rash which is variable (pimples, vesicles, and nodules), burrows may be seen in finger webs, and itching particularly at night. If there is impaired immunity, large numbers of mites may present (Norwegian Scabies)</p> <p>If healthcare staff are infected they can return to work once treatment is completed</p>

continued

Appendix II continued

<i>Staphylococcus aureus</i>	<p>Distribution: Worldwide, but highest rates of resistant strains are in countries with liberal infection control policies such as Japan and Korea. It is carried as a skin commensal at any one time by about 30% of the population. Strains resistant to Penicillinase stable β-lactams are referred to as methicillin resistant <i>staphylococcus aureus</i> (MRSA). Recent additional problems include the emergence of resistance to mupirocin, the mainstay of treatment of skin or nasal carriage, and case reports of intermediate-level resistance to vancomycin (VISA) in Japan, France, and United States</p>
Disease and infectious agent	<p>Features</p> <p>Mode of acquisition: The significance of MRSA is that the organism colonises the skin, nose, and throat of both patients and healthcare staff, spreads readily by direct contact, and hence is an important cause of hospital acquired infections. While patients are usually responsible for spread of infection, the introduction of MRSA into unaffected areas by colonised staff is well documented, and staff hands are an important route of cross-infection</p> <p>Incubation period: 4-10 days, but disease may not occur until several months after colonisation</p> <p>Clinical features: Infection may cause both trivial and deep-seated infections; particular problems include infected bedsores or surgical wounds</p> <p>Control of MRSA is therefore essential to patient care, and relies on scrupulously applied infection control programmes and stringent antibiotic policies</p>
<p>Viral haemorrhagic fevers Lassa, Ebola, Marburg, and Crimean/Congo fevers Notifiable diseases</p>	<p>Distribution: Africa, South America, Middle East, and Eastern Europe</p> <p>Mode of acquisition: Main concern is that of potential secondary infection in healthcare workers as a result of accidental exposure to infected blood or body fluids</p> <p>Incubation period: 3-21 days</p> <p>Clinical features: Initial symptoms include general malaise, fever, headache, and muscle and joint pain. Obvious bleeding occurs at a later or terminal stage</p> <p>In the England and Wales, the Advisory Committee on Dangerous Pathogens provides guidelines on response to a suspected case. Patients at moderate or high risk should be admitted to special isolation facilities, and strict infection control is necessary. For close contacts of high risk cases, daily surveillance for 21 days from the last possible exposure date is necessary</p>

Preface

Psychological medicine has a long history. Until the development of pharmacological and other specific treatments, it was a mainstay of a physician's practice. Since then the successes of biomedical theory during the 20th century have led to a loss of interest in the psychological aspects of medicine and core clinical skills have sometimes been neglected. Although many modern doctors are comfortable with the latest advances in molecular medicine, they lack confidence in applying similar intellectual rigour to the psychological problems of their patients. These deficiencies are particularly apparent in the management of patients with chronic disease and of patients whose symptoms seem out of proportion to disease pathology.

Accumulating research evidence now clearly shows that psychological variables make a substantial contribution to the outcome of most common medical conditions. The identification of problems, appropriate formulation and the implementation of appropriate treatment results in not only better outcomes for patients but also in greater satisfaction for the doctors treating them. A rediscovery of the psychological aspects of medicine is underway.

This *ABC of psychological medicine* is a practical and evidence based overview of the psychological aspects of medical practice. It aims to guide practitioners and to provide them with not only relevant information but also an intellectual structure for assessing and managing their patients. The emphasis is on day to day practice and problems rather than psychological theory. The book assumes knowledge of medical assessment, investigation, and treatment.

The opening three chapters describe general principles within which individual assessment and treatment can be formulated. They include the clinical examination and the initiation of treatment but also a critique of the structure within which care is delivered, which can often be as critical as the individual's consultation. The following three chapters describe the core skills of psychological medicine: the assessment and management of anxiety, depression, and functional somatic symptoms. The remaining chapters then describe how these skills are transferred and adapted in specific situations including the care of patients with cancer, trauma, musculoskeletal pain, fatigue, chest pain, abdominal pain, and delirium. This list is not comprehensive but provides a range of examples that should help the reader to adapt the principles to their own practice.

Psychological medicine is an extension of existing clinical knowledge and skills. Indeed many practitioners will recognise it as a formalisation of the medicine they have been practising for many years. We hope that this book will both engage the curiosity and interest of those to whom the subject matter is novel, and encourage and inform those who already understand and apply its principles.

Richard Mayou, Michael Sharpe, Alan J Carson, 2002

Introduction

It is becoming increasingly clear that we can improve medical care by paying more attention to psychological aspects of medical assessment and treatment. The study and practice of such factors is often called psychological medicine. Although the development of specialist consultation-liaison psychiatry (liaison psychiatry in the United Kingdom) and health psychology contribute to psychological medicine, the task is much wider and has major implications for the organisation and practice of care. This book aims to explain some of those implications.

Disorders that are traditionally, and perhaps misleadingly, termed “psychiatric” are highly prevalent in medical populations. At least 25-30% of general medical patients have coexisting depressive, anxiety, somatoform, or alcohol misuse disorders.¹ Several factors account for the co-occurrence of medical and psychiatric disorders. First, a medical disorder can occasionally be a cause of the psychiatric disorder (for example, hypothyroidism as a biological cause of depression). Second, cardiovascular diseases, neurological disorders, cancer, diabetes, and many other medical diseases increase the risk of depression and other psychiatric disorders. Such so called comorbidity is common, but its causal linkage with psychological conditions remains poorly understood. A third factor is coincidence—common conditions such as hypertension and depression may coexist in the same patient because both are prevalent.

Another reason for psychological medicine is the prevalence of symptoms that are unexplained by disease. Although physical symptoms account for more than half of all visits to doctors, at least a third of these symptoms remain medically unexplained.^{2,3} This phenomenon is referred to as somatisation—the seeking of health care for somatic symptoms that suggest a medical disorder but represent instead an underlying depressive, anxiety, or somatoform disorder. Most patients with these mental disorders preferentially report somatic rather than emotional symptoms. Further, there are the common but poorly understood symptom syndromes such as fibromyalgia, irritable bowel syndrome, and chronic fatigue syndrome, for which the relative contributions of mind and body are not yet elucidated.⁴

Psychological medicine is important in the management of all these problems; both psychotropic medications and cognitive behavioural treatments have proved effective in the treatment of common physical symptoms and syndromes in numerous studies in general practice.^{5,6} Although such treatments have traditionally been considered “psychiatric”, they are also beneficial in patients without overt psychiatric disorders. Countries on both sides of the Atlantic have a long way to go in developing psychological medicine, the chasm in America between medical and psychiatric care is particularly deep. The “carve out” or organisational separations of mental health services in the managed care systems in the United States is one example of how ingrained the dualism of mind and body still is and of the reconciliation that must occur.

Psychological medicine does not mean relabelling all such patients as “psychiatric”. Many patients prefer to have these problems regarded as “medical” and conceptualised in terms of a neurotransmitter imbalance or a functional bodily disturbance.⁷ Concomitant psychological distress is best framed in terms of being a consequence rather than a cause of persistent physical symptoms. Premature efforts to reattribute somatic complaints to psychological mechanisms may be perceived by the patient as rejection. A more aetiologically neutral but psychologically sophisticated approach that initially focuses on symptomatic treatment, reassurance, activation, and restoration of function has proved more effective.⁸

There are better alternatives than simply to relegate such problems to the province of specialist psychiatry. One is to train general practitioners to diagnose and treat common “psychiatric” disorders.⁹ Although treatment with psychotropic medication is their most feasible option, general practitioners can also be trained to deliver other psychological treatments. A second option is to use nurses or social workers with specialised training who can work with general practitioners or psychiatrists to manage medication as well as deliver psychotherapies and behavioural interventions. A third model is collaborative care, where the general practitioner’s management is augmented but not replaced by visits to a psychiatrist, often on site in the general practitioner’s surgery. Stepped care provides an overall principle of management whereby patients only move on to more complex and expensive forms of care where simpler management by the healthcare team is either ineffective or inappropriate. Most studies have been conducted in general medical practices, but patients seen by medical specialists also warrant attention.³

Psychological medicine may also be delivered in innovative ways. Promising data exist for behavioural interventions conducted outside the doctor’s office, including case management by telephone, cognitive behavioural therapy given through a computer, bibliotherapy—self study by patients—and home visits (for example, for chronic fatigue syndrome).

Medical treatment that integrates a psychological approach has been shown to improve patient outcomes. The benefits of treating common physical symptoms and psychological distress effectively in medical patients include not only improved quality of life and social and work functioning, but also greater satisfaction on the part of patient and doctor and reduced use of healthcare services.²

What do we need to do? Better detection of these problems need not be time consuming. For example, screening for depression may require as few as one or two questions. Optimal management of patients with persistent physical symptoms and common mental disorders may require longer or more frequent visits to a doctor, help in educating and following up patients by a nurse case manager, other system changes, and specialist mental health consultations for more complex cases.¹⁰ The competing demands of general practice must be explicitly addressed if we are to enable the general practitioner to practise psychological medicine effectively.¹¹

Yet this approach is no different to what is also required for many chronic medical disorders such as diabetes, asthma, and heart disease, for which it has been proved that care in concordance with guidelines requires appreciable reorganisation of medical services.¹²

Neither chronic “medical” nor “psychiatric” disorders can be managed adequately in the current environment of general practice, where the typical patient must be seen in 10–15 minutes or less. The quick visit may work for the patient with a common cold or a single condition, such as well controlled hypertension, but will not suffice for the prevalent and disabling symptoms and disorders comprising psychological medicine. Evidence based treatments exist. Using them in a way that is integrated with general medical care will improve both patients’ physical health and their psychological wellbeing.

1 The consultation

Linda Gask, Tim Usherwood

The success of any consultation depends on how well the patient and doctor communicate with each other. There is now firm evidence linking the quality of this communication to clinical outcomes.

The dual focus—Patients are not exclusively physically ill or exclusively emotionally distressed. Often they are both. At the start of a consultation it is usually not possible to distinguish between these states. It is the doctor's task to listen actively to the patient's story, seeking and noticing evidence for both physical illness and emotional distress.

Involving patients—Changes in society and health care in the past decade have resulted in real changes in what people expect from their doctors and in how doctors view patients. In addition, greater emphasis has been placed on the reduction of risk factors, with attempts to persuade people to take preventive action and avoid risks to health. Many patients want more information than they are given. They also want to take some part in deciding about their treatment in the light of its chances of success and any side effects. Some patients, of course, do not wish to participate in decision making; they would prefer their doctor to decide on a single course of action and to advise them accordingly. The skill lies in achieving the correct balance for each patient.

A comprehensive model—The “three function” model for the medical encounter provides a template for the parallel functions of the clinical interview. This is now widely used in medical schools.

Starting the interview

Research has shown the importance of listening to patients' opening statements without interruption. Doctors often ask about the first issue mentioned by their patients, yet this may not be what is concerning them most. Once a doctor has interrupted, patients rarely introduce new issues. If uninterrupted, most patients stop talking within 60 seconds, often well before. The doctor can then ask if a patient has any further concerns, summarise what the patient has just said, or propose an agenda—“I wonder if I could start by asking you some more questions about your headaches, then we need to discuss the worries that your son has been causing you.”

Detecting and responding to emotional issues

Even when their problems are psychological or social, patients usually present with physical symptoms. They are also likely to give verbal or non-verbal cues. Verbal cues are words or phrases that hint at psychological or social problems. Non-verbal cues include changes in posture, eye contact, and tone of voice that reflect emotional distress.

It is important to notice and respond to cues at the time they are offered by patients. Failure to do so may inhibit patients from further disclosures and limit the consultation to discussion of physical symptoms. Conversely, physical symptoms must be taken seriously and adequately evaluated. Several of the skills of active listening are valuable in discussing physical, psychological, and social issues with patients. These skills have been clearly shown to be linked to recognition of emotional problems when used by general practitioners.

Visiting the sick woman, by Quiringh Gerritsz van Brekelenkam (c 1620-68)

Three functions of the medical consultation

1 Build the relationship

- Greet the patient warmly and by name
- Active listening
- Detect and respond to emotional issues

2 Collect data

- Do not interrupt patient
- Consider other factors
- Elicit patient's explanatory model
- Develop shared understanding

3 Agree a management plan

- Provide information
 - Make links
 - Appropriate use of reassurance
 - Negotiate behaviour change
 - Negotiate a management plan
-

Responding to patients' “cues”

Verbal cues

- State your observation—“You say that recently you have been feeling fed-up and irritable”
- Repeat the patient's own words—“Not well since your mother died”
- Seek clarification—“What do you mean when you say you always feel tired?”

Non-verbal cues

- Comment on your observation—“I can hear tears in your voice”
 - Ask a question—“I wonder if that upsets you more than you like to admit?”
-

Aspects of interview style that aid assessment of patients' emotional problems

Early in the interview

- Make good eye contact
- Clarify presenting complaint
- Use directive questions for physical complaints
- Begin with open ended questions, moving to closed questions later

Interview style

- Make empathic comments
 - Pick up verbal cues
 - Pick up non-verbal cues
 - Do not read notes while taking patient's history
 - Deal with over-talkativeness
 - Ask more questions about the history of the emotional problem
-

Active listening skills

Open ended questions—Questions that cannot be answered in one word require patient to expand

Open-to-closed ones—Move towards closed questions at the end of a section of the consultation

Checking—Repeat back to patient to ensure that you have understood

Facilitation—Encourage patient both verbally (“Go on”) and non-verbally (nodding)

Legitimising patient’s feelings—“This is clearly worrying you a great deal,” followed by, “You have an awful lot to cope with,” or, “I think most people would feel the same way”

Surveying the field—Repeated signals that further details are wanted: “Is there anything else?”

Empathic comments—“This is clearly worrying you a great deal”

Offering support—“I am worried about you, and I want to know how I can help you best with this problem”

Negotiating priorities—If there are several problems draw up a list and negotiate which to deal with first

Summarising—Check what was reported and use as a link to next part of interview. This helps to develop a shared understanding of the problems and to control flow of interview if there is too much information

Eliciting a patient’s explanatory model

When people consult a doctor, they do so with explanatory ideas about their problems and with anxieties and concerns that reflect these ideas. They are also likely to have hopes and expectations concerning the care that they will receive. It is important not to make assumptions about patients’ health beliefs, concerns, and expectations but to elicit these as a basis for providing information and negotiating a management plan.

People’s health beliefs and behaviours develop and are sustained within families, and families are deeply affected by the illness of a family member. “Thinking family” can help to avoid difficult and frustrating interactions with family members.

Providing information

Doctors should consider three key questions when providing information to a patient:

- What does the patient already know?
- What does the patient want to know?
- What does the patient need to know?

The first question emphasises the importance of building on the patient’s existing explanatory model, adding to what he or she already knows, and correcting inaccuracies. The second and third reflect the need to address two agendas, the patient’s and the doctor’s. In addition, it is important for the doctor to show ongoing concern and emotional support, making empathic comments, legitimising the patient’s concerns, and offering support.

Negotiating a management plan

The ideal management plan is one that reflects current best evidence on treatment, is tailored to the situation and preferences of the patient, and addresses emotional and social issues. Both patient and doctor should be involved in developing the plan, although one or the other may have the greater input depending on the nature of the problem and the inclinations of the patient.

Appropriate use of reassurance

Reassurance is effective only when doctors understand exactly what it is that their patients fear and when they address these fears truthfully and accurately. Often it is not possible to reassure patients about the diagnosis or outcome of disease, but it is always possible to provide support and to show personal concern for them.

Dealing with difficult emotions: denial, anger, and fear

Denial—When patients deny the seriousness of their illness you should never be tempted to force them into facing it. The decision on how to address denial must be based on how adaptive the denial is, what kind of support is available to the patient, and how well prepared the patient is to deal with the fears that underlie the denial.

Think family

When interviewing an individual

- Ask how family members view the problem
- Ask about impact of the problem on family function
- Discuss implications of management plan for the family

When a family member comes in with patient

- Acknowledge relative’s presence
- Check that patient is comfortable with relative’s presence
- Clarify reasons for relative coming
- Ask for relative’s observations and opinions of the problem
- Solicit relative’s help in treatment if appropriate
- If patient is an adolescent accompanied by an adult always spend part of consultation without the adult present
- Never take sides

Negotiating a management plan

Ascertain expectations

- What does patient know?
- What does patient want?—Investigation? Management? Outcomes?

Advise on options

- Elicit patient’s preferences

Develop a plan

- Involve patient
- Tailor preferred option to patient’s needs and situation
- “Think family”

Check understanding

- Ensure that patient is clear about plan
- Consider a written summary

Advise on contingency management

- What should patient do if things do not go according to plan?

Agree arrangements for follow up and review

Reassurance is an essential skill of bedside medicine. (Hippocrates (469-399 BC), the “father of bedside medicine”)

Anger—If patients or relatives become angry, try to avoid being defensive. Acknowledge the feelings that are expressed and ask about the reasons for these. Take concerns seriously and indicate that you will take appropriate action.

Fear—Many patients are frightened that they may have some serious disease. It is crucial to ensure that you have addressed what a patient is really worried about as well as checking that the patient has correctly understood what you are concerned about.

Motivation

Efforts to help people reduce alcohol consumption, stop smoking, and manage chronic illness have highlighted the importance of good interviewing skills in motivating patients to change their behaviour. This is not to say that patients no longer have the responsibility for such change, but doctors should recognise that they bear some responsibility for ensuring that patients get the best possible help in arriving at the decision to change.

Making the link between emotions and physical symptoms

Particular strategies may be needed to help people who present with physical symptoms of psychological distress but who have not made the link between these and their emotional and life problems. However, it is essential that you do not go faster than the patient and try to force the patient to accept your explanation.

Feeling understood—Ensuring that the patient feels understood is essential. It is crucial to get the patient on your side and show that you are taking his or her problems seriously. Start from the patient's viewpoint and find out what the patient thinks may be causing the symptoms, while at the same time picking up any verbal and non-verbal cues of emotional distress.

Broadening the agenda can begin when all the information has been gathered. The aim is to broaden the agenda from one where the problem is seen essentially as physical to one where both physical and psychological problems can be acknowledged. Acknowledging the reality of the patient's pain or other symptoms is essential and must be done sensitively. Summarise by reminding the patient of all the symptoms, both physical and emotional, that you have elicited and link them to life events if this is possible.

Negotiating explanations can involve various techniques. Only one or two will be appropriate for each patient, and different techniques may be useful at different times. Simple explanation is the commonest, but it is insufficient to say "Anxiety causes headaches." A three stage explanation is required in which anxiety is linked to muscle tension, which then causes pain. A similar approach can be used to explain how depression causes lowering of the pain threshold, which results in pain being felt more severely than it otherwise would be.

Once the patient and doctor have agreed that psychological distress is an important factor in the patient's illness, they can start to examine management options to address this. Even if the patient has significant physical disease, it is important to detect and manage psychological comorbidity.

Visiting the sick woman is held at the Hermitage and is reproduced with permission of Bridgeman Art Library.

Helping patients to change their behaviour

Explore motivation for change

- Build rapport and be neutral
- Help draw up list of problems and priorities
- Is problem behaviour on patient's agenda?
- If not, raise it sensitively
- Does patient consider the behaviour to be a problem?
- Do others?

Clarify patient's view of the problem

- Help draw up a balance sheet of pros and cons
- Empathise with difficulty of changing
- Reinforce statements that express a desire to change
- Resist saying why you think patient ought to change
- Summarise frequently
- Discuss statements that are contradictory

Promote resolution

If no change is wanted negotiate if, when, and how to review

- Enable informed decision making
 - Give basic information about safety or risks of behaviour
 - Provide results of any examination or test
 - Highlight potential medical, legal, or social consequences
 - Explain likely outcome of potential choices or interventions
 - Get feedback from patient
 - Give patient responsibility for decision
-

Key stages in linking somatic symptoms of emotional distress

- Helping patient to feel understood
 - Broadening agenda to cover physical, psychological, and social issues
 - Negotiating explanations for how physical symptoms, psychological distress, and social problems may be linked via physiological mechanisms
-

Evidence based summary

- The style with which a doctor listens to a patient will influence what the patient says
- Effective communication between doctor and patient leads to improved outcome for many common diseases
- Patients' compliance will be improved if the management plan has been negotiated jointly

2 Beginning treatment

Jonathan Price, Laurence Leaver

Traditionally, the management of newly presenting patients has two stages—assessment and then treatment. However, this two stage approach has limitations. When underlying disease pathology is diagnosed there may be delays in starting effective treatment. If no disease is found reassurance is often ineffective. In both cases many patients are left feeling uncertain and dissatisfied. Lack of immediate information and agreed plans may mean that patients and their families become anxious and draw inappropriate conclusions, and an opportunity to engage them fully in their management is missed.

If simple diagnosis is supplemented with fuller explanation, patient satisfaction and outcomes are improved. This can be achieved by integrating assessment and treatment. The aim of an integrated consultation is that the patient leaves with a clear understanding of the likely diagnosis, feeling that concerns have been addressed, and knowledge of the treatment and prognosis (that is, the assessment becomes part of the treatment). This approach can be adopted in primary and secondary care and can be applied to patients with or without an obvious disease explanation for their symptoms. The integrated approach may require more time, but this is offset by a likely reduction in patients' subsequent attendance and use of resources.

This article describes principles and practical procedures for effective communication and simple interventions. They can be applied to various clinical situations—such as straightforward single consultation, augmenting brief medical care, and promoting an effective start to continuing treatment and care.

General principles

Integrating physical and psychological care

Somatic symptoms are subjective and have two components, a somatic element (a bodily sensation due to physiology or pathology) and a psychological element (related to thoughts and beliefs about the symptoms). Traditional management focuses only on the somatic component, with the aim of detecting and treating underlying pathology. Addressing the psychological component in the consultation as well, with simple psychological interventions, is likely to reduce distress and disability and reduce the need for subsequent specialist treatment.

Providing continuity

Seeing the same doctor on each visit increases patient satisfaction. Continuity may also improve medical outcomes, including distress, compliance, preventive care, and resource use. Problems resulting from lack of continuity can be minimised by effective communication between doctors.

Involving the patient

The psychological factors of beliefs and attitudes about illness and treatment are major determinants of outcome. Hence, strategies that increase understanding, sense of control, and participation in treatment can have large benefits. One example is written management plans agreed between doctor and patient. This approach is the basis of the Department of Health's "Expert Patient Programme," which aims to help patients to "act as experts in managing their own condition, with appropriate support from health and social care services."

Mismatch of expectations and experiences

What patients want	What some patients get
To know the cause	No diagnosis
Explanation and information	Poor explanation that does not address their needs and concerns
Advice and treatment	Inadequate advice
Reassurance	Lack of reassurance
To be taken seriously by a sympathetic and competent doctor	Feeling that doctor is uninterested or believes symptoms are unimportant

Disease centred versus patient centred consultations

Disease centred—Doctor concentrates on standard medical agenda of diagnosis through systematic inquiries about patient's symptoms and medical history

Patient centred—Doctor works to patient's agenda, including listening and allowing patient to explain all the reasons for attending, feelings, and expectations. Decision making may be shared, and plans are explicit and agreed. Patient centred consultations need take no longer than traditional disease centred consultations

Taking time to listen to and address patients' ideas, concerns, and expectations can improve outcomes (*Charcot at the Salpêtrière* by Luis Jimenez y Aranda, 1889, in the Provincial Museum of Art, Seville)

Communication between doctors

- Reduce need for communication between doctors by providing continuity of care whenever possible
 - Brief, structured letters are more likely to be read than lengthy, unstructured letters
 - Letters from primary to secondary care should provide relevant background information and a clear reason for referral
 - Letters from secondary to primary care should provide only essential information, address the needs of referrer, and outline a proposed management plan and what has been discussed with patient
 - Avoid using letters for medical records purposes rather than communication
 - The telephone can be a prompt and effective means of communication and is particularly useful in complex cases
-

Thinking “family”

Relatives' illness beliefs and attitudes are also crucial to outcome and are therefore worth addressing. Key people may be invited to join a consultation (with the patient's permission) and their concerns identified, acknowledged, and addressed. Actively involving relatives, who will spend more time with the patient than will the doctor, allows them to function as co-therapists.

Effective communication**Gaining and demonstrating understanding**

Simple techniques can be used to improve communication. The first two stages of the three function approach (see previous article) are appropriate. The first stage is building a relationship in which a patient gives his or her history and feels understood. The second stage is for the doctor to share his or her understanding of the illness with the patient. In cases that are more complicated it may be most effective to add an additional brief session with a practice or clinic nurse.

Providing information for patients

Patients require information about the likely cause of their illness, details of any test results and their meaning, and a discussion of possible treatments. Even when this information has been given in a consultation, however, many patients do not understand or remember what they are told. Hence, the provision of simple written information can be a time efficient way of improving patient outcomes.

One way of providing written information is to copy correspondence such as referral and assessment letters to the patient concerned. For those not used to doing this, it may seem a challenge, but any changes needed to make the letters understandable (and acceptable) to patients are arguably desirable in any case. Letters should be clearly structured, medical jargon minimised, pejorative terms omitted, and common words that may be misinterpreted (such as “chronic”) explained.

Well written patient information materials (leaflets and books) are available, as are guidelines for their development. The National Electronic Library of Health (www.nelh.nhs.uk) is a new internet resource that aims to provide high quality information for healthcare consumers and is linked to NHS Direct Online (www.nhsdirect.nhs.uk/main.jhtml). There are also many books to recommend—such as *Chronic Fatigue Syndrome (CFS/ME): The Facts* (see Further reading list). Information is most helpful if it addresses not only the nature of the problem, its prognosis, and treatment options, but also self care and ways of coping.

The assessment as treatment**Reassurance**

Worry about health (health anxiety) is a common cause of distress and disability in those with and without serious disease. Reassurance is therefore a key component of starting treatment.

The first step is to elicit and acknowledge patients' expectations, concerns, and illness beliefs. This is followed by history taking, examination, and if necessary investigation. Premature reassurance (such as “I'm sure its nothing much”) may be construed as the doctor not taking the problem seriously. Finally, the explanation should address all of a patient's concerns and is best based on the patient's understanding of how his or her body functions, which may differ from the doctor's.

A modest increase in consultation time, provision of written information, and perhaps the use of trained nursing staff to

Gaining understanding of patients' concerns

- Read referral letter or notes, or both, before seeing patient
- Encourage patients to discuss their presenting concerns without interruption or premature closure
- Explore patients' presenting complaints, concerns, and understanding (beliefs)
- Inquire about disability
- Inquire about self care activities
- Show support and empathy
- Use silence appropriately
- Use non-verbal communication such as eye contact, nods, and leaning forward

Showing your understanding of patients' concerns

- Relay key messages—such as, “The symptoms are real,” “We will look after you,” and “You're not alone”
- Take patients seriously and make sure they know it
- Don't dismiss presenting complaints, whether or not relevant pathology is found
- Explain your understanding of the problem—what it is, what it isn't, treatment, and the future. A diagram may help
- Consider offering a positive explanation in the absence of relevant physical pathology
- Reassure
- Avoid mixed messages
- Encourage and answer questions
- Share decisions
- Communicate the management plan effectively, both verbally and in writing
- Provide self care information, including advice on lifestyle change
- Explain how to get routine or emergency follow up, and what to look out for that would change the management plan

Providing information

- Invite and answer questions
- Use lay terms, and build on patient's understanding of illness wherever possible
- Avoid medical jargon and terms with multiple meanings, such as “chronic”
- Involve relatives
- Provide written material when available
- Provide a written management plan when appropriate

The complexity of reassurance**General reassurance**

- To know it will be OK
- To know I will be looked after
- To know there are others like me

Reassurance about cause

- To know what it is
- To know what it is not
- To know it's not serious
- “There are several possible causes, not just cancer”
- “It's not cancer”
- “It will get better”

Reassurance about cure

- To know it can be treated
- To know it will be treated
- To know how it will be treated
- To know the complaint will go away

facilitate information giving, can all enhance doctor-patient communication and, therefore, reassurance. Although extra time and effort may be needed, it may well reduce subsequent demand on resources.

Being positive

Doctors themselves are potentially powerful therapeutic agents. There is evidence that being deliberately positive in a consultation may increase this effect. In one randomised trial, general practice patients received either a positive consultation (firm diagnosis and good prognosis) or a non-positive consultation (no firm diagnosis and uncertain prognosis). Two weeks later, the positive consultation, which was simple and brief, had improved symptoms, with a number needed to treat of four (95% confidence interval 3 to 9).

Using tests as treatment

Tests should ideally be informative and reassuring for both doctors and patients. However, there is increasing evidence that tests may not reassure some patients and may even increase their anxiety. This is most likely with patients who are already anxious about their health. When weighing the pros and cons of ordering a test, doctors should take account of the potential psychological impact on their patient (both positive and negative).

Providing explanations after negative investigation

Even when tests are reported as normal, some patients are not reassured. Such patients may benefit from an explanation of what is wrong with them, not just what is not wrong. A cognitive behavioural model can be used to explain how interactions between physiology, thoughts, and emotion can cause symptoms without pathology. Simple headache provides an analogy: the pain is real, and often distressing and disabling, but is usually associated with "stress." Diagnoses such as "tension headache" and "irritable bowel syndrome" can be helpful in reducing patients' anxiety about sinister causes for their symptoms.

Planning for the future

Maintaining and increasing activities

Sometimes patients unnecessarily avoid or reduce their activities for fear it will make their illness worse. This coping strategy magnifies disability. Planning a graded return towards normal activities is one of the most effective ways of helping such patients. A plan should specify clearly what activity, for how long, when, with whom, and how often. It is best if the plan is written down and reviewed regularly. A collaborative approach increases the chances of success.

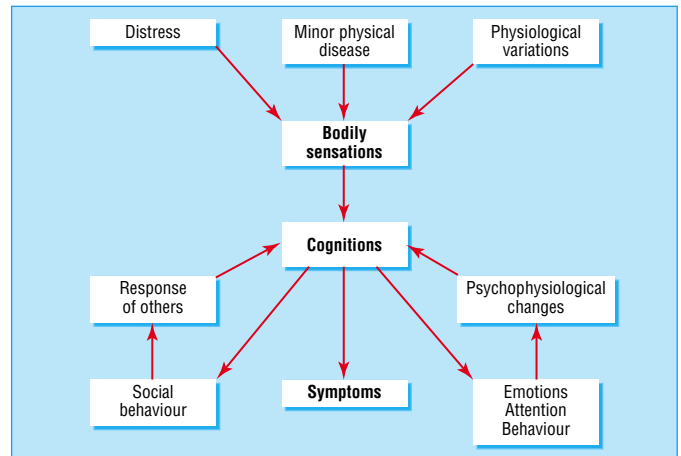

Follow up

Positively following up patients who have presented for the first time can be an effective use of time. It allows review and modification of the management plan and may be particularly effective if the same doctor is seen.

The painting of Charcot is reproduced with permission of the Wellcome Library.

Characteristics of brief psychological intervention

- Brief, single session intervention
- Suitable for more complex problems, such as in secondary care
- Delivered with or soon after clinic attendance
- Integrated with usual care
- Uses cognitive understanding of health anxiety
- Minimises negative aspects of patient experience
- Reinforces positive aspects of patient experience
- Provides explicit explanation and reassurance

A simple cognitive model of physical symptoms. A cognitive model is one in which the patient's thoughts and beliefs are seen as central to the aetiology, perception, and presentation of the problem

Evidence based summary

- The quality of communication, both in history taking and in discussing a management plan, influences patient outcome
- Patients should be encouraged to take an active role in maintaining or improving their own health, and doctors should ensure they are given the necessary information and opportunities for self management
- Reassurance involves eliciting and acknowledging patients' expectations, concerns, and illness beliefs

3 Organising care for chronic illness

Michael Von Korff, Russell E Glasgow, Michael Sharpe

A major and increasing task for health services is the management of chronic illness. Although the details of chronic illness management will depend on the illness in question, many of the principles are common to all chronic conditions.

Principles of effective management

Whatever health services may offer, most of the day to day responsibilities for the care of chronic illness fall on patients and their families. Planners and organisers of medical care must therefore recognise that health care will be most effective if it is delivered in collaboration with patients and their families. To enable patients to play an active role in their care, health services must not only provide good medical treatment but also improve patients' knowledge and self management skills. This can be done by supplementing medical care with educational and cognitive behavioural interventions. Chronic disease treatment programmes have tended to underestimate the need for this aspect of care, and, consequently, many treatment programmes have been psychologically naive and, as a result, less effective than they could have been.

Services also need to be not merely reactive to patients' requests but proactive with planned follow up. Finally, to be most efficient, interventions are best organised in a stepped fashion—that is, the more complex and expensive interventions are given only when simpler and cheaper ones have been shown to be inadequate or inappropriate.

Collaboration with patients and families

To win the collaboration of patients and their families, those providing care need to elicit, negotiate and agree on a definition of the problem they are working on with each patient. They must then agree on the targets and goals for management and develop an individualised collaborative self management plan. This plan should be based on established cognitive behavioural principles and on the evidence relating to the management of the chronic condition.

In order to implement collaborative care, patients and their families require access to the necessary information and services to enable them to play a full and informed role. The need for collaborative care in which patients play an active role has been highlighted in Britain with the development of the concept of the "expert patient."

Encouraging self care

Active self care is critical to the optimal management of chronic illness. Interventions to optimise self care are based on cognitive behavioural principles.

They start with an assessment of patients' attitudes and beliefs about their illness and their chosen coping behaviours. This assessment then guides the provision of information, the resolution of misunderstandings and misinterpretations, and collaborative goal setting. These are agreed between patient and members of the healthcare team.

The outcome of this initial assessment takes the form of a personal action plan, a written agreement between those delivering care and the patient. The patient keeps a copy of the plan, and the healthcare team keeps another. The plan can be written on brief, standardised forms. The plan is not static but is

Treating chronic conditions must involve the family

Common elements of effective chronic illness management

- Collaboration between service providers and patients
 - A personalised written care plan
 - Tailored education in self management
 - Planned follow up
 - Monitoring of outcome and adherence to treatment
 - Targeted use of specialist consultation of referral
 - Protocols for stepped care
-

Principles of collaboration

- Understanding of patients' beliefs, wishes, and circumstances
 - Understanding of family beliefs and needs
 - Identification of a single person to be main link with each patient
 - Collaborative definition of problems and goals
 - Negotiated agreed plans regularly reviewed
 - Active follow up with patients
 - Regular team review
-

The UK "expert patient" programme*

- Encouragement of self care protocols, nationally and locally
- Development of electronic and written self care material
- Training programmes, national and local
- Integrating self care into local health planning
- Nurse led telephone service (NHS Direct)

* From; Department of Health. *The expert patient: a new approach to chronic disease management for the 21st century* (www.ohm.gov.uk/ohm/people/expert)

developed over time: the initial goals and the care plan designed to achieve them are refined in view of the patient's progress and the identification of factors that are either helpful or unhelpful in achieving the desired outcome.

Active follow up

The personal action plan guides the patient's follow up contacts. Active planned follow up ensures that the plan is carried out and that modifications to it are made as needed. These steps are repeated in an iterative, ongoing, and flexible way rather than all at once in a single visit. Because the care of chronic illness is a long term process, the work of supporting self care does not need to be done all at once but can be spread over many contacts.

Individualised stepped care

Stepped care provides a framework for using limited resources to greatest effect. Professional care is stepped in intensity—that is, it starts with limited professional input and systematic monitoring and is then augmented for patients who do not achieve an acceptable outcome. Initial and subsequent treatments are selected according to evidence based guidelines in light of a patient's progress.

The principle of increasing intensity of professional input for those who do not respond to initial management is familiar in primary care. However, organised stepped care requires the systematic monitoring of progress and higher levels of coordination between specialist care, care management, and primary care than generally exist. The primary care team, a specialist consultant (when needed), and a care manager (when needed) work together to provide the level of professional support needed to achieve a favourable outcome. Stepped care is individualised according to each patient's preferences and progress.

Skills required by those delivering care

The team providing care must not only be familiar with a patient's condition but must also possess the psychological skills to help the patient achieve self care. They also need access to specialists in psychological and psychiatric management to provide supervision and consultation in selected cases. The necessary psychological skills include

- Anxiety management
- Recognition and treatment of depression
- Cognitive behavioural analysis
- Cognitive behavioural principles of step by step change
- Ability to monitor patient's progress.

Changes in the organisation of care

Achieving collaboration between healthcare providers and chronically ill patients requires organisational changes in six related areas.

Organisation of care—Clinical leadership should encourage efforts to improve quality, including development of incentives for improved care and reorganisation of acute care to encourage self care.

Clinical information systems—A disease (or disorder) registry should be set up that identifies the population to be served and includes information on the performance of guideline based care, including self care tasks. The registry should permit identification of patients with specific needs, reminder systems, and tailored treatment planning.

Plan for collaborative self care

1 Assessment

- Assess patient's self management beliefs, attitudes, and knowledge
- Identify personal barriers and supports
- Collaborate in setting goals
- Develop individually tailored strategies and problem solving

2 Goal setting and personal action plan

- List goals in behavioural terms
- Identify barriers to implementation
- Make plans that address barriers to progress
- Provide a follow up plan
- Share the plan with all members of the healthcare team

3 Active follow up to monitor progress and support patient

Levels of stepped care

- 1 Systematic routine assessment and preventive maintenance
 - 2 Self care with low intensity support
 - 3 Care management in primary care
 - 4 Intensive care management with specialist advice
 - 5 Specialist care
-

Assumptions of stepped care

- Different individuals require different levels of care
 - The optimal level of care is determined by monitoring outcomes
 - Moving from lower to higher levels of care based on patient outcomes can increase effectiveness and lower costs
-

Example of changes in organisation of care for patients with diabetes

Organisation of care

- Primary care clinic initiates year long effort to reorganise diabetes care
- Team is set up and meets regularly to make changes, monitor progress, and address obstacles

Clinical information systems

- Team develops a register of all patients with diabetes in the clinic, with records of HbA_{1c} values, eye and foot examinations, and goals and key elements of patients' personal action plans

Delivery system design

- Clinic nurses assigned responsibility for diabetes case management
- Doctors agree to provide planned visits for all diabetic patients at least once a year, including preventive services (such as eye and foot examinations, ordering HbA_{1c} tests, screening for depression)
- Clinic support staff maintain the register and print out a status report before each visit

Decision support

- Team agrees on standard evidence based guidelines and adapts them to clinic and liaison with the specialist diabetic clinic
- Team agrees a standard form for planned visits

Community resources

- Nurse case managers plan training in diabetes self management. The nurses are trained to co-lead the course at regular intervals

Self care support

- Nurse case managers decide that every diabetic patient will have a personal action plan developed within a year
 - Each nurse sees one patient a week until this goal is accomplished
 - Nurses telephone patients who have not been seen for six months and those who need extra support to achieve their goals
-

Delivery system design—Practice team roles should be changed in the organisation of visits and in follow up care. Useful innovations include group visits, planned visits, and telephone delivered care.

Decision support—Evidence based practice guidelines and protocols should be made effective by integrating information and reminders into visits. There should be collaborative support from relevant medical specialties.

Community resources—Links should be established with community resources, especially for vulnerable populations such as elderly, low income, and deprived populations.

Self care support—Tailored educational resources, skills training, and psychosocial support are effective. Successful self care programmes rely on collaboration; patient centred interventions for managing illness are especially beneficial.

Is this approach feasible for the large numbers of patients seen in busy primary and secondary care settings? There is growing experience with integrating support for self care to the delivery of routine medical care. Specific techniques such as cognitive behavioural interventions and the use of nurses and other staff as care managers have been found to be both feasible and effective. However, the full implementation of this approach in primary care requires substantial organisational changes. These enable medical and other expertise to be used more effectively and efficiently. They also enable doctors to obtain greater satisfaction in being responsible for higher quality care.

Evidence that it works

Collaborative self care has been used to guide efforts to improve the quality of chronic illness care in many different healthcare settings and for many different chronic conditions including diabetes, heart failure, geriatric care, depression, and asthma. This approach gives patients the confidence and skills for self care and for getting what they need from the healthcare system (that is, becoming active, informed patients). Such effective support of patients is more likely to occur when the providers of care themselves have the information, training, resources, and time to deliver effective interventions (that is, are a well prepared, proactive practice team).

There is now considerable evidence and practical experience that supports fundamental changes in the way we organise and deliver health care to better support patients who are living with a chronic condition. Consequently, we need to include psychological and behavioural expertise as essential supplements to basic medical treatment.

Patient centred care is more than a respectful attitude or a style of clinical interviewing. It means that healthcare systems are organised to maximise the effectiveness of patients to manage their chronic illness themselves.

Psychological medicine will make its full contribution only when an awareness of the importance of psychological and behavioural factors is fully integrated into general medical care.

Work on this article was supported by grants from the Robert Wood Johnson Foundation National Program for Improving Chronic Illness Care, NIMH grants MH51338 and MH41739, and NIH grant P01 DE08773.

Making evidence based care time and cost effective

Problems

- Time for patient care
- Time for assessing evidence
- Unrealistic patient expectations and demands
- Lack of patient understanding of behavioural basis of self care
- Lack of involvement of patients in clinical decisions
- Lack of professional skills
- Access to disparate community and medical services

Solutions

- Treatment protocols
 - Involvement of healthcare team
 - Use of self help procedures
 - Formalising links with local health, social, and voluntary agencies
 - Liaison with specialist medical, psychiatric, and psychological services
 - Continuing professional development
-

Evidence based summary

- Collaborative and adaptive approaches to self care that are structured and integrated into medical services improve outcomes for many chronic diseases
- Systematic setting of therapeutic goals and monitoring of clinical treatment and outcomes are integral to this approach
- Such an approach to health care will often require changes to the way in which teams and primary and secondary care services interact

4 Depression in medical patients

Robert Peveler, Alan Carson, Gary Rodin

Depressive illness is usually treatable. It is common and results in marked disability, diminished survival, and increased healthcare costs. As a result, it is essential that all doctors have a basic understanding of its diagnosis and management. In patients with physical illness depression may

- Be a coincidental association
- Be a complication of physical illness
- Cause or exacerbate somatic symptoms (such as fatigue, malaise, or pain).

Clinical features and classification

The term depression describes a spectrum of mood disturbance ranging from mild to severe and from transient to persistent. Depressive symptoms are continuously distributed in any population but are judged to be of clinical significance when they interfere with normal activities and persist for at least two weeks, in which case a diagnosis of a depressive illness or disorder may be made. The diagnosis depends on the presence of two cardinal symptoms of persistent and pervasive low mood and loss of interest or pleasure in usual activities.

Adjustment disorders are milder or more short lived episodes of depression and are thought to result from stressful experiences.

Major depressive disorder refers to a syndrome that requires the presence of five or more symptoms of depression in the same two week period.

Dysthymia covers persistent symptoms of depression that may not be severe enough to meet the criteria for major depression, in which depressed mood is present for two or more years. Such chronic forms of depression are associated with an increased risk of subsequent major depression, considerable social disability, and unhealthy lifestyle choices such as poor diet or cigarette smoking.

Manic depressive (bipolar) disorder relates to the occurrence of episodes of both major depression and mania.

Epidemiology

The World Health Organization estimates that depression will become the second most important cause of disability worldwide (after ischaemic heart disease) by 2020. Major depressive disorder affects 1 in 20 people during their lifetime. Both major depression and dysthymia seem to be more common in women.

Depressive illness is strongly associated with physical disease. Up to a third of physically ill patients attending hospital have depressive symptoms. Depression is even more common in patients with

- Life threatening or chronic physical illness
- Unpleasant and demanding treatment
- Low social support and other adverse social circumstances
- Personal or family history of depression or other psychological vulnerability
- Alcoholism and substance misuse
- Drug treatments that cause depression as a side effect, such as antihypertensives, corticosteroids, and chemotherapy agents.

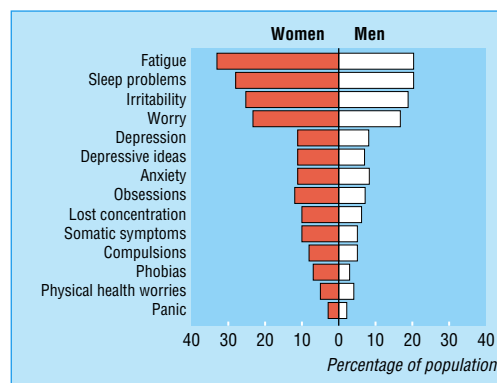

Aretaeus of Cappadocia (circa 81-138 AD) is credited with the first clinical description of depression

Criteria for major depression*

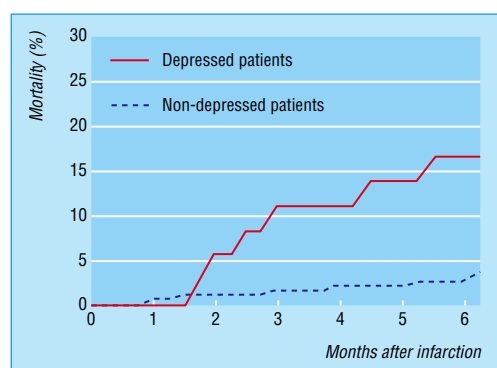

Five or more of the following symptoms during the same two week period representing a change from normal

- Depressed mood†
- Substantial weight loss or weight gain
- Insomnia or hypersomnia
- Feelings of worthlessness or inappropriate guilt
- Recurrent thoughts of death or suicide or suicide attempt
- Decreased interest or pleasure†
- Psychomotor retardation or agitation
- Fatigue or loss of energy
- Diminished ability to think or concentrate

*From *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition
†One of these symptoms must be present

“Neurotic” symptoms, including depression, are continuously distributed in the UK population

The association between depression and mortality after myocardial infarction

Risk factors

Anxiety, sadness, and somatic discomfort are part of the normal psychological response to life stress, including medical illness. Clinical depression is a final common pathway resulting from the interaction of biological, psychological, and social factors. The likelihood of this outcome depends on such factors as genetic and family predisposition, the clinical course of a concurrent medical illness, the nature of the treatment, functional disability, the effectiveness of individual coping strategies, and the availability of social and other support.

In the attempts to understand the relation between physical illness and depression there has been much debate about the direction of causality. In particular, there has been speculation that certain illnesses—such as stroke, Parkinson’s disease, multiple sclerosis, and pancreatic cancer—may cause depression via direct biological mechanisms. Stroke has perhaps received the most attention, but studies have failed to convincingly show direct aetiological mechanisms.

Recognition and diagnosis

In spite of its enormous clinical and public health importance, depressive illness is often underdiagnosed and undertreated, particularly when it coexists with physical illness. This often causes great distress for patients who have mistakenly assumed that symptoms such as weakness or fatigue are due to an underlying medical condition.

All medical practitioners must be able to diagnose and manage depressive illness effectively. This depends on

- Alertness to clues in interviews
- Patients’ manner
- The use of screening questions in those at risk—in particular, two questions about low mood and lack of pleasure in life can detect up to 95% of patients with major depression.

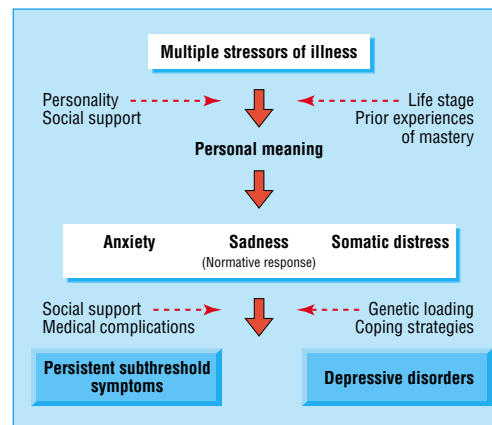

Self report screening instruments, such as the Beck depression inventory (BDI) and the hospital anxiety and depression scale (HADS) cannot replace systematic clinical assessment, but they are useful in drawing attention to depression and other emotional disturbances in clinical settings where mood is not routinely assessed. Doctors must be aware that persistent low mood and lack of interest and pleasure in life cannot be accounted for by severe physical illness alone. The usual response to illness and treatment is impressive resilience.

If there is doubt about the diagnosis, a doctor may resort to an empirical trial of treatment to establish whether there is benefit. The wider availability of safer drugs and psychological treatments makes this option more attractive than in the past.

Management

The main aims of treatment are to improve mood and quality of life, reduce the risk of medical complications, improve compliance with and outcome of physical treatment, and facilitate the “appropriate” use of healthcare resources. The development of a treatment plan depends on systematic assessment that should, whenever possible, not only involve the patients but also their partners or other key family members.

Milder or briefer adjustment disorders can be managed by primary care staff without recourse to specialist referral. Education, advice, and reassurance are of value. It is important that primary care staff are familiar with the properties and use of the commoner antidepressant drugs, and the value of brief psychological treatments such as cognitive behaviour therapy, interpersonal therapy, and problem solving.

Pathways to depression

Reasons why depression is missed

- Difficulty distinguishing psychological symptoms of depression, such as sadness and loss of interest, from a “realistic” response to stressful physical illness
- Confusion over whether physical symptoms of depression are due to an underlying medical condition
- Negative attitudes to diagnosis of depression
- Unsuitability of clinical setting for discussion of personal and emotional matters
- Patients’ unwillingness to report symptoms of depression

Screening questions for depression

- How have you been feeling recently?
- Have you been low in spirits?
- Have you been able to enjoy the things you usually enjoy?
- Have you had your usual level of energy, or have you been feeling tired?
- How has your sleep been?
- Have you been able to concentrate on newspaper articles or your favourite television or radio programmes?

Physical symptoms that may be due to depression

Patients with more enduring or severe symptoms will usually require specific forms of treatment, usually drug treatment. Staff should also be able to assess suicidal thinking and risk. For patients with suicidal ideation or those whose depression has not responded to initial management, specialist referral is the next step in management.

Drug treatment

Antidepressants have been shown to be effective in treating major depressive disorder irrespective of whether the mood disturbance is “understandable.” There have been far fewer trials of antidepressants in patients who are also physically unwell, but the available evidence is in keeping with the treatment of depression generally.

One of the commonest questions is which antidepressant should be used. For non-specialists, the range of available drugs, and the claims made about them can be bewildering. There are four main classes of antidepressant

- Tricyclics
- Selective serotonin reuptake inhibitors
- Monoamine oxidase inhibitors
- Others (noradrenaline reuptake inhibitors).

Choice of agent

Data from the Cochrane Collaboration and other systematic reviews show that the differences in overall tolerability between different preparations is minimal. In general, patients are slightly less likely to drop out of trials because of unacceptable side effects when taking a selective serotonin reuptake inhibitor but are slightly less likely to drop out because of treatment inefficacy when taking a tricyclic. Rather than continuously experimenting with a range of different drugs, clinicians should stick to prescribing one drug from each class in order to become familiar with their dosing regimens, actions, interactions, and side effects. Clinicians should also be aware that in certain situations one class of drug may be more advisable than others.

Adequacy of treatment

The debate about different preparations has obscured a potentially more important issue—that of drug dose and compliance. Most prescriptions for antidepressants are for inadequate doses and for inadequate time periods. This problem is compounded by only a minority of patients complying with the prescribed treatment. A recent household survey by the Royal College of Psychiatrists showed that many people believed that antidepressants were addictive and could permanently damage the brain.

Explanation

To treat patients successfully with antidepressants, doctors must be able to show their patient that they have understood the patient’s problems, considered the issues, and are advising the best available treatment (see previous chapters). Before starting treatment, patients should be given an explanation of side effects and be reassured that side effects tend to be worse during the first two weeks of treatment and then diminish. They need to be warned that they are unlikely to feel benefits from treatment in the first four weeks. They should be given follow up appointments during this period in order to encourage compliance.

Duration of treatment

After initial treatment has led to remission of symptoms, subsequent treatment can be divided into two phases. Firstly, four to six months of continuous treatment at full dose are

Clinical assessment of suicidal intent

Low level risk

Clinical picture

- Suicidal ideation but no suicide attempts
- Supportive environment
- Physically healthy
- No history of psychiatric illness

Action

Consider referral to mental health professional for routine appointment (not always necessary)

Moderate level risk

Clinical picture

- Low lethality suicide attempt (patient’s perception of lethality)
- Frequent thoughts of suicide
- Previous suicide attempts
- Persistent depressive symptoms
- Serious medical illness
- Inadequate social support
- History of psychiatric illness

Action

Refer to mental health professional, to be seen as soon as possible

High level risk

Clinical picture

- Definite plan for suicide (When? Where? How?)
- Major depressive disorder, severe
- High lethality suicide attempt or multiple attempts
- Advanced medical disease
- Social isolation
- History of psychiatric illness

Action

Refer to mental health professional for immediate assessment

Meta-analysis of randomised controlled trials of drug treatment of depression in the physically ill

Chart of clinical course indicating remission, recovery, and relapse

necessary to consolidate remission and prevent early relapse. Secondly, consideration must be given to preventive maintenance treatment, to reduce the risks of recurrence of depression. This is usually indicated if the patient has had two or more episodes of depression within the past five years. Psychological treatment may also help to prevent recurrence and can be used in combination with drug treatment.

Psychological treatment

Psychological treatment can range from discussion and simple problem solving to more specialised cognitive or dynamic behavioural psychotherapies. In many cases, brief treatment by non-specialists in primary and secondary care can be effective. Such interventions may include education and reassurance about the common reactions to the threats and losses associated with illness and empathic listening to patients' views, uncertainties, and beliefs about the illness. Education and advice about the medical condition and associated depression may prevent needless worry, reduce feelings of helplessness, and diminish irrational fears. Therapeutic approaches that support or promote active coping strategies are an important aspect of treatment in physically ill patients.

Cognitive behavioural principles may be used by non-specialists to correct distorted thinking and to encourage behaviours that contribute to patients' sense of mastery and wellbeing. Training in briefer forms of treatment using cognitive behavioural principles for primary care staff may be a worthwhile investment.

Cognitive behaviour therapy, interpersonal therapy, and problem solving have all been shown to be effective for treating depression, although there has been only limited evaluation of their effectiveness in physically ill populations. Although time consuming by comparison with drug treatment, psychological treatment may reduce relapse rates and may be cost effective in the long run. Some patients may require preliminary treatment with drugs to enable them to make best use of psychological treatment.

Service organisation

Depression is so common in physically ill patients that it is not feasible for all cases to be managed by mental health specialists. There are advantages to collaborative management with primary care staff working closely with mental health specialists. Community based mental health services may be less accessible to general hospitals and often lack specialist knowledge about assessment and treatment when an important physical illness is also present. Liaison psychiatry services are often well placed to provide support, training, and psychiatric expertise to general hospital patients in a timely fashion.

Problem solving in psychological treatment

- Define and list the problems
 - Choose a problem for action
 - List alternative courses of action
 - Evaluate courses of action and choose the best
 - Try the action
 - Evaluate the results
 - Repeat until major problems have been solved
-

Evidence based summary

- Depressive illness is an important cause of morbidity and disability in physically ill patients
- All patients with depression should be examined for suicidal ideation

5 Anxiety in medical patients

Allan House, Dan Stark

Doctors often consider anxiety to be a normal response to physical illness. Yet, anxiety afflicts only a minority of patients and tends not to be prolonged. Any severe or persistent anxious response to physical illness merits further assessment.

What is anxiety?

Anxiety is a universal and generally adaptive response to a threat, but in certain circumstances it can become maladaptive. Characteristics that distinguish abnormal from adaptive anxiety include

- Anxiety out of proportion to the level of threat
- Persistence or deterioration without intervention (>3 weeks)
- Symptoms that are unacceptable regardless of the level of threat, including

- Recurrent panic attacks

- Severe physical symptoms

- Abnormal beliefs such as thoughts of sudden death

- Disruption of usual or desirable functioning.

One way to judge whether anxiety is abnormal is to assess whether it is having a negative effect on the patient's functioning.

Abnormal anxiety can present with various typical symptoms and signs, which include

- Autonomic overactivity
- Behaviours such as restlessness and reassurance seeking
- Changes in thinking, including intrusive catastrophic thoughts, worry, and poor concentration
- Physical symptoms such as muscle tension or fatigue.

Classification of abnormal anxiety

Abnormal anxiety can be classified according to its clinical features. In standardised diagnostic systems there are four main patterns of abnormal anxiety.

Anxious adjustment disorder—Anxiety is closely linked in time to the onset of a stressor.

Generalised anxiety disorder—Anxiety is more pervasive and persistent, occurring in many different settings.

Panic disorder—Anxiety comes in waves or attacks and is often associated with panicky thoughts (catastrophic thoughts) of impending disaster and can lead to repeated emergency medical presentations.

Phobic anxiety—Anxiety is provoked by exposure to a specific feared object or situation. Medically related phobic stimuli include blood, hospitals, needles, doctors and (especially) dentists, and painful or unpleasant procedures.

Additionally, anxiety often presents in association with depression. Mixed anxiety and depressive disorders are much more common than anxiety disorders alone. Treatment for the depression may resolve the anxiety. Anxiety can also be the presenting feature of other psychiatric illnesses common in physically ill people, such as delirium or drug and alcohol misuse.

William Cullen (1710-90) coined the term *neurosis* (though the term as he used it bears little resemblance to modern concepts of anxiety disorders)

Somatic and psychological symptoms of anxiety disorders

In all anxiety disorders

- Palpitations, pounding heart, accelerated heart rate
- Trembling or shaking
- Difficulty in breathing
- Chest pain or discomfort
- Feeling dizzy, unsteady, faint, light headed
- Fear of losing control, going crazy, passing out
- Sweating
- Dry mouth
- Feeling of choking
- Nausea or abdominal discomfort
- Feeling that objects are unreal or that self is distant
- Fear of dying
- Numbness or tingling sensations
- Hot flushes or cold chills

In more severe or generalised anxiety disorders

- Muscle tension or aches and pains
- Feeling keyed up, on edge, or mentally tense
- Exaggerated response to minor surprises or being startled
- Persistent irritability
- Restlessness, inability to relax
- Sensation of difficulty swallowing, lump in the throat
- Difficulty concentrating or "mind going blank" from anxiety or worry
- Difficulty in getting to sleep because of worry

Distinguishing features of anxiety disorders

Anxious adjustment disorder

Prevalence in general population—Not known

Cardinal features

- Onset of symptoms within 1 month of an identifiable stressor
- No specific situation or response

Generalised anxiety disorder

Prevalence in general population—31 cases/1000 adults

Cardinal features

- Period of 6 months with prominent tension, worry, and feelings of apprehension about everyday problems
- Present in most situations and no specific response

Panic disorder

Prevalence in general population—8 cases/1000 adults

Cardinal features

- Discrete episode of intense fear or discomfort with crescendo pattern; starts abruptly and reaches a maximum in a few minutes
- Occurs in many situations, with a hurried exit the typical response

Phobia

Prevalence in general population—11 cases/1000 adults

Cardinal features

- No specific symptom pattern
 - Occurs in specific situations, with an avoidance response
-

Detecting anxiety and panic

Who is at risk?—Certain groups are more vulnerable to anxiety disorders: younger people, women, those with social problems, and those with previous psychiatric problems. However, such associations are less consistent in the setting of life threatening illness, perhaps because susceptibility to anxiety becomes less important as the stressor becomes more severe. Pathological anxiety is commoner among patients with a chronic medical condition than in those without.

Excluding physical causes—There are many presentations with physical complaints whose aetiology may be due to anxiety. Equally, several physical illnesses can cause anxiety or similar symptoms. When such disorders cannot be reliably distinguished from anxiety by clinical examination they need to be excluded through appropriate investigation. A firm diagnosis of anxiety should therefore be made only when a positive diagnosis can be supported by the presence of a typical syndrome and after appropriate investigation.

Use of screening questionnaires—Screening, with self completed questionnaires, has been widely used to improve detection of psychiatric morbidity, including anxiety. Such questionnaires are acceptable to patients and can be amenable to computerised automation in the clinic. The hospital anxiety and depression scale, the general health questionnaire, and many quality of life instruments include anxiety items. No one questionnaire has been consistently shown to be preferable to another.

Iatrogenic anxiety—Anxiety symptoms can be caused by poor communication (see chapters 1 and 2) and by prescribed drugs. Well known causes include corticosteroids, β adrenoceptor agonists, and metoclopramide, but doctors should remember that many less commonly used drugs can cause psychiatric syndromes.

Treatment of anxiety and panic

General management

Treating anxiety is part of the management of most medical conditions. It can lead to direct improvement of symptoms or improve patient compliance. It is important to intervene if a positive diagnosis of anxiety is made. Without treatment, anxiety is associated with increased disability, increased use of health service resources, and impaired quality of life.

Involving a mental health professional is not always possible for anxious patients, particularly those in general hospital settings. The range of available services is often limited, and not all patients are prepared to accept referral. Since many patients have to be managed without recourse to psychiatric services, treating anxiety should be considered a core skill for all doctors.

Giving information is often the first step in helping anxious patients, so much so that it has been said that knowledge is reassurance. While information must be tailored to the wishes of the individual, many patients want more information than they are given. Such a simple step as showing people where they are to be cared for can reduce anxiety.

Effective communication is central to information giving, with evidence that anxiety is associated with poor communication. Training doctors to use open questions, discuss psychological issues, and summarise—and to avoid reassurance, “advice mode,” and leading questions—has been shown to lead to greater disclosure and enduring change in patients with psychological problems.

Reassurance is one of the most widely practised clinical skills. Doctors often need to tell patients that their symptoms are not due to occult disease. Simple reassurance, however, may be

Common physical problems that may be caused by anxiety

Medical conditions mimicking or directly resulting in anxiety

- Poor pain control—Such as ischaemic heart disease, malignant infiltration
- Hypoxia—May be episodic in both asthma and pulmonary embolus
- Hypocapnia—May be due to occult bronchial hyperreactivity
- Central nervous system disorders (structural or epileptic)
- Anaemia
- Hypoglycaemia
- Hyperkalaemia
- Alcohol or drug withdrawal
- Vertigo
- Thyrotoxicosis
- Hypercapnia
- Hyponatraemia

Self reported questionnaires used to assess anxiety

Hospital anxiety and depression scale

Advantages

- Excludes somatic symptoms of disease
- Brevity (14 items in all, 7 concerning anxiety)
- Widespread use in cancer and other physical illnesses
- More effective than many other instruments
- Used as a screen and a measure of progress

Disadvantages

- Recent concern that, used alone, it is poor at detecting depression

State-trait anxiety inventory

Advantages

- Specific to anxiety
- Used as a screen and a measure of progress

Disadvantages

- Used alone does not detect depression
- Longer (20-40 items) than many other self reported questionnaires

General health questionnaire

Advantages

- Brevity (12 or 28 items)
- Excludes somatic symptoms of disease
- Used as a screen and a measure of progress

Disadvantages

- May not be accurate in detecting chronic problems

Common drug causes of anxiety

- Anticonvulsants—Carbamazepine, ethosuximide
- Antimicrobials—Cephalosporins, ofloxacin, aciclovir, isoniazid
- Bronchodilators—Theophyllines, β_2 agonists
- Digitalis—At toxic levels
- Oestrogen
- Insulin—When hypoglycaemic
- Non-steroidal anti-inflammatory drugs—Indomethacin
- Antidepressants—Specific serotonin reuptake inhibitors
- Antihistamines
- Calcium channel blockers—Felodipine
- Dopamine
- Inotropes—Adrenaline, noradrenaline
- Levodopa
- Corticosteroids
- Thyroxine

Many drugs can cause palpitation or tremor, but these should be easily distinguished from anxiety by clinical examination

ineffective for anxious patients; their anxiety may be reduced initially by the consultation, but it rapidly returns. Several theoretical models of this problem have been suggested, based on the patterns of thinking (“cognitions”) of people who are difficult to reassure.

Preparation for unpleasant procedures can remove the additional burden of facing the unknown. It may also allow planning of short term tactics for dealing with anxiety provoking circumstances. Anxious patients are highly vigilant and overaware of threatening stimuli. They often use “quick fix” techniques based on avoidance of threat to reduce anxiety; such strategies are generally maladaptive and result in increasing disability. In some medical situations, however, such avoidance may not be a bad thing if the threat is temporary. A similar effect is seen with use of benzodiazepine to provide temporary relief from anxiety symptoms that will not recur because the stressor is not persistent.

Behavioural treatments are among the most effective treatments for anxiety disorders. Many patients restrict their activities in response to anxiety, which often has the effect of increasing both the level of anxiety and the degree of disability in the longer term. The principle of treatment is that controlled exposure to the anxiety producing stimulus will eventually lead to diminution in symptoms. Although specific behavioural treatments will normally be conducted by specialists, other clinicians should be aware of the basic principles. It is important to encourage and help patients to maintain their normal activities as much as possible, even if this causes temporary increases in anxiety.

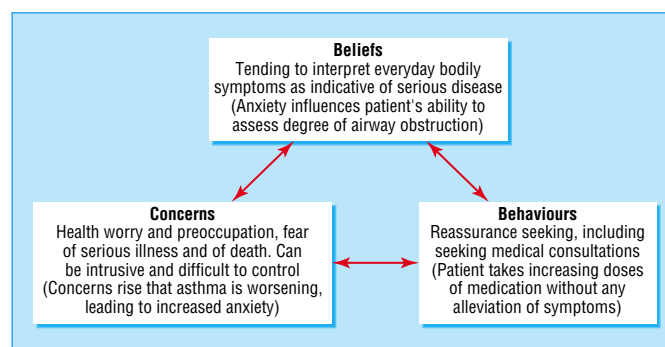

Drug treatments—Several drugs can be used to treat anxiety, each with its own advantages and disadvantages. Long term benzodiazepine dependence and misuse are considered by many to be a problem in medical practice. Although the evidence for this is conflicting, the use of benzodiazepines may be reserved for the short term treatment of anxiety and for emergencies.

Drug withdrawal—Dependence on other substances, particularly analgesics and alcohol, occurs fairly frequently in the context of anxiety. This often results from self medication for anxiety. In this situation withdrawal from the existing “treatment” will be an important part of the anxiety management programme.

Role of specialist psychological treatment

Clinical studies indicate that psychological interventions for anxiety can be effective both in general psychiatric settings and for physically ill patients. The most popular, and those with the best evidence to support them, are based on the principles of behaviour, cognitive behaviour, or interpersonal therapy.

In behaviour and cognitive behaviour therapies the main aim is to help patients identify and challenge unhelpful ways of thinking about and coping with physical symptoms and their meaning, about themselves, and about how they should live their lives. In interpersonal therapies the main focus is on relationships with family members and friends—how such relationships are affected by illness and how they influence patients’ current emotional state. Patients need to know that such therapies may be both brief and practical. Fewer than six sessions may be enough, concentrating on symptoms or the immediate problems associated with them and learning new ways of dealing with problems. In only a minority of cases is more extended therapy needed, usually when anxiety is longer standing and only partially due to associated physical disease.

Characteristic features of health anxiety (using the example of asthma)

Drug interventions in anxious medical patients

β Blockers

- Benefits unproved in randomised controlled trials
- Help to control palpitation and tremor, but not anxiety itself
- Often used for performance anxiety, such as in interviews or examinations

Tricyclic antidepressants (such as imipramine)

- Likely to be beneficial (number needed to treat = 3)
- Anxiolytic effect is slow in onset (weeks)
- Not dependency inducing
- Useful in panic disorder or in anxiety with depression
- Anticholinergic effects can be ameliorated by a low starting dose

Selective serotonin reuptake inhibitors (such as sertraline)

- Benefit unproved but suggested
- Less anticholinergic effects than tricyclic antidepressants
- Start at low dose in anxious patients

Short acting benzodiazepines (such as alprazolam)

- Effectiveness and relative lack of toxicity well established
- All benzodiazepines can induce dependency
- Rapid onset of effect, but problems may recur on withdrawal
- Less likely to accumulate in liver

Antipsychotics (such as haloperidol)

- Benefits unproved in randomised controlled trials
- Useful adjunct to benzodiazepines
- Less respiratory depression than benzodiazepines
- Not dependency inducing
- Risk of acute dystonia, akathisia, and parkinsonism
- Avoid long term use because of risk of tardive dyskinesia

Buspirone

- Limited evidence for effectiveness from randomised controlled trials, few clinicians are convinced
- Causes some nausea and dizziness

6 Functional somatic symptoms and syndromes

Richard Mayou, Andrew Farmer

Concern about symptoms is a major reason for patients to seek medical help. Many of the somatic symptoms that they present with—such as pain, weakness, and fatigue—remain unexplained by identifiable disease even after extensive medical assessment. Several general terms have been used to describe this problem—somatisation, somatoform, abnormal illness behaviour, medically unexplained symptoms, and functional symptoms. We will use the term functional symptoms, which does not assume psychogenesis but only a disturbance in bodily functioning.

Classification of functional syndromes

Most functional symptoms are transient, but a sizeable minority become persistent. Persistent symptoms are often multiple and disabling and may be described as functional syndromes. Although different medical and psychiatric classifications of functional syndromes exist, these are simply alternative ways of describing the same conditions.

Medical syndromes (such as fibromyalgia and chronic fatigue, chronic pain, and irritable bowel syndromes) highlight patterns of somatic symptoms, often in relation to particular bodily systems. Although they are useful in everyday medical practice, recent studies show there is substantial overlap between them.

Psychiatric syndromes (such as anxiety, depression, and somatoform disorders) highlight psychological processes and the number of somatic symptoms irrespective of the bodily system to which they refer. Depression and anxiety often present with somatic symptoms that may resolve with effective treatment of these disorders. In other cases the appropriate psychiatric diagnostic category is a somatoform disorder.

The existence of parallel classificatory systems is confusing. Both have merits, and both are imperfect. For many functional symptoms, a simple description of the symptom qualified with the descriptors single or multiple and acute or chronic may suffice. When diagnosis of a functional syndrome seems appropriate a combination of medical and psychiatric descriptors conveys the most information, such as “irritable bowel syndrome with anxiety disorder.”

A major obstacle to effective management is patients feeling disbelieved by their doctor. Patients who present with symptoms that are not associated with disease may be thought by some to be “putting it on.” The deliberate manufacture of symptoms or signs, however, is probably rare in ordinary practice.

Epidemiology

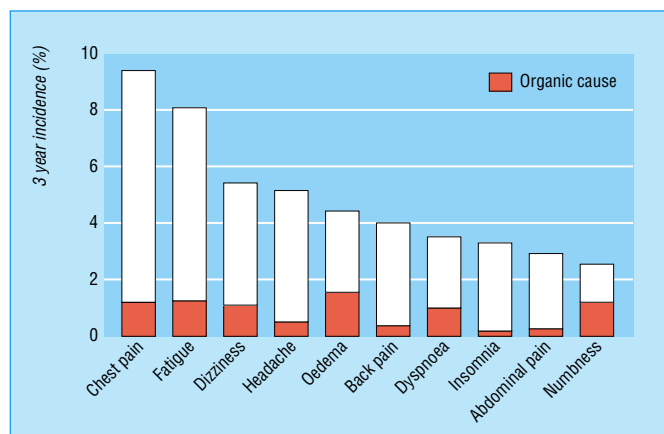

Community based studies report annual prevalences of 6-36% for individual troublesome symptoms. In primary care only a small proportion of patients presenting with such symptoms ever receive a specific disease diagnosis. The World Health Organization found functional symptoms to be common and disabling in primary care patients in all countries and cultures studied. Up to half of these patients remain disabled by their symptoms a year after presentation, the outcome being worse for those referred to secondary and tertiary care. The clinical and public health importance of functional symptoms has been greatly underestimated.

Some common functional symptoms and syndromes

- Muscle and joint pain (fibromyalgia)
- Low back pain
- Tension headache
- Atypical facial pain
- Chronic fatigue
- Non-cardiac chest pain
- Palpitation
- Non-ulcer dyspepsia
- Irritable bowel
- Dizziness
- Insomnia

René Descartes, who formulated the philosophical principle of separation of brain and mind. This has led to continuing dualism—separation of body and mind—in Western medicine and difficulty in accepting the interaction of physical and psychological factors in aetiology

Three year incidence of 10 common presenting symptoms and proportion of symptoms with a suspected organic cause in US primary care

Causal factors

The cause of functional symptoms and syndromes is not fully understood, and it is therefore best to remain neutral regarding aetiological theories. In practice, functional symptoms are often attributed to single cause, which may be pathological (such as “a virus”) or psychological (such as “stress”). This simplistic and dualistic approach is unhelpful both in explaining the cause to a patient and in planning treatment. The available evidence suggests that biological, psychological, interpersonal, and healthcare factors are all potentially important.

The dualistic, single factor view has tended to emphasise psychological over biological factors, as exemplified by the commonly used term “somatisation.” However, recent evidence suggests that biological factors (especially reversible functional disturbance of the nervous system) are relevant to many functional syndromes, as they are to depression and anxiety disorders. A pragmatic doctor therefore asks not whether symptoms are “physical” or “mental” but whether they are fixed or are reversible by appropriate intervention.

The role of interpersonal factors in general, and of doctors and the health system in particular, in exacerbating functional symptoms has received less attention than it deserves. Raising fears of disease, performing unnecessary investigations and treatments, and encouraging disability are probably common adverse effects of medical consultations. However, denying the reality of patients’ symptoms may damage the doctor-patient relationship and drive patients from evidence based care into the arms of the unhelpful, unscientific, and unscrupulous.

Aetiological factors can also be usefully divided into the stage of illness at which they have their effect. That is, they may be predisposing, precipitating, or perpetuating. Predisposing and precipitating factors are useful in producing a fuller understanding of why a patient has the symptom, while perpetuating factors are the most important for treatment.

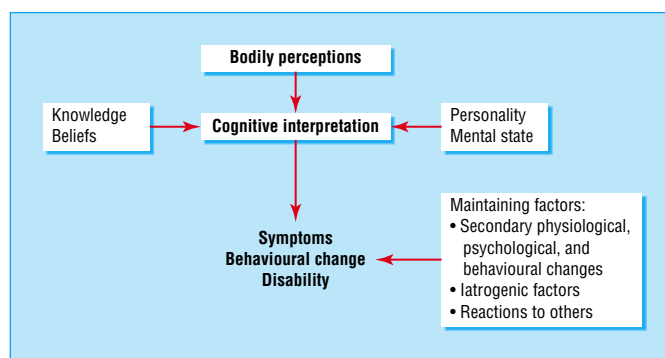

Precipitating factors—Symptoms may arise from an increased awareness of physiological changes associated with stress, depression, anxiety and sometimes disease and injury. They become important to the patients when they are severe and when they are associated with fears of, or belief in, disease.

Predisposing factors increase the chance that such symptoms will become important. Some people are probably biologically and psychologically predisposed to develop symptoms. Fear of disease may result from previous experience—for example, a middle aged man with a family history of heart disease is likely to become concerned about chest pain.

Perpetuating factors are those that make it more likely that symptoms and associated disability persists. Patients’ understandable attempts to alleviate their symptoms may paradoxically exacerbate them. For example, excessive rest to reduce pain or fatigue may contribute to disability in the longer term. Doctors may also contribute to this by failing to address patients’ concern or unwittingly increasing fear of disease (such as by excessive investigation). The provision of disability benefits can also be a financial disincentive for some patients to return to jobs they dislike, and the process of litigation may maintain a focus on disability rather than recovery.

Detection and diagnosis

Almost any symptom can occur in the absence of disease, but some, such as fatigue and subjective bloating, are more likely to be functional than others. Surprisingly, the more somatic symptoms a person has, the less likely it is that these symptoms reflect the presence of disease and the more likely there is associated depression and anxiety.

Interactive aetiology of “unexplained symptoms”

Iatrogenic factors in development of medically unexplained symptoms

- Appearance of uncertainty and inability to provide an explanation
- Expressed concern about disease explanations
- Failure to convince patient that the complaint is accepted as genuine
- Reassurance without a positive explanation being given
- Ambiguous and contradictory advice
- Excessive investigation and treatment

Individualised aetiological formulation for patient with chronic pain

Causes	Predisposing factors	Precipitating factors	Perpetuating factors
Biological	Genetic?	Injury at work	Effect of immobility Physiological mechanisms
Psychological	Lack of care as child	Trauma	Fear of worsening pain Avoid activity
Interpersonal	Family history of illness Dissatisfaction with work	Response of employer	Oversolicitous care Litigation process
Medical system	—	Misleading explanation of pain	Focus solely on somatic problems

Association between number of unexplained physical symptoms and psychiatric disorder (anxiety and depression) in an international study of primary care attenders

Patients with functional symptoms can be detected by maintaining an awareness of the problem when seeing new patients and by the use of somatic symptom questionnaires (large numbers of symptoms are more likely to be functional).

Management

Although it is essential to consider disease as the cause of the patient's symptoms an approach exclusively devoted to this can lead to difficulties if none is found. Making explicit from the start the possibility that the symptoms may turn out to be functional keeps the option of a wider discussion open. Even if more specialist treatment is needed, then the problem has, from the outset, been framed in a way that enables psychological treatment to be presented as part of continuing medical care rather than as an unacceptable and dismissive alternative. In this way it is possible to avoid an anxious disabled patient being treated by a bewildered frustrated doctor.

Investigation

An appropriate physical examination and necessary medically indicated investigation are clearly essential. Thereafter, before further investigation is done, the potential adverse psychological effect on the patient should be balanced against the likelihood and value of new information that may be obtained.

Reassurance and explanation

Most patients are reassured by being told that the symptoms they have are common and rarely associated with disease and that their doctor is familiar with them. This is especially so if accompanied by the promise of further review should the symptoms persist.

Reassurance needs to be used carefully, however. It is essential to elicit patients' specific concerns about their symptoms and to target reassurance appropriately. The simple repetition of bland reassurance that fails to address patients' fears is ineffective. If patients have severe anxiety about disease (hypochondriasis) repeated reassurance is not only ineffective but may even perpetuate the problem.

A positive explanation for symptoms is usually more helpful than a simple statement that there is no disease. Most patients will accept explanations that include psychological and social factors as well as physiological ones as long as the reality of symptom is accepted. The explanation can usefully show the link between these factors—for example, how anxiety can lead to physiological changes in the autonomic nervous system that cause somatic symptoms, which, if regarded as further evidence of disease, lead to more anxiety.

Further non-specialist treatment

A minority of patients need more than simple reassurance and explanation. Treatment should address patients' illness fears and beliefs, reduce anxiety and depression, and encourage a gradual return to normal activities.

There is good evidence that antidepressants often help, even when there are no clear symptoms of depression. Practical advice is needed, especially on coping effectively with symptoms and gradually returning to normal activity and work. Other useful interventions include help in dealing with major personal, family, or social difficulties and involving a close relative in management. Other members of the primary care or hospital team may be able to offer help with treatment, follow up, and practical help.

Functional somatic symptoms were common after combat in the first world war, such as this soldier's "hysterical pseudohypertrophic muscular spasms." The course and outcome of such symptoms can now be seen to have been substantially determined by varied medical and military approaches to prevention and treatment

Principles of assessment

- Identify patients' concerns and beliefs
 - Review history of functional symptoms
 - Explicitly consider both disease and functional diagnoses
 - Appropriate medical assessment with explanation of findings
 - Ask questions about patients' reaction to and coping with symptoms
 - Use screening questions for psychiatric and social problems
 - Consider interviewing relatives
-

Principles of treatment

- Explain that the symptoms are real and familiar to doctor
 - Provide a positive explanation, including how behavioural, psychological, and emotional factors may exacerbate physiologically based somatic symptoms
 - Offer opportunity for discussion of patient's and family's worries
 - Give practical advice on coping with symptoms and encourage return to normal activity and work
 - Identify and treat depression and anxiety disorders
 - Discuss and agree a treatment plan
 - Follow up and review
-

Non-specialist specific treatments

- Provide information and advice
 - Agree a simple behavioural plan with patient and family
 - Give advice about anxiety management
 - Encourage use of diaries
 - Advise about graded increase in activities
 - Prescribe antidepressant drug
 - Explain use of appropriate self help programmes
-

Specialist treatments

- Full and comprehensive assessment and explanation based on specialist assessment
 - Cognitive behaviour therapy
 - Supervised programme of graded increase in activity
 - Antidepressants when these were previously not accepted or ineffective
 - Illness specific interventions (such as rehabilitation programme for chronic pain)
-

Referral for specialist treatment

There is always a temptation to refer difficult patients to another doctor. However, this can result in greater long term difficulties if not carefully planned. When there is a good reason for further medical or psychiatric referral, then a clear explanation to the patient of the reason and an appropriately worded referral letter are essential.

Psychiatric treatments that may be required include more complex antidepressant drug regimens and specialist psychological interventions. Cognitive behaviour therapy has been shown to be effective in randomised controlled trials for a variety of functional syndromes (such as non-cardiac chest pain, irritable bowel, chronic pain, and chronic fatigue) and for patients with hypochondriasis.

Functional symptoms accompanying disease

Functional symptoms are also common in those who also have major disease. For example, after a heart attack or cardiac surgery, minor muscular chest aches and pains may be misinterpreted as evidence of angina, leading to unnecessary worry and disability. Explanation and advice, perhaps in the context of a cardiac rehabilitation programme, may make a substantial contribution to patients' quality of life.

Conclusion

An understanding of the interaction of biological, psychological, interpersonal, and medical factors in the predisposition, precipitation, and perpetuation of functional somatic symptoms allows convincing explanations to be provided for patients and effective treatment to be planned.

Important components of general management include effective initial reassurance, a positive explanation, and practical advice. It is also important to identify early those who are not responding and who require additional specific interventions.

The difficulty that health systems have in effectively dealing with symptoms that are not attributable to disease reflects both intellectual and structural shortcomings in current care. The most salient of these is the continuing influence of mind-body dualism on our education and provision of care. In the longer term, scientific developments will break down this distinction. For the time being, it places primary care in a pivotal role in ensuring appropriate care for these patients.

7 Chronic multiple functional somatic symptoms

Christopher Bass, Stephanie May

The previous article in this series described the assessment and management of patients with functional somatic symptoms. Most such patients make no more than normal demands on doctors and can be helped with the approach outlined. However, a minority have more complex needs and require additional management strategies. These patients typically have a longstanding pattern of presenting with various functional symptoms, have had multiple referrals for investigation of these, and are regarded by their doctors as difficult to help.

Terminology

Because such patients may evoke despair, anger, and frustration in doctors, they may be referred to as “heartsink patients,” “difficult patients,” “fat folder patients,” and “chronic complainers.” The use of these terms is inadvisable. If patients read such descriptions in their medical notes they are likely to be offended and lose faith in their doctor and may make a complaint. In psychiatric diagnostic classifications these patients are often referred to as having somatisation disorder. We prefer the term “chronic multiple functional symptoms” (CMFS).

Epidemiology and detection

The prevalence of CMFS depends upon the number of different symptoms required for diagnosis and on the setting. Whilst each primary care doctor will have an average of 10-15 of such patients, they are more common in specialist medical settings where they may account for as many as 10% of referrals.

Most patients with CMFS are women. They often have recurrent depressive disorder and a longstanding difficulty with personal relationships and may misuse substances. There is an association with an emotionally deprived childhood and childhood physical and sexual abuse. Some patients will clearly have general disturbances of personality.

The risk of iatrogenic harm from over-investigation and over-prescribing for somatic complaints makes it important that patients with CMFS are positively identified and their management planned, usually in primary care. Potential CMFS patients may be identified simply by the thickness of their paper notes, from records of attendance and hospital referral, and by observation of medical, nursing, or clerical staff.

Management in primary care

Assessment

It is helpful if one doctor is identified as a patient’s principal carer. Once a patient is identified as possibly having CMFS a systematic assessment is desirable. The case notes should be reviewed and the patient seen for one or more extended consultations.

Case notes—Patients with CMFS often have extensive case notes. Unless these are reviewed, much potentially useful information may remain hidden. It is also helpful to compile a summary of these records and to evaluate critically the accuracy of any previously listed complaints and diagnoses. The summary should include key investigations performed to date and any information about patients’ personal and family circumstances.

Long appointment—During one or more long appointment a patient’s current problems and history should be fully explored.

Charles Darwin (1809-82) suffered from chronic anxiety and varied physical symptoms that began shortly after his voyage in the *Beagle* to South America (1831-6). Despite many suggested medical explanations, these symptoms, which disabled him for the rest of his life and largely confined him to his home, remain medically unexplained

“Fat files” are a simple indicator of a high level of contact with medical services, which may indicate multiple chronic functional somatic complaints

Patients should be encouraged to talk not only about their symptoms but also about their concerns, emotional state, and social situation and the association of these with their symptoms. At the end of the assessment, patient and doctor should agree a current problem list, which can then be recorded in the notes.

Management

The initial long interviews serve not only to derive a problem list but also to foster a positive relationship between doctor and patient. Thereafter, the doctor should arrange to see the patient at regular, though not necessarily frequent, fixed intervals. These consultations should not be contingent on the patient developing new symptoms. Consultation outside these times should be discouraged.

Planned review

All symptoms reported by patients during these consultations must be acknowledged as valid. A detailed review of symptoms enhances the doctor-patient relationship and minimises the likelihood of missing new disease.

Reassurance that “nothing is wrong” may be unhelpful, possibly because a patient’s aim may be to develop an understanding relationship with the doctor rather than relief of symptoms. Focused physical examination can be helpful, but there is a risk of patients receiving multiple diagnostic tests and referrals to specialists, and these should be minimised. Patients also often accumulate unnecessary prescribed drugs, and if so these should be reduced gradually over time.

If a satisfactory rapport can be established with a patient, new information about his or her emotional state, relationship difficulties, or childhood abuse may be revealed. In such cases the doctor may need to offer the patient a further long appointment to reassess the need for specialist psychological care.

Support for doctors

General practitioners managing patients with CMFS should arrange ongoing support for themselves, perhaps from a partner or another member of the primary care team with whom they can discuss their patients. A doctor and, for example, a practice nurse can jointly manage some of these patients if there is an agreed management plan and clear communication.

Referral to psychiatric services

Not all doctors will consider that they have the necessary skills or time to manage these patients effectively. Review by an appropriate specialist can then be helpful. Unfortunately, the decline in the number of “general physicians” and specialist mental health services’ increasing focus on psychotic illness mean there are few appropriate specialists to refer to.

If referral is sought two questions must be considered: “Are there any local and appropriate psychiatric services?” and “How can I prepare the patient for this referral?” If available, liaison psychiatry services are often the most appropriate and experienced in this area of practice. To prepare the patient, a discussion emphasising the distressing nature of chronic illness and the expertise of the services in this area, together with a promise of continuing support from the primary care team, can help to make the referral seem less rejecting. If possible, the psychiatrist should visit the practice or medical department and conduct a joint consultation.

Assessment of chronic multiple functional somatic symptoms

- Elicit a history of the current complaints, paying special attention to recent life events
 - Find out what the patient has been told by other doctors (as well as friends, relatives, and alternative practitioners). Does this accord with the medical findings?
 - Elicit an illness history that addresses previous experience of physical symptoms and contact with medical services (such as illness as a child, illness of parents and its impact on childhood development, operations, time off school and sickness absence)
 - Explore psychological and interpersonal factors in patient’s development (such as quality of parental care, early abusive experiences, psychiatric history)
 - Interview a partner or reliable informant (this may take place, consent permitting, in the patient’s presence)
 - After the interview attempt a provisional formulation
-

Useful interviewing skills for doctors managing patients with multiple physical complaints

- Adopt a flexible interviewing style—“I wonder if you’ve thought of it like this?”
 - Try to remind the patient that physical and emotional symptoms often coexist—“I’m struck by the fact that, in addition to the fatigue, you’ve also been feeling very low and cannot sleep”
 - Try “reframing” the physical complaints to indicate important temporal relationship between emergence of patient’s somatic and emotional symptoms and relevant life events
 - Respond appropriately to “emotional” cues such as anger
 - Explore patient’s illness beliefs and worst fears—“What is your worst fear about this pain?”
-

Management strategy for patients with chronic multiple functional somatic symptoms

- Try to be proactive rather than reactive—Arrange to see patients at regular, fixed intervals, rather than allowing them to dictate timing and frequency of visits
 - During appointments, aim to broaden the agenda with patients—This involves establishing a problem list and allowing patients to discuss relevant psychosocial problems
 - Stop or reduce unnecessary drugs
 - Try to minimise patients’ contacts with other specialists or practitioners—This will reduce iatrogenic harm and make containment easier if only one or two practitioners are involved
 - Try to co-opt a relative as a therapeutic ally to implement your management goals
 - Reduce your expectation of cure and instead aim for containment and damage limitation
 - Encourage patients (and yourself) to think in terms of coping and not curing
-

Explanations to the patient

Present patient’s problems as a summary with an invitation to comment:

“So let me see if I’ve understood you properly: you have had a lot of pain in your abdomen, with bloating and distension for the past four years. You have been attending the (GP) surgery most weeks because you’ve been very worried about cancer (and about your husband leaving you). You also told me that these pains often occur when you are anxious and panicky, and at these times other physical complaints such as trembling and nausea occur.

“I’m struck by the fact that all these complaints began soon after you had a very frightening experience in hospital, when your appendix was removed and you felt that ‘No one was listening to my complaints or pain.’

“Have I got that right, or is there anything I’ve left out?”

Summary of a 15 year “segment” of the life of a patient with chronic multiple functional somatic symptoms

Date (age)	Symptoms (life events)	Referral	Investigations	Outcome
1970 (18)	Abdominal pain	GP to surgical outpatients	Appendicectomy	Normal appendix
1973 (21)	Pregnant (boyfriend in prison)	GP to obstetrics and gynaecology outpatients	Termination of pregnancy	—
1975-7 (23-25)	Bloating, abdominal pain, blackouts (stressful divorce)	GP to gastroenterology and neurology outpatients	All tests normal	Diagnosis of irritable bowel syndrome and unexplained syncope. Treated with fibre
1979 (27)	Pelvic pain (wants to be sterilised)	GP to obstetrics and gynaecology outpatients	Sterilised, ovaries preserved	Pelvic pain persists for 2 years after surgery
1981 (29)	Fatigue (problems at work)	GP to infectious disease clinic	Nothing abnormal detected	Diagnosis of myalgic encephalomyelitis made by patient. Joins self help group
1983 (31)	Aching, painful muscles	GP to rheumatology clinic	Mild cervical spondylosis. No treatment	Treated with amitriptyline 50 mg on referral to pain clinic. Some improvement
1985 (34)	Chest pain and breathlessness (son truanting from school)	Accident and emergency to chest clinic	Nothing abnormal detected, probable hyperventilation	Refer to psychiatric services

Specialist assessment

Before interviewing a patient, it is useful to request both the general practice and hospital notes and summarise the medical history. A typed summary of the “illness history” can be kept as a permanent record in the notes. This summary can guide future management and is especially useful when a patient is admitted subsequently as an emergency or when the receiving doctor has no prior knowledge of the patient.

Several important interviewing skills should be used during the assessment. These skills can be learnt using structured role playing and video feedback. They form the basis of a technique called reattribution, which has been developed to help the management of patients with functional somatic symptoms.

Specialist management

If a patient can understand and agree an initial shared formulation of the problems, an important first stage is reached. From this a plan of management can be negotiated. It is best to adopt a collaborative approach rather than a didactic or paternalistic manner. If it is difficult to arrive at an understanding of why the patient developed these symptoms at this particular time, then an alternative approach may have to be adopted. In essence this involves the doctor attempting to address those factors that are maintaining the symptoms.

Assessment and management go hand in hand. One of the main aims of management is to modify patients’ often unrealistic expectations of the medical profession and to remind them of the limits to medicine. In many cases hopes may have been falsely raised, and patients expect either a cure or at least a considerable improvement in symptoms. Although this is desirable, it may not be attainable. Instead, the doctor should attempt to broaden the agenda, with an emphasis on helping patients to address personal concerns and life problems as well as somatic complaints. It is also necessary to encourage them to concentrate on coping rather than seeking a cure.

This process requires patience, and a capacity to tolerate frustration and setbacks. It may require several discussions in which the same issues are reviewed. In the long term, however, it can be rewarding for both patient and doctor.

Common problems in management

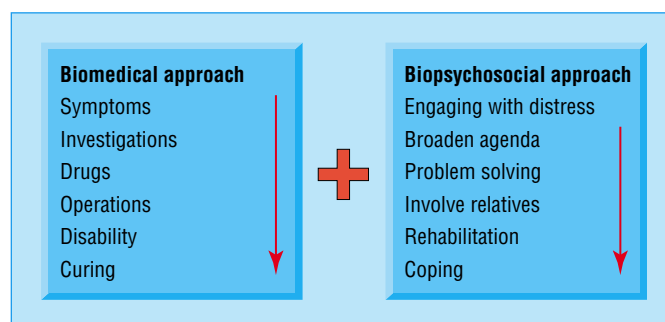

Management may be complicated by various factors. Firstly, preoccupation and anxious concern about symptoms may lead patients to make unhelpful demands of their doctor, which prove difficult to resist.

What is the cause of functional somatic symptoms?

- A variety of biological, psychological, and social factors have been shown to be associated with functional symptoms; the contribution of these factors will vary between patients
- Recent developments in neuroscience show altered functioning of the nervous system associated with functional symptoms, making the labelling of these as “entirely psychological” increasing inappropriate
- With our current knowledge, it is best to maintain “aetiological neutrality” about the cause of functional symptoms
- The main task of treatment is to identify those factors that may be maintaining a patient’s symptoms and disability

Maintaining factors that should be focus of treatment in patients with multiple somatic symptoms

- Depression, anxiety, or panic disorder
- Chronic marital or family discord
- Physical inactivity
- Occupational stress
- Abnormal illness beliefs
- Iatrogenic factors
- Pending medicolegal and insurance claims

The aim of treatment for patients with chronic multiple functional symptoms is to add a biopsychosocial perspective to the existing biomedical approach

Secondly, there may be evidence of longstanding interpersonal difficulties, as indicated by remarks such as “Nobody cares” or “It’s disgusting what doctors can do to you.” Such comments may suggest that the patient’s relationship with the doctor may reflect poor quality parental care or emotional deprivation in childhood. They are important for two reasons: firstly, the doctor may take these remarks personally, become demoralised or angry, and retaliate, which will destroy the doctor-patient relationship; and, secondly, the attitudes revealed may require more detailed psychological exploration.

Finally, iatrogenic factors may intervene that are beyond the treating doctor’s control. Because these patients have often visited several specialists, conventional and alternative, they may have been given inappropriate information and advice, inappropriate treatment, or, in some cases, frank misdiagnosis.

Factitious disorders and malingering

Factitious disorders

Factitious disorders are characterised by feigned physical or psychological symptoms and signs presented with the aim of receiving medical care. They are therefore different from functional symptoms. The judgment that a symptom is produced intentionally requires direct evidence and exclusion of other causes. Most patients with factitious disorders are women with stable social networks, and more than half of these work in medically related occupations. Once factitious disorder is diagnosed, it is important to confront the patient but remain supportive. When factitious disorder is established in a person working in health care it is advisable to organise a multidisciplinary meeting involving the patient’s general practitioner, a physician and surgeon, a psychiatrist, and a medicolegal representative.

If, and only if, the deliberate feigning of symptoms and signs can be established (such as by observation of self mutilation) should patients be confronted. It is helpful if both a psychiatrist and the referring doctor (who should have met to discuss the aims, content, and possible outcomes of the meeting beforehand) can carry out the confrontation jointly. This “supportive confrontation” is done by gently but firmly telling the patient that you are aware of the role of their behaviour in the illness whilst at the same time offering psychological care to help with this. After confrontation, patients usually stop the behaviour or leave the clinic. Only sometimes do they engage in the psychiatric care offered.

Malingering

A distinction should be made between factitious disorders and malingering. Malingerers deliberately feign symptoms to achieve a goal (such as to avoid imprisonment or gain money). Malingering is behaviour and not a diagnosis. The extent to which a doctor feels it necessary to confront this issue will depend on the individual circumstances.

Conclusion

Patients with multiple longstanding functional symptoms are relatively uncommon, but their interaction with the health system is memorable in that it often leaves both them and their doctors frustrated. Their effective management requires that special attention be paid to their interpersonal difficulties (including those arising in their relationship with the doctor), the limiting of unhelpful demands, and the avoidance of iatrogenic harm. As with any chronic illness, confident management and getting to know a patient as a person can change what is often a frustrating task into a rewarding one.

Failing to recognise and institute appropriate management for patients with multiple functional somatic symptoms may lead to iatrogenic harm from excessive and inappropriate medical and surgical intervention

Münchhausen’s syndrome

- Münchhausen’s syndrome is an uncommon subtype of factitious illness in which the patient, who is often a man with sociopathic traits and an itinerant lifestyle, has a long career of attending multiple hospitals with factitious symptoms and signs
- Management is as for factitious disorder, but engagement with psychiatric treatment is rare

Evidence based summary

- Prevalence of chronic multiple functional somatic symptoms depends on how many functional symptoms are required—the fewer symptoms the higher the prevalence
- Patients with chronic multiple functional somatic symptoms (somatisation disorder) can be effectively managed in primary care, with resulting cost savings

8 Cancer

Craig A White, Una Macleod

Cancer is the most feared of diseases. Unsurprisingly, it causes considerable psychological distress in patients, families, carers, and often those health professionals who care for them. Only a minority of cancer patients develop psychiatric illness, but other psychologically and socially determined problems are common. These include unpleasant symptoms such as pain, nausea, and fatigue; problems with finances, employment, housing, and childcare; family worries; and existential and spiritual doubts. Well planned care that fully involves patients and their families can minimise these problems.

Psychological consequences

Though often dismissed as “understandable,” distress is a treatable cause of reduced quality of life and poorer clinical outcome. Some patients delay seeking help because they fear or deny their symptoms of distress. Presentation can be obvious, as depressed or anxious mood can manifest as increased severity of somatic complaints such as breathlessness, pain, or fatigue. Adjustment disorder is the commonest psychiatric diagnosis, and neuropsychiatric complications may occur. The risk of suicide is increased in the early stages of coping with cancer.

Depression

Depression is a response to perceived loss. A diagnosis of cancer and awareness of associated losses may precipitate feelings similar to bereavement. The loss may be of parts of the body (such as a breast or hair), the role in family or society, or impending loss of life. Severe and persistent depressive disorder is up to four times more common in cancer patients than in the general population, occurring in 10-20% during the disease.

Anxiety, fear, and panic

Anxiety is the response to a perceived threat. It manifests as apprehension, uncontrollable worry, restlessness, panic attacks, and avoidance of people and of reminders of cancer, together with signs of autonomic arousal. Patients may overestimate the risks associated with treatment and the likelihood of a poor outcome. Anxiety may also exacerbate or heighten perceptions of physical symptoms (such as breathlessness in lung cancer), and post-traumatic stress symptoms (with intrusive thoughts and avoidance of reminders of cancer) occasionally follow diagnosis or treatment that has been particularly frightening.

Certain cancers and treatments are associated with specific fears. Thus, patients with head and neck cancers may worry about being able to breathe and swallow. Patients may develop phobias and conditioned vomiting in relation to unpleasant treatments such as chemotherapy.

Neuropsychiatric syndromes

Delirium and dementia may arise from brain metastases, which usually originate from lung cancer but also from tumours of the breast and alimentary tract and melanomas. Brain metastases occasionally produce psychological symptoms before metastatic disease is discovered. Certain cancers (notably cancers of the lung, ovary, breast, or stomach and Hodgkin's lymphoma) sometimes produce neuropsychiatric problems in the absence of metastases (paraneoplastic syndromes). The aetiology is thought to be an autoimmune response to the tumour.

Squamous cell carcinoma on lip after radiotherapy. As well as the fear of cancer itself, an additional source of distress can be the potentially disfiguring nature of the disease and its treatment

“Distress is an unpleasant emotional experience of a psychological, social, or spiritual nature that may interfere with a patient’s ability to cope with cancer and its treatment. Distress extends along a continuum, ranging from common normal feelings of vulnerability, sadness, and fear to problems that can become disabling, such as depression, anxiety, panic, social isolation, and spiritual crisis”

US National Comprehensive Cancer Network

Challenges faced by people with cancer

- Maintaining activity and independence
 - Coping with treatment side effects
 - Accepting cancer and maintaining a positive outlook
 - Seeking and understanding medical information
 - Regulating the feelings associated with cancer experiences
 - Seeking support
 - Managing stress
-

Who becomes distressed?

The severity of emotional distress is more closely related to a patient's pre-existing vulnerability than to the characteristics of the cancer. Distress is also more likely to occur at specific points in a patient's experience of cancer:

Diagnosis—Investigation and diagnosis are particularly stressful and can cause shock, anger, and disbelief as well as emotional distress. These resolve without intervention in most patients, but especially high levels of distress at this time are predictive of later emotional problems. It can help if doctors explain that patients' feelings are expected and normal ("I would expect you to have times when you feel tearful and cannot get it out of your head").

During treatment—Treatment itself can be a potent cause of distress. It may involve hospital attendance but also unpleasant surgery, radiotherapy, or chemotherapy. Side effects include hair loss and disfigurement. Patients worry about whether treatment is working and are likely to become distressed at times of apparent treatment failure.

End of treatment—At the end of apparently successful treatment some patients can experience "rebound" distress associated with the fear that the cancer might recur or spread. The ending of a prolonged relationship with the cancer service staff can lead to a sense of loss and vulnerability. It is only at this time that some patients become fully aware of the impact of their cancer experience.

After treatment—Like those with other life threatening illnesses, patients who survive cancer may reorder their life priorities and experience psychological benefits including a greater appreciation of some aspects of their life. Others need help to overcome continuing worries, including preoccupation with loss and illness, a tendency to avoid reminders of cancer, and difficulties coping with intimacy, return to work, and fears of recurrence. Fear of recurrence can manifest as a form of health anxiety with misinterpretation of physiological sensations (such as believing that pain associated with a muscle strain represents a recurrence of cancer) and the anxious seeking of reassurance.

Recurrence—Patients who believe they have been cured (that is, those most likely to be surprised by recurrence) are at greater risk of severe distress if recurrence occurs. Most patients report recurrence of cancer as more distressing than receiving the initial diagnosis.

Terminal disease—About 40% of people who develop cancer will die as a result. The terminal phase commonly brings fear of uncontrolled pain, of the process of dying, of what happens after death, and of the fate of loved ones. Depression is common in the terminal phase, especially in those with poorly controlled physical symptoms.

Management

People with cancer benefit from care in which psychological and medical care are coordinated. Apart from the obvious

Risk factors for psychiatric disorder

Patient

- History of psychiatric disorder
- Social isolation
- Dissatisfaction with medical care
- Poor coping (such as not seeking information or talking to friends)

Cancer

- Limitation of activities
- Disfiguring
- Poor prognosis

Treatment

- Disfiguring
 - Isolating (such as bone marrow transplant)
 - Side effects
-

Issues to be considered in planning care

- Patient's and family's understanding of the illness and its treatment
 - Patient's and family's understanding of help available
 - Explanation of how symptomatic relief will be provided
 - How the patient can be fully involved in care
 - Who will be managing the treatment plan
 - Routine and emergency contact arrangements
 - Practical help in everyday activities
 - Support at home—role of hospital and residential care
 - Involving and supporting family and friends
-

Depression is common in the terminal phase of cancer, especially in patients with poorly controlled physical symptoms (*Resignation* by Carl Wilhelm Wilhelmson (1866-1928))

Psychological care for cancer patients

In primary care

- Need for agreed local protocols
- Multidisciplinary skills and resources
- Individually agreed collaborative care for each patient
- Regular liaison with specialist units and local agencies
- Local training for all involved

In specialist units

- Training in psychological aspects of care for all staff
 - Regular review of all individual treatment plans
 - Protocols for routine management of "at risk" patients (such as relapse after chemotherapy)
 - Involvement of specialist nurses and other staff with psychological expertise
 - Access to psychiatrists and clinical psychologists with special interest in managing cancer problems for consultation and supervision
 - Use of self help methods and voluntary agencies
-

benefits to quality of life, there is some evidence that encouraging an active approach to living with cancer can improve survival.

Most of the psychological care of cancer patients will be delivered in primary care. As for all chronic illness, a multidisciplinary approach and management protocols that include psychological as well as medical assessment and intervention are required. These protocols need not be specific for cancer as the issues are common to many medical conditions. The important point is that the staff involved have the skills to address psychological as well as medical problems. The danger is that psychological care can be neglected by the medical focus on cancer treatment. A case manager, whether nurse or doctor, who can coordinate the often diverse agencies involved in a cancer patient's care can ensure that treatment is delivered efficiently.

Assessment

Depressive and anxiety disorders are often unrecognised. There is therefore a need for active screening by simply asking patients about symptoms of anxiety and depression. A self-rated questionnaire such as the hospital anxiety and depression scale (HADS) may be helpful. Doctors should be aware that patients may be distressed because of factors unrelated to cancer.

Treatment

Information—Doctors often underestimate the amount and frankness of information that most patients need and want. It is best given in a staged fashion with checks on patients' understanding and desire to hear more at each stage.

Repetition and written information may be helpful. Summaries of agreed management plans have been found to improve patients' satisfaction and their adherence to medical treatment.

Social support—Most patients will receive this from family and friends. They may, however, not want to "burden others" and consequently may need encouragement to use this support by talking about their illness. Additional support can be provided by specific cancer-related services such as the primary care team and specialist nurses.

Addressing worries—Staff often find it most difficult to help patients who talk about worries that reflect the reality of cancer (such as, "I am going to die"). It is important to do so because this may help planning and may reveal misconceptions, such as the inevitability of uncontrolled pain, that can then be addressed by giving accurate information about methods of pain control.

Managing anxiety—Accurate information (such as which physical symptoms are due to anxiety and which are due to cancer) and practical help are important. Anxious patients can be helped by relaxation strategies, including breathing exercises. Severe persistent anxiety may merit the short-term prescription of anxiolytic drugs such as diazepam.

Managing depression—Depressive disorders should be managed in the same ways as they are in patients without cancer. Discussion, empathy, reassurance, and practical help are essential. Antidepressants have been shown to be effective in patients with cancer in randomised trials, although surprisingly few trials have been conducted. If in doubt about what drug to choose or about possible interactions with cancer treatment, it is important to check with a pharmacist. Specialist psychological intervention, such as formal cognitive-behavioural therapy, may also be required to treat persistent depression or anxiety.

Specialist referral

Structured psychological interventions (such as psycho-education and cognitive-behavioural based therapies)

Questions for assessing patients' anxiety and depression

- How are you feeling in yourself? Have you felt low or worried?
 - Have you ever been troubled by feeling anxious, nervous, or depressed?
 - What are your main concerns or worries at the moment?
 - What have you been doing to cope with these? Has this been helpful?
 - What effects do you feel cancer and its treatment will have on your life?
 - Is there anything that would help you cope with this?
 - Who do you feel you have helping you at the moment?
 - Is there anyone else outside of the family?
 - Have you any questions? Is there anything else you would like to know?
-

Principles of treatment

- Sympathetic interest and concern
 - A clearly identified principal therapist who can coordinate all care
 - Effective symptomatic relief
 - Elicit and understand patient's beliefs and needs
 - Collaborative planning of continuing care
 - Information and advice—oral and written
 - Involve patient in treatment decisions
 - Involve family and friends
 - Early recognition and treatment of psychological complications
 - Clear arrangements to deal with urgent problems
-

Useful sources of information

- National Comprehensive Cancer Network. Distress management guidelines (www.nccn.org/physician_gls/index.html)

 - Macmillan Cancer Relief (www.macmillan.org.uk/)
 - Cancer Research UK (www.cancer.org.uk)
 - International Psycho-Oncology Society (www.ipos-aspboa.org/iposnews.htm)
-

Specialist treatments

- Antidepressant drugs
 - Effective drug treatment of pain, nausea, and other symptoms
 - Problem solving discussion
 - Cognitive-behavioural treatment of psychological complications
 - Joint and family interviews to encourage discussion and planning
 - Group support and treatment
 - Cognitive-behavioural methods to help cope with chemotherapy and other unpleasant treatments
-

Referral decisions

- What specialist expertise in psycho-oncology is available at my local cancer centre or unit?
 - What has helped when this patient has had problems before?
 - Are there local cancer support groups that could help?
 - Does this patient have problems that might benefit from specialist psychological or psychiatric intervention?
 - Does this patient want to be referred to specialist services?
 - Does this patient prefer individual or group based psychological intervention?
-

have been shown to reduce anxiety and depression in cancer patients and to improve adherence to medical treatment.

Patients with severe or persistent distress may need referral to an experienced clinical psychologist or psychiatrist. An increasing number of mental health professionals are attached to cancer centres and units, and other staff such as appropriately trained specialist nurses play an increasingly important role.

Increasing numbers of non-NHS agencies also offer psychological care for patients with cancer. When referring patients to such services it is important to check their quality and to ensure that their contribution is coordinated within an overall care plan.

9 Trauma

Richard Mayou, Andrew Farmer

Minor physical trauma is a part of everyday life, and for most people these injuries are of only transient importance, but some have psychiatric and social complications. Most people experience major trauma at some time in their lives.

Psychological, behavioural, and social factors are all relevant to the subjective intensity of physical symptoms and their consequences for work, leisure, and family life. As a result, disability may become greater than might be expected from the severity of the physical injuries.

Psychological and interpersonal factors also contribute to the cause of trauma, and clinicians should be alert to these and their implications for treatment. Tactful questioning, careful examination, and detailed record keeping are essential, especially for non-accidental injury by a patient or others:

- Ask for a detailed description of the cause of the incident
- Ask about previous trauma
- Ask about substance misuse—alcohol and drugs
- Look for patterns of injuries that may be non-accidental, deliberate self harm, or inflicted by others
- Check records
- If suspicious speak to other informants
- Discuss findings and suspicions with a colleague.

Dealing with the acute event

At a major incident it is important that members of the emergency services, especially ambulance staff and police, should seem calm and in control. This helps to relieve distress and prevent victims from suffering further injury. Explanation and encouragement can reduce fear at the prospect of being taken to hospital by ambulance. The needs of uninjured relatives and others involved should also be considered. Clearly recorded details of the incident, injury, and the extent of any loss of consciousness may be useful in later assessment as well as in the preparation of subsequent medicolegal reports.

Many people attend hospital emergency departments for minor cuts, bruises, or pain, or for “a check up” after being involved in an incident, whereas others attend their general practitioner. Immediate distress is common. Clear explanation, advice, and discussion at the outset can prevent later problems in returning to normal activities and enable early recognition of psychological and social consequences. A sympathetic approach is needed that includes suitable analgesia, reassurance about the likely resolution of symptoms, and encouragement to return to normal activity. Some patients may already be considering compensation, and records should be kept with this in mind.

Advice about return to work and other activities

Patients with painful injuries that should improve within days or weeks are often uncertain how to behave and how soon to return to work. The assessment is an opportunity to give advice about this. Patients need information on the cause of their symptoms, their likely impact on daily life, and a positive plan for return to normal activity; this includes discussing the type of work normally done, the employer's attitude to time away from work, and opportunities for a graded increase in activity. Good, rapid communication between hospital and primary care is essential.

Detail of *Very Slippery Weather* by James Gillray (1757-1815)

Lifetime prevalence of specific traumatic events (n=2181)

Type of trauma	Prevalence
Assault	38%
Serious car or motor vehicle crash	28%
Other serious accident or injury	14%
Fire, flood, earthquake, or other natural disaster	17%
Other shocking experience	43%
Diagnosed with a life threatening illness	5%
Learning about traumas to others	62%
Sudden, unexpected death of close friend or relative	60%
Any trauma	90%

Immediate effects of frightening trauma

- Causes a varied picture of anxiety, numbness, dissociation (feeling distanced from events, having fragmentary memories), and sometimes apparently inappropriate calmness
- Those who believe they are the innocent victims of others' misbehaviour are often angry, and this may be exacerbated by subsequent frustrations
- The term “acute stress disorder” is now used for a combination of distress, intrusive memories (flashbacks, nightmares), avoidance, and numbing in the months after the trauma. It occurs in 20-50% of those who have suffered major trauma
- The severity of emotional symptoms is much more closely related to how frightening the trauma was than to the severity of the injury; even uninjured victims may suffer considerable distress
- Severe distress is usually temporary but indicates a risk of long term post-traumatic symptoms

Immediate management

- Physical treatment, including adequate analgesia
- Sympathetic discussion of acute distress
- Explanation and appropriate reassurance about treatment and prognosis
- Appropriate encouragement for graded return to work and other activities
- Indicate what help will be available for continuing psychological symptoms and social problems
- Information and support to relatives

Immediate psychological interventions

Many employers and medical and voluntary groups recommend routine “debriefing” after frightening trauma. However, the evidence shows this is not only ineffective but may be harmful.

It is better, therefore, to concentrate on the immediate relief of distress through support and sympathetic reassurance and on practical help, while encouraging further early consultation if problems persist. This is especially so in groups who may be regularly exposed to frightening and distressing circumstances, such as members of the armed forces, police, and ambulance staff. Severe immediate distress and perception of the trauma as having been very frightening indicate an increased risk of chronic post-traumatic symptoms, and early review is recommended to identify those who need extra help. Victims of crime can be helped by referral to the charity Victim Support.

Later consequences and care

Treatment should include clear, agreed plans for mobilisation and return to optimal activity. Physiotherapists are often involved in rehabilitation and need to be aware of the psychological as well as the physical factors that are perpetuating disability. If necessary, a multidisciplinary approach should be established.

Chronic pain and disability

A small number of those who have suffered trauma continue to complain of physical symptoms and disabilities that are difficult to explain. Investigations are negative or ambiguous, and the relationship between doctors and patients may become fraught. Doctors may feel their patient is disabled for psychological reasons, whereas patients may feel that doctors do not believe that their symptoms are real and that they are unsympathetic and are not offering appropriate treatment.

Arguments about whether symptoms are physical or psychological are rarely helpful. Instead, it is essential to agree a coordinated behavioural and rehabilitative approach with patient and family that aims to achieve the maximum improvement. Unfortunately, there is a shortage of appropriate multidisciplinary specialist services for such people. This leaves primary care teams in the key role in monitoring progress and implementing a biopsychosocial approach to rehabilitation.

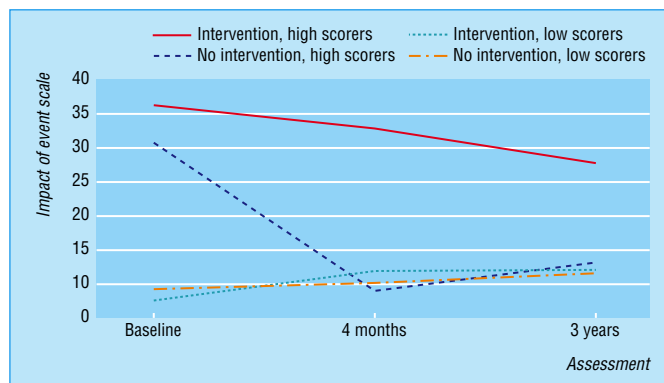

Psychological symptoms and syndromes

Depression, post-traumatic stress disorder, and phobic anxiety are common after frightening trauma and can be severe, whether or not there is evidence of previous psychological and social vulnerability. These psychological complications are not closely related to the severity of any physical injury. The general principles of assessment are those for similar psychological problems occurring in the absence of trauma.

Depression—A failure to recognise depression is distressingly common, perhaps because care focuses on physical injuries. Inquiries about depressive symptoms should therefore be routine.

Post-traumatic stress disorder is also common and disabling. It is characterised by intrusive memories of the trauma, avoidance of reminders of it, and chronic arousal and distress. It may be complicated by alcohol misuse. It usually has an early onset in the first few weeks (acute stress disorder). Many people improve rapidly but, if symptoms are still present two or three months after the injury, they are likely to persist for much longer. A few cases have a delayed onset. Psychological treatment is effective.

Phobic anxiety may be associated with post-traumatic stress disorder but can occur separately. A particularly common form

Effect of immediate debriefing on victims of road traffic injury. Those with high initial scores on the impact of events scale (intrusive thoughts and avoidance) had worse outcome than untreated controls at 4 months and 3 years

Reasons for people being offered help by Victim Support 1997-8

Unexplained and disproportionate disability and pain

- Lack of explanation or overcautious advice often leads to misunderstandings and secondary disability
- Delays in assessment and treatment exacerbate problems and make treatment more difficult
- Lack of coordination (between general practice, physiotherapy, hospital, etc) frequently exacerbates problems
- Low mood, misunderstandings, and inactivity worsen pain and disability
- Agree on consistent, collaborative plans with patient and family
- Early access to specialist rehabilitation and pain clinics providing high quality cognitive and behavioural psychological treatments

Psychologically determined consequences of trauma

- Acute anxiety, numbing, arousal (acute stress disorder)
- Anxiety disorder
- Major depressive disorder
- Post-traumatic symptoms and disorder
- Avoidance and phobic anxiety
- Pain and apparently disproportionate disability
- Unexplained physical symptoms
- Impact on family (such as family arguments, depression in family members)

Cognitive behavioural approach to treating post-traumatic stress disorder

- *Talking it through*—Encourage victim to discuss and relive feelings about the incident
- *Tackling avoidance*—Discuss graded increase in activities, such as return to travel after a road crash
- *Coping with anxiety*—Anxiety management techniques (relaxation, distraction)
- *Dealing with anger*—Encourage discussion of incident and of feelings
- *Overcoming sleep problems*—Emphasise importance of regular sleep habits and avoidance of excessive alcohol and caffeine
- *Treat associated depression*—Antidepressant drugs, limited role for hypnotics immediately after trauma

is anxiety about travel, both as a driver and as a passenger, after a road traffic crash. This anxiety may lead to distress and limitation of activities and lifestyle. Early advice about the use of anxiety management techniques and the need for a graded return to normal travel is helpful, but more specialist behavioural treatment may be required and is usually effective.

Detection of psychological problems

During a clinical assessment, a few brief screening questions can be useful as a guide to identify depression, anxiety, post-traumatic stress disorder and drinking problems. It is often helpful to speak to someone close to the victim who can offer an independent view.

Personal injury and compensation

Victims who believe that others are to blame for their trauma increasingly consult specialist lawyers, who are alert to psychiatric complications such as post-traumatic stress disorder and phobic avoidance. Acrimonious discussion about a small number of controversial cases of alleged exaggeration and simulation has obscured a more productive discussion of psychiatric disorder.

Head injury

Most head injuries are mild. These were once believed to be without consequences, but recent evidence has suggested that almost half of patients experiencing mild head injuries (Glasgow coma scale 13-15) remain appreciably disabled a year later. The effects of more severe head injuries on personality and cognitive performance may be greater than is apparent in a clinical interview and commonly affect “executive” functions such as social judgment and decision making.

Such deficits are often not detected by standard bedside screening tools such as the mini-mental state examination. Patients with head injury should therefore not be pushed to return to demanding activities too quickly, and there should be a low threshold for seeking a specialist opinion or undertaking psychometric assessment.

Consequences for others

Family members may also suffer distress, especially if they have been involved in the traumatic incident. Seeing the relatives of the traumatised person is usually helpful in the management of persistent problems.

Those involved in treating trauma will encounter particularly distressing incidents with severely injured victims and distraught relatives. These often occur when those involved in treatment are working under considerable pressure. Clear procedures for training and support of staff are essential. For those working in large emergency services the provision of regular specialist support is advisable.

Types of trauma

The pattern of consequences varies with the type of trauma experienced. All services that see trauma emergencies need management plans for psychological as well as medical care. This includes planning for major events in which there are many victims and for the much commoner road traffic and other incidents in which there are often several victims, some of whom may be severely injured and who may well be related or know one another. Emergency departments and primary care need procedures for helping the patients and for supporting the staff that are involved.

Treating avoidance and phobic anxiety

- *Diary keeping*—Encourage detailed diary of activity and associated problems as a basis for planning and monitoring progress
 - *Anxiety (stress) management*—Relaxation, distraction, and cognitive procedure for use in stressful situations
 - *Graded practice*—Discuss a hierarchy of increasing activities; emphasise importance of not being overambitious and need to be consistent in following step by step plan
-

Compensation

- Simulation of disability and exaggeration are uncommon in routine clinical contacts
 - Many victims want recognition of their suffering as much as financial compensation
 - Innocent victims of trauma are generally slower to return to work than those victims who accept that they were to blame
 - Financial and social consequences of trauma and blighting of ambitions may be considerable and are often unrecognised
 - Compensation procedures and reports may hinder development and agreement about treatment and active rehabilitation
 - Compensation may allow interim payments and funding of specialist care to treat complications and prevent chronic disability
-

Head injury

- Assessment should involve questions about possible unconsciousness and post-traumatic amnesia
 - Cognitive consequences of minor head injury are often not recognised
 - Minor impairments may be obscured in clinical situations but be disabling in work and everyday activities
 - Recovery may be prolonged
 - Complaints of confusion and poor memory can be due to depression
 - Specialist assessment may be needed
-

Relatives' needs

Immediately after severe or frightening trauma

- Make comfortable
- Inform relatives of trauma in a sympathetic manner
- Practical assistance
- Clear information

Later

- Information about injuries, treatment, and prognosis
 - Discuss effects on everyday life
 - Discuss needs for practical help and availability
 - Ask about possible psychiatric problems and indicate help available
-

Types of trauma

- *Occupational*—Return to work often slower than in other types of injury. Liaison with employer essential. Compensation issues may impede return to work
 - *Sporting*—May be associated with physical unfitness or with inappropriate activity for age
 - *Domestic*—Assess role of alcohol, consider possible family and other problems, assess risk of further incidents
 - *Assault (including sexual)*—Assess role of alcohol, keep detailed records, suggest availability of help for major, and especially for sexual, assault
 - *Road traffic crash*—Psychological complications may occur even if no significant physical injury. Whiplash injuries should be treated by well planned mobilisation and encouragement, together with alertness to possible psychological complications
-

Disasters

All medical services and other institutions should have a disaster plan that is readily available and regularly reviewed. It should include a specification for immediate psychological care and information, together with proactive follow up so that psychological problems are identified early. Those involved in coping with disasters also require support and encouragement, and a minority may require specialist psychological help. The disaster plan should also set out procedures for giving information to relatives and offering them practical help.

Conclusion

The psychological aspects of trauma may be important, even when injury seems trivial. Clear, sympathetic care, which takes account of patients' needs, can do much to promote optimal recovery. Specialist advice should be sought for persistent problems within the first few months of an injury. Long delays in providing adequate assessment and treatment lead to unnecessary suffering and disability and may make such problems much more difficult to treat.

10 Fatigue

Michael Sharpe, David Wilks

Fatigue can refer to a subjective symptom of malaise and aversion to activity or to objectively impaired performance. It has both physical and mental aspects. The symptom of fatigue is a poorly defined feeling, and careful inquiry is needed to clarify complaints of “fatigue,” “tiredness,” or “exhaustion” and to distinguish lack of energy from loss of motivation or sleepiness, which may be pointers to specific diagnoses (see below).

Prevalence—Like blood pressure, subjective fatigue is normally distributed in the population. The prevalence of continuously significant fatigue depends on the threshold chosen for severity (usually defined in terms of associated disability) and persistence. Surveys report that 5-20% of the general population suffer from such persistent and troublesome fatigue. Fatigue is twice as common in women as in men but is not strongly associated with age or occupation. It is one of the commonest presenting symptoms in primary care, being the main complaint of 5-10% of patients and an important subsidiary symptom in a further 5-10%.

Fatigue as a symptom—Patients generally regard fatigue as important (because it is disabling), whereas doctors do not (because it is diagnostically non-specific). This discrepancy is a potent source of potential difficulty in the doctor-patient relationship. Fatigue may present in association with established medical and psychiatric conditions or be idiopathic. Irrespective of cause, it has a major impact on day to day functioning and quality of life. Without treatment, the prognosis of patients with idiopathic fatigue is surprisingly poor; half those seen in general practice with fatigue are still fatigued six months later.

Causes of fatigue

The physiological and psychological mechanisms underlying subjective fatigue are poorly understood. Fatigue may rather be usefully regarded as a final common pathway for a variety of causal factors. These can be split into predisposing, precipitating, and perpetuating factors.

Predisposing factors include being female and a history of either fatigue or depression.

Precipitating factors include acute physical stresses such as infection with Epstein-Barr virus, psychological stresses such as bereavement, and social stresses such as work problems.

Perpetuating factors include physical inactivity, emotional disorders, ongoing psychological or social stresses, and abnormalities of sleep. These factors should be sought as part of the clinical assessment.

Other physiological factors such as immunological abnormalities and slightly low cortisol concentration are of research interest but not clinical value.

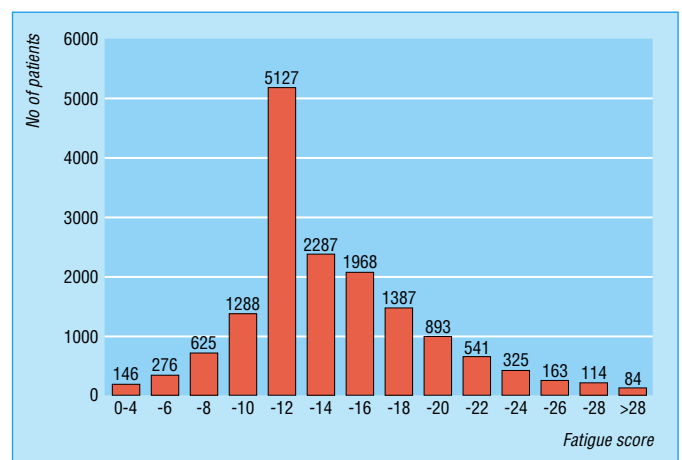

Diagnoses associated with fatigue

Among patients who present with severe chronic fatigue as their main complaint, only a small proportion will be suffering from a recognised medical disease. In no more than 10% of patients presenting with fatigue in primary care is a disease cause found. The rate is even lower in patients seen in secondary care.

Fatigue is a major symptom of many psychiatric disorders, but for a substantial proportion of patients with fatigue the

Weary 1887 by Edward Radford (1831-1920)

Distribution of the complaint of fatigue in the population

Medical conditions that may present with apparently unexplained fatigue

- **General**—Anaemia, chronic infection, autoimmune disease, cancer
- **Endocrine disease**—Diabetes, hypothyroidism, hypoadrenalism
- **Sleep disorders**—Obstructive sleep apnoea and other sleep disorders
- **Neuromuscular**—Myositis, multiple sclerosis
- **Gastrointestinal**—Liver disease
- **Cardiovascular**—Chronic heart disease
- **Respiratory**—Chronic lung disease

symptom remains unexplained or idiopathic. In general, the more severe the fatigue and the larger the number of associated somatic (and unexplained) complaints, then the greater the disability and the greater the likelihood of a diagnosis of depression.

Chronic fatigue syndromes

Chronic fatigue syndrome is a useful descriptive term for prominent physical and mental fatigue with muscular pain and other symptoms. It overlaps with another descriptive term, fibromyalgia, that has often been used when muscle pain is predominant but in which fatigue is almost universal. There is also substantial overlap of the diagnoses with other symptom based syndromes, the so called functional somatic syndromes.

The term myalgic encephalomyelitis (or encephalopathy) has been used in Britain and elsewhere to describe a poorly understood illness in which a prominent symptom is chronic fatigue exacerbated by activity. This is a controversial diagnosis that some regard as simply another name for chronic fatigue syndrome and that others regard as a distinct condition. This article will focus on chronic fatigue syndrome.

Prevalence and outcome—Chronic fatigue syndrome can be diagnosed in up to 2% of primary care patients. Untreated, the prognosis is poor, with only about 10% of patients recovering in a two to four years. A preoccupation with medical causes seems to be a negative prognostic factor.

Assessment and formulation

History—The nature of the fatigue is an important clue to diagnosis, and it is therefore important to clarify patients' complaints. Fatigue described as loss of interest and enjoyment (anhedonia) points to depression. Prominent sleepiness suggests a sleep disorder. The history should also cover

- Systematic inquiry for diseases and medications often associated with fatigue
- Symptoms of depression anxiety and sleep disorder
- Patients' own understanding of their illness and how they cope with it
- Current social stresses.

Examination—Both a physical and mental state examination must be performed in every case, to seek medical and psychiatric diagnoses associated with fatigue.

Routine investigations—If there are no specific indications for special investigations, a standard set of screening tests is adequate.

Special investigations—Immunological and virological tests are generally unhelpful as routine investigations. Sleep studies can be useful in excluding other diagnoses, especially obstructive sleep apnoea and narcolepsy.

Psychological assessment—It is important to inquire fully about patients' understanding of their illness (questions may include "What do you think is wrong with you?" and "What do you think the cause is?"). Patients may be worried that the fatigue is a symptom of a severe, as yet undiagnosed, disease or that activity will cause a long term worsening of their condition.

Formulation—A formulation that distinguishes predisposing, precipitating, and multiple perpetuating factors is valuable in providing an explanation to patients and for targeting intervention.

General management

Persistent fatigue requires active management, preferably before it has become chronic. When a specific disease cause of fatigue

Psychiatric diagnoses commonly associated with fatigue

- Depression
 - Anxiety and panic
 - Eating disorders
 - Substance misuse disorders
 - Somatisation disorder
-

Diagnostic criteria for chronic fatigue syndrome

Inclusion criteria

- Clinically evaluated, medically unexplained fatigue of at least 6 months' duration that is
 - Of new onset (not life long)
 - Not result of ongoing exertion
 - Not substantially alleviated by rest
 - Associated with a substantial reduction in previous level of activities
- Occurrence of 4 or more of the following symptoms
 - Subjective memory impairment, sore throat, tender lymph nodes, muscle pain, joint pain, headache, unrefreshing sleep, post-exertional malaise lasting more than 24 hours

Exclusion criteria

- Active, unresolved, or suspected medical disease or psychotic, melancholic, or bipolar depression (but not uncomplicated major depression), psychotic disorders, dementia, anorexia or bulimia nervosa, alcohol or other substance misuse, severe obesity
-

Screening tests for fatigue

- Full blood count
 - Erythrocyte sedimentation rate or C reactive protein
 - Liver function tests
 - Urea, electrolytes, and calcium
 - Thyroid stimulating hormone and thyroid function tests
 - Creatine kinase
 - Urine and blood tests for glucose
 - Urine test for protein
-

Factors to consider in a formulation of chronic fatigue

	Predisposing cause	Precipitating cause	Perpetuating cause
<i>Biological</i>	Biological vulnerability	Acute disease	Pathophysiology Excessive inactivity Sleep disorder Side effects of drug treatment Untreated disease
<i>Psychological</i>	Vulnerable personality	Stress	Depression Unhelpful beliefs about cause Fearful avoidance of activity
<i>Social</i>	Lack of support	Life events Social or work stress	Reinforcement of unhelpful beliefs Social or work stress

can be identified this should be treated. If no disease diagnosis can be made, or if medical treatment of disease fails to relieve the fatigue, a broader biopsychosocial management strategy is required. A discussion with the patient about fatigue and its treatment can be supplemented with written material (see below).

Patients should be told that they are suffering from a common and treatable condition that the doctor takes seriously and for which behavioural treatment can be helpful. While patients may be concerned about possible disease and the need for medical investigation and treatment, it can be explained that no disease has been found, and hence there is no disease based treatment, but that with help there is a great deal that the patients can do themselves.

Identifying unhelpful beliefs—Potentially unhelpful beliefs should be discussed. If a patient has a simple aetiological model (such as “It is all due to a virus”) an alternative approach based on a biopsychosocial formulation can be outlined. This has the advantage of highlighting potential perpetuating factors, as these may be regarded as obstacles to recovery. Doctor and patient can then work together to overcome these. It is rarely productive to argue over the best name for the illness; instead, the emphasis should be on agreeing a positive and open minded approach to rehabilitation.

Managing activity and avoidance—Gradual increases in activity can be advised unless there is a clear contraindication. It is critical, however, to distinguish between carefully graded increases carried out in collaboration with patients and “forced” exercise. It is also important to explain that erratic variation between overactivity on “good” days and subsequent collapse does not help long term recovery and that “stabilising” activity is a prerequisite to graded increases.

Depression and anxiety—If there is evidence of depression a trial of an antidepressant drug is worth while. Patients with fatigue are often sensitive to the side effects of antidepressants. However, if they are given adequate information about what to expect when treatment begins, with small doses, most patients can tolerate them. Randomised trials have shown psychological therapies such as cognitive behaviour therapy to be equally effective for mild to moderate depression.

Managing occupational and social stresses—Patients who remain in work may be overstressed by it. Those who have left work may be inactive and demoralised and may not wish to return to the same job. These situations require a problem solving approach to consider how to manage work demands, achieve a return to work, or to plan an alternative career.

Drug Treatments for Fatigue—A variety of pharmacological drugs including stimulants and steroids have been advocated for the treatment of fatigue. There is a limited evidence base for any of these pharmacological treatments, most of which may lead to substantial adverse effects. The role for these drugs is therefore limited and they should only be prescribed with great caution.

Referral for specialist management

Most patients with fatigue are managed in primary care, but certain groups may require referral to specialist care:

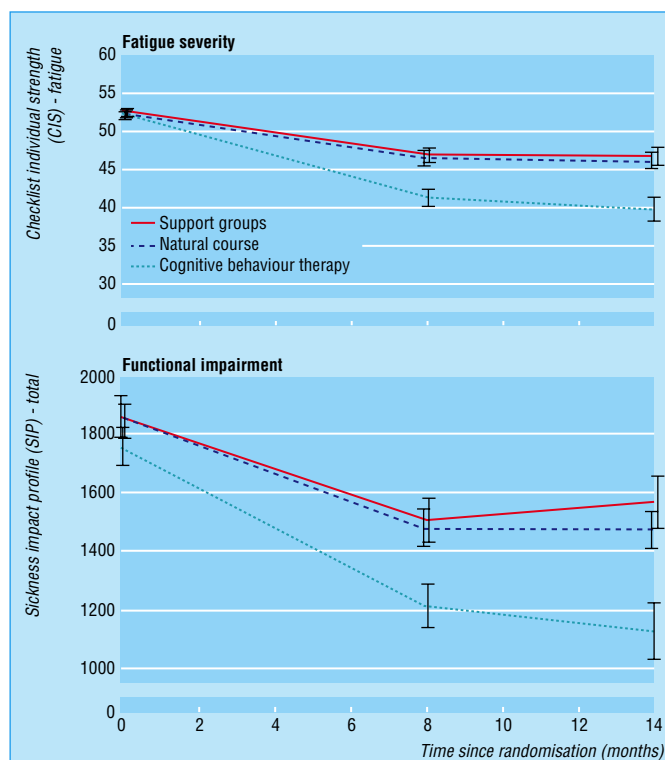

- Children with chronic fatigue
- Patients in whom the general practitioner suspects occult disease
- Patients with severe psychiatric illness
- Patients requiring specialist management of sleep disorders
- Patients unresponsive to management in primary care.

Management of chronic fatigue

- 1 Assessment
 - Empathise
 - History
 - Examination
 - Limited investigation
 - Biopsychosocial formulations
- 2 Treat treatable medical and psychiatric conditions
- 3 Help patient to overcome perpetuating factors
 - Educate
 - Reduce distress
 - Gradual increase in activity
 - Solve social and occupational problems
- 4 Follow up

Patients should be encouraged to gradually increase their activity (“Mrs Bradbury’s establishment for the recovery of ladies nervously affected”)

Efficacy of cognitive behaviour therapy for treating chronic fatigue syndrome

What is cognitive behaviour therapy?

- Brief pragmatic psychological therapy
- Targets beliefs and behaviours that might perpetuate symptoms
- An established treatment for depression and anxiety
- Has been adapted for somatic complaints of pain and fatigue
- Requires a skilled therapist

Referral may be to a physician or psychiatrist as is deemed most appropriate. Psychologists may be able to offer cognitive behaviour therapy. Where available, joint medical and psychiatric clinics are ideally suited to the assessment of chronic fatigue and related problems. It is essential there is close liaison between primary and specialist care to ensure a clear, consistent, and encouraging approach by all concerned.

Rehabilitation

Rehabilitation based on behavioural principles is currently the most effective specialist treatment approach.

Cognitive behaviour therapy is a collaborative psychological rehabilitation that incorporates graded increases in activity but also pays greater attention to patients' beliefs and concerns.

Graded exercise therapy is a structured progressive exercise programme administered and carefully monitored by a therapist.

Both may be used in conjunction with antidepressant drugs. Both have been found to be effective in randomised trials of hospital referred cases of chronic fatigue syndrome. Some general practitioners are able to provide graded exercise or cognitive behaviour therapy in their practice or clinic. Others may wish to refer to a trained therapist.

Conclusion

Fatigue is a ubiquitous symptom that is important to patients and has a major impact on their quality of life. It remains poorly understood and has hitherto probably been not been given adequate attention by doctors. Early and active management of fatigue in primary care may prevent progression to chronicity. Patients who have developed a chronic fatigue syndrome can benefit from specific treatments. Paying more attention to the symptom of fatigue may help to avoid the distress and poor outcome that is associated with patients feeling that their problems are neither accepted nor understood. It may also reduce the numbers who turn to a variety of unproved, and even harmful, alternative approaches.

What is graded exercise therapy?

- Explanation of fatigue as a physiological consequence of inactivity, poor sleep, and disturbed circadian rhythms
 - Discussion, agreement, and implementation of graded exercise plans
 - Monitoring of progress and setting of appropriate new targets
-

Evidence based summary

- Chronic fatigue syndrome is a descriptive term for a disabling syndrome that probably has multiple causes (physical and psychological)
- Graded exercise and cognitive behaviour therapies are effective in treating chronic fatigue syndrome

11 Musculoskeletal pain

Chris J Main, Amanda C de C Williams

Musculoskeletal symptoms of various types (neck pain, limb pain, low back pain, joint pain, chronic widespread pain) are a major reason for consultation in primary care. This article uses the example of low back pain because it is particularly common and there is a substantial evidence base for its management. The principles of management outlined are also applicable to non-specific musculoskeletal symptoms in general.

The increasing prevalence of musculoskeletal pain, including back pain, has been described as an epidemic. Pain complaints are usually self limiting, but if they become chronic the consequences are serious. These include the distress of patients and their families and consequences for employers in terms of sickness absence and for society as a whole in terms of welfare benefits and lost productivity. Many causes for musculoskeletal pain have been identified. Psychological and social factors have been shown to play a major role in exacerbating the biological substrate of pain by influencing pain perception and the development of chronic disability. This new understanding has led to a “biopsychosocial” model of back pain.

Research has also shown that there are many different reasons for patients to consult their doctor with pain—seeking cure or symptomatic relief, diagnostic clarification, reassurance, “legitimation” of symptoms, or medical certification for work absence or to express distress, frustration, or anger. Doctors need to clarify which of these reasons apply to an individual and to respond appropriately.

Managing acute back pain

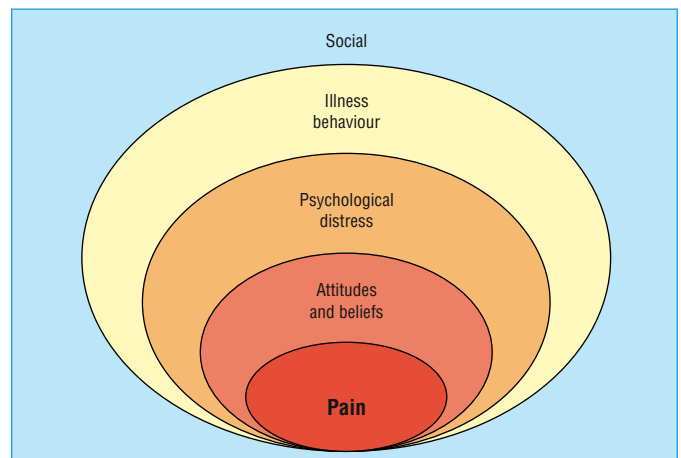

Most patients can be effectively managed with a combination of brief assessment and giving information, advice, analgesia, and appropriate reassurance. Minimal rest and an early return to work should be encouraged. Explanation and advice can be usefully supplemented with written material.

Doctors’ tasks include not only the traditional provision of diagnosis, investigation, prescriptions, and sickness certificates but also giving accurate advice, information, and reassurance. Primary care and emergency department doctors are

potentially powerful therapeutic agents and can provide effective immediate care, but they may also unintentionally promote progression to chronic pain. The risk of chronicity is reduced by

- Paying attention to the psychological aspects of symptom presentation
- Avoiding unnecessary, excessive, or inappropriate investigation
- Avoiding inconsistent care (which may cause patients to become overcautious)
- Giving advice on preventing recurrence (such as by sensible lifting and avoiding excessive loads).

Research evidence supports a change of emphasis from treating symptoms to early prevention of factors that result in progression to chronicity. This has led to the development of new back pain management guidelines for both medical management and occupational health. The shift in emphasis from rest and immobilisation to active self management requires broadening the focus of the consultation from examination of symptoms alone to assessment, which includes

Biopsychosocial model of the clinical presentation and assessment of low back pain and disability at a point in time

Excerpt from information booklet *The Back Book**

It's your back

Backache is not a serious disease and it should not cripple you unless you let it. We have tried to show you the best way to deal with it. The important thing now is for you to get on with your life. How your backache affects you depends on how you react to the pain and what you do about it yourself.

There is no instant answer. You will have your ups and downs for a while—that is normal. But look at it this way

There are two types of sufferer

One who avoids activity, and one who copes

- The *avoider* gets frightened by the pain and worries about the future
- The *avoider* is afraid that hurting always means further damage—it doesn't
- The *avoider* rests a lot and waits for the pain to get better
- The *avoider* knows that the pain will get better and does not fear the future
- The *coper* carries on as normally as possible
- The *coper* deals with the pain by being positive, staying active, or staying at work

*Roland M et al, Stationery Office, 2002.

patients' understanding of their pain and how they behave in response to it. The shift towards self directed pain management recasts the role of primary care doctor to the more rewarding one of guide or coach rather than a mere "mechanic."

Identify risk factors for chronicity

Guidelines for primary care management of acute back pain highlight the identification of risk factors for chronicity. A useful approach has been developed in New Zealand. It aims to involve all interested parties—patient, the patient's family, healthcare professionals, and, importantly, the patient's employer. Four groups of risk factors or "flags" for chronicity are accompanied by recommended assessment strategies, which include the use of screening questionnaires, a set of structured interview prompts, and a guide to behavioural management. The focus is on key psychological factors or "yellow flags" that favour chronicity:

- The belief that back pain is due to progressive pathology
- The belief that back pain is harmful or severely disabling
- The belief that avoidance of activity will help recovery
- A tendency to low mood and withdrawal from social interaction
- The expectation that passive treatments rather than active self management will help.

The assessment of "red flags" will identify the small number of patients who need referral for an urgent surgical opinion. Similarly, patients with declared suicidal intent require immediate psychiatric referral. These two groups of patients need to be managed separately.

For the vast majority of patients, however, the identification of contributory psychological and social factors should be seen as an investigation of the normal range of reactions to pain rather than the seeking of psychopathology. Questions in the form of interview prompts have been designed to elicit potential psychosocial barriers to recovery in the "yellow flags" system. They can be used at the time of initial presentation by the general practitioner.

Establish collaboration

Recent studies of miscommunications between doctors and patients with pain show that adequate assessment and collaborative management cannot be achieved without good communication between doctors and patients: only then will patients fully disclose their concerns.

The essence of good communication is to work toward understanding a patient's problem from his or her own perspective. In order to do this, the doctor must first gain the patient's confidence. A patient who has been convinced that the doctor takes the pain seriously will give credence to what the doctor says. Unfortunately, the converse is more common, and patients who feel that a doctor has dismissed or under-rated their pain are unlikely to reveal key information or to adhere to treatment advice.

Enhance accurate beliefs and self management strategies

It is easy to overlook the value of simple measures. Many patients respond positively to clear and simple advice, which enables them to manage and control their own symptoms.

Examples of simple management strategies

- Explain the difference between "hurt" and "harm"
- Reassure patients about the future and the benign nature of their symptoms
- Help patients regain control over pain
- Get patients to "pace" activities—that is, perform activities in manageable, graded stages

Factors associated with chronicity and outcome

Distress

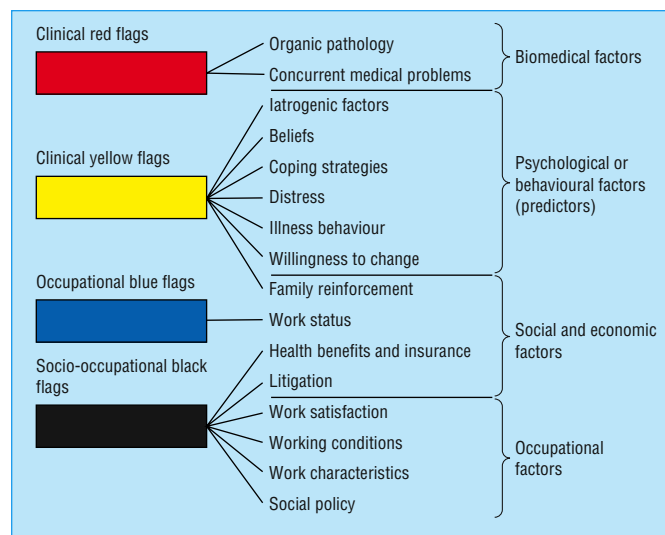

- Symptom awareness and concern
- Depressive reactions; helplessness

Beliefs about pain and disability

- Significance and controllability
- Fears and misunderstandings about pain

Behavioural factors

- Guarded movements and avoidance patterns
- Coping style and strategies

The clinical flags approach to obstacles to recovery from back pain and aspects of assessment

Structured interview prompts

- What do you understand is the cause of your back pain?
- What are you expecting will help you?
- How are others responding to your back pain (employer, coworkers, and family)?
- What are you doing to cope with back pain?
- Have you had time off work in the past with back pain?
- Do you think that you will ever return to work? When?

Guidelines for collaborative management of patients with pain

- Listen carefully to the patient
- Carefully observe the patient's behaviour
- Attend not only to what is said but also how it is said
- Attempt to understand how the patient feels
- Offer encouragement to disclose fears and feelings
- Offer reassurance that you accept the reality of the pain
- Correct misunderstandings or miscommunications about the consultation
- Offer appropriate challenges to unhelpful thoughts and biases (such as catastrophising)
- Understand the patient's general social and economic circumstances

- Advise that analgesic drugs be taken on a regular rather than a pain contingent basis
- Set realistic goals such as small increases in activity
- Suggest rewards for successful achievement (such as listening to some favourite music)

Some of these strategies may seem self evident or even trivial, but they are not. Only by building confidence slowly is it possible to prevent the development of invalidity. Occasionally patients will seem to “get stuck” and become demoralised or distressed. Suggesting ways to enhance positive self management can help maintain progress towards a more satisfactory lifestyle.

The success of the cognitive and behavioural approach described below has stimulated the development of secondary prevention programmes designed to prevent those with low back pain from becoming chronically incapacitated by it. Intervention programmes based on cognitive behaviour therapy have also been shown to be effective in reducing disability.

Manage distress and anger

If patients show evidence of distress or anger, find out why. Various strategies for dealing with distress and anger have been developed.

Managing disabling chronic back pain

A minority of patients become increasingly incapacitated and require more detailed management of what has become a chronic pain problem. Research has shown that the most important influences on the development of chronicity are psychological rather than biomechanical. The psychological factors are high levels of distress, misunderstandings about pain and its implications, and avoidance of activities associated with a fear of making pain worse.

For patients with established chronic disabling pain specialist referral is required. The treatment of choice is an interdisciplinary pain management programme (IPMP). In these programmes the focus is changed from pain to function, with particular emphasis on perceived obstacles to recovery.

These pain management programmes address the clinical flags. The most commonly used therapeutic approach is a cognitive-behavioural perspective with emphasis on self management. Treatment approaches based on cognitive and behavioural principles have been found to be more effective than traditional biomedical or biomechanically oriented interventions.

Specific chronic pain syndromes

Many specific and more widespread pain syndromes have been described—such as “chronic pain,” late whiplash syndrome, chronic widespread pain, fibromyalgia, somatoform pain disorder, repetitive strain disorder. It seems unlikely that these are distinct entities, and they are best seen as overlapping descriptive terms that do not have specific aetiological significance. Multidisciplinary treatment that includes psychological, behavioural, and psychiatric assessment and interventions is usually required.

Conclusion

There needs to be a revolution in the day to day management of musculoskeletal pain. Not only do we need to abandon prolonged rest and enforced inactivity as a form of treatment, but we also need to appreciate that addressing patients’ beliefs, distress, and coping strategies must be an integral part of management if it is to be effective.

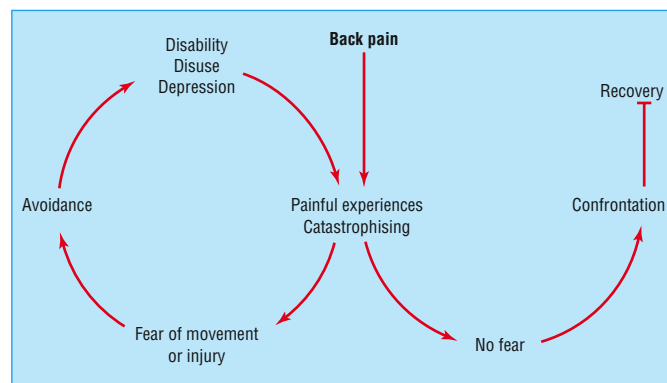

Ways of enhancing positive self management

Get patients to

- Identify when they are thinking in unrealistic, unhelpful ways about their pain (such as “It will keep getting worse”) and to change to making a more balanced positive evaluation
 - Notice when they are becoming tense or angry and then take steps to interrupt their thoughts and to use relaxation strategies
 - Change how they respond when the pain gets bad (such as pause and take a break)
 - Document their progress
 - Elicit and use the help of others to establish and maintain successful coping strategies
-

Key strategies for assessing and managing distress and anger associated with pain

- Distinguish distress associated with pain and disability from more general distress
 - Identify iatrogenic misunderstandings
 - Identify mistaken beliefs and fears
 - Try to correct misunderstandings
 - Identify iatrogenic distress and anger
 - Listen and empathise
 - Above all, don’t get angry yourself
-

Effects of confrontation or avoidance of pain on outcome of episode of low back pain: fear of movement and re-injury can determine how some people recover from back pain while others develop chronic pain and disability

Defining characteristics of modern pain management programmes

- Focus on function rather than disease
 - Focus on management rather than cure
 - Integration of specific therapeutic ingredients
 - Multidisciplinary management
 - Emphasis on active rather than passive methods
 - Emphasis on self care rather than simply receiving treatment
-

Lessons learnt in the management of chronic low back pain have direct relevance to the early and specialist management of musculoskeletal pain in general.

Evidence based summary

- Acute back pain is best treated with minimal rest and rapid return to work and normal activity
- Psychological and behavioural responses to pain and social factors are the main determinants of chronic pain disability
- Specialist psychological treatments and pain management programmes are effective in treating chronic pain

12 Abdominal pain and functional gastrointestinal disorders

Elsbeth Guthrie, David Thompson

Various functional gastrointestinal pain syndromes have been defined, but there is substantial overlap between them. There is also substantial overlap with other functional disorders such as chronic fatigue syndrome, fibromyalgia, and chronic pelvic pain. The classification system for functional gastrointestinal disorders (FGID) therefore remains controversial and is seldom used outside specialist and research settings. Furthermore, the psychological management of these different syndromes is essentially similar.

In primary care about half of the patients seen with gut complaints have FGID, the most common disorder being irritable bowel syndrome. A UK general practitioner is estimated to see eight patients with irritable bowel syndrome every week, one of whom will be presenting for the first time.

The quality of life of patients with chronic FGID is far poorer than in the general population, and is even significantly lower than in patients with many other chronic illnesses. These patients are not merely the “worried well.” It is also important to resist the temptation to think of FGID as exclusively psychological disorders. A biopsychosocial approach is preferable. Physiological studies have suggested that patients with FGID have abnormal visceral sensation and abnormal patterns of bowel motility. Both psychological and physiological factors are involved, with the relative contribution of these varying among patients.

Aetiological factors include physiological and psychological predisposition, early life experience, and current social stresses. It has been shown that a combination of psychological factors and sensitisation of the gut after infection can trigger irritable bowel syndrome in adults.

Emotional distress—The degree of associated emotional distress with FGID depends on the treatment setting. In the community and general practice the prevalence of psychological distress in patients with functional abdominal pain is about 10-20%, whereas in clinic and outpatient settings it is 30-40%, and is even higher for patients who are “treatment resistant.”

Abuse—Women with severe FGID often have a history of sexual and emotional abuse. This is as high as 30% in those attending gastroenterology clinics.

Initial management

Most patients with FGID have relatively mild symptoms and can be managed effectively in primary care. Only a third of patients seen in primary care with irritable bowel syndrome are referred to gastrointestinal specialists for further assessment and treatment.

Symptomatic treatment—Drug treatments for FGID are aimed at improving the predominant symptoms, such as constipation, diarrhoea, abdominal pain, or upper gastrointestinal symptoms. Standard treatments for lower bowel symptoms, depending on the predominant symptom, include dietary fibre, laxatives, antispasmodic agents (including anticholinergics and direct smooth muscle relaxants), and antidiarrhoeals. Treatment for upper gastrointestinal symptoms include H₂ receptor antagonists and prokinetics. There are several useful reviews of the efficacy of these agents in FGID (see further reading).

Functional gastrointestinal disorders

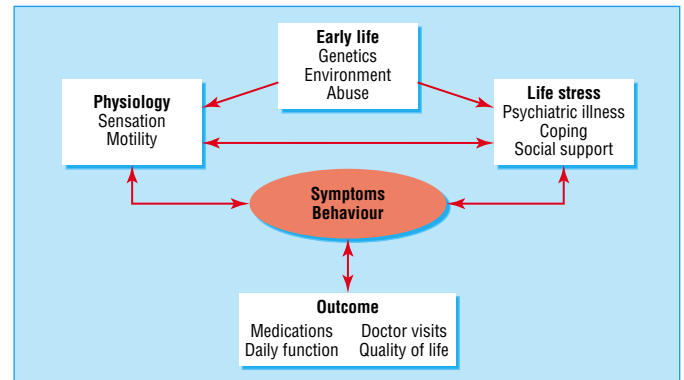

- Functional dyspepsia
- Ulcer-like dyspepsia
- Dysmotility-like dyspepsia
- Unspecified dyspepsia
- Functional diarrhoea
- Functional constipation
- Irritable bowel syndrome
- Functional abdominal bloating
- Unspecified functional bowel disorder
- Functional abdominal pain syndrome
- Unspecified functional abdominal pain

Diagnostic criteria for irritable bowel syndrome

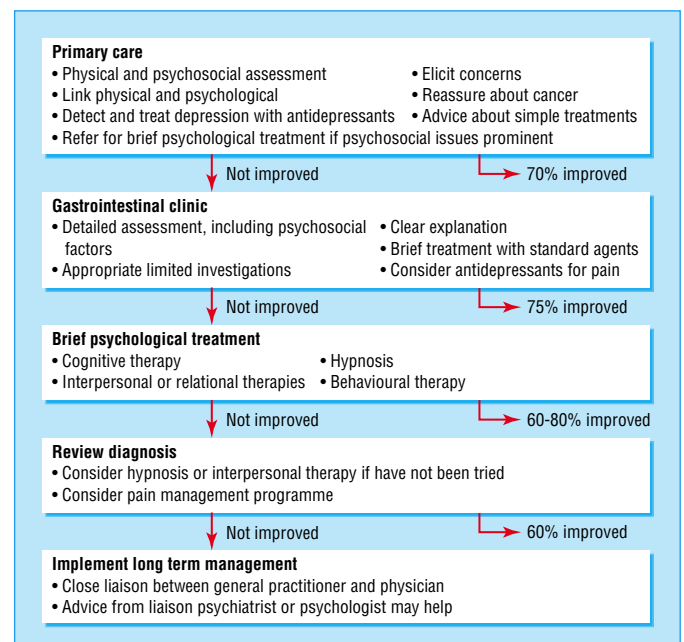

In preceding 12 months at least 12 weeks of abdominal discomfort with 2 of 3 features: relieved with defecation, onset associated with change in frequency of stool, onset associated with change in form of stool

Supportive symptoms include

- Fewer than 3 bowel movements a week
- More than 3 bowel movements a day
- Straining during bowel movement
- Urgent bowel movements
- Feeling of incomplete bowel movement
- Hard or lumpy stools
- Loose or watery stools
- Passing mucus
- Abdominal fullness, bloating, or swelling

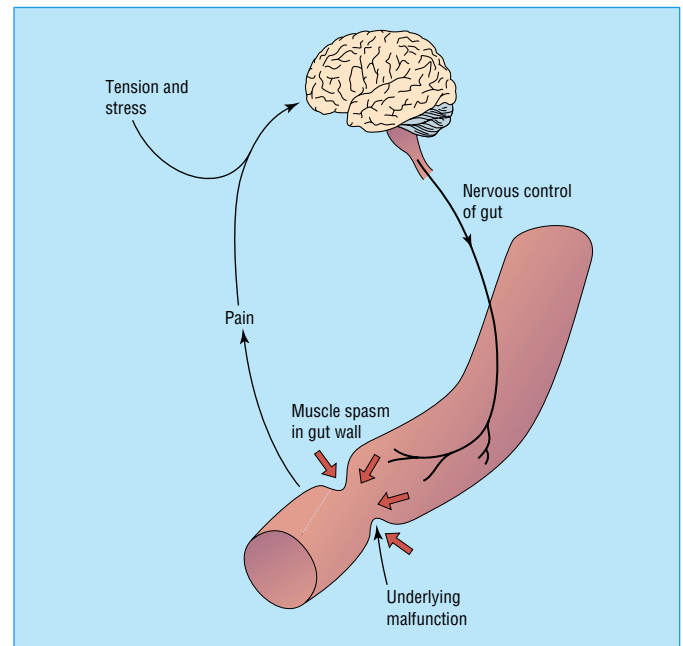

Biopsychosocial model for functional abdominal pain

Algorithm for treating patients with functional gastrointestinal disorders

Psychological management—Initial management can be enhanced by incorporating brief psychological management strategies. Many patients with FGID are afraid that they have a serious underlying disease such as cancer, and attempts should be made to elicit such fears and address them. It is also important to provide a positive and credible explanation for the symptoms. The explanation should include both physiological and psychological factors. One way of explaining symptoms is to describe how the bowel is a segmented tube in which food is propelled down by the sequential squeezing of each segment. The nervous control of this system is delicate and complicated, and disruption of it consequently produces muscle spasm in the bowel wall, which results in pain and gas. Stress and other psychological factors such as anxiety cause bowel symptoms by affecting this nervous control.

Antidepressants—A recent meta-analysis of 12 randomised controlled trials of antidepressants for treating FGID concluded that they are moderately effective. On average, 3.2 patients need to be treated to substantially improve one patient's symptoms. Antidepressants should therefore be considered if there is clear evidence of a depressive disorder, but they may also help to reduce pain in the absence of depression.

Explanation of how physiological and psychological factors combine to produce abdominal pain

Management of chronic problems

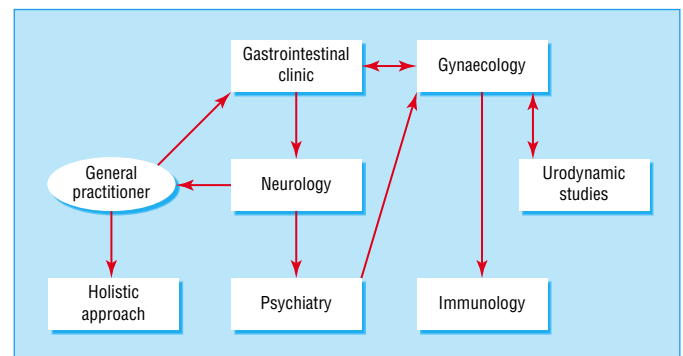

In the case of patients with chronic symptoms that have not responded to treatment, psychological factors are likely to be important. Doctors should try to elicit patients' concerns, seek evidence of emotional distress, and, over several consultations if necessary, help them to make tentative connections between psychological factors, life stresses, and the pain.

The following strategies are suggested:

- Set aside an appointment that is longer than usual, so there is time to deal with a patient's concerns. This is better than several fruitless, rushed consultations focusing only on symptoms
- Make sure that any investigations are based on the patient's history and examination. Do not allow yourself to be pushed into ordering investigations that are not clinically indicated. Try to avoid setting up a "referral matrix," with the patient being referred on from one specialty to another
- Emphasise the role that patients can play in improving or relieving pain by carrying out agreed strategies or exercises. Include the patient in decision about treatment options. Encourage membership of self help groups and organisations. The International Federation for Functional Gastrointestinal Disorders is a well respected organisation that provides useful information for patients. For patients with irritable bowel syndrome, the IBS Network is UK based and is also helpful
- Avoid changing treatments too often; improvement will be slow. Patients are likely to raise concerns about their condition at every consultation, so be prepared to give an explanation of the symptoms more than once. Make a note in the records of what you have said so that you don't contradict yourself
- Be prepared for patients to continually question your approach and think about ways to address this before each consultation. It may be helpful to discuss your management with a psychologist or psychiatrist with a special interest in somatic problems, even if patients do not wish to be referred for psychological treatment
- If you are concerned about a potential complaint, keep a detailed record of consultations, including any requests for investigations and the medical reasons for not ordering them. Repeated investigations that are not medically indicated can be unhelpful in increasing a patient's illness concerns. If you are worried about possible litigation, discuss the situation with a colleague and ask him or her to review the notes

Management of chronic functional abdominal pain

- Set the agenda
- Provide unambiguous information about findings
- Time planning; a longer planned session may save time in long run
- Identify psychosocial factors
- Set limits for investigations
- Encourage patient to take responsibility
- Don't treat what patient doesn't have

"Referral matrix" that can develop when managing a patient with chronic functional abdominal pain

Helpful patient organisations

- International Foundation for Functional Gastrointestinal Disorders. www.iffgd.org/
- IBS Network. <http://homepages.uel.ac.uk/C.P.Dancey/ibs.html>

- The aim of treatment should be to improve patients' symptoms and functioning rather than to abolish them. Although some patients may remain chronically disabled despite treatment, appropriate and consistent management can prevent deterioration and protect patients from unnecessary surgery.

Referral for psychological treatment

For patients who have not responded to initial management, four different kinds of psychological treatment have been evaluated in FGID. They are cognitive therapies, behavioural therapies, interpersonal therapies, and hypnosis. Each therapy has a different mechanism of action, but they have the common aims of reducing symptoms and improving functioning. Most treatments are delivered on a one to one basis, once weekly, over a period of two to four months.

Although most trials indicate a positive outcome for psychological treatment, many have methodological flaws and further studies are required before definitive recommendations about treatment can be given. The most convincing evidence for the efficacy of specific psychological treatments is for patients with chronic or refractory abdominal symptoms. However, there may also be an important role for earlier intervention in order to prevent such long term difficulties.

Psychological treatments are not always available. As in any other specialty, therapists need to have experience of treating chronic abdominal pain or chronic bowel disorders to develop and retain competence. Psychological services based in primary care are an option for patients with mild to moderate symptoms, but counsellors are unlikely to develop the expertise to enable them to treat patients with severe or refractory abdominal symptoms. Similarly, referral to a psychiatrist or psychologist who is more used to managing severe mental illness is unlikely to be fruitful. Dedicated medical liaison services with experience of somatic problems are more likely to be effective. If these do not exist consideration should be given to establishing a hospital based psychological medicine service.

The diagram of a biopsychosocial model for functional abdominal pain is adapted from Drossman DA et al, *Gut* 1999;45(suppl):II25-30.

Psychological treatments

Cognitive therapy

- Modifies patients' maladaptive beliefs about their pain and symptoms
- Encourages associated behaviour changes
- Patients keep diaries to monitor pain and other symptoms, associated thoughts, and behaviour
- As therapy progresses, it may be possible to identify underlying beliefs or fears about pain that drive preoccupation and worry
- Therapeutic work directed at activating three change mechanisms:
 - 1 Rational self analysis or self understanding (patients explore idiosyncratic beliefs and fears and connect these to their pain)
 - 2 Decentring (patients gain distance from their selves by identifying their self talk and labelling it)
 - 3 Experiential disconfirmation (patients challenge their fears or irrational beliefs through planned behavioural experiments)

Behavioural therapies

- Focus on changing behaviour; they do not address motives or fears
- Patterns that reinforce abnormal behaviour are identified and reversed
- Activity is gradually increased, particularly for functional activities such as social recreation and physical exercise
- Pain behaviours are ignored and activity related behaviours are reinforced
- Patients usually receive educational packages to increase their understanding of the condition
- Anxiety management strategies often included in treatment
- Biofeedback can be used to teach patients to reduce tension in affected muscles and to promote relaxation as a coping strategy

Interpersonal therapies

- Focus on resolving difficulties in interpersonal relationships that underlie or exacerbate abdominal symptoms
- Key problem areas include unresolved grief or loss, role transitions, and relationship discord
- Initial focus is on the patient's abdominal symptoms, which are explored in great detail
- Emotional distress and abnormal feeling states arising from or linked to physical symptoms are identified
- Key problem areas in relationships and their link to physical and psychological symptoms are understood
- Maladaptive relationship patterns, which may have developed after key childhood experiences (such as sexual abuse) are identified
- Solutions to interpersonal difficulties are tested out in therapy and implemented in real world

Hypnosis

- Directed at general relaxation
 - Hypnosis is induced using an arm levitation technique, which is followed by deepening procedures
 - General positive comments about health and wellbeing are made
 - Patients are asked to place their hand on abdomen, feel a sense of warmth, and relate this to asserting control over gut function
 - This is reinforced with visualisation (if patient has ability to do this)
 - Sessions are concluded with positive, ego strengthening suggestions
 - After third session patients are given a tape for daily autohypnosis
-

Evidence based summary

- Treating functional gastrointestinal disorders with antidepressants is effective even in the absence of depression
- Although several psychological treatments show promise in treating functional bowel disorders, no trial has yet provided unequivocal evidence of effectiveness

13 Chest pain

Christopher Bass, Richard Mayou

Chest pain is one of the commonest reasons for consultation in primary care. Chest pain is usually mild and transient, but further management is required in some cases. These are of two main types—acute severe pain and persistent pain associated with distress and functional limitation. Acute central chest pain accounts for 20-30% of emergency medical admissions. Chronic chest pain is the commonest reason for referral to cardiac outpatient clinics.

Management of chest pain

The improved diagnosis and early treatment of ischaemic heart disease have not been accompanied by similar advances either in the delivery of long term rehabilitation of patients with ischaemic heart disease or in the management of non-cardiac causes of chest pain. Since at least half of those referred to cardiac outpatient clinics and about two thirds of emergency admissions have a non-cardiac cause for their chest pain, there is a pressing need to address this problem.

Primary care

Primary care doctors have a major responsibility for the continuing care of patients with angina and those with chronic non-cardiac chest pain, as well as a role in secondary prevention. They therefore need good communication with specialist cardiac services and access to appropriate resources, including psychological treatments.

Patients with a low risk of coronary disease (such as young women with no cardiac risk factors and atypical pain) do not usually need cardiac investigation. Some, however, especially those with chest pain who have a family history of heart disease or other risk factors, may need investigation. In such cases it is important that the possibility of a non-cardiac cause of the chest pain is explained before referral. If investigation reveals no cardiac cause for the pain patients need their worries to be fully discussed, need advice about coping with symptoms, and should be encouraged to maintain activity.

Patients with an intermediate or high risk (such as middle aged male smokers) often require investigations even if the chest pain is “not typical” of ischaemic pain. This will usually be achieved by referral to a cardiology outpatient clinic or to an emergency assessment service. When referring patients in whom the cause of chest pain is uncertain it is important to avoid giving them the impression that the diagnosis of ischaemic heart disease is already established (such as by prescribing anti-anginal drugs). This is because, if patients come to believe that they have ischaemic heart disease, such beliefs can be difficult to change even if they are subsequently disproved by investigation.

Secondary care

The best way to organise emergency care remains uncertain. A long wait for specialist investigations such as angiography is likely to increase anxiety and disability, as has been shown in patients waiting for coronary artery surgery. Quicker access to assessment (such as by rapid access clinics and observation units) can be helpful but needs to be accompanied by a greater emphasis on aftercare for all patients assessed, not only those who have had infarction or are undergoing cardiac surgery.

British soldier admitted for observation with the diagnosis of “disordered action of the heart”—a post-combat syndrome in the first world war characterised by rapid heartbeat, shortness of breath, fatigue, and dizziness. (From Lewis T. The tolerance of physical exertion, as shown by soldiers suffering from so-called ‘irritable heart’. *BMJ* 1918;3:363-5)

Assessment and management of chest pain in primary care

- History of pain, other symptoms and risk factors
 - If at high risk of heart disease, refer for specialist assessment
 - If at low risk:
 - Identify non-cardiac causes
 - Give a positive explanation
 - Advise how to cope with symptoms and return to normal activity
 - Discuss worries
 - Offer review if symptoms are persistent
-

Clinical priorities in managing patients with chest pain

Primary care

- Recognise and refer possible heart disease
- Reassure minor chest pain
- Basic treatment of persistent non-cardiac pain
- Reassess chronic pain as required, monitor and coordinate continuing care
- Advise on secondary prevention need

Hospital emergency care

- Immediate diagnosis and treatment plus initiating continuing care of angina
- Make a positive diagnosis; reassure if non-cardiac and arrange follow up to determine investigation and treatment needs
- Full and rapid communication with primary care

Cardiac outpatient care

- Initiate immediate and continuing care of angina
- Reassure and advise if non-cardiac; plan treatment or review

Other specialist care

- Cardiac rehabilitation or aftercare
 - Psychological or psychiatric referral
-

Types of chest pain

Angina

The English national service framework for coronary heart disease recognises that patients' beliefs, attitudes, emotions, and behaviour are powerful determinants of clinical outcomes and suggests not only routine psychosocial assessment but also the integration of psychological approaches into cardiac rehabilitation programmes. Self help behavioural treatment programmes have also been shown to be of benefit. The general principles of treatment described below for non-cardiac chest pain are also applicable to angina.

Myocardial infarction and depression

About one in six patients who have a myocardial infarction develop major depression. The occurrence of depression has been found to be independently associated with poor outcome, including poor quality of life, increased heart disease, and probably increased mortality. There is some evidence that those who have the severest heart disease are at greatest risk of an adverse outcome attributable to depression. It is in just these patients that depression is most likely to be missed because both doctor and patient understandably focus their attention on the heart disease and its treatment, rather than on psychological factors.

Myocardial infarction, angina, and non-cardiac chest pain

Patients who have had a myocardial infarction or who have proved angina often report other chest pains that are clearly non-cardiac. Inevitably, they tend to misinterpret these symptoms as evidence of heart disease. The consequence is often greater disability and distress and a high and inappropriate use of medical care.

Non-cardiac chest pain

Fewer than half of the patients referred to emergency departments and cardiac outpatient clinics have heart disease. Over two thirds of these continue to be disabled by symptoms in the long term, and many also remain dissatisfied with their medical care. Some continue to take cardiac drugs and to attend emergency departments, primary care, and outpatient clinics. Hence, although these patients have a good outcome in terms of mortality, they suffer considerable morbidity.

It is desirable to make an early and confident diagnosis of non-cardiac chest pain because appropriate management of this condition in primary care can reduce subsequent morbidity.

Causes of non-cardiac chest pain

Explanations in terms of a single cause are rarely helpful. Instead, the cause is often best understood as an interaction of biological, psychological, and social factors. In many cases there is an interaction between normal or abnormal physiological processes (such as extrasystoles, oesophageal spasm or reflux, and costochondral discomfort), psychological factors (such as how somatic sensations are perceived, interpreted, and acted on), and the behaviour and reactions of other people, including doctors.

Establishing a positive diagnosis of non-cardiac chest pain

The key to establishing a positive diagnosis of non-cardiac chest pain, both in primary care and cardiac clinics, is, first, to consider the pattern of chest pain symptoms and, second, to seek evidence for non-cardiac causes.

Main components of cardiac rehabilitation treatment programme for patients with myocardial infarctions

- Provide education about heart attacks and secondary prevention and correct misconceptions
- Agree and record goals for exercise, return to work, and everyday activities; provide copies for patients, medical notes, and primary care
- Offer home exercise programme or community group exercise, or both
- Routine early review of symptoms, activity, and progress with rehabilitation and secondary prevention goals
- Menu of specific interventions, including stopping smoking, diet, and identification and treatment of psychological and behavioural difficulties

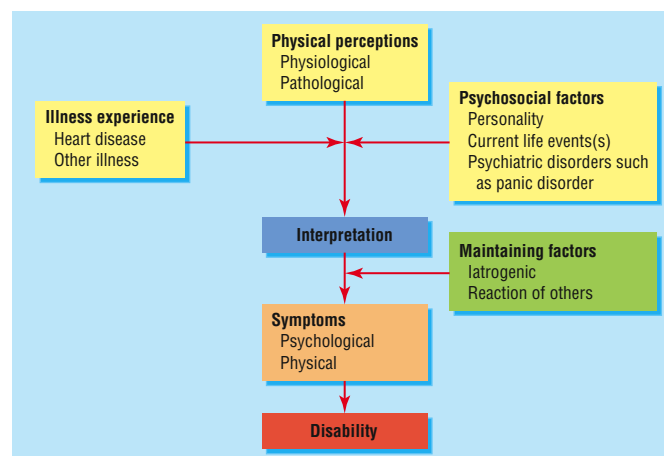

Non-cardiac pain in patients with diagnosis of angina

Diagnostic uncertainty may result in

- Non-cardiac pain being wrongly attributed to angina
- Increased antianginal medication
- Increased iatrogenic distress and disability
- Unnecessary investigations
- Unnecessary admissions and consultations

Common causes of non-cardiac chest pain

- Oesophageal disorders—Gastro-oesophageal reflux, oesophageal dysmotility
- Musculoskeletal—Costochondritis, increased muscular tension
- Referred pain from thoracic spine
- Hyperventilation
- Psychological—Panic attacks, depression

Interaction of biological, psychological, and social factors to cause non-cardiac chest pain and subsequent disability

Iatrogenic factors maintaining symptoms and disabilities

- Giving probable diagnosis of angina before investigation
- Immediate prescription of antianginal drugs without explanation of possible causes before investigation
- Lack of explanation for distressing and continuing symptoms
- Inconsistent or ambiguous information
- Reassurance contradicted by continued antianginal drugs or other indications of uncertainty
- Lack of communication with all involved in care leading to contradictory and conflicting advice

Quality of chest pain

Attempts to identify certain characteristics of chest pain that can help to establish a positive diagnosis of non-cardiac chest pain have been encouraging. For example, as few as three questions can differentiate patients with chest pain but normal coronary arteries from those with coronary heart disease.

Evidence for common non-cardiac causes

Oesophageal disorders are often associated with chest pain, but chest pain is poorly correlated with objective oesophageal abnormalities. Symptomatic treatment (such as proton pump inhibitors) can be useful. Psychological issues may need addressing whether or not there is oesophageal pathology. Gastro-oesophageal reflux is an important cause of atypical chest pain, but there is no convincing evidence that such chest pain is often related to disturbances of oesophageal motility.

Emotional disorders—Only a minority of patients who present to family doctors with non-cardiac chest pain are suffering from conspicuous anxiety or depressive disorders. The rate of such disorders is, however, higher among those referred for specialist assessment in cardiac clinics, especially those who undergo angiography and are shown to have normal coronary arteries. It is important to seek evidence of (a) the key symptoms of depression (which include hopelessness; lack of interest, pleasure, and concentration; poor sleep; and irritability as well as low mood) and (b) an association of the chest pain with anxiety and panic attacks.

Patients' beliefs and worries

Even if no definite psychiatric diagnosis can be made, it is essential to ask patients what goes through their mind when they experience chest pain.

Stressful life events

Distressing life events can precipitate not only anxiety and depressive disorders, but also functional symptoms such as chest pain. Events signifying loss, threat, and rejection are of particular importance. Open questions are most effective in eliciting these—such as: “Tell me about any changes or setbacks that occurred in the months before your chest pain began.”

Treatment of non-cardiac pain

Early and effective intervention is crucial, but how can this best be provided? Because patients vary not only in the frequency and severity of symptoms and associated disability but also in their needs for explanation and treatment of their physical and psychological problems, management needs to be flexible.

Avoiding iatrogenic worries—A consultation for chest pain is inherently worrying. Inevitably, many patients assume that they have severe heart disease, which will have major adverse effects on their life. These concerns may be greatly increased by delays in investigation, by comments or behaviours by doctors, and by contradictory and inconsistent comments.

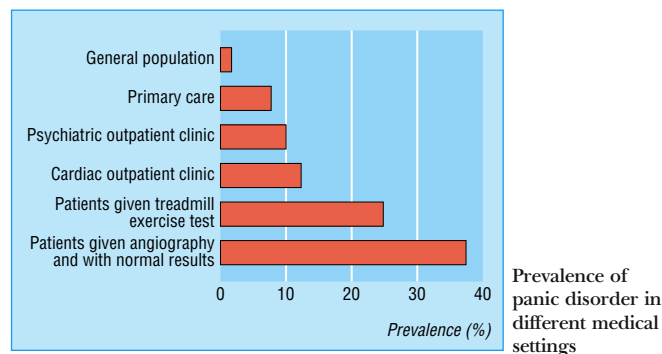

Symptomatic treatment—In some patients the pain is obviously musculoskeletal in origin and can be treated with non-steroidal anti-inflammatory drugs. Proton pump inhibitors provide effective relief from the symptoms typical of gastro-oesophageal reflux, even in those with an essentially normal oesophageal mucosa. In some cases oesophageal function testing may reveal a motility disorder or acid reflux unresponsive to first line drugs. These patients may require specialist gastroenterological referral.

Communication—Problems in the care of patients with chest pain often arise from failures in communication between primary and secondary care. Lack of information and contradictory or inconsistent advice makes it less likely that patients and their

Questions to differentiate patients with non-cardiac chest pain from those with coronary heart disease

Question	Response	
	Typical	Atypical
If you go up a hill (or other stressor) on 10 separate occasions on how many do you get the pain?	10/10	<10/10
Of 10 pains in a row, how many occur at rest?	<2/10	≥2/10
How many minutes does the pain usually last?	<5	≥5

When answers to all three questions are “atypical” the chance of coronary disease is only 2% in patients aged <55 years and 12% in those aged ≥55

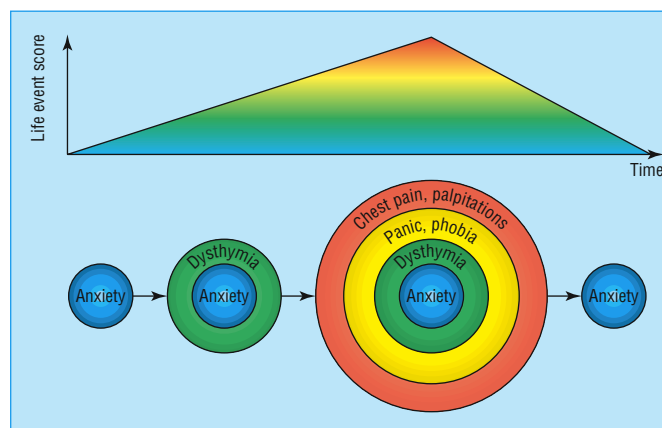

Screening questions for panic attacks

- In the past six months have you ever had a spell or an attack when you suddenly felt frightened, anxious, or very uneasy?
- In the past six months have you ever had a spell or an attack when for no reason your heart suddenly began to race, you felt faint, or you couldn't catch your breath?

If the answer is yes to either question then continue

- Obtain description
- Did any of these spells happen when you were not in danger or the centre of attention, such as in a crowd or when travelling?
- How many times have you had these spells in the past month?

Life events and symptom reporting. Stress of adverse life events may result in increases in reporting of psychological and physical symptoms

Management of non-cardiac chest pain

General management

- Explanation of the diagnosis
- Reassurance that it is a real, common, and well recognised problem
- Advice on specific treatments
- Advice on behaviour—such as not avoiding exercise
- Discussion of concerns
- Provision of written information
- Involvement of relatives
- Follow up to review

Specialist treatments

- Cognitive behaviour therapy
- Antidepressant drugs
- Psychosocial intervention for associated psychological, family, and social difficulties

families will gain a clear understanding of the diagnosis and of treatment plans. The increasing use of computerised exchange of key information may reduce this problem, although it remains important to ensure that the information is passed on to and understood by patients and relatives.

Effective reassurance—Those with mild or brief symptoms may improve after negative investigation and simple reassurance. Further hospital attendance may then be unnecessary. Others with more severe symptoms and illness concerns will benefit from a follow up visit four to six weeks after the cardiac clinic visit (or emergency room visit), which allows time for more discussion and explanation. This may be with either a cardiac nurse in the cardiac clinic or a doctor in primary care. It also provides a valuable opportunity to identify patients with recurrent or persistent symptoms who may require further help.

Specialist treatments—Psychological and psychopharmacological treatment should be considered for patients with continuing symptoms and disability, especially if these are associated with abnormal health beliefs, depressed mood, panic attacks, or other symptoms such as fatigue or palpitations. Both cognitive behaviour therapy and selective serotonin reuptake inhibitors have been shown to be effective. Tricyclic antidepressants are helpful in reducing reports of pain in patients with chest pain and normal coronary arteries, especially if there are accompanying depressive symptoms.

Organising care

Because of the heterogeneity of the needs of patients who present with chest pain, we propose a “stepped” approach to management. A cardiologist working in a busy outpatient clinic may require access to additional resources if he or she is to provide adequate management for large numbers of patients with angina or non-cardiac chest pain. One way of doing this is to employ a specialist cardiac nurse who has received additional training in the management of these problems. The nurse can provide patient education, simple psychological intervention, and routine follow up in a separate part of the cardiac outpatient clinic. For those patients who require more specialist psychological care, it is important for the cardiac department (possibly the cardiac nurse) to collaborate with the local psychology or liaison psychiatry service.

Conclusion

The management of coronary heart disease has received much attention in recent years, whereas non-cardiac chest pain has been relatively neglected. The structuring of cardiac care for both angina and non-cardiac chest pain to incorporate a greater focus on psychological aspects of medical management would be likely to produce considerable health gains.

The picture of a soldier with “disordered action of the heart” is reproduced with permission of Wellcome Trust. The box of questions to identify patients with non-cardiac chest pain is adapted from Cooke R et al, *Heart* 1997;78:142-6. The figure showing link between life events and range of psychological and physical complications is adapted from Tyrer P, *Lancet* 1985;i:685-8. The figure of stepped care for managing non-cardiac chest pain is adapted from Chambers J et al, *Heart* 2000;84:101-5.

Effective reassurance

- Accept reality of symptoms
- Give explanation of causes
- Explain that symptoms are common, well recognised, and have a good prognosis
- Understand patient's and family's beliefs and worries
- Plan and agree simple self help
- Provide written information and plans
- Offer to see patient's partner or other close relative
- Offer follow up if required

“Stepped” care in the management of non-cardiac chest pain

Evidence based summary

- Half of patients referred from general practice to a cardiac clinic with chest pain or palpitations do not have cardiac disease, but, despite the absence of disease, their symptoms tend to persist
- Psychological treatment and antidepressant drugs can be effective in treating non-cardiac chest pain

14 Delirium

Tom Brown, Michael Boyle

Delirium is a common cause of disturbed behaviour in medically ill people and is often undetected and poorly managed. It is a condition at the interface of medicine and psychiatry that is all too often owned by neither. Although various terms have been used to describe it—including acute confusional state, acute brain syndrome, and acute organic reaction—delirium is the term used in the current psychiatric diagnostic classifications and the one we will use here.

Clinical features

Delirium usually develops over hours to days. Typically, the symptoms fluctuate and are worse at night. The fluctuation can be a diagnostic trap, with nurses or relatives reporting that patients had disturbed behaviour at night whereas doctors find patients lucid the next day.

Impaired cognitive functioning is central and affects memory, orientation, attention, and planning skills. Impaired consciousness, with a marked variability in alertness and in awareness of the environment is invariably present. A mistaken idea of the time of day, date, place, and identity of other people (disorientation) is common. Poor attention, and disturbed thought processes may be reflected in incoherent speech. This can make assessment difficult and highlights the need to obtain a history from a third party. Relatives or other informants may report a rapid and drastic decline from premorbid functioning that is useful in distinguishing delirium from dementia.

Disturbed perception is common and includes illusions (misperceptions) and hallucinations (false perceptions). Visual hallucinations are characteristic and strongly suggest delirium. However, hallucinations in auditory and other sensory modalities can also occur.

Delusions are typically fleeting, often persecutory and usually related to the disorientation. For example, an elderly person may believe that the year is 1944, that he or she is in a prisoner of war camp, and that the medical staff are the enemy. Such delusions can be the basis of aggressive behaviour,

Delirium can have a profound effect on affect and mood. A patient's affect can range from apathy and lack of interest to anxiety, perplexity, and fearfulness that may sometimes amount to terror. A casual assessment can result in an erroneous diagnosis of depression or anxiety disorder.

Disturbances of the sleep-wake cycle and activity are common. A behaviourally disturbed patient with night time agitation wandering around the ward is usually easy to recognise. However, presentations where a patient is hypo-alert and lethargic may go unrecognised.

Detection of delirium

Delirium often goes undiagnosed. Non-detection rates as high as 66% have been reported. Detection and diagnosis are important because of the associated morbidity and mortality: although most patients with delirium recover, some progress to stupor, coma, seizures, or death. Patients may die because of failure to treat the associated medical condition or from the associated behaviour—inactivity may cause pneumonia and decubital ulcers, and wandering may lead to fractures from falls.

Sensory misperceptions, including hallucinations and illusions, are common in delirium. (*Don Quixote and the Windmill* by Gustave Doré, 1832-1883)

Diagnostic criteria for delirium*

- Disturbance in consciousness with reduced ability to focus, sustain, or shift attention
- Change in cognition (such as memory, disorientation, speech, disturbance) or development of perceptual disturbance not better accounted for by pre-existing or evolving dementia
- Disturbance develops over hours to days and fluctuates in severity

*Adapted from *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV)

Alcohol addiction often goes undetected at the time of admission to hospital. All admitted patients should be asked about their alcohol consumption

Differential diagnosis

The main differential diagnosis of delirium is from a functional psychosis (such as schizophrenia and manic depression) and from dementia. Functional psychoses are not associated with obvious cognitive impairment, and visual hallucinations are more common in delirium. Dementia lacks the acute onset and markedly fluctuating course of delirium. Fleeting hallucinations and delusions are less common in dementia. It is important to note that delirium is commonly superimposed on a pre-existing dementia.

Prevalence

Most prevalence studies of delirium have been carried out in hospitalised medically ill patients, in whom the prevalence is about 25%. Most at risk are elderly patients, postoperative patients, and those who are terminally ill. The epidemiology of delirium in primary care and the community is unknown, but, with shorter length of stay in hospital and more surgery on a day case basis, it is likely to be increasingly common in the community and in residential care homes. It has been estimated that, among hospital inpatients with delirium, less than half have fully recovered by the time of discharge.

Aetiology

Delirium has a large number of possible causes. Many of these are life threatening, and delirium should therefore be regarded as a potential medical emergency. It is increasingly recognised that most patients have multiple causes for delirium, and consequently there may be several factors to be considered in diagnosis and management. Causes of delirium may be classified as

- Underlying general medical conditions and their treatment
- Substance use or withdrawal
- Of multiple aetiology
- Of unknown aetiology.

Prescribed drugs and acute infections are perhaps the commonest causes, particularly in elderly people. Prescribed drugs are implicated in up to 40% of cases and should always be considered as a cause. Many prescribed drugs can cause delirium, particularly those with anticholinergic properties, sedating drugs like benzodiazepines, and narcotic analgesics.

Withdrawal from alcohol or from sedative hypnotic drugs is a common cause of delirium in hospitalised patients separated from their usual supply of these substances. Delirium tremens is a form of delirium associated with alcohol withdrawal and requires special attention.

In addition to looking for precipitating causes of delirium, it is important to consider risk factors. These include age (with children and elderly people at particular risk), comorbid physical illness or dementia, and environmental factors such as visual or hearing impairment, social isolation, sensory deprivation, and being moved to a new environment.

Management

There are four main aspects to managing delirium:

- Identifying and treating the underlying causes
- Providing environmental and supportive measures
- Prescribing drugs aimed at managing symptoms
- Regular clinical review and follow up.

Good management of delirium goes beyond mere control of the most florid and obvious symptoms.

Distinguishing delirium from dementia

	Delirium	Dementia
Onset	Acute or subacute	Insidious
Course	Fluctuating, usually revolves over days to weeks	Progressive
Conscious level	Often impaired, can fluctuate rapidly	Clear until later stages
Cognitive defects	Poor short term memory, poor attention span	Poor short term memory, attention less affected until severe
Hallucinations	Common, especially visual	Often absent
Delusions	Fleeting, non-systematised	Often absent
Psychomotor activity	Increased, reduced, or unpredictable	Can be normal

Prevalence of delirium

Setting	% with delirium
Hospitalised medically ill patients*	10-30%
Hospitalised elderly patients	10-40%
Hospitalised cancer patients	25%
Hospitalised AIDS patients	30-40%
Terminally ill patients	80%

*High risk conditions and procedures include cardiomy, hip surgery, transplant surgery, burns, renal dialysis, and lesions of the central nervous system

Causes of delirium due to underlying medical conditions

- Intoxication with drugs—Many drugs implicated especially anticholinergic agents, anticonvulsants, anti-parkinsonism agents, steroids, cimetidine, opiates, sedative hypnotics. Don't forget alcohol and illicit drugs
- Withdrawal syndromes—Alcohol, sedative hypnotics, barbiturates
- Metabolic causes
 - Hypoxia, hypoglycaemia, hepatic, renal or pulmonary insufficiency
 - Endocrinopathies (such as hypothyroidism, hyperthyroidism, hypopituitarism, hypoparathyroidism or hyperparathyroidism)
 - Disorders of fluid and electrolyte balance
 - Rare causes (such as porphyria, carcinoid syndrome)
- Infections
- Head trauma
- Epilepsy—Ictal, interictal, or postictal
- Neoplastic disease
- Vascular disorders
 - Cerebrovascular (such as transient ischaemic attacks, thrombosis, embolism, migraine)
 - Cardiovascular (such as myocardial infarction, cardiac failure)

Features of delirium tremens

- Associated with alcohol withdrawal
- Delirium with prominent anxiety and autonomic hyperactivity
- There may be associated metabolic disturbance and fits
- Chronic alcoholics are at risk of Wernicke's encephalopathy, in which delirium becomes complicated by ataxia and ophthalmoplegia. Urgent treatment with parenteral thiamine is required to prevent permanent memory damage

Making the diagnosis

Most patients with delirium are identified only because of marked behavioural disturbance. It would be preferable for all older patients to be screened for risk factors at admission to hospital. These would include substance misuse (particularly alcohol) and pre-existing cognitive impairment (assessed with the Hodkinson mental test or similar). Although such screening questions are part of the admission form in many hospitals, in our experience junior doctors seldom complete them. Once patients are admitted, minor episodes of confusion, behavioural disturbance, or increasing agitation should be taken seriously and investigated as appropriate. They should not be simply dismissed as "old age" or psychological reactions to hospitalisation.

Identifying and treating the cause

Delirium, by definition, is secondary to one or more underlying cause. Identifying such causes is often difficult, especially when patients are unable to give a coherent history or cooperate with physical examination. On occasions, it can be necessary to sedate a patient before conducting an adequate assessment. The interviewing of third parties is often helpful. Once a cause is found, appropriate treatment should be started without delay.

The environment

The aims of environmental interventions are, firstly, to create an environment that places minimum demands on a patient's impaired cognitive function and, secondly, to limit the risk of harm to the patient and others that may result from disturbed behaviour. Nursing should, as far as possible, be done by the same member of staff (preferably one trusted by the patient). This consistency should be supported with other strategies such as clear and if necessary repeated communication, adequate lighting, and the provision of clocks as aids to maintaining orientation. Visits from family and friends and provision of familiar objects from home can also be helpful. The correction of sensory impairments (such as by providing glasses or hearing aids) to help patients' grip on reality is sometimes overlooked.

It is also important to minimise any risk to a delirious patient, other patients on the ward, and staff by ensuring that the patient is in a safe and separate area and that potentially dangerous objects are removed.

Drug treatment

Drug treatment of delirium should only be used when essential and then with care. This is because drugs such as antipsychotics and benzodiazepines can make the delirium worse and can exacerbate underlying causes (for example, benzodiazepines may worsen respiratory failure).

Antipsychotic drugs

Antipsychotics are the most commonly used drugs. Their onset of action is usually rapid, with improvement seen in hours to days. Haloperidol is often used because it has few anticholinergic side effects, minimal cardiovascular side effects, and no active metabolites. As it is a high potency drug it is less sedating than phenothiazines and therefore less likely to exacerbate delirium. It is, however, prone to causing parkinsonism, which may exacerbate a patient's tendency to fall. Low dose haloperidol (1-10 mg/day) is adequate for most patients. In severe behavioural disturbance haloperidol may be given intramuscularly or intravenously.

It is preferable to use a fixed dose that is frequently reviewed from the time of diagnosis rather than always giving the drug "as required" in response to disturbed behaviour. It is essential,

Hodkinson mental test

Score one point for each question answered correctly and give total score out of 10

Question

- Patient's age
 - Time (to nearest hour)
 - Address given, for recall at end of test (42 West Street)
 - Name of hospital (or area of town if at home)
 - Current year
 - Patient's date of birth
 - Current month
 - Years of the first world war
 - Name of monarch (or president)
 - Count backwards from 20 to 1 (no errors allowed but may correct self)
-

Environmental and supportive measures in delirium

- Education of all who interact with patient (doctors, nurses, ancillary and portering staff, friends, family)
 - Reality orientation techniques
Firm clear communication—preferably by same member of staff
Use of clocks and calendars
 - Creating an environment that optimises stimulation (adequate lighting, reducing unnecessary noise, mobilising patient whenever possible)
 - Correcting sensory impairments (providing hearing aids, glasses, etc)
 - Ensuring adequate warmth and nutrition
 - Making environment safe (removing objects with which patient could harm self or others)
-

Simple measures to help orientation (such as glasses, hearing aids, and clocks) are effective in the management of delirium

In postoperative patients judicious use of oxygen can treat delirium effectively

yet often forgotten, to monitor patients for both adequate response and unacceptable side effects. While a patient is in hospital this consists of at least a daily assessment of symptoms, level of sedation, and examination for extrapyramidal and other unwanted drug effects.

Preliminary experience with new antipsychotics suggest they may also be effective in delirium, but their advantages remain unestablished.

Benzodiazepines

Benzodiazepines are usually preferred when delirium is associated with withdrawal from alcohol or sedatives. They may also be used as an alternative or adjuvant to antipsychotics when these are ineffective or cause unacceptable side effects. Intravenous or intramuscular lorazepam may be given up to once every four hours. In patients with delirium due to hepatic insufficiency, lorazepam is preferred to haloperidol. Excessive sedation or respiratory depression from benzodiazepines is reversible with flumazenil.

Review

One of the most consistent failings in the management of delirium is lack of review. The acute symptoms are usually dealt with “out of hours” by junior staff and are forgotten by the next day. It is essential to review management of delirium and of the underlying causes for the duration of the hospital stay.

Patients’ capacity and consent

Increasingly issues of capacity and informed consent may be raised in relation to the treatment of delirium. Urgent interventions needed to prevent serious deterioration or death or necessary in the interests of a patient’s safety are deemed to be covered by common law in the United Kingdom. Although opinions differ, most agree that (a) if medical colleagues would deem a treatment appropriate and (b) if reasonable people would want the treatment themselves, then it can be given if urgently necessary.

Explaining the diagnosis

Effective management requires that not only the doctors and nurses caring for a patient understand the condition, but that the patient’s family and friends appreciate the reasons for the dramatic change in the person’s behaviour and that it is usually a reversible condition.

Aftercare

Many patients with delirium still have residual symptoms at the time of discharge from hospital. There is therefore a need for continued vigilance about medication, environmental change, and sensory problems during discharge planning and aftercare. Close liaison between hospital and primary care is an essential part of discharge planning.

Patients or their families will often need reassurance that an episode of delirium is not the start of an inevitable progression to dementia and that a full recovery can usually be expected. Delirious patients may erroneously be placed in long term care as “demented”: decisions to place patients in care should be made only after an adequate assessment that differentiates delirium from dementia.

Excessive use of sedative drugs often causes more problems that it solves

Key medicolegal judgments about patients’ capacity and consent (English Law)

Re c (mental patients: refusal of treatment) [1994] 1 WLR 290

An adult has the capacity to consent to or refuse treatment if he or she can

- Understand and retain the information relevant to the decision in question
- Believe that information
- Weigh the information in the balance to arrive at an informed choice

Re f (mental health sterilisation) v West Berkshire Health Authority (1989) 2 WLR 1025; (1989) All ER 673

“not only (1) must there be a necessity to act when it is not practicable to communicate with the assisted person but also (2) the action taken must be such as a reasonable person would in all circumstances take, acting in the best interests of the assisted person.”

“Action properly taken to preserve life, health or wellbeing of the assisted person (which) may well transcend such measures as surgical operations or substantial treatment and may extend to include such humdrum matters as routine medical or dental treatment, even such simple care as dressing and undressing and putting to bed.”

Evidence based summary

- A quarter of hospitalised elderly patients will have delirium
- Occurrence of delirium predicts poorer outcome and greater length of stay even after controlling for other variables, including severity of illness
- Positive identification and management of risk factors can reduce incidence and severity of delirium in elderly patients

Preface to the fifth edition

The First Year of Life was the first series of ABC articles commissioned and published weekly by the *BMJ* and later collected and published as a book. This new fifth edition is called *ABC of the First Year* to identify it with the ABC series. The ABC series is continuing to tackle new subjects in all branches of medicine and surgery: 46 series have been published and 43 books are still in print. The first edition of *The First Year of Life* was printed in black and white and some colour was introduced in the last edition. The majority of the pages in this new edition are in colour and nearly 100 new photographs have been added. Each chapter has been thoroughly revised with considerable changes in the chapters on prenatal assessment, infants of low birthweight, breathing difficulties in the newborn, and diarrhoea. The charts for developmental review have incorporated the latest recommendations of the Department of Health. New sections have been added on the infant of low birthweight at home, advice on travelling abroad with an infant, and paediatric HIV infection.

The book was written for family doctors, GP vocational trainees, medical students, midwives, and nurses. It has become the standard textbook for several undergraduate and postgraduate courses. The emphasis has been on the practical aspects of management, based on clinical experience, but theory is introduced where it is essential for understanding the basis of management. No previous experience of paediatrics is assumed.

I welcome Dr Roslyn Thomas who has joined me as co-author of this edition. I wish to thank the staff of the *BMJ*, and especially Alex Stibbe who has acted as midwife for the fifth edition of the book, and my wife who has constantly supported me and encouraged me to write.

For ease of reading and simplicity a single pronoun has been used for both feminine and masculine subjects; a specific gender is not implied.

Bernard Valman

Foreword to the first edition

The care of infants and their mothers has changed rapidly in the past 10 years and it is often difficult to identify those advances that will prove of lasting value to the clinician.

Dr Bernard Valman's articles on the first year of life, published recently in the *BMJ* and collected in book form, aim at providing the clinician in the community and in hospital with generally accepted views on the medical management of infants.

The main difference between paediatrics and general medicine is the range of normality, which changes with age. The greatest changes occur in the first year of life. Dr Valman's articles provide an account of normal development during this year, with particular emphasis on its assessment, so that deviations may be easily recognised. These articles have been collected together to provide a practical guide for general practitioners and the many other staff who care for the new born and young infants.

Stephen Lock
Editor, *BMJ* 1980

1 Prenatal assessment

Recent advances in ultrasound technique, equipment, and training together with rapid advances in molecular biology have increased the range of antenatal diagnoses. Some methods are available only at specialised centres. This chapter will give a background to successful techniques. An anomaly may be detected during routine examination of the fetus which is carried out by ultrasound between 18 and 24 weeks of gestation. Maternal serum screening for Down's syndrome is performed as a double, triple or two stage integrated test (see below).

After the birth of an abnormal baby or the detection of genetic disease in an older child, a paediatrician or geneticist may recommend a specific test at a particular week in the subsequent pregnancy. Some tests are at an early stage in development and the false positive and negative rates have not been assessed. Some genetic tests are not yet sufficiently precise to enable an accurate prognosis to be given to every family with that disease.

At the first antenatal visit it is still important to carry out a full blood count and haemoglobin electrophoresis, blood grouping, rhesus antibody titre, tests for rubella and hepatitis B, human immunodeficiency virus (HIV), and syphilis. The haemoglobin electrophoresis may show that the mother has β -thalassaemia trait or sickle cell trait and the father's red cell investigations may suggest that further studies of the fetus are needed.

Ultrasound studies

The first routine examination of the fetus by ultrasound is usually performed at the gestational age of 12 weeks. The gestational age is confirmed and anomalies of the central nervous system or cystic hygromas may be detected. A further scan at 18–24 weeks may detect anomalies of the central nervous system, heart, kidneys, intestinal tract, and skeleton. Signs which suggest a chromosome abnormality include choroid plexus cysts, echogenic cardiac foci, renal pelvic dilatation or echogenic bowel. They occur in approximately 1:250 pregnancies and are associated with a 1:300 risk of a chromosome abnormality. These isolated signs in the presence of normal serum screening probably do not merit the fetal risks of amniocentesis but full discussion is necessary and the patient may still opt for karyotyping to be performed. Mothers with a family history of congenital heart disease should be offered a detailed cardiac ultrasound scan at 18–24 weeks as the risk of the fetus having a heart problem is 3–5%. The consultant obstetrician, ideally with the paediatrician, should discuss the diagnosis and prognosis of an anomaly with both parents. Termination of the pregnancy may need to be considered or serial ultrasound examination performed during the pregnancy and in the neonatal period.

Ultrasound guidance is used in taking samples of the amniotic fluid (amniocentesis) and in selected centres it has been used to take blood samples from the umbilical cord (cordocentesis) and to give blood transfusion by that route.

The samples can be used in gene probe techniques, enzyme estimation, and chromosome studies. In rhesus incompatibility a low haematocrit in the cord blood indicates the need for fetal transfusion.

Amniocentesis

Amniotic fluid is removed by passing a needle into the amniotic cavity through the mother's abdominal wall and uterus under

ultrasound guidance. Amniocentesis yields amniotic fluid containing cells that have been shed from the skin of the fetus. Examination of the cultured cells reveals the chromosome constitution of the fetus, including sex. Specific enzymes can be sought and deoxyribonucleic acid (DNA) probes used. Women who are found to be at higher risk for Down's syndrome on serum screening are offered amniocentesis. In high risk women fluorescent *in situ* hybridisation (FISH test) may be offered which uses the polymerase chain reaction (PCR) to detect chromosome abnormalities such as the common trisomies, 21, 18, and 13 – Down's, Edward's, and Patau syndrome respectively – the results of which are available within a few working days.

Chorionic villus biopsy

Chorionic villus biopsy is carried out mainly by the transabdominal route under ultrasound guidance after 10 weeks gestation. The main indications have been maternal age, previous chromosome anomaly, fetal sexing, enzyme assay, and gene probe assessment. Gene probes have been developed for several diseases including cystic fibrosis, Duchenne muscular dystrophy, and the haemoglobinopathies. DNA is extracted from the chorionic villus sample and the probe is used to determine whether a specific part of a particular gene is present or absent.

There is a higher miscarriage rate with chorionic villus biopsy compared to amniocentesis. As there is a risk of limb reduction deformities and facial anomalies when it is performed early, it should be carried out after the 10th week of gestation.

Maternal serum screening for Down's syndrome

The majority of babies with Down's syndrome are born to mothers under the age of 37 years because they form the largest proportion of mothers. The serum screening for Down's syndrome should be offered to all mothers irrespective of maternal age as it provides an assessment of the risk but not a definite diagnosis of Down's syndrome. The double or triple test is offered at the initial antenatal visit to all mothers. Three biochemical parameters (serum α -fetoprotein, β -human chorionic gonadotrophin (HCG), and oestriol) are taken with an accurate gestational age assessed by ultrasound and maternal age to assess the risk of Down's syndrome. If all those mothers identified as being at risk (screen positive = risk greater than 1: 250) using the triple test had an amniocentesis, then it is thought that 60–65% of Down's syndrome babies would be detected. It is hoped that with the addition of ultrasound to detect signs such as an increase in nuchal thickness and other biochemical tests, it may be possible to improve the risk assessment even more, using a two-stage integrated test (see Box 1.3). It is hoped that in future, with improved techniques of DNA gene replication, it might be possible to karyotype a fetus from fetal cells in the maternal circulation.

Risks

The risk to a particular fetus depends on the gestational age of the fetus, the indication for the procedure, and the experience of the operator. The incidence of complications has fallen as skill in the newer techniques has increased. The abortion rates

Box 1.3 Two-stage integrated test

Stage one at 10–13 weeks

1. Ultrasound scan to determine gestational age and nuchal thickness
2. Blood level of plasma protein A (PAPP-A)

Stage two at 15–22 weeks

1. Blood levels of:
 - α -fetoprotein (AFP)
 - free β -human chorionic gonadotrophin (β -hCG)
 - unconjugated oestriol (uE₃)
 - inhibin-A (inhibin)
2. Integration of results from the two stages to estimate risk of Down's syndrome or a neural tube defect

are difficult to assess but Table 1.1 opposite has been compiled from expert advice on the available evidence. The risk of abortion after amniocentesis at 15 weeks is about 1%, which is about twice the spontaneous incidence in normal pregnancies. Fetal or maternal bleeding has been considerably reduced by the use of ultrasound, but a slight risk of infection remains and the incidence of respiratory distress syndrome and orthopaedic problems, such as talipes, is probably slightly increased in fetuses who have undergone early amniocentesis. Chorionic villus biopsy has a higher risk of abortion of about 5% against a background of spontaneous abortion of 3%. Chorionic villus biopsy carried out at about 10 weeks gestation provides a result early in pregnancy, when termination of the pregnancy is less traumatic and more acceptable for many mothers. Some tests are slightly more accurate when the sample is obtained by amniocentesis. Some investigations can be performed only on a specific sample.

Screening for bacterial vaginosis

Preterm birth is the major cause of death and disability in babies. The aetiology of preterm labour is multifactorial but there is increasing evidence to implicate infection as a possible cause in up to 40% of cases. This information may not help once a woman is admitted in preterm labour, since by that time there may be irreversible changes in the cervix. Where the information may be useful is in the prediction and prevention of preterm labour. A few recent studies have reported that abnormal colonisation of the vagina in the form of bacterial vaginosis carries a risk of up to fivefold for the subsequent development of preterm labour and late miscarriage. Whether by reversing this condition it is possible to reduce the incidence of preterm labour and delivery is currently being tested.

Follow-up of fetal renal tract anomalies

Mild dilatation (<10 mm) of the fetal renal pelvis is often found on the routine antenatal ultrasound scan done at 18–20 weeks gestation. Serial scans at 2–4 weekly intervals will establish whether there is any progressive change before birth. The finding of reduced liquor, a distended thick-walled bladder or progressive dilatation >20 mm may be suggestive of an obstructive uropathy. Preterm delivery or antenatal surgical intervention is rarely indicated, except very occasionally in a male fetus where posterior urethral valves are causing renal compromise at <34 weeks gestation.

For most infants, postnatal investigation with several ultrasound scans over the first few months of life and sometimes a micturating cystourethrogram (MCUG) or renal isotope scan will be necessary. Until the results of these investigations are known, most infants will be given a small daily dose of prophylactic oral antibiotics (usually trimethoprim 1–2 mg/kg). This is to prevent urinary tract infections in those infants who may be at risk because they have vesicoureteric reflux. The radiological investigations are rarely urgent and some are more meaningful when the infant is a little older (for example, isotope scans).

All infants should be followed up postnatally as it is not easy to predict which infants will have significant ongoing dilatation, but most antenatally diagnosed fetal renal tract dilatation is found to be benign or transient on serial postnatal follow-up. A small number of infants will be diagnosed as having pelviureteric obstruction, multicystic dysplastic kidney or bladder outlet obstruction, but only the latter requires urgent diagnosis and surgery in the neonatal period.

Table 1.1 Risk of abortion

Procedure	Gestational age performed (weeks)	Spontaneous abortion (%)	Risk of abortion after procedure (%)
Amniocentesis	14–18	0.5	1
Chorionic villus biopsy	>10	2–3	3–5
Cordocentesis	18–20	<1	1–2

Figure 1.4 Bacterial vaginosis.

Figure 1.6 Postnatal scan showing dilation of renal pelvis.

2 Resuscitation of the newborn

Wherever babies are delivered there should be a person with adequate skill and experience in resuscitation immediately available throughout the 24 hours. The majority of babies can be resuscitated with a closely fitting mask and an inflatable bag with a valve. The equipment is cheap, simple to use, and can be carried in a small case. Some infants cannot be resuscitated by this method but require intubation, which to be successful should be done by a doctor or midwife with continual experience of the procedure.

Babies who have developmental brain abnormalities before labour may develop fetal distress during the stress of labour and may have difficulty in establishing spontaneous respiration. For this reason, the contributions of brain development and perinatal management in the causation of later cerebral palsy are often difficult to resolve.

Assessment

The following high risk factors indicate that resuscitation may be needed:

- fetal distress
- caesarean section
- preterm infant
- breech delivery
- forceps delivery
- twins
- maternal anaesthetic
- maternal diabetes
- rhesus incompatibility.

These factors predict about 70% of the babies needing resuscitation. The remainder arise unexpectedly. The APGAR scoring system is used to assess the infant's condition one minute and five minutes after birth. A numerical score is given for each of five features. The heart rate and respiratory effort determine the action to be taken.

Procedure

Suctioning the oropharynx

The rare indications for suction of the oropharynx are meconium aspiration and blood in the mouth. It is best not to use mucus extractors, as there is a risk of the operator swallowing or inhaling infectious material. Use a suction catheter (size FG 8) connected to the Resuscitaire or directly to a wall suction unit. The mouth can safely be suctioned but care must be taken in the oropharynx. This should be done under direct vision and is usually part of tracheal intubation. Do not blindly push the catheter as far as it will go since this can cause a vagally mediated bradycardia and apnoea and is invariably associated with a fall in oxygen saturation.

Administering facial oxygen

Set the oxygen flow rate to 5 l/min and hold the funnel-shaped mask just in front of the baby's face. The oxygen may be connected either to the funnel-shaped mask or to the bag and mask apparatus, but in the case of the latter, it is prevented from flowing out of the mask by the valve unless the bag is

Figure 2.1 Resuscitation kit in case.

Table 2.1 APGAR scoring system

	0	1	2
Appearance (colour)	Blue, pale	Body pink, extremities blue	Completely pink
Pulse (heart rate)	Absent	Below 100	Over 100
Grimace (response to stimulation)	No response	Grimace	Cry
Activity (muscle tone)	Limp	Some flexion in extremities	Active movements
Respiration (respiratory effort)	Absent	Slow irregular	Strong cry

Figure 2.2 Giving oxygen.

compressed. However, it will come out of the corrugated tube that is attached to the other end of the bag, so turn it round and hold the end of this tube to the baby's face.

Using the bag and mask

If the infant does not breathe by 30 seconds after birth, the closely fitted mask is applied to the face with the head in the neutral position. For a right handed person, the left hand is used to hold the mask to the baby's face while the right hand squeezes the bag. Place the little and ring fingers of your left hand under the baby's chin, taking care not to push too hard. Alternatively the jaw is elevated with two fingers on the angle of the mandible. This prevents the head from moving around and straightens the upper airways, ensuring their patency. With the other fingers and thumb, apply the mask firmly to the baby's face to ensure a tight seal. A proper seal is confirmed when you squeeze the bag, as there is a characteristic rasping noise as the valve opens. If the seal is inadequate, the valve makes no noise and you will not feel any resistance when squeezing the bag. This can be practised with the mask against the palm of your hand. Use only the thumb and two fingers, rather than your whole hand, to squeeze the bag. Do not empty the bag but gently depress it to a few centimetres only. This will safeguard against a pneumothorax. The smaller the baby, the more gentle you must be. The rate should be maintained at 40/min with an inflation time of approximately 1 second. The first five inflations should be slightly prolonged as lung fluid is still present in the airway. Check you are producing an adequate chest expansion. Air can be used but oxygen should be used if it can be introduced into a side arm.

Figure 2.3 Operator holding mask with *right* hand to show how to place the infant's head in the neutral position.

Intubation

If there are no spontaneous respiratory movements at the end of one minute after birth or if the heart rate is less than 100 beats/min at any time the infant should be placed supine on a flat surface. A special resuscitation trolley is ideal. The laryngoscope is held in the left hand and passed over the infant's tongue as far as the epiglottis. The tip of the blade is advanced over the epiglottis about another 0.5 cm and is then withdrawn slightly. This presses the epiglottis against the root of the tongue, revealing the glottis. In the newborn the glottis is a slit in the centre of a small pink mound and the slit may expand into a triangular opening during a gasp. Gentle backward pressure on the infant's larynx by an assistant may help to bring the glottis into view. Secretions in the pharynx should be aspirated with a large catheter – for example, FG 9. The endotracheal tube held in the right hand is then guided through the larynx about 1–2 cm into the trachea. A metal introducer inside the endotracheal tube makes introduction easier but it is essential to ensure that it does not extend beyond the end of the tube.

Intermittent positive pressure should be applied at a rate of 40 times per minute with an inflatable bag with a valve.

The positive pressure applied should not usually be higher than 30 cmH₂O; otherwise there is a danger of rupturing the lung and producing a pneumothorax or pneumomediastinum. These low pressures are enough to induce a gasp reflex, which is then followed by normal respiratory movements of the chest. Occasionally in an infant with a severe lung problem, such as severe meconium aspiration or diaphragmatic hernia, higher pressures are needed. A return to a normal heart rate is a good sign that resuscitation is satisfactory. If the endotracheal tube has to be left in place for a short period the tube should be fixed to the cheek by adhesive tape or a special tube holder.

Figure 2.4 Passing the laryngoscope over the tongue.

Aspiration of secretions in the endotracheal tube and in the trachea can be carried out with a fine catheter (suction catheter FG 6). Either a straight or a shouldered tube is satisfactory for emergency resuscitation of the newborn. The shoulder on the endotracheal tube is designed to prevent the tube going too far down through the vocal cords and therefore into the right main bronchus, but this may still occur. If breath sounds are heard equally on both sides of the chest the tube is probably in the trachea and not beyond the bifurcation.

Intermittent positive pressure should be stopped every three minutes for about 15 seconds to determine whether spontaneous respiratory movements will start.

During prolonged apnoea the blood pressure is maintained initially but later falls. If the heart rate is less than 100/min a short period of cardiac massage should be given at the same time as efforts to start respiratory movements. Cardiac massage is carried out by applying firm pressure with two fingers over the lower sternum one finger's breadth below an imaginary line between the two nipples.

Hypothermia is a special hazard for infants who have been resuscitated and exposed during these procedures. Rapid initial drying of the infant with a warm towel is the most important preventive factor, but resuscitation should also be carried out under a radiant heater of at least 400 watts. After resuscitation, infants should be wrapped up and handed to their mothers for at least a minute or two even if they have to be placed in a transport incubator and taken to the special care unit. Most full term infants who have required resuscitation do not need to be admitted to the special care unit.

Failure to improve

The best sign that resuscitation has been successful is an increase in heart rate. If this does not occur within about 15 seconds the following should be considered. (1) The gas cylinders may be empty or the pipe line disconnected. (2) The endotracheal tube may have been misplaced into the oesophagus or have slipped out of the trachea during extension of the neck. If there is any doubt the tube should be removed and a fresh tube inserted immediately. (3) The endotracheal tube may be in the right main bronchus. After these possibilities have been excluded other diagnoses to be considered are pneumothorax, pulmonary hypoplasia associated with Potter's syndrome (renal agenesis with a squashed facial appearance and large, low set floppy ears), and diaphragmatic hernia.

Drugs

Ventilation using bag and mask or intubation is usually effective in resuscitation of the newborn and drugs are rarely necessary.

If the mother has recently received pethidine or morphine, a chemical antagonist can be given to the infant. If the infant needs both intubation and drugs, intubation should always be performed first. The only chemical antagonist available is naloxone, but its period of action is short. The manufacturer's current recommended dose is 10–20 micrograms per kilogram body weight, which can be given intramuscularly or intravenously and may be repeated at 2–3 minute intervals. Alternatively, a single dose of 60 micrograms/kg body weight may be given intramuscularly at birth.

An adequate supply of oxygen quickly reverses acidosis and it is rarely necessary to consider giving intravenous sodium bicarbonate or glucose solution.

Figure 2.5 Pressing the epiglottis against the root of the tongue.

Figure 2.6 Misplacement of the endotracheal tube into the pharynx or oesophagus.

Table 2.2 Recommended doses

Drug	Concentration	Route	Dose (ml/kg)	Dose for 3 kg baby (ml)
Adrenaline	1 in 10 000 (0.1 mg/ml)	IT*, IV, IC	0.1	0.3
Sodium bicarbonate	8.4% (1 mmol/ml)	IV	2–4 (diluted 1 in 2 with water)	6–12
Glucose	10%	IV	1–2	3–6
Albumin	5%	IV	10–20	30–60

* Double the dose and add 2 ml of 0.9% sodium chloride solution for intratracheal route.

If there are no spontaneous respiratory efforts by three minutes after starting resuscitation, blood is taken for urgent pH and bicarbonate estimations. Without waiting for the result, the probable acidosis is partially reversed by giving 2–4 ml/kg of 4.2% sodium bicarbonate solution slowly at a rate that does not exceed 2 ml/min. The standard 8.4% sodium bicarbonate solution must be diluted 1 in 2 with sterile water for intravenous use. The solution should be given by a peripheral vein if possible, as the solution is hypertonic and may cause local vascular damage. If this is not possible, an umbilical vein catheter can be used in an emergency.

Ten percent glucose solution can be given if a glucometer shows hypoglycaemia.

Adrenaline can be given if there is asystole or there is persistent severe bradycardia. If there is no response, the adrenaline can be repeated. The use of volume expanders, albumin or 0.9% sodium chloride solution is not recommended routinely in the resuscitation of the newborn. Shock in the newborn is usually related to hypoxaemia and responds to administered oxygen but a volume expander may be needed where there is volume loss. The infant is transferred to the neonatal intensive care unit.

There is no specific treatment for the hypoxic-ischaemic encephalopathy that may follow perinatal asphyxia. The infant may be apnoeic and need continuous positive pressure ventilation, have fits, episodes of bradycardia, lethargy, or be reluctant to suck. Mannitol, frusemide, steroids, and phenobarbitone in high doses have been used to prevent or treat possible cerebral oedema but there is no evidence that they are effective.

These infants will also need long term follow-up to assess neurological development. The survival rate of full term newborn infants who have taken 20 minutes to breathe spontaneously is about 50% and about 75% of the survivors are neurologically intact.

When to stop

Poor outcome can be predicted when spontaneous respirations are not established by 30 minutes. If, in addition, there is no cardiac output, then survival cannot be expected. It is at this stage that attempts at resuscitation should cease.

When not to start

This can be an extremely difficult decision and should not be made by the most junior paediatrician, so begin resuscitation and call for help. If the heart rate has been recorded at any time during the second stage of labour, resuscitation should be attempted even if there is no heartbeat at birth. With fetal

Figure 2.7 Intubation is performed before giving drugs.

ABC of the First Year

monitoring it is uncommon for babies to die during labour and stillbirths are usually expected. Babies who have been dead for longer than 12 hours have an obvious “macerated” appearance with gross peeling of the skin.

A baby born at less than 22 weeks gestation cannot survive and often a paediatrician will not be called if the obstetrician is sure of the dates. Certain conditions are non-viable, such as anencephaly or gross hydrocephalus, but fortunately these are usually detected prior to birth and a decision is reached with the parents before delivery.

Vitamin K

Vitamin K is given to all babies as prophylaxis against haemorrhagic disease of the newborn. More predictable blood levels are produced by intramuscular compared to oral vitamin K. A single intramuscular dose protects against the early form of haemorrhagic disease, which occurs between the second and fourth day, and the late form, which occurs after three or four weeks. Following controversy on the safety of the intramuscular route, some paediatricians recommend that breastfed babies receive oral vitamin K in the neonatal period and during the subsequent two months. Infants receiving a commercial cows’ milk preparation exclusively have an adequate intake of vitamin K.

Discussion with parents

An infant who is breathing normally should be given to the mother after a rapid examination. She should be told that the infant seems to be normal and that it is common for infants to need help with breathing at birth. It is important to emphasise that the infant’s progress will be no different from that of other infants who have not needed resuscitation. Most infants who have required intubation should go with their mothers to the postnatal wards and receive routine observation. Only if there has been a prolonged period before the establishment of spontaneous respiration should the infant be taken to the special care unit.

When an infant dies

If resuscitation of an infant has not been successful, the most senior clinician involved, preferably accompanied by a midwife or nurse, should see the parents immediately to impart the news in a sensitive manner. The parents should be given as much factual information as is known to the clinicians at the time about the likely cause of the death. It should also be made clear that further discussion will need to take place, particularly if the death is sudden or unexpected. The term “birth asphyxia” should not be used as it may be misleading and there is increasing evidence that neonatal deaths and morbidity are more likely to be due to developmental brain problems or antenatal insults rather than problems occurring during birth. The family doctor should be informed of the death by telephone as soon as possible.

Parents should be encouraged to spend as much time as they want with their infant after death and should be supported by an experienced nurse or midwife. An infant with severe congenital anomalies can be suitably wrapped for the parents to cuddle. Many parents appreciate being able to see the anomalies with a supportive clinician present to discuss any questions they may have at the time. Other family members,

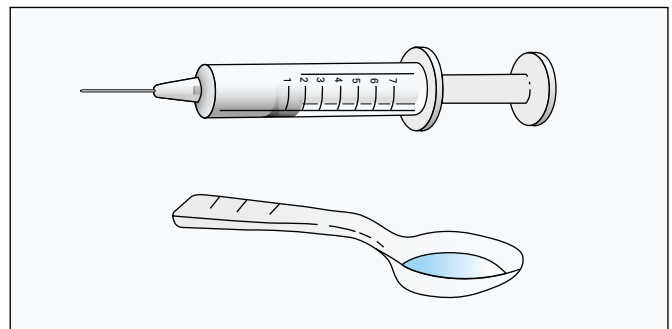

Figure 2.10 Vitamin K may be given intramuscularly or orally.

Figure 2.11 Discussion with parents.

Figure 2.12 Anencephaly.

including siblings and grandparents, should also be encouraged to see the dead infant over the next few hours or days. It is now clear that the grieving process is helped by family participation in seeing and cuddling their dead infant. Many parents also welcome the opportunity to participate in the care of their dead infant by bathing and dressing the infant in baby clothes of their choice with the assistance of a sympathetic and unhurried nurse. However, health professionals should also be aware that there may be cultural and religious differences that should be respected if parents decline involvement in such procedures after the death of their baby.

Photographs of the dead infant and the family group together with the infant should be encouraged. Photographs should be kept in a safe place if the family do not want to take them away with them immediately, and they may still request them, sometimes even many years later. Hand and footprints and a lock of hair can also be taken as lasting and tangible mementoes for the family.

Discussion with parents will help to decide who will be best able to help the grieving family. There may be a supportive network of family and friends and for some, religious advisers or bereavement counsellors may provide support. If the death occurs in hospital, the family doctor and health visitor should be informed as soon as possible as they will have an important role in supporting the bereaved family in the long term. Siblings should be able to see the dead baby with their parents and should be reassured that they are loved, safe, and not in any way to blame for the distress of the parents. Children can accept the death of a baby in a very matter of fact way if they are allowed to be involved and are not excluded from the family at the time of the death. Expert help is rarely necessary for siblings with whom there has been communication and involvement in a manner that is understandable to the child in the bereaved family.

The potential benefits of a postmortem examination should be discussed with the parents by a senior doctor, preferably a

consultant. The nature of the autopsy process should be explained in a sympathetic but factual manner and parents should be aware of the possibility of a limited examination of certain body cavities or organs if they do not want to contemplate a full examination. They should be made aware that the face of the baby will not usually be disfigured by the autopsy and that the body can be viewed again later, suitably clothed.

It is important that a health professional with knowledge of the local arrangements for the burial and cremation of infants is available to meet with the parents within a few days of the death in order to assist them to decide how they wish to proceed with funeral arrangements. Although there is a legal requirement to register the death of a baby within five working days of the death in the UK, the funeral does not have to take place immediately unless it is a requirement of the religious beliefs of the family. Some families prefer to take some time to decide about arrangements, particularly when the mother of the infant may not be able to be present immediately after a difficult birth.

A follow-up bereavement appointment should be arranged with the parents some weeks later. The results of the postmortem examination should be conveyed to them and they should be given the opportunity to ask questions about the illness and death of their infant. It is usually helpful to parents if the clinicians, including obstetricians or midwives who were present at the birth or involved in the care of the infant, can attend this bereavement discussion. An assessment of whether the family are likely to need expert help and support to progress with their bereavement can also be made at this time. Some parents may also find it helpful to talk to other bereaved families or voluntary organisations providing support, for example SANDS (Stillbirth and Neonatal Death Society).

3 Infants of low birthweight

Low birthweight infants weigh 2500 g or less at birth. Infants may be small at birth owing to a short gestation period (born too early) or because of a restricted growth rate. When the period of gestation is less than 37 completed weeks the infant is called preterm. A baby with restricted growth rate is “light for dates” or small for gestational age (SGA) and may be either malnourished or, rarely, hypoplastic (for example, an infant with a chromosome abnormality). Some babies who are preterm are also light for dates.

The length of gestation can be calculated from the first day of the mother’s last menstrual period, provided the periods are regular. The routine ultrasound examination carried out before 18 weeks is considered to be the most accurate method of assessing gestational age. Detecting restriction in growth of the fetus is difficult, but palpation of the fetus can be supplemented by serial ultrasound measurements of the fetal skull, abdominal girth, femur length and crown–rump length.

The gestational age of the infant can be assessed by a detailed neurological examination of the infant, as the development of the central nervous system is related to the gestational age. Scoring systems using both the neurological development and specific external features can be used to estimate the gestational age but require considerable experience for accuracy.

Most neonatal units consider that infants with a birthweight below the 10th centile for the gestational age are light for dates, although a more accurate definition is below the third centile with an adjustment for maternal size.

Ultrasound studies have shown that when intrauterine malnutrition starts early in pregnancy the head circumference and weight are in proportion with each other, but when malnutrition starts late in pregnancy the head is disproportionately large, owing to relatively normal growth of the brain.

The preterm infant is especially prone to developing hypothermia, the respiratory distress syndrome, infection, and intracranial haemorrhage. The light for dates infant is particularly prone to hypothermia, hypoglycaemia, and hypocalcaemia.

Temperature

Small infants become hypothermic quickly. Heat loss may be considerable because they have a large surface area in relation to body weight and they are also deficient in subcutaneous fat, which provides insulation. They also lack “brown fat”, which is usually present in a full term baby and can be metabolised rapidly to produce heat.

Hypothermia is associated with a raised metabolic rate and increased energy consumption. To prevent hypothermia small infants should be kept in a high constant environmental temperature. Excessive heat loss by radiation can be minimised by an additional tunnel of Perspex, a heat shield, placed immediately over an infant in an incubator. The dangers of hypothermia can be reduced by carrying out resuscitation under a heat lamp or radiation heat canopy, bearing in mind the danger of burns if the lamp is too close. When an infant is transferred from one hospital to another for special care, there is a danger of hypothermia. A swaddler made of aluminium foil has been designed to prevent this and is commercially available, but wrapping the baby with Gamgee wool is also satisfactory.

Figure 3.1 Growth chart showing birth weights of preterm and light for dates infants.

Figure 3.2 Open incubator with infant receiving artificial ventilation.

The portable incubator must be kept warm continuously and ready for immediate use.

Infection

A separate plastic apron or waterproof gown should be used for nursing each infant, mainly to prevent soiling the nurses' clothes.

Scrupulous washing of the hands should be carried out before and after touching each infant. Washing with soap and water is adequate, although many units use a disinfectant soap solution. Scrubbing with a brush is unnecessary. Although this principle is simple, it may be difficult to ensure that it is carried out. Proper use of elbow taps is often difficult because of their poor design. Using disposable plastic gloves when changing infants' napkins may reduce cross-infection.

Ideally, any infant who develops an infection should be barrier nursed in a separate cubicle.

Feeding

Preterm infants have poor sucking and cough reflexes and methods of feeding must prevent aspiration into the lungs. Infants who are not able to suck are given frequent tube feeds of small volumes or continuous intragastric feeds to avoid sudden falls in arterial oxygen concentrations and apnoeic attacks, which are associated with abdominal distension. Intravenous feeding with glucose amino acid solutions and lipids is used for infants who do not tolerate tube feeding, but a scrupulous aseptic technique in managing the solutions is necessary to avoid septicaemia.

Early feeding, within two hours of birth, prevents hypoglycaemia and reduces the maximum plasma bilirubin concentrations. Asymptomatic hypoglycaemia can be detected early by performing regular blood glucose measurements using a glucometer on all babies of low birthweight in the first 24 hours. If the infant is feeding well and the blood glucose level is consistently above 2.6 mmol/l, the tests are stopped after 24 hours. From the second week onwards vitamin supplements are added so that infants receive an additional dose of 400 units of vitamin D and 50 mg of vitamin C daily. Vitamin preparations usually contain small amounts of vitamin B complex and vitamin A. Vitamin supplements should be given until the age of two years and additional iron supplements until the age of six months.

The low birthweight infant at home

As more extremely low birthweight infants are surviving, community health professionals need to be aware of a few specific needs and problems of these infants in the first year of life.

Home oxygen

Infants who still require a small amount of oxygen but who are feeding and are otherwise well can often be cared for at home by their parents. The family doctor may be asked to prescribe an oxygen concentrator for use at home as the continuous provision of oxygen cylinders is impractical in the long term. A small portable cylinder which can be carried on a pram or pushchair will be useful to enable the infant to accompany the family on brief trips outside the home environment.

Figure 3.3 Light for dates: 1800 g at 40 weeks.

Figure 3.4 Closed incubator.

Figure 3.5 Hand washing prevents cross-infection.

Figure 3.6 Syringe pump for giving milk.

ABC of the First Year

A community neonatal or paediatric nurse will support the family at home and will monitor the oxygen saturation of the infant intermittently until no additional oxygen is required, sometimes weeks or even months after discharge from hospital. Family carers will have been taught basic life support by the community nurse.

Respiratory problems

Preterm infants, particularly those who have required artificial ventilation, have an increased risk of respiratory illnesses in the first year of life. Wheezing is common in association with viral infections, but only those infants with a strong family history of atopy have an increased incidence of asthma. Smoking should be strongly discouraged in homes where there is a preterm infant.

Immunisations

Routine immunisation with DTP triple vaccine, Hib, meningococcal C and oral polio vaccine can be commenced at two months after birth, irrespective of the gestational age of the infant. Even infants of very early gestation have been shown to mount an appropriate immune response to childhood vaccines. In practice, many preterm infants will still be in the neonatal unit at two months of age and some will have had their immunisations commenced before discharge from hospital. The administration of oral polio vaccine will be delayed by three months if intravenous immunoglobulin has been given to the infant at risk of serious infection.

Vitamins and iron supplementation

Preterm infants require vitamin A, B, C, and D supplementation until two years of age. Some extremely immature infants may also require additional phosphate for adequate bone mineralisation during the period of rapid growth in the first year of life.

Additional oral iron is usually given from four weeks to six months of age.

Growth and development

The growth and development of preterm infants born at <30 weeks gestation should be assessed according to their corrected age (chronological age – period of prematurity). Most will have caught up with their peers born at full term by around 18 months to two years of age. Some extremely low birthweight infants, particularly those born at <26 weeks gestation, remain <3rd centile in all growth parameters despite being otherwise healthy. Around 90% of infants <28 weeks gestation who survive to go home achieve normal developmental milestones for their corrected age, but many experience minor motor and educational difficulties by school age. Myopia is also common in children who were preterm.

4 Breathing difficulties in the newborn

Breathing difficulties in the newborn are called respiratory distress. One or more of the following features are present:

- respiratory rate over 60 per minute
- an expiratory grunt
- subcostal or intercostal recession or sternal retraction
- cyanosis.

Respiratory distress syndrome

The respiratory distress syndrome (hyaline membrane disease) is the commonest cause of respiratory problems in the newborn and a common cause of death in preterm infants. Cerebral ischaemia and haemorrhage or lung damage may occur in the acute phase and cause death or long term morbidity. Hypoxia before, during, or after birth is a predisposing factor.

The cause is a deficiency of pulmonary surfactant, a substance normally present on the alveolar walls. Surfactant lowers the surface tension in the alveoli so that during the first few breaths the same pressure is required to inflate them all. This produces uniform inflation of all alveoli. Surfactant also prevents the alveolar walls from collapsing during expiration. Without surfactant the surface tension is great in the smaller alveoli, causing them to collapse, while large alveoli continue to expand easily. Thus there is uneven expansion, with increasingly widespread alveolar collapse. Surfactant production in the fetal lung increases with gestational age and reaches adequate levels for normal lung function by about the 36th week. At 27–31 weeks 35–50% of all infants are affected by the respiratory distress syndrome. The use of antenatal steroids given to the mother has reduced this prevalence in infants of less than 34 weeks gestation.

Microscopy of postmortem specimens often shows the presence of amorphous material lining the terminal bronchioles and alveoli, which is called hyaline membrane. There are also multiple areas of alveolar collapse.

When animal surfactant extract or artificial surfactant is placed in the trachea at birth or during the first day of life, the severity and mortality of the respiratory distress syndrome are reduced. Supplementary surfactant has been shown to be effective in babies of more than 26 weeks of gestation. Supplementary surfactant is given at birth to all babies less than 30 weeks gestation and to more mature infants who have developed specific features of surfactant deficiency that suggest that the course of the disease will be of moderate or greater severity (rescue treatment).

Clinical features and general management

An expiratory grunt, a respiratory rate over 60 per minute, and recession of the chest wall begin within four hours of birth. Central cyanosis may appear later. Usually auscultation of the lungs reveals only reduced breath sounds, but crepitations may be present. The present approach to intensive care is to monitor the blood arterial oxygen, carbon dioxide, and pH levels from birth and to start treatment early. This may prevent the appearance of the features described above, especially

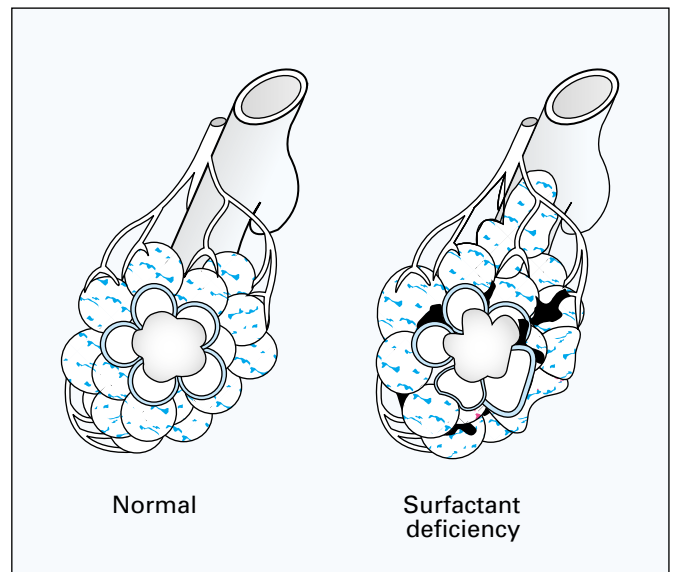

Figure 4.1 Cross-section of lungs showing uneven expansion with alveolar collapse in the surfactant deficient lung.

Figure 4.2 Arrow indicates hyaline membrane.

ABC of the First Year

where artificial ventilation is used electively from birth in infants weighing less than 1 kg.

In most infants the chest radiograph shows normal lung fields in the early stages of the disease, but later a fine reticular pattern or generalised loss of translucency (the ground glass appearance) may be present. The contrast between the air in the bronchi and the opaque lung fields produces an air bronchogram. The greatest value of the chest radiograph is in excluding other conditions (see below).

The object of management is to support infants until further surfactant is produced. Infants should be handled as little as possible, as their condition may deteriorate abruptly. Elective monitoring of blood oxygen saturation, heart rate, temperature and respiratory rate has reduced the need to handle the infant. Infants should be given oxygen, their arterial blood oxygen and carbon dioxide concentrations should be monitored, and body temperature, fluid, and electrolyte balance maintained.

Oxygen treatment and measurement

During oxygen treatment the arterial oxygen tension should not fall below 6.7 kPa (50 mmHg) or rise above 12 kPa (90 mmHg). Below 6.7 kPa the risk of cerebral palsy and mental retardation increases and above 12 kPa there is a possibility of retrolental fibroplasia and subsequent blindness. Some infants may need high concentrations of inhaled oxygen to prevent hypoxia. This can be given safely only if there are facilities for making frequent estimations of the blood oxygen concentrations.

The ideal arterial carbon dioxide level is 5–7 kPa (37.5–52 mmHg). Lower carbon dioxide levels may cause cerebral artery constriction and reduce cerebral blood flow. Higher carbon dioxide levels may lead to cerebral artery dilatation followed by systemic hypotension or intraventricular haemorrhage.

There are several methods of measuring oxygen concentrations in the blood. Firstly, samples can be taken from an umbilical artery catheter at regular intervals or they can be obtained by repeated puncture of one of the radial arteries.

Secondly, an oxygen sensitive electrode implanted into the tip of an umbilical artery catheter measures oxygen levels continuously, but the electrode must be calibrated at regular intervals with samples of blood aspirated through the lumen of the same catheter.

Thirdly, a heated transcutaneous oxygen and carbon dioxide electrode increases the blood flow to the skin, where the gas tensions are measured. The electrode must be moved every four hours to avoid burns. The method is not invasive and the electrode is calibrated with a gas mixture. The levels shown by the transcutaneous electrode must be compared with levels estimated in arterial blood at regular intervals. The blood samples are also used to measure pH, bicarbonate, and base deficit.

Artificial ventilation

Results of artificial ventilation have improved considerably and deaths are now usually due to complications rather than respiratory failure. Respiratory tract infection and displacement of the endotracheal tube are constant hazards and this form of treatment can only be undertaken where there are adequate nursing and medical staff and enough patients for an effective service to be provided.

Box 4.1 Management

- Arterial oxygen
- Carbon dioxide
- pH
- Blood pressure
- Plasma, Na, K, creatinine

Figure 4.3 Intensive care in a closed incubator.

Figure 4.4 Blood oxygen analyser.

Figure 4.5 Ventilator.

Positive pressure ventilation is needed if one of the following is present:

- failure to establish effective spontaneous respiration at birth
- recurrent apnoeic attacks
- arterial oxygen tension (PaO_2) less than 7 kPa in 60% oxygen
- arterial carbon dioxide tension (PaCO_2) more than 7 kPa
- rapid deterioration in blood gas values associated with clinical deterioration.

Other aspects of treatment

Incubators are used to improve observation and to provide warmth and humidified air. There are two types: the conventional incubator and an open type. A perspex head box can be used to maintain an oxygen concentration above that in the air.

Adequate fluids and electrolytes must be given. The methods will vary with the severity of the respiratory problem. Milk can be given by continuous gastric infusion. Alternatively, small volumes of milk can be given intermittently at frequent intervals. Some infants need intravenous fluids which may include total parenteral nutrition (TPN) which contains glucose, amino acids, lipids, and vitamins.

The group B *Streptococcus* may produce a clinical picture similar to that of respiratory distress syndrome and infants with the respiratory distress syndrome are given antibiotics to cover this possibility. Intravenous antibiotics must be given until blood culture results are known, as the syndrome cannot be differentiated from group B streptococcal pneumonia in the early stages.

Complications

A pneumothorax should be suspected in any infant who deteriorates rapidly for no obvious reason. The diagnosis may be confirmed quickly by transilluminating each side of the chest with a powerful fibreoptic light source. A chest radiograph can be used to confirm the condition, but if symptoms are severe the pneumothorax can be drained before the radiograph has been obtained. A disposable cannula is inserted into the pleural space and connected to an under water seal. Pneumothorax may also follow intermittent positive pressure ventilation during resuscitation of the newborn or it may occur as a result of the initial vigorous spontaneous respiratory efforts of a normal infant.

Cerebral lesions

Periventricular haemorrhage is the most common form of haemorrhage in the newborn infant. Advances in neonatal care have led to increased survival of preterm infants who are susceptible to periventricular haemorrhage. When ultrasound scans have been performed routinely within the first few days of life about 10% of infants with a birthweight less than 1500 g have evidence of periventricular haemorrhage. The majority of these haemorrhages are small and localised and they are associated with a good prognosis but early mortality is high and long term handicap is common in infants with extensive haemorrhages. These haemorrhages originate in the subependymal germinal matrix and may spread to involve the ventricular system or may extend into the cerebral parenchyma adjacent to the lateral ventricle. Most of the infants with

Figure 4.6 Pneumothorax.

Figure 4.7 Arrow shows intraventricular haemorrhage.

Figure 4.8 Arrow indicates periventricular leucomalacia.

periventricular haemorrhage have no specific symptoms but some have recurrent apnoeic attacks, impaired spontaneous limb movements, and hypotonia or sudden severe clinical deterioration.

Periventricular leucomalacia is considered to be related to hypoxia and ischaemia of the brain. Small cysts are shown in the periventricular region in ultrasound scans of the brain taken after the third week of life. These lesions are associated with later major handicaps such as cerebral palsy, blindness, or deafness.

About 15% of infants who survive the neonatal period have some degree of developmental problem but about 7% have a severe problem.

Bronchopulmonary dysplasia

This is a chronic respiratory disease occurring in preterm babies who are very preterm or have needed artificial ventilation. The causes include inflammation, barotrauma from artificial ventilation, recurrent aspiration of milk or postnatal infection. The infant requires increased inflation pressures or ambient oxygen concentrations as coarse streaking and areas of hyperinflation appear on the chest radiograph after the first two or three weeks of life. After weaning from the ventilator, supplementary oxygen is often required for several months and those with severe disease die usually about the third month of life. The survivors have a high prevalence of recurrent episodes of wheezing but usually have no further clinical respiratory symptoms after about 18 months of age. The duration of oxygen dependency may be reduced by dexamethasone but further studies are needed to determine the optimal time to start it. A transcutaneous oxygen saturation monitor is used to monitor the oxygen requirement and to assess the effects of treatment.

Figure 4.9 Bronchopulmonary dysplasia.

Other causes of respiratory problems

The main causes are pulmonary, cardiac, and central nervous system disorders.

Transient tachypnoea of the newborn is found in full term infants after a short labour or elective caesarean section, before or at term. It can occur in preterm infants but there may be difficulty in distinguishing it from mild respiratory distress syndrome. Transient tachypnoea usually resolves within 48 hours. The chest radiograph often shows a streaky appearance of the lung fields but may be normal. This syndrome may be due to failure of normal reabsorption of the lung fluid at birth or it may be a mild form of respiratory distress syndrome.

Diaphragmatic hernia may present with difficulty in resuscitating the baby or with a raised respiratory rate and an apex beat on the right side. The hernia is most commonly left sided and the heart is often displaced to the right. Most diaphragmatic hernias are detected by antenatal ultrasound scans. The diagnosis is confirmed by a chest radiograph that shows loops of small gut or solid organs in the thorax. It may take 12 hours from birth for air to reach the colon and produce the characteristic radiographic appearances.

The first symptoms of *congenital heart disease* are often noticed by the nurse or mother when the infant has dyspnoea during feeding or is reluctant to feed. There may be no murmurs with some lesions. The respiratory rate is raised and there may be recession of the chest wall. Excessive weight gain and enlargement of the liver are early confirmatory signs. The edge of the liver is normally about 2 cm below the costal margin in the right midclavicular line in the full term newborn.

Figure 4.10 Diaphragmatic hernia.

Pneumonia may occur if there has been rupture of the membranes for longer than 24 hours: the infant may inhale infected liquor before birth and so develop pneumonia. If the mother has had ruptured membranes for over 24 hours before delivery antibiotics should be considered for the mother to prevent or treat pneumonia in the fetus.

Group B streptococcal infection may present with a raised respiratory rate and a chest radiograph may show extensive areas of consolidation in both lungs or may appear normal.

Meconium aspiration usually occurs in an infant who has become hypoxic before delivery. The infant may start respiratory movements before the mouth and pharynx have been cleared. Aspiration of meconium may cause bronchial obstruction, secondary collapse, and subsequent infection of the distal segments of the lungs. Oxygen and antibiotics are often needed and mechanical ventilation may be required for a few days.

Preterm infants have a poor cough reflex and material such as regurgitated milk in the pharynx is easily aspirated into the lungs and may cause pneumonia. Signs may be minimal and are often limited to a small increase in respiratory rate, but a chest radiograph may show extensive changes.

Severe anaemia may cause a raised respiratory rate with a metabolic acidosis.

Choanal atresia or stenosis – a congenital posterior nasal obstruction makes it difficult for newborn infants to breathe, as they depend on a clear nasal airway. An oropharyngeal airway produces immediate improvement and an ENT surgeon should be consulted. The diagnosis can be confirmed quickly by noting the absence of movement of a wisp of cotton wool placed just below the nares.

Apnoea

Apnoeic attacks are defined as episodes of cessation of respiratory movements for more than 10 seconds. They may be due to cerebral hypoxia during the perinatal period, hypoxaemia due to the respiratory distress syndrome, hypoglycaemia, or meningitis. An ultrasound scan of the brain may help in determining the presence and site of any intracranial haemorrhage.

Morphine or pethidine given to the mother before delivery may cause apnoea in the newborn (see p. 6).

Recurrent apnoeic episodes are common in preterm infants of less than 32 weeks gestation. The babies are otherwise well and the episodes start when the infants are a few days old. The apnoea may be accompanied by bradycardia and a fall in oxygen saturation levels. Recent research suggests that some episodes are of central and others of laryngeal origin. The diagnosis of apnoea of prematurity can be made only after excluding other causes; which are:

- pulmonary disease
- airway obstruction, for example due to aspiration of feeds
- hypoglycaemia
- hypocalcaemia
- intracranial haemorrhage
- convulsions, which may be misdiagnosed as apnoea
- cardiac disease.

Several attacks may occur daily for the first month of life. These may be difficult to manage and may be followed by cerebral palsy at a later date if the episodes are prolonged. The various forms of treatment include stimulation of a limb during attacks or prophylaxis with oral caffeine or continuous positive airways pressure.

5 Birth trauma

Cephalhaematoma

Cephalhaematoma is a subperiosteal haemorrhage that is limited by surrounding sutures. In most cases there is probably a hairline fracture of the underlying cranial bone, which may be difficult to demonstrate but is unimportant since it affects only the outer table. There is usually no brain damage. A surprisingly large amount of blood may be present and blood transfusion is occasionally required. The lesion may not be noticed until the third day.

During resolution a calcified rim may appear, which wrongly suggests a depressed fracture, or there may be a hard swelling that takes several months to disappear.

Cephalhaematoma must be distinguished from caput succedaneum, which is a soft tissue swelling due to oedema of the part of the head presenting at the cervix and which is not limited by the sutures.

Vacuum extraction injuries

Vacuum extraction is often associated with a “chignon”, which is subcutaneous oedema where the cap has been applied. In some cases a large haematoma may form and occasionally the skin becomes necrotic. Nevertheless, the skin grows rapidly from the borders to cover the area within a few weeks.

Reduced arm movements

Fractures of the clavicle or humerus and stretching of the brachial plexus present as lack of spontaneous movement and an absent Moro reflex in the arm on that side. The clavicle and humerus should be radiographed. Fracture of the clavicle needs no treatment, but if the humerus is fractured the arm should be splinted to the infant’s body with a crêpe bandage. Injuries to the brachial plexus (Erb’s palsy) will be recognised as lack of spontaneous movement of the shoulder and arm with the hand held in dorsiflexion at the wrist (waiter’s tip position). Movements of the fingers are associated with good long term prognosis with spontaneous resolution. Early referral to a physiotherapist and orthopaedic surgeon is advised as injuries to the brachial plexus sometimes have a poor prognosis. Diaphragmatic paralysis often accompanies stretching of the brachial plexus and may cause a raised respiratory rate. Another condition that may be mistaken for injury of the brachial plexus is temporary paralysis of the dorsiflexors of the wrist caused by pressure on the radial nerve in the radial groove of the humerus. A fracture of the humerus may injure the radial nerve at this site.

Intracranial injuries

When the fetal head is large in relation to the pelvic outlet or delivery is precipitate or by the breech, there is a risk of extracerebral haemorrhage due to laceration of the tentorium cerebelli or falx cerebri affecting a venous sinus.

Infants may be unduly lethargic or especially irritable shortly after birth and there are usually no helpful confirmatory signs then. Later there may be pallor, a high pitched cry, poor muscle tone or increased tone, convulsions,

Figure 5.1 Cephalhaematoma.

Figure 5.2 Chignon.

Figure 5.3 Three sites of injury causing reduced arm movements.

reluctance to suck, vomiting, or apnoeic attacks, and fast or periodic breathing. Rarely the tension of the anterior fontanelle is raised, the heart rate is slow, or the pupils fail to react to light. A blood glucose test should be performed to exclude hypoglycaemia, a plasma calcium concentration estimated, and a lumbar puncture considered to exclude meningitis.

Infants should be nursed in an incubator for easy observation but if they weigh over 3000 g, the thermostat should be turned to the minimum level. This type of haemorrhage is now rare. The prognosis is poor.

Other conditions

A sternomastoid "tumour" is not noticeable at birth but usually presents after the first week. A firm mass, 1–2 cm in diameter, is usually found in the middle or lower third of the sternomastoid muscle but it may be anywhere along its length. It will disappear within a year and usually the infant will then be perfectly normal. The mother is taught by a physiotherapist to move the infant's head passively through the whole range of normal movements daily until the lesion resolves. Without treatment about 10% of the infants develop torticollis in the second year of life and a further 10% when they are over five years old.

Subconjunctival haemorrhages, like petechiae on the head and neck, are common and unimportant. But if there are petechiae on the trunk further investigations are indicated.

Subcutaneous fat necrosis produces a firm subcutaneous area at the site of pressure, especially of the obstetric forceps. It may be red and tender. No treatment is needed. If the site is unusual and the swelling not noticed until a few days after birth, the area of necrosis may be confused with a pyogenic abscess.

Pressure on the facial nerve before birth or from obstetric forceps may cause a transient palsy which lasts up to two weeks. Care of the exposed cornea is essential.

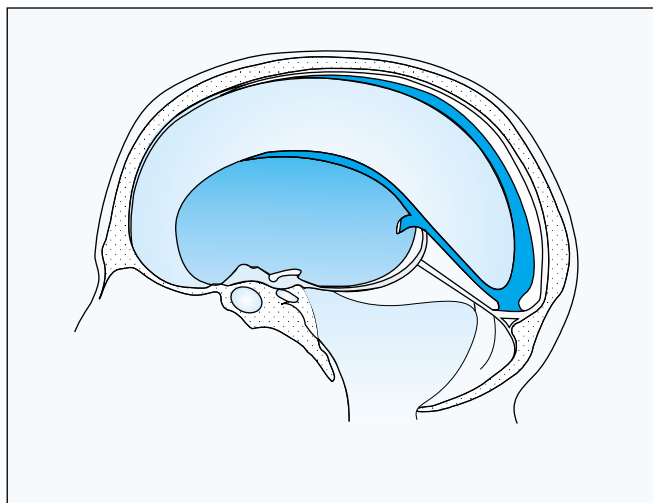

Figure 5.4 Extracerebral haemorrhage may be due to laceration of a venous sinus.

Figure 5.5 Facial palsy.

6 Some congenital abnormalities

Myelomeningocele

A myelomeningocele is a flat or raised neural plaque partly devoid of skin in the midline over the spine due to abnormal development of the spinal cord and associated deficiency of the dorsal laminae and spines of the vertebrae. It is usually found in the lumbar region. The absence of the various coverings that normally protect the cord allows meningitis to occur easily. If there are no active movements in the legs and the anus is patulous, the infant will probably be incontinent of urine and faeces for life and never be able to walk unaided. Thoracic lesions and kyphosis are signs of poor prognosis.

Infants with a good prognosis need urgent treatment, so all affected infants should either be seen by a consultant paediatrician without delay or sent to a special centre, where selection for surgery can be made. About 30% of the infants have surgery as a result of this policy. During the first operation the lesion on the back is covered by skin.

Most of these infants develop progressive hydrocephalus later and those considered suitable for surgery require insertion of a catheter with a valve from a cerebral ventricle to the peritoneal cavity to reduce the cerebrospinal fluid pressure.

Hydrocephalus can be detected by ultrasound examination of the brain. Serial measurements show whether ventricular size is increasing rapidly. In addition, progressive hydrocephalus is confirmed by measuring the circumference of the head at its largest circumference (occipitofrontal) every three days with a disposable paper tape measure, plotting these values on a growth chart, and showing that the head is growing faster than normal.

Raised concentrations of α -fetoprotein are found in the amniotic fluid when the fetus has an open myelomeningocele or anencephaly. In anencephaly there is absence of the cranial vault and most of the brain.

A routine anomaly scan at 18–24 weeks of gestation will detect most neural tube defects and the parents may decide that the pregnancy should be terminated in view of the poor prognosis. Anencephaly is a lethal condition but some infants survive for a few hours or days after birth.

Microcephaly

The signs of microcephaly are a small head and forehead that is particularly small in relation to the face. The diagnosis is confirmed by showing a small head circumference in relation to the baby's weight and gestational age. It is usually associated with mental impairment. Other congenital abnormalities may be present. Evidence of an intrauterine infection such as toxoplasmosis should be sought and the parents should receive accurate genetic counselling. The diagnosis may be difficult at birth but the increasing discrepancy between the head circumference centile and the weight and length centiles with developmental delay clarifies the diagnosis.

Cleft lip and palate

Mothers are often severely disturbed by the appearance of these infants and may be reassured by seeing photographs of similar patients before and after their repair operations. Cleft lip and cleft palate are often associated. A cleft lip, caused by

Figure 6.1 Myelomeningocele.

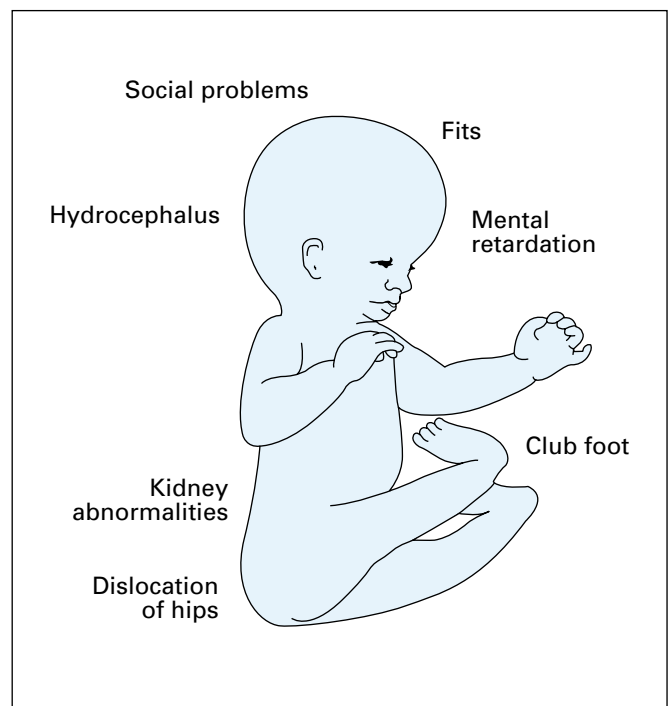

Figure 6.2 Associated features of myelomeningocele.

failure of the maxillary process growing towards the midline to fuse with the premaxilla, may be unilateral or bilateral. Minor degrees of cleft palate may be easily missed if the posterior part of the palate is not seen and palpated. Most of these infants feed normally from the breast or bottle. If there are feeding difficulties, a special teat, a large normal teat, a special spade-like spoon, or an ordinary spoon may be tried. The lip is usually repaired at three months and the palate by the age of a year. The value of an obturator before operative closure of the palate is controversial. If an obturator is needed, it should be made and fitted within 24 hours of birth. Despite excellent operative results these children are prone to recurrent otitis media and problems with speech development.

Figure 6.3 Cleft lip and palate.

Figure 6.4 Same patient after operation.

Umbilical hernia

An umbilical hernia, usually containing omentum and gut, is most common in African infants or West Indians of African descent. About 30% of preterm infants who have received mechanical ventilation have an umbilical hernia. No treatment is needed, as the hernia usually disappears spontaneously by the age of three years, although in West Indian infants it may take a further three years.

In contrast to an umbilical hernia the sac of an omphalocele is covered by peritoneum but incompletely by skin. An omphalocele is a hernia into the base of the umbilical cord and contains gut and sometimes solid organs like the liver. Immediate transfer to a surgical unit is needed.

Oesophageal atresia

Oesophageal atresia will be suspected in any newborn baby who has a continual accumulation of frothy secretions in the mouth with drooling, sometimes with cyanotic attacks.

The diagnosis of oesophageal atresia is confirmed by attempting to pass a tube down the oesophagus. The tube should have a relatively wide lumen (FG 10), must be stiff enough to prevent coiling in the upper oesophageal pouch, and should have a radio-opaque line so that the position can be checked by a chest radiograph. The tube should be aspirated every few minutes to keep the upper pouch clear until the infant reaches a specialised surgical unit.

Oesophageal atresia will be suspected antenatally if there is polyhydramnios and difficulty in detecting a normal stomach bubble at the routine 18–24 weeks anomaly scan.

Figure 6.5 Umbilical hernia.

Figure 6.6 Oesophageal atresia.

Multiple abnormalities

Infants with multiple abnormalities should be examined and investigated by a paediatrician without delay to ensure correct management of the infant and to provide the information needed for genetic counselling. Some of the infants may have a recognisable syndrome and the investigations may show a chromosomal defect or evidence of intrauterine infection.

The most common problem is the infant with possible Down's syndrome (mongolism). Although a scoring system for a large number of clinical features has been used in the past, any infant with suspected Down's syndrome should have a blood chromosome analysis performed.

The most useful features suggesting the diagnosis are the facial appearance with palpebral fissures that slant upwards and outwards, prominent epicanthic folds, baggy cheeks, and white spots on the iris. A flat occiput, poor limb tone, and single palmar crease are suggestive but not specific signs. About 2% of normal infants have a single palmar crease in one hand and prominent epicanthic folds are even more common. If the infant has congenital heart disease, it may be detected by performing an ultrasound study, as a definite murmur may not be present until several weeks after birth. All infants with Down's syndrome have developmental delay, but it may be possible to reduce maternal depression and increase the infant's drive and ability to learn by introducing the parents to an occupational therapist in the neonatal period.

Figure 6.7 Down's syndrome.

7 Routine examination of the newborn

Immediately after birth all infants should be examined for the presence of gross congenital abnormalities or evidence of birth trauma. Later, preferably on the morning after delivery, every infant should be examined again in detail. The obstetric notes should be checked to determine whether the infant has been at special risk – for example, from maternal rubella or a difficult delivery. A systematic approach should be used so that abnormalities are not missed. The infant must be completely undressed and in a good light. The mother should be present during the examination so that the results of the examination can be discussed with her and so that she can voice her anxieties.

Skin

Diffuse capillary naevi on the face, eyelids, or occiput are common and resolve within a few months.

The “strawberry mark” starts as a tiny red spot and grows rapidly for several weeks until it has a raised red appearance with small white areas, suggesting the seeds of a strawberry. Such marks are common in preterm babies. They may occur anywhere on the body but cause no symptoms, except on the eyelids, where they may prevent easy opening of the eyes and need treatment. Strawberry naevi grow, often rapidly, for 3–9 months, but at least 90% resolve spontaneously, either completely or partially. Resolution usually begins at 6–12 months and is complete in half the children by the age of five and in 70% by the age of seven years. In 80% of cases these naevi resolve completely without trace.

The port wine stain is not raised and may be extensive. It does not resolve, but the skin texture remains normal. When the naevus occurs in the distribution of the trigeminal nerve, there may be an associated intracranial vascular anomaly.

Neonatal erythema (erythema “toxicum”) consists of blotchy ill defined areas of bright erythema surrounding white or yellow wheals which may resemble septic spots. It usually appears on the second day of life and in most infants clears within 48 hours. The lesions contain many eosinophils and have no pathological importance. Neonatal erythema is more common in full term infants. By ringing individual lesions with a skin pencil they can be shown to disappear in a few hours, to be replaced by others elsewhere. This contrasts with septic lesions, which appear later and do not resolve so quickly.

Mongolian blue spots are patchy accumulations of pigment, especially over the buttocks and lower back in infants of races with pigmented skins. They are common in babies of African or Mongolian descent, but also occur in Italian and Greek babies. They may be mistaken for bruises and a wrong diagnosis of non-accidental injury made. They become less obvious as the skin darkens.

A midline pit over the spine is most commonly found over the coccyx, where it does not usually communicate with the spinal canal. A midline pit anywhere else along the spine may be connected with an underlying sinus, which may communicate with the spinal canal and requires excision to prevent the entry of bacteria and meningitis.

Head and neck

An infant with the Pierre Robin syndrome has a small lower jaw, glossoptosis, and cleft palate. The infant must be nursed prone to prevent his tongue falling backwards and occluding

Figure 7.1 Strawberry naevus.

Figure 7.2 Port wine stain.

Figure 7.3 Neonatal erythema.

Figure 7.4 Pierre Robin syndrome.

the airway. A small jaw may occur alone or with other abnormalities. As the child grows the small size of the lower jaw becomes less obvious.

Nodules of epithelial cells resembling pearls (Epstein's pearls) just lateral to the midline on the hard palate are a normal finding. A cluster of these pearls is present at the junction of the hard and soft palates.

Heart murmurs

In the first two days of life one of the most common problems is an infant who is feeding normally but is found to have a short systolic murmur during a routine examination. The murmur is usually due to a patent ductus arteriosus and has usually disappeared by the time the infant is examined again at seven days. An electrocardiogram (ECG) or chest radiograph is unnecessary.

If a long murmur is first heard around the eighth day of life, a chest radiograph, ECG, and echocardiogram should be performed and the infant seen by a paediatrician. Most of these murmurs are due to a ventricular septal defect or mild pulmonary stenosis with no symptoms. Most of the ventricular septal defects (VSD) close spontaneously before the infant reaches the age of five years.

The normal respiratory rate at rest is less than 60/min and there should be no recession of the chest wall or below the mandible. If there is any murmur and the infant is feeding poorly or has a respiratory rate faster than 60/min at rest, a chest radiograph and ECG should be performed and the baby seen by a paediatrician urgently. These symptoms and signs indicate congestive heart failure usually due to multiple heart defects.

Cyanosis of the hands and feet is common in newborn infants and has no importance if the tongue is of normal colour and the infant is feeding normally.

Abdomen

The liver edge is normally 1–2 cm below the costal margin in the midclavicular line. In a thin, relaxed infant the kidneys may be palpable bimanually.

The inguinal areas are inspected for the presence of a hernia. Absence of the femoral pulses suggests that coarctation of the aorta is present. The blood pressure is measured in all four limbs and the advice of a cardiologist is obtained urgently.

Failure to pass urine in the first 36 hours or a poor urinary stream suggests posterior urethral valves in a boy. An enlarged bladder may be palpable. Diagnosis is confirmed by an ultrasound examination, which may show hydronephrosis, and cystourethrogram.

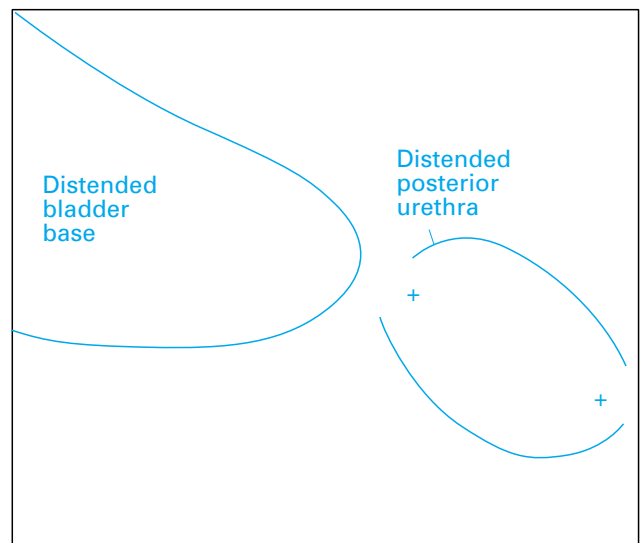

Patency of the anus is confirmed by inspection.

Figure 7.5 Echocardiogram showing ventricular septal defect (VSD).

(a)

(b)

Figure 7.6 Ultrasound scan (a) and diagram (b) showing distended bladder and distended posterior urethra due to urethral valves.

Genitalia

The foreskin is attached to the penis at birth and no attempt should be made to retract it.

A hooded prepuce suggests hypospadias with the urethral orifice at the base of the glans penis. If the urethral meatus is adequate, no immediate treatment is needed, but the infant must not be circumcised and should be referred to the paediatric urologist's next clinic.

If the urethral orifice is nearer the perineum, the adrenogenital syndrome should be considered. In the adrenogenital syndrome cortisol secretion fails and the adrenals produce excessive androgen. Girls become virilised, with enlargement of the clitoris and fusion of the labia, and may be mistaken for boys (see p. 52). In boys the genitalia are normal.

Intersex is a less common cause of ambiguity of the external genitalia and a paediatrician should be consulted without delay. An accurate diagnosis is an emotional and social emergency. The parents should be advised that the baby should not be named until the results of chromosome studies are available.

Small hydrocoeles usually disappear spontaneously during the first month but an associated inguinal hernia should be sought.

Poor development of the scrotum suggests that an undescended testis is present. Undescended testis is especially common in preterm infants, in whom the testes usually descend during the first three months after birth. An undescended testis is present in 30% of preterm and 3% of term infants at birth. An infant with an undescended testis should be seen again at the age of three months. At that time 5% of preterm infants and 1% of term babies will still have an undescended testis and they should be referred for surgery, which is performed at about the age of two years. If the baby develops an associated hernia, the operation will be needed as an emergency.

As the cremasteric reflex is usually absent at birth, the testis cannot be retractile. If there is any doubt about whether a testis is descended the examiner should (a) palpate the pubic tubercle with one hand, (b) hold the testis between the thumb and forefinger of the other hand and gently draw it down to its fullest extent then (c) measure the distance from the pubic tubercle to the centre of the firm globular testis. At term the testis, if fully descended, lies 4–7 cm from the tubercle. If the distance is under 4 cm the testis has not completely descended. In preterm babies, who are more likely to have undescended testes and whose testes are smaller, 2.5 cm has been arbitrarily chosen to divide descent from non-descent.

Spontaneous primary descent of the testes rarely occurs after the age of four months and never after one year. After the neonatal period an active cremasteric reflex can easily pull the testis out of the scrotum, especially if the examiner's hands are cold. The mother will often have noted whether the testes are both in the scrotum after a hot bath, and a retractile testis will descend into the scrotum when the thigh and knee are maximally flexed on that side.

In girls a small amount of vaginal bleeding is common, usually five to seven days after birth, and follows withdrawal of maternal or placental oestrogens, which are transmitted to the fetus before birth. White vaginal discharge or prolapse of the vaginal mucosa is normal.

In either sex physiological enlargement of the breast may occur towards the end of the first week. This enlargement, which may be unilateral, resolves within a few weeks, but if there is local redness, a breast abscess should be suspected.

Figure 7.7 Hypospadias.

Figure 7.8 Measurement of testicular descent.

Figure 7.9 Flexion of thigh and knee to determine testicular descent.

Figure 7.10 Prolapse of the vaginal mucosa.

Circumcision

In 95% of babies the foreskin and glans of the penis are still united at birth. It has been found that the foreskin can be retracted by the age of one year in about half the babies and by the age of three years in nine out of ten. But no attempt should be made to retract the foreskin until the baby is about four years old. Attempts to retract the foreskin earlier are likely to injure the mucosa, causing bleeding followed by adhesions, and circumcision may later become necessary. Mothers often request circumcision to be carried out because the prepuce orifice appears small. In most cases the adequacy of the orifice can be shown by gently stretching the foreskin *distally* and no attempt should be made to retract the foreskin. Before the age of four years the only medical indications for circumcision are recurrent purulent balanitis and ballooning of the foreskin at the beginning of micturition.

Most circumcisions are performed as a religious ritual, in Jewish families on the eighth day of life and in Muslim boys between the ages of three and 15 years.

Figure 7.11 Stretching foreskin distally.

(a)

Figure 7.12 (a) Postural.

(b)

Figure 7.12 (b) Structural.

Club foot and extra digits

Muscular imbalance due to the posture of the infant's feet *in utero* is the commonest cause of club foot. In postural club foot it should be possible to dorsiflex the foot fully and to obtain passive inversion to 90°. The mother should be taught to manipulate the foot through the whole range of movements after each feed for several days after birth, although the shape usually reverts to normal within a few weeks even without treatment. In contrast, in structural club foot the range of passive movements is restricted and orthopaedic advice on strapping, manipulation, or serial plasters is needed within 24 hours of birth.

To detect extra digits, the digits should be counted with the infant's palms open, or an extra thumb may be missed. Polydactyly requires the advice of a plastic surgeon to determine which digit should be removed at the age of 3–4 years for the best functional results. Extra fingers and toes are often familial and vary from an apparently normal digit to a skin tag. The latter can be tied off with a sterile silk thread and will separate by aseptic necrosis.

Central nervous system and eyes

To assess the central nervous system the alertness of the infant and the symmetry of spontaneous movements should be noted. The tension of the anterior fontanelle and the width of the fontanelle should be palpated while the infant is at rest and the head circumference should be measured. A more detailed

Figure 7.13 Extra thumb.

Figure 7.14 Eyes open when the infant is held over the mother's shoulder.

neurological examination is not required unless there is a special indication.

Babies will open their eyes when being fed or when held upright over their mother's shoulder. Babies will follow the movements of an examiner's face provided that the distance is 50 cm or more. The pupils of every baby should be examined with an ophthalmoscope at a distance of 50 cm. A bright red glow is seen, which is a reflection of light from the back of the retina. Absence of this "red reflex" is found in congenital cataract, which produces a dull grey appearance.

Watering eye

If there is persistent watering of the eye with clear fluid, the tear duct is probably blocked. No action is required until at least the age of one year, when the infant can be referred to an ophthalmic surgeon.

Rarely, the tear duct is probed, but most ophthalmic surgeons prefer to take no action because the condition resolves spontaneously in virtually all infants and probing may induce fibrosis of the tear duct. If there is repeated or persistent purulent discharge, the possibility of chlamydia infection should be considered and arrangements made with the laboratory for specimens to be taken.

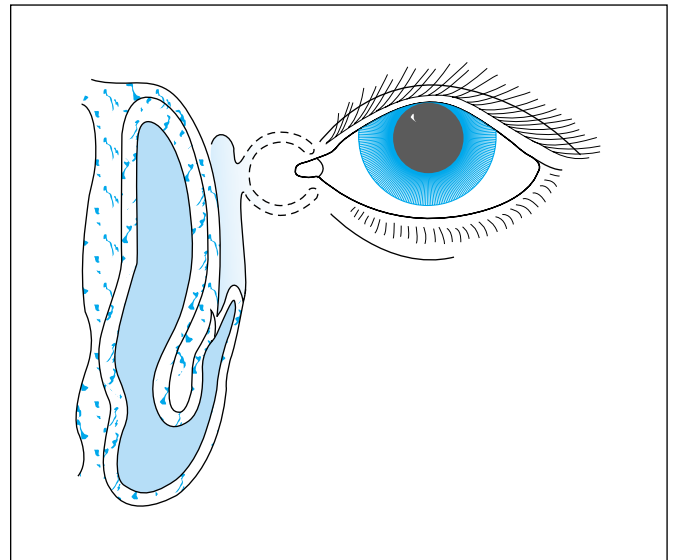

Figure 7.15 Tear duct.

Taking blood

Capillary blood taken from infants aged up to two years can be used for a variety of tests. The commonest is the Guthrie test, but capillary blood may also be used for blood glucose testing, haemoglobin estimations, and most biochemical tests.

The best site for taking capillary blood from an infant aged under six months is the heel. In older infants the thumb is a better site. The heel must be warm. If it is cold, the infant's foot should be dipped into hand hot water (40°C) for five minutes and dried thoroughly. The examiner then holds the infant's foot by encircling the ball of the heel with thumb and forefinger. The site selected for the heel prick must be on the side of the heel; if the ball or back of the heel is used a painful ulcer may form.

The site is wiped with isopropyl alcohol and allowed to dry. A spring loaded lancet introducer is used.

The initial drop of blood should be wiped away with a dry cotton swab and succeeding drops allowed to drip into the container, onto the Guthrie test card or onto the end of a glucometer strip. To milk blood into the heel the examiner should squeeze and release the fingers around the infant's calf and keep the heel below the rest of the leg. Up to 2 ml of blood can be obtained. When the required volume has been obtained, the heel is wiped and the wound pressed with a clean cotton wool ball. A small plaster should then be applied.

Figure 7.16 Holding foot for taking blood.

Phenylketonuria and hypothyroidism

The Guthrie test detects high blood concentrations of phenylalanine, which indicate that the infant probably has phenylketonuria. Drops of blood are taken by heel prick after six days' breast or bottle feeding (usually the seventh day of life) and placed on the special absorbent card provided. The blood is usually taken by the midwife if the infant is at home on the seventh day. If the test is positive, the infant should be admitted to hospital to confirm the diagnosis, as he or she may need a special low phenylalanine diet to prevent brain damage.

Figure 7.17 Sites for insertion of lancet.

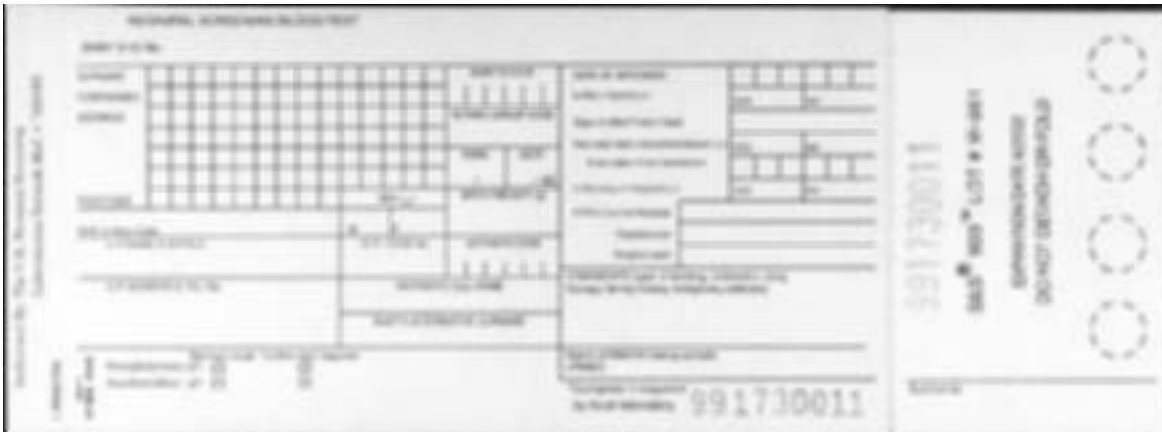

Figure 7.18 Screening blood card.

A capillary tube of blood can be used (for the Scriver test) instead of the dried blood spot.

Some laboratories use the plasma thyroid stimulating hormone and others the plasma thyroxine value as the screening test for hypothyroidism. The screening blood card is used for both the Guthrie test and the test for hypothyroidism.

Talking to parents

Whenever possible both parents should be seen together. If an abnormality is found during the routine examination some indication must be given to the mother so that arrangements can be made to see both parents. Particularly if the problem is likely to be long term, the doctor who will continue the long term care should speak to the parents initially. Ideally, a nurse should be present as well since the parents will probably ask all the questions again as soon as the doctor has left.

The diagnosis should be explained in terms that the parents can understand and the positive aspects should be emphasised. For example, if the probable diagnosis is ventricular septal defect, it is not necessary to explain that there is a remote possibility of multiple cardiac defects. After a difficult forceps delivery it is better to say that most babies develop normally rather than say they may be slightly backward. An unnecessarily pessimistic prognosis based on out of date information may alter a mother's attitude towards her baby and impair her attachment to him or her.

In discussing management the help and support that will be given by social workers or physiotherapists should be emphasised and the parents advised to tell their relations and friends the diagnosis rather than hide it.

A doctor with only limited experience of a particular problem should tell the parents that he or she needs to seek further advice rather than guess at the answer. Parents often cling to the first opinion and may find it difficult to accept a more experienced view later. A statement of the facts – for example, that there is an abnormality of the spine – may be given with the assurance that a more experienced doctor will discuss them later.

Useful advice for new mothers

Sleeping position of infants

It is recommended that babies should be placed on their back to sleep as this has been shown to reduce the risk of cot death.

Figure 7.19 Talking to parents.

Figure 7.20 Position for sleeping.

Healthy babies placed on their backs are not more likely to choke if they vomit. The mattress used in a baby's cot should be firm, flat, clean, and covered in waterproof material like PVC. Pillows should not be used. To prevent the baby wriggling down under the covers, a baby's feet should be placed at the foot of the cot or pram.

By 6–7 months of age, many babies will roll over onto their front during sleep. There is no need for concern about this, as the risk of cot death is markedly reduced by this age. There are, however, certain circumstances in which babies should be nursed on their side or prone (on their front). These include some babies in neonatal units, babies with severe gastro-oesophageal reflux, babies receiving treatment in splints for unstable hips, and babies with Pierre Robin syndrome.

Cellular blankets are ideal and duvets or loose bedding should be avoided. An infant should not sleep on a sofa or bed with a parent. It has been recommended that the infant should sleep in the same room as the parent for the first six months of life.

Avoid smoking near babies

Smoking in pregnancy by the mother will reduce the birthweight of the infant by approximately 200 g at term and increases the risk of cot death. Babies exposed to cigarette smoke after birth are also more likely to suffer wheezing and respiratory infections. It is best if everyone, especially parents, refrains from smoking in the same house or room as a baby.

Temperature

Overheating a baby may increase the risk of cot death. A room temperature of about 18°C (65°F) is comfortable for babies as well as adults.

Car seats

Whenever a baby is taken in a car, he should always be strapped into a baby seat or rear facing infant carrier. It is not safe to nurse a baby on the lap in a car, even if the adult is wearing a seat belt.

Cot deaths

About one baby in every 2000 born alive dies suddenly and unexpectedly between the ages of one week and two years. Typically, an apparently healthy baby (or, occasionally, one with only minor symptoms) is put in a cot to rest and some time later is found dead. Although an infant may be face down in the cot with the bedclothes over him or her, suffocation should not be assumed. Sometimes vomit, which may be blood tinged, is found around the mouth or on the bedding, but regurgitation usually occurs after death and is not the cause of death.

In some cases necropsy discloses an unsuspected congenital abnormality or rapidly fatal infection. But usually there is no evidence of severe disease, though there might be slight reddening of the tracheal mucosa, which in other babies normally resolves spontaneously.

Parents often blame themselves and may worry that the infant suffocated as a result of neglect. They should be told that their feelings of guilt are a natural reaction and the doctor should explain to them, and to anyone who was looking after the baby when death occurred, that cot death is a well recognised but ill understood condition and that no one is to blame for the infant's death.

Figure 7.21 Correct sleeping position, with feet at the bottom of the cot.

ROOM	°C	°F	BEDDING
	27	80	Sheet only
<i>Too hot</i>	24	75	Sheet + 1 blanket*
	21	70	Sheet + 2 blankets*
<i>Just right</i>	18	65	Sheet + 3 blankets*
	15	60	
<i>Too cold</i>	13	55	Sheet + 4 blankets*
	10	50	

*A double layer of blankets counts as two blankets

Figure 7.22 Amount of bedding required for a range of room temperatures to keep the infant's temperature at the optimum level.

Box 7.1 Foundation for the Study of Infant Deaths (FSID)

Artillery House, 11–19 Artillery Row, London SW1 1RT
 General enquiries telephone: 020 7222 8003
 24-hour helpline: 020 7233 2090

Box 7.2 Prevention of sudden infant death

Although sudden infant death is very rare, it is important to follow the latest guidelines for prevention. These are:

- Put your baby to sleep on his or her back
- Do not smoke; keep your baby out of smoky atmospheres
- Do not let your baby get too warm
- Put your baby at the foot of the cot so that he or she cannot wriggle under the covers
- Contact your doctor if you think your baby is unwell

Parents must also be told that because the death is of unknown cause the coroner will have to be told as a matter of routine and that there will be a necropsy. If the parents want to see the infant's body (and they should be asked), the infant is clothed and a doctor or nurse should be present to answer questions and provide support. Parents should be encouraged to see the infant's body as this will help the grieving process. Discussion with the parents will determine who is best to help with their grieving.

The family doctor and health visitor should be informed of the death immediately. The family doctor should explain the results of the necropsy to the parents or arrange for a paediatrician to do this.

Brothers and sisters of the infant who has died will need reassurance that they will not die and are in a safe and loving environment. The concept of the finality of death may not be attained until the age of eight years. Children may be disturbed by the emotional distress of the parents and this may cause behavioural or sleep problems.

Foreign travel with infants

Families are more mobile and are increasingly seeking advice about air travel with young children. Infants are at increased risk of experiencing earache during take-off and landing because the drainage of their Eustachian tubes may be partially blocked with fluid and mucus. Feeding the infant may help by producing a partial Valsalva manoeuvre, but may not be possible because of safety restrictions in the aircraft.

Travel to foreign countries is best avoided until the completion of the routine infant immunisations at four months of age. BCG should also be given if travelling to a country with a high prevalence of tuberculosis.

Antimalarial prophylaxis is essential for young infants and can be safely given to all infants, provided that they do not have neonatal jaundice, if travelling to a country where malaria is endemic. The same drugs as are prescribed for adults can be used in appropriate dosage for infants:

- first month of life – one eighth adult dose
- one month to one year of age – one quarter adult dose.

Boiled or bottled water should be used for drinking water and preparation of infant formula feeds abroad. Parents should be advised not to use commercially produced mineral water with a sodium content more than 20 mg/l, as a high salt intake can be harmful in young infants. Changes in drinking water and diet may cause an alteration in intestinal flora and diarrhoea in young infants. Meticulous attention to hygiene will help to prevent gastroenteritis. Families of infants should be advised to carry sachets of powdered oral infant rehydration mixture when they travel abroad, as it may not be readily available elsewhere.

The skin of young infants is very susceptible to sunburn and must always be protected with liberal applications of high factor sunblock, hats, and sun shields or umbrellas in hot sunny climates.

8 Dislocated and dislocatable hip in the newborn

Congenital dislocated hip and dislocatable hip are probably the most important asymptomatic congenital abnormalities to detect, as early treatment is simple and usually effective. In the first 12 hours of life ten in 1000 infants in Britain have a hip abnormality. When the examination is carried out 24–36 hours after birth the incidence falls to about seven per 1000 births. Formerly, when they were all left untreated in the newborn, the incidence of established dislocated hip was one in 800 children. There may be a family history of the condition; the anomaly is more common in girls and after the extended breech position *in utero*. There is a higher incidence in some countries, such as Italy and the former Yugoslavia.

The best time to examine the infant's hips is between the ages of 12 and 36 hours, as the tendency to provoke regurgitation is less and there is less ligamentous laxity by that time. The examiner's hands should be warm and the infant should be placed on her back with the sheet spread completely flat. She should be fully relaxed and this may be encouraged by putting an empty sterile feeding teat in her mouth if necessary. The gentle abduction test, followed by Barlow's test, should be carried out in all cases. Unnecessary trauma to the delicate hip joint and its capsule must be avoided.

Gentle abduction test

The gentle abduction test will detect hips that are in the dislocated position at rest. Each hip should be examined separately, while the opposite thigh is gently fixed by the examiner's other hand. Both the knee and the hip should be flexed to a right angle and the knee held so that the examiner's thumb is parallel to the medial aspect of the lower thigh, while the middle two fingers lie along the whole length of the lateral aspect of the femur. The tips of the examiner's fingers thus lie over the greater trochanter.

The thigh should be held *lightly* and neither pushed down towards the cot surface nor pulled up towards the examiner's face. It should then be allowed to abduct very gently and slowly by the weight of the infant's leg until abduction is complete. The thigh should never be forcibly abducted and it is unnecessary to obtain abduction beyond 10° above the flat. While abducting the thigh, the examiner may feel or see the head of the femur slip, jerk, or jolt forward into the acetabulum. A temporary interruption in the flow of abduction at a point about midway through abduction precedes the sensation of this abnormal movement of the head of the femur.

If the joint capsule is very lax, the reduction jolt may be missed unless great care is taken.

Barlow's test

The object of Barlow's test is to identify dislocatable hips in which the head of the femur can be gently jolted posteriorly over the posterior lip of the acetabular labrum to lie temporarily out of the acetabulum and those dislocated hips in which the head of the femur can be jolted forwards to lie temporarily in the acetabulum.

Each hip should again be examined separately while the opposite thigh is gently fixed by the examiner's other hand. The infant's hip should be flexed to a right angle and the knee more acutely flexed. The examiner should place a thumb as high as

Figure 8.1 Gentle abduction test.

Figure 8.2 Gentle abduction test.

Figure 8.3 Barlow's test.

possible on the medial aspect of the upper femur while the tips of the middle two fingers grasp the greater trochanter laterally.

The thigh is held lightly in a position of only minimal abduction and then an attempt is made to push the femoral head gently posteriorly and slightly superiorly, while at the same time the examiner's hand is internally rotated through not more than 25°. This is followed by reversing the whole movement. No excessive force is used and only a very limited range of movement employed in the test.

The movement of the head of the femur out and in, or in and out, of the acetabulum produces a jolting or jerking movement, *which can be seen and felt by the examiner. It cannot be heard by an individual with average hearing.* The sensation is like that of a gear lever engaging.

Hips that show excessive movement of the head of the femur within the joint, without being actually dislocatable, are classified as normal.

Ligamentous laxity. In at least 10% of infants this examination evokes a noise, click, snap, or grating sensation, but there is no abnormal movement of the femoral head. Such hips should be considered normal and no follow-up is required. Because of confusion about its meaning, the term "clicking hip" should be abandoned.

Examination of the hips should be performed more than 15 hours after birth because few ligamentous clicks will be found.

Ultrasound in screening

If ultrasound screening is undertaken in every infant before leaving hospital, imaging facilities will be required seven days a week. Twenty percent of hips may be considered abnormal and the majority will resolve to normal within four weeks.

Selective screening with ultrasound of infants with a clinical hip abnormality or risk factors for congenital dislocated hip (breech delivery, positive family history, or foot deformity) reduces the screened population and allows treatment options to be delayed and targeted effectively. A recent study showed that this approach has not reduced the prevalence of late cases of congenital dislocated hip and it has been suggested that selective ultrasound screening is dependent upon more vigorous clinical screening and careful selection of risk factors.

Ultrasound in diagnosis and management

Shallow acetabulae occur with normal hips and delayed ultrasound screening examination to 4–6 weeks in clinically stable hips will allow treatment to be targeted to those hips that require splintage and thus reduce treatment rates without compromising the results of this treatment.

Weekly ultrasound studies can be used to confirm hip relocation and treatment progress while the infant is in a malleable splint or Pavlik harness. Sonographic evidence of continuing femoral head dislocation, despite splintage, allows treatment to be abandoned and thus the risk of avascular necrosis is reduced. The appearance of the ossific nucleus in the cartilaginous femoral head (usually delayed in congenital dislocated hip) is identified sonographically several weeks before it is visualised radiologically.

Recommended screening

Babies born after a vertex presentation who have normal hips on clinical examination and do not have any risk factors will

(a)

Figure 8.4 (a) Ultrasound of normal hip (b) diagram.

(a)

Figure 8.5 (a) Ultrasound of abnormal hip (b) diagram.

continue to receive clinical screening using the neonatal examination and thereafter by their general practitioner in surveillance clinics.

Babies who are judged to be at risk of congenital dislocated hip because they:

- were born in breech position, or
- have a family history of congenital dislocated hip, or
- have a foot deformity

should have ultrasound at 4–6 weeks of age, in addition to the clinical screening tests. If they are clinically normal and the ultrasound is normal no follow-up is needed. The general practitioner should be sent a standard letter advising that they have been screened by ultrasound but still require follow-up in the surveillance clinic.

If any of the above children have minor abnormalities on the ultrasound scan then they should have a second ultrasound scan six weeks later. Children with subluxed or dislocated hips on ultrasound should be seen again in the paediatric orthopaedic clinic.

Any child who has a clinically dislocated or dislocatable hip at birth should have an immediate ultrasound and be referred to the next paediatric orthopaedic clinic within a week.

Management of abnormal hips

Apart from cases of irreducible hip dislocation, an infant with a dislocated or dislocatable hip should have a splint applied at about the age of two weeks. Further delay may cause poorer results. The Pavlik harness or variants of the von Rosen splint are used. They are made of malleable metal that has been padded and then covered with waterproof material. The splint acts equally on both hips, keeping both thighs flexed and at an optimum degree of abduction. Unless substitution by a larger splint is required, the splint must remain in position continuously for at least two months if the hip is dislocatable or for at least three months if it is dislocated at rest. Early consultation with an orthopaedic surgeon, who will continue long term care, is essential.

Before the splint is first applied, the mother must be told exactly what this treatment entails. She should be encouraged to continue breastfeeding, even though this may prove awkward initially. The infant should be placed naked on the splint, which has been fashioned so that the posterior cross bar is grooved to protect the skin over the spine. If the hip is dislocated, the dislocation must first be gently reduced and the thigh held in the abducted position while the splint is carefully applied. Potential pressure points may be protected by inserting pieces of cotton wool or similar material. The mother should be told to replace these when they become wet or soiled without disturbing the splint. The baby's clothes should be put over the splint and not under it.

Once the splint is in place, the infant should be washed, weighed, and examined without the splint being removed. The splint will need scrupulous adjustment at each visit to allow for growth and to ensure that the hip is not being overabducted. The degree of full abduction in a normal infant diminishes slightly but steadily over the early weeks of life so that the splint should give the comfortable degree of full abduction that is appropriate for the child's age. Failure to adjust progressively for this may cause avascular necrosis of the femoral head. On the other hand, if the degree of thigh abduction is inadequate because the splint is applied too loosely, the hip may remain dislocated. The splint should be checked daily for several days after

Figure 8.7 Radiograph of normal hips at 18 months.

application and thereafter at intervals of not more than one or two weeks.

Once the splint is finally removed, an anteroposterior radiograph of the hips should be taken with the thighs held parallel, and the infant should be followed up at the ages of six and 12 months, at the least.

Late diagnosis

If a dislocated hip is “missed” in the newborn infant the clinical diagnosis is often difficult until, after some weeks, the classic signs of lack of thigh abduction and, in unilateral cases, asymmetry of the lower buttock creases become apparent. Before the age of four months an ultrasound study is the most useful aid to diagnosis. Radiologically, once ossification occurs in the upper femoral epiphysis at about the age of 3–4 months a dislocation can be more clearly shown.

9 Infection in the newborn

Some infections are fulminating and the infant dies within a few hours. More commonly, however, the onset is insidious and the vague features may include the refusal of feeds by an infant who has previously fed normally, lethargy, hypotonia, apnoeic attacks, or fever. Fever is arbitrarily defined as a temperature over 37.5°C, but newborn infants with infection often have a normal or even a subnormal temperature.

The most common pathogens are group B streptococci, *Escherichia coli*, *Staphylococcus aureus*, and *Pseudomonas*. The pathogens causing infection at a particular site can sometimes be predicted (for example, *Staph. aureus* in paronychia) but swabs for bacterial culture should still be taken before giving an antibiotic. Usually an antibiotic needs to be given before the organism has been isolated, but the treatment can be changed later once the sensitivity of the pathogen to antibiotics has been tested *in vitro*. The sensitivity of the pathogens in a particular unit is often known, which may give a guide to effective treatment. If septicaemia is suspected and there is no obvious site of entry of the pathogen, both a penicillin and an aminoglycoside (for example, gentamicin) must be given after a blood culture has been taken.

Intestinal absorption is variable and regurgitation of antibiotics common, so that the intramuscular or intravenous route should always be used initially. Intramuscular injections should be given deeply into the upper lateral aspect of the thigh. Schemes for rotating the sites are essential to prevent local necrosis and to avoid further injections being given into a relatively avascular area. Intravenous antibiotics are given slowly by bolus injection rather than by adding them to the bottle of intravenous fluid.

Group B streptococcal infections

The group B *Streptococcus* is the commonest pathogen that causes severe infection in the first week of life. It is acquired during birth from the maternal vagina. Although about 10% of mothers are colonised and about 25% of their infants acquire this organism, only one in 1000 infants has symptoms. About half of those with symptoms die. In the early onset type, which occurs in the first few days of life, there may be a persistently raised respiratory rate followed by the vague features of septicaemia and later peripheral cyanosis. The chest radiograph may show extensive areas of consolidation in both lungs or it may be normal. The same organism may cause a more insidious septicaemia and meningitis towards the end of the first week.

Parents should be warned that recurrent group B streptococcal infection may occur for up to three months after birth and intravenous antibiotics will be the only effective treatment.

Escherichia coli infections

The use of antibiotics with a wide spectrum of action tends to eliminate all bacteria except *E. coli* and *Pseudomonas*, which flourish in a warm, moist environment. The preterm infant, who has a greater susceptibility to infection, nursed in an incubator with increased humidity provides the ideal setting for these infections, especially if broad spectrum antibiotics are

Figure 9.2 Infection of the umbilicus.

being given. The umbilicus may become infected and this may be followed by septicaemia and later meningitis.

Early symptoms are ill defined and the nurse may report that the infant appears vaguely unwell. He may have lethargy, anorexia, jaundice, and purpura. The early symptoms of meningitis are similar to those of septicaemia, but late features are vomiting, a high pitched cry, convulsions, raised anterior fontanelle tension, but rarely neck stiffness.

A urinary tract infection may easily be missed if a specimen of urine is not examined in every infant with fever or who is unwell. Rarely, there are physical signs of an associated congenital abnormality of the urinary tract, such as an enlarged kidney due to hydronephrosis or a persistently palpable bladder and poor urinary stream caused by obstruction from urethral valves in a boy.

Outbreaks of acute gastroenteritis due to rotavirus may occur in newborn nurseries.

Staphylococcal infections

Conjunctivitis – *Staph. epidermidis* is often cultured from eye swabs of infants with conjunctivitis and it is impossible to determine whether this is the primary cause of the conjunctivitis or whether it is secondary to chemical inflammation. Chemicals, such as chlorhexidine, used in swabbing the mother's perineum may enter the infant's conjunctiva during delivery. Primary infection with *Staph. aureus* may cause severe conjunctivitis. After taking an eye swab from an infant with conjunctivitis, neomycin ophthalmic ointment should be applied to both eyes three times daily for a week.

If mild conjunctivitis persists longer than a week, the possibility of infection with *Chlamydia trachomatis* should be considered. The laboratory may be able to isolate the organism using special techniques. The best treatment consists of a course of tetracycline eye ointment, which should be continued for at least three weeks; a course of oral erythromycin should also be given for two weeks. (See below for gonococcal conjunctivitis.)

Skin sepsis – Clusters of yellow pustules in the axilla or groin that first appear on the fourth day or later are usually due to staphylococci. They may resemble the lesions of neonatal erythema, but those lesions appear earlier and resolve within 48 hours. If there is any doubt, the lesions should be treated as staphylococcal pustules.

Bullous impetigo of the newborn is a rare bullous eruption which can be rapidly fatal and very infectious if adequate antibiotics as intravenous flucloxacillin are not given.

Umbilical infection, shown by a localised red area and a serous exudate, may be due to *Staph. aureus* or a wide variety of other pathogens.

Paronychia is an infection along the side of the nail of the fingers or toes. It often affects several digits together. The lesion appears trivial but it may lead to any of the more serious infections due to the Staphylococcus. Surgery is not required but a long course of flucloxacillin should be given.

A *breast abscess* is a red, tender swelling, which may not affect the whole breast; usually there are enlarged lymph nodes in the axilla on the same side. Physiological enlargement may be unilateral. Surgical drainage is usually required as well as antibiotics for a breast abscess.

Pneumonia – The signs are the same as those of other types of pneumonia: raised respiratory rate, recession, and sometimes focal or generalised signs in the lungs. The infant appears extremely ill because of the accompanying septicaemia. A chest radiograph may initially show generalised non-specific changes and later lobar consolidation with

Figure 9.3 Regular repeated examinations of the urine.

Figure 9.4 Pustules.

Figure 9.5 Bullous impetigo.

Figure 9.6 Breast abscess.

ABC of the First Year

characteristic pneumatocoeles, which are air filled spaces. Complications are pneumothorax and empyema.

In *osteomyelitis* there are often no specific signs, just an ill infant who will not feed. Reluctance to move a limb and crying when the limb is moved or touched are valuable localising signs, but swelling at the site of the lesion is a late sign. A radioisotope scan may show changes at an early stage of neonatal osteomyelitis and later a radiograph of the limb may show a soft tissue swelling or a raised and thickened periosteum. Rarely, osteomyelitis in the newborn is not due to *Staph. aureus*.

Gonococcal infection

Gonococcal conjunctivitis may be unilateral, usually does not respond completely to local neomycin, and is often present within 48 hours of birth. In cases of severe conjunctivitis, particularly when bilateral and associated with severe oedema, gonococcal infection should be suspected and special arrangements for taking swabs must be made with the laboratory. If the conjunctivitis does not respond rapidly to treatment, swabs should be taken again for gonococcal infection. The paediatrician should be told as soon as the laboratory confirms the diagnosis in view of the medical and legal implications. Urethral, cervical, and rectal swabs should be taken from the mother.

If gonococcal infection is suspected, even if smears do not confirm it, intravenous penicillin is given and the diagnosis is reconsidered when the results of the cultures are available. In addition, chloramphenicol eyedrops are given half hourly for the first six hours and then chloramphenicol ointment is applied two hourly for three days.

Candida infections (fungal)

Candida infections are encouraged by the use of broad spectrum antibiotics. Candida infection of the mouth produces white plaques (thrush) and may make the infant reluctant to feed. It also causes a fiery red scaly eruption of the perineum, usually secondary to ammoniacal dermatitis. A swab made damp with sterile sodium chloride solution should be used to obtain a specimen for laboratory confirmation of the cause of the perineal rash. Oral nystatin suspension should be given after feeds for at least a week for the oral lesions. Nystatin ointment should be applied to the perineal rash each time the napkin is changed until the rash has resolved for a week. Miconazole oral gel and miconazole ointment may be used if nystatin suspension is not effective.

Management and treatment

Careful evaluation of the features noted above may enable a tentative diagnosis to be made and to be confirmed by a single investigation. In many infants, however, there are no specific signs and the following investigations should be carried out.

Urine microscopy and culture – Specimens must be collected carefully and examined promptly to produce reliable results. A fresh midstream clean catch specimen can often be obtained after gentle suprapubic stimulation, especially in boys. If the urine specimen contains more than 10×10^6 pus cells per litre or bacteria are seen in a fresh specimen, a further urine specimen is obtained by suprapubic bladder puncture. Bacteria cultured from this specimen confirm a urinary tract infection.

Figure 9.7 Osteomyelitis.

Figure 9.8 Gonococcal ophthalmitis.

Figure 9.9 Candia infection.

Figure 9.10 Suprapubic puncture for urine collection.

Ultrasound renal scan should be performed in all infants with a confirmed urinary tract infection before discharge from the unit. Arrangements are made for the infant to be reassessed at regular intervals in the outpatient clinic and further investigations may be needed later. Inadequately treated neonatal urinary infections may cause permanent renal scars and later renal failure.

Other investigations that may need to be performed are (a) culture of gastric aspirate, ear swab, and umbilical swab; (b) chest radiograph; (c) blood culture from a peripheral vein, avoiding the femoral vein; and (d) lumbar puncture.

After the age of two days a blood neutrophil polymorph count higher than $10 \times 10^9/l$ suggests infection. A very low neutrophil polymorph count also suggests overwhelming infection.

As infants may deteriorate rapidly, treatment is started immediately for the most likely organisms involved if the child is ill. If the infant appears ill, antibiotics suitable for septicaemia should be given intravenously or intramuscularly after all the specimens have been taken. If the diagnosis is uncertain after physical examination, investigation of the urine, chest radiograph, and examination of the cerebrospinal fluid (CSF), and the infant appears well, it is better to withhold antibiotics until a paediatrician has been consulted.

Suitable antibiotics are intramuscular or intravenous flucloxacillin for staphylococcal infections; intravenous penicillin for group B streptococcal infections; and intravenous gentamicin for *E. coli* septicaemia. Intravenous cefotaxime or ceftriaxone is suitable for *E. coli* meningitis.

To treat urinary tract infection intravenous or intramuscular gentamicin and ampicillin should be given. Once the sensitivities are established it may be possible to continue treatment with one drug such as trimethoprim. In any case gentamicin should not be given for longer than a week, as eighth nerve damage may occur. Every infant who has had a confirmed urinary tract infection should have a repeat examination of the urine for the presence of infection every three months for two years.

Gentamicin is an effective antibiotic but it can cause deafness and blood levels must be monitored. The serum concentrations of gentamicin should be between 5 and 10 mg/l one hour after the previous dose. The trough blood level, taken just before the next dose is due, should be less than 2 mg/l.

Paediatric HIV

Perinatal transmission of HIV from an infected mother to her infant can now be reduced to <5% by preventive measures taken during pregnancy and the perinatal period. It is recommended that all mothers should be encouraged to have an HIV screening test as part of their routine antenatal screening. It is now known that infants are most at risk of becoming infected with HIV during vaginal delivery, when they swallow maternal secretions containing the virus, and later during breastfeeding. The administration of anti-retroviral therapy (ART) to the mother during pregnancy is not harmful to the fetus and, together with elective caesarean section, avoidance of breastfeeding, and the administration of AZT (zidovudine) to the infant, has been shown to reduce the rate of vertical transmission from 15–30% to <5% in countries where these measures are safe and affordable. The risk of transmission is related to maternal viral load in the third trimester and if this is undetectable in mothers who are on ART, caesarean section may not confer any additional

advantage. Although breastfeeding doubles the rate of vertical transmission, in developing countries it may still be the preferred method of infant feeding because of greater health risks associated with formula feeding.

All infants born to HIV positive mothers will also test HIV antibody positive for at least the first 12–18 months of life, even those who are uninfected, because of the passage of maternal IgG across the placenta to the baby. Uninfected infants can usually be identified by showing absence of the virus on at least 2–3 tests by PCR (polymerase chain reaction) in the first four months of life. Until the results of the PCR tests are known, the infant will be given oral co-trimoxazole (daily or at least three times a week) from one month of age, in order to prevent infection with PCP (*Pneumocystis carinii*), which can cause a severe life threatening pneumonia in infected infants. Routine immunisation with the triple, Hib, and meningococcal vaccines should be given at the usual age. Some paediatricians recommend IM polio instead of oral polio vaccine for the infant, in order to avoid the small risk of immunocompromised adults in the family developing poliomyelitis. BCG vaccination is usually delayed until the infant is confirmed to be uninfected with HIV.

Infants infected with HIV may remain asymptomatic for 10–12 years after birth but around 20% will develop serious problems in the first year of life. Recurrent thrush, skin rashes, lymphadenopathy, hepatosplenomegaly, failure to thrive, developmental delay, and severe respiratory tract infections are common symptoms in HIV positive infants. ART is only necessary when the infant is shown to have a high viral load and a low number of CD4 lymphocytes. The survival of infected children has been greatly improved by early diagnosis and treatment but there is no definitive cure for HIV infected individuals as yet.

Families with HIV, even those where the children are not infected, benefit from support and help from sympathetic, well informed health care professionals.

Common napkin rashes

Napkin rashes are usually due to ammoniacal dermatitis, seborrhoeic dermatitis, or perianal excoriation.

Ammoniacal dermatitis is caused by ammonia produced by faecal bacterial enzymes acting on urea in the urine. Erythema, papules, scaling, and erosions appear in areas that have been in contact with napkins soaked with urine. The depths of the skinfolds are spared and the prepuce and scrotum are especially vulnerable. The principle of treatment is to keep urine and faeces away from the skin. Initial treatment includes changing napkins frequently or leaving the child without a napkin. A zinc cream is applied to the affected area every time the napkin is changed; in resistant cases a silicone cream is used. Some authorities consider that the formation of ammonia does not play a major part in this condition and they prefer the term “irritant napkin dermatitis”.

If the rash does not improve within 10 days *Candida* infection of the lesions should be considered. This rash has a fiery red appearance with a scaly edge, often with a few early papules separated from the main eruption. Nystatin cream should be applied to the rash each time the napkin is changed for at least a week. The infant’s mouth should be examined to determine whether white plaques of *Candida* are present and an oral suspension of nystatin is needed. Alternatively, miconazole oral gel may be used. In breastfed infants the mother’s nipples should be examined, as a scaling dermatitis of the nipples can be due to *Candida* and may reinfect the infant.

Figure 9.12 Cervical lymphadenopathy due to HIV infection.

Figure 9.13 Ammoniacal dermatitis.

Figure 9.14 Seborrhoeic dermatitis.

Any infant with a rash in the napkin area should be undressed completely to ensure that he or she does not have a rash elsewhere. In *seborrhoeic dermatitis* the erythema and scaling may also affect the axillae, neck, the area behind the ears, scalp, forehead, and eyelids. The scalp may be covered with adherent hard crusted plaques (cradle cap). Secondary infection by staphylococci, streptococci, or *Candida* is common. The condition always begins before the age of three months and clears completely without treatment by nine months. In contrast to the infant with ammoniacal dermatitis, the infant with seborrhoeic dermatitis is oblivious of the rash. The cause is unknown and there is usually no family history of dermatitis. Treatment with 1% hydrocortisone ointment is rapidly effective and the lesions usually clear completely within a few weeks. In severe cases nystatin or an antibacterial agent may be added to the cream. Cradle cap can be removed by shampoo containing 0.5% salicylic acid.

If the rash affects mainly the perianal area, it is probably due to persistently loose stools. *Perianal excoriation* is commonly found in infants with gastroenteritis and resolves when the diarrhoea stops. Zinc cream or exposure may hasten the resolution of the lesions, but changes in the stool pH and consistency are the most important factors.

Figure 9.15 Perianal excoriation.

10 Jaundice in the newborn

Jaundice is a yellow colour of the skin caused by a high concentration of bilirubin. Very severe jaundice may damage the cells of the basal ganglia and brainstem. This damage is produced by the fat soluble unconjugated bilirubin. If jaundice is severe, high bilirubin levels may result in deafness, cerebral palsy, or death.

Neonatal jaundice is due to an increased bilirubin load with a transient inefficiency of hepatic excretion resulting from decreased activity of glucuronyl transferase in the liver. There are additional factors. Some of the conjugated bilirubin excreted in the bile is normally deconjugated in the small intestine and reabsorption is enhanced by the slower gut transit in the newborn who takes small volumes of milk. Bilirubin is absorbed from meconium and there is no intestinal flora to degrade bilirubin to urobilinogen.

Jaundice in the skin is visible to the naked eye in white babies at a serum bilirubin level of about $80 \mu\text{mol/l}$. In black babies the sclerae should be examined as jaundice is more difficult to recognise. Jaundice first appears in the face and spreads to the periphery of the limbs (Figure 10.3). The level is more than $270 \mu\text{mol/l}$ if the hands or feet are jaundiced.

Common causes of jaundice in the newborn

Common causes of jaundice include hepatic immaturity, red cell incompatibility, infection, and breastfeeding.

Jaundice due to hepatic immaturity, or “physiological” jaundice, is common both in preterm and in full term babies. A temporary deficiency of glucuronyl transferase enzymes reduces the rate of conjugation of bilirubin, with a consequent retention of unconjugated bilirubin. In full term infants the jaundice always appears after the first 24 hours of life and reaches a peak on the fourth or fifth day. In preterm infants it usually begins 48 hours after birth and may last up to two weeks.

In babies with red cell incompatibility jaundice appears within 24 hours of birth. The main causes are: (a) incompatible rhesus grouping, and (b) incompatible ABO grouping; the mother’s blood is usually group O and the infant’s group A or, less commonly, group B.

The common infective causes of jaundice are septicaemia and urinary tract infection. Septicaemia is especially likely to be present if the jaundice appears after the fourth day of life, but it is a possibility in any infant who seems ill. In urinary tract infections the jaundice is of hepatic origin.

In about 2.5% of infants who are breastfed the serum bilirubin rises to levels between 260 and $360 \mu\text{mol/l}$ in the second or third week of life. These infants have no symptoms. If breastfeeding continues the level remains constant for three or four weeks and falls to normal levels at 4–16 weeks. An abnormal progesterone has been shown in the milk of some of the mothers.

Rare causes of jaundice in the newborn

Rare causes of jaundice include hypothyroidism, galactosaemia, viral hepatitis, and atresia of the bile ducts. These cause prolonged jaundice lasting more than 10 days.

Figure 10.1 Formation and excretion of bilirubin.

Box 10.1 Causes of jaundice

Cause	Onset
Red cell incompatibility	Within 24 hours of birth
Physiological jaundice	After 24 hours
Septicaemia	Usually after fourth day

Figure 10.2 Breast feeding.

Glucose-6-phosphate dehydrogenase deficiency is another cause of prolonged jaundice, but it can also produce a clinical picture similar to blood group incompatibility.

In hypothyroidism physiological jaundice is prolonged, the plasma thyroxine (T4) concentration is reduced, and the thyroid stimulating hormone (TSH) concentration is increased.

In infants with viral hepatitis, which is usually due to intrauterine infection, the stools are pale, the urine dark owing to bile, and there is a high level of conjugated bilirubin in the plasma.

It is difficult to differentiate between hepatitis and atresia of the bile ducts clinically, and they may represent the two ends of a range of disease. If jaundice persists more than 10 days, the advice of a paediatrician should be sought.

In galactosaemia the urine gives a positive result on testing for reducing substances, but the test for glucose may be negative. The infant needs to be referred to a paediatrician immediately for special investigations.

Glucose-6-phosphate dehydrogenase deficiency occurs in infants of Mediterranean, African, or Chinese stock. This hereditary red cell enzyme defect is found in babies with haemolytic episodes that often occur without the usual precipitating factors of drugs or infection. The enzyme is necessary for maintaining the stability of the red cell membrane.

Management of jaundice starting in the first 24 hours

If jaundice appears within 24 hours of birth it must be considered to be due to blood group incompatibility, with a high risk of cerebral palsy, until proved otherwise. Most rhesus problems should be anticipated before the neonatal period. Urgent exchange transfusion may be indicated in infants severely affected by haemolytic disease of the newborn, and it is advisable for the infant to be admitted to hospital immediately for investigation. If the mother is rhesus negative, the infant rhesus positive, and the Coombs test positive, jaundice is due to rhesus incompatibility. The plasma bilirubin concentration should be measured every five to eight hours and the results plotted on a special chart (see p. 44). Once the second estimation has been performed the maximum concentration can be predicted, as the rate of increase is linear. When the serial concentrations fall below the printed line, the infant is unlikely to need any treatment.

Management of jaundice starting after the first 24 hours

The possibility of septicaemia or urinary tract infection should be considered in any ill baby who develops jaundice after the first 24 hours of life. If there is any doubt about when the jaundice first appeared, the possibility of blood group incompatibility should be investigated.

When a doctor visits the infant at home a guide to the plasma bilirubin concentration can be provided by the dermal icterometer. This is a piece of transparent perspex with yellow lines of various shades that correspond to plasma bilirubin concentrations. It should be compressed gently on the infant's nose to indicate the approximate plasma bilirubin concentrations. The dermal icterometer is not accurate in artificial light, when bilirubin values are rising rapidly, or

Figure 10.5 Dermal icterometer

when phototherapy has been given. In infants with pigmented skin the dermal icterometer should be compressed against the gums, not the nose.

In full term infants if the dermal icterometer suggests that the plasma bilirubin concentration is about $250 \mu\text{mol/l}$ or the result lies above the line on the chart the infant should be transferred to hospital immediately. If the plasma bilirubin level is very high, urgent exchange transfusion or phototherapy may be needed.

In neonatal units there is usually a ward bilirubinometer that measures plasma bilirubin concentrations within a few minutes, using a small specimen of blood obtained by heel prick. If two estimations fall below the line on the chart, treatment will probably not be needed. Those with values above the line may need exposure to light under a phototherapy unit. Phototherapy produces geometric stereoisomers of bilirubin, which have no known long term deleterious effect on the infant. The infant's eyes are shielded with eye pads, but the mother should have the procedure explained first. Although phototherapy units have a shield to reduce transfer of heat from the lamp to the infant, monitoring of the temperature of the infant is essential. Extra fluids may be needed to compensate for the additional evaporative loss and this can be given as plain water to breastfed infants or additional milk to bottlefed babies. Oral fluid decreases the gut transit time and improves the excretion of bilirubin and the associated compounds. The indications for phototherapy are controversial but many units give phototherapy if the plasma bilirubin level is above the line on the chart. Despite phototherapy, an exchange transfusion may still be needed, but the critical level varies with the unit and the gestational age of the infant. Exchange transfusion should be considered if the plasma bilirubin level exceeds $450 \mu\text{mol/l}$ in a full term infant and $300 \mu\text{mol/l}$ in a preterm infant. Some units start treatment at lower levels of bilirubin in sick infants.

Prolonged jaundice

If jaundice persists longer than 14 days in a full term infant, blood should be taken for plasma thyroxine and TSH estimations and a specimen of urine collected to measure reducing substances and glucose. The urine should be examined in the laboratory for the presence of infection. If the parents are of Mediterranean, African, or Chinese origin, the screening test for red cell glucose-6-phosphate dehydrogenase should also be performed.

Bilirubin chart

$400 \mu\text{mol/l} = 23.4 \text{ mg/100 ml}$ $100 \mu\text{mol/l} = 5.8 \text{ mg/100 ml}$
 $300 \mu\text{mol/l} = 17.5 \text{ mg/100 ml}$ $17.1 \mu\text{mol/l} = 1.0 \text{ mg/100 ml}$
 $200 \mu\text{mol/l} = 11.7 \text{ mg/100 ml}$

Figure 10.6 Indications for phototherapy and exchange transfusion.

Figure 10.7 Phototherapy.

Pale stools and a plasma conjugated bilirubin level greater than $30 \mu\text{mol/l}$ suggest the possibility of hepatitis or atresia of the bile ducts, and the advice of a paediatrician is needed.

If there is a suspicion that the jaundice is related to breastfeeding, the other conditions causing jaundice should be excluded and the mother advised to continue breastfeeding. If the plasma bilirubin concentration is rising rapidly and breastfeeding is stopped for 48 hours, the infant's plasma bilirubin concentration will fall abruptly and will not usually rise on return to breastfeeding. Although the mother can continue lactation by expressing her milk during this diagnostic test there is a risk that breastfeeding will not be resumed.

11 Convulsions in the newborn

Although the involuntary movements of a convulsion are usually generalised, they may affect only one limb, the face, or tongue. The distinctive feature is repetitive jerky movements, which may be accompanied by loss of consciousness, apnoea, or rigidity. Often the convulsion has stopped by the time the baby is seen by a doctor. A brisk Moro reflex or jerky normal movements in a baby may be misinterpreted as a convulsion by an inexperienced observer. If the convulsion is not seen, apnoea or cyanosis may indicate that it has occurred, and if there is any doubt it is safer to investigate the baby on the assumption that there has been a convulsion.

Management

A baby not already in hospital should be admitted. After hypoglycaemia has been excluded by a blood glucose estimation, an anticonvulsant should be given if the convulsion is continuing or recurs while waiting for the results of other investigations. The order of carrying out the various procedures is important. Hypoglycaemia and hypocalcaemia should each be sought for and excluded in that order before the next test. Hypoglycaemia is the more dangerous condition.

The infant is placed on his side and the airway cleared by suction of the pharynx under direct vision. The baby should be nursed in an incubator to improve observation. Oxygen is given in high concentration with a funnel or head box until the convulsion has stopped.

If the plasma glucose and calcium concentrations are normal, a paediatrician should decide whether a lumbar puncture is indicated.

Hypoglycaemia

A specimen of blood should be taken from a heel prick immediately for glucose measurement in a glucometer. If the value is less than 3.0 mmol/l, hypoglycaemia may be present. A further blood sample should be taken and part of it used to repeat the glucometer test and the remainder taken into a fluoride tube for the laboratory to check the blood glucose concentration. Hypoglycaemia is defined as a laboratory estimated blood glucose level less than 2.6 mmol/l. If the second glucometer value is low, 5 ml of 10% glucose solution per kg body weight should immediately be given intravenously slowly by a scalp or limb vein. A continuous intravenous infusion of 10% glucose solution is then set up at a rate of 60 ml/kg a day.

Hypoglycaemia accompanied by fits is treated with intravenous glucose and when the fits have ceased, continuous intragastric milk should be given.

The amount of intravenous glucose should be reduced gradually over at least 24 hours. During this period three hourly glucometer tests are carried out, supplemented by regular laboratory blood glucose measurements. If an intravenous infusion of glucose is stopped suddenly by accident, severe reactive hypoglycaemia may follow and cause severe convulsions.

In contrast, asymptomatic hypoglycaemia has a good prognosis. Intragastric milk should be given by continuous infusion but the milk volume should be increased by 25% to raise the blood glucose concentration. Oral or intravenous

Figure 11.1 Repetitive similar movements indicate a convulsion.

Box 11.1

Exclude:

- 1 hypoglycaemia

Figure 11.2 Glucometer.

Figure 11.3 Syringe pump for milk.

glucose should be prescribed only on the advice of a senior member of the unit. The blood glucose level is repeated an hour after starting the milk.

Hypocalcaemia

If the glucometer test result is normal, blood should be taken for emergency plasma calcium estimation. If convulsions are still occurring or recur after hypoglycaemia has been excluded by the glucometer intramuscular paraldehyde should be given while the results of detailed tests are awaited. If the plasma calcium concentration is lower than 1.8 mmol/l (7 mg/100 ml) treatment depends on whether the convulsions are still occurring or recurring. If the convulsions have stopped, 1–2 ml of 10% calcium gluconate is added to each feed. The calcium gluconate should be added to the feed and not given directly to the infant. The total dose of calcium gluconate in 24 hours should not exceed 12 ml of the 10% solution in the full term infant.

If the convulsions continue and the plasma calcium concentration is low, 10% calcium gluconate should be diluted to 2.5% with 5% glucose solution in a syringe and given slowly intravenously into a scalp or limb vein until the convulsions cease or until a maximum of 4 ml/kg body weight of the 2.5% diluted solution has been given. The heart rate is monitored with a cardiac monitor or stethoscope during the procedure and the injection stopped if bradycardia occurs. Calcium gluconate should be added to the feeds until the plasma calcium concentration rises to normal. Calcium gluconate must never be given intramuscularly or allowed to escape out of a vein as severe tissue necrosis may occur.

Intravenous calcium may not control hypocalcaemic convulsions immediately. Some authorities have found that hypocalcaemic convulsions are treated effectively by intramuscular magnesium sulphate (0.2 ml/kg of a 10% solution/dose).

Hypomagnesaemia

In some units there is a high incidence of fits associated with low plasma magnesium concentrations. If there are recurrent fits or the plasma calcium concentration does not rise despite supplementary calcium gluconate, the plasma magnesium concentration should be estimated. If this is less than 0.6 mmol/l (1.5 mg/100 ml) intramuscular magnesium sulphate is given. The dose is 0.2 ml/kg of a 10% solution given intramuscularly every six hours; if the plasma level is normal no further treatment is needed. The plasma estimation must be repeated after two days. The main toxic effect is hypotonia, which can be reversed by intravenous calcium gluconate if the features are severe.

Prognosis

Hypoglycaemia and hypocalcaemia may be found together, especially in infants of diabetic mothers, but hypoglycaemia is the more dangerous. Symptomatic hypoglycaemia may be followed by mental impairment but symptomatic hypocalcaemia or hypomagnesaemia has an excellent prognosis, although enamel hypoplasia, which predisposes to dental caries, is a late complication of hypocalcaemia. Intravenous glucose is not hazardous provided that the correct dose is given, but intravenous calcium salts may lead to cardiac arrest.

Figure 11.4 Calcium supplements.

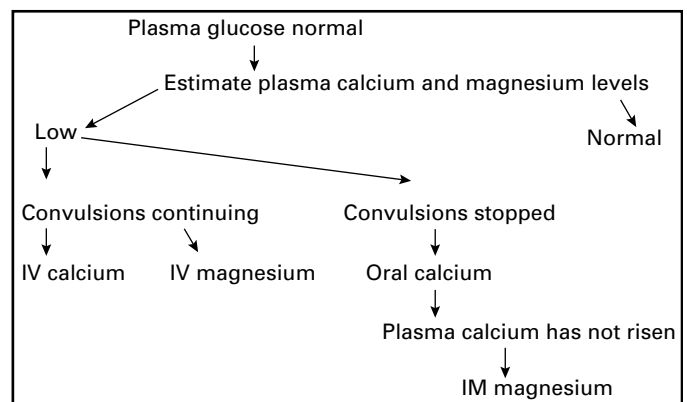

Figure 11.5 Biochemical investigation of a convulsion.

Box 11.2 Prognosis

- Symptomatic hypoglycaemia: cautious prognosis
- Symptomatic hypocalcaemia: good prognosis

Cerebral lesions

After hypoglycaemia and hypocalcaemia have been excluded, meningitis, intracranial haemorrhage, and cerebral oedema due to perinatal asphyxia should be considered. Lethargy, hypotonia, and raised tension of the anterior fontanelle are suggestive of a cerebral lesion but meningitis may be present with no specific symptoms or signs. Lumbar puncture is indicated if there is a possibility of meningitis. Ultrasound examination is reliable in excluding an intraventricular or intracerebral haemorrhage but may not detect a small subarachnoid or subdural haemorrhage.

If the first convulsion is prolonged or the convulsion recurs, intravenous phenytoin or phenobarbitone should be given. The initial dose of phenytoin or phenobarbitone is 15 mg/kg given intravenously over half an hour. The maintenance dose is started 24 hours later and is usually required for only two or three days.

12 Vomiting

Vomiting in the newborn: types of vomit

Vomiting is the forceful expulsion of gastric contents through the mouth. Mothers often confuse vomiting with mild regurgitation, which is the effortless bringing up of small amounts of milk during and between feeds, usually accompanied by air. If the milk dribbles down the chest it is likely to be regurgitation. Babies often bring up small amounts of milk with air and this is of no importance. Recurrent vomiting may be a sign of lethal disease, but a careful history and examination enable a diagnosis to be made with the minimum of special investigations.

Frothy mucoid vomit

Oesophageal atresia with tracheo-oesophageal fistula may present with vomiting, coughing, and cyanosis when the infant begins the first feed. Many of these infants drool frothy material continuously rather than vomit. Vomiting of *frothy* mucoid material may be the only definite observation, but the condition should be suspected in any baby who has *any* symptoms during the first feed. As the fluid expelled is not gastric contents, vomiting is not an accurate description but this is the term often used.

Bilestained vomit

The vomit in infants with intestinal obstruction is usually yellow, due to bile staining, but occasionally it consists only of milk. The cause may be atresia, stenosis, or volvulus of the small gut, necrotising enterocolitis, or congenital intestinal aganglionosis (Hirschsprung's disease) of the large gut. Abdominal distension is usually present and there may be visible peristalsis. A plain radiograph should be taken in the erect position immediately. An alternative is a radiograph in the supine position and, in addition a lateral view with the baby lying on his or her back and a horizontal X-ray beam. They often show fluid levels, dilated loops of gut proximal to the obstruction, and the absence of gas shadows distally. Ideally, every infant who vomits bile should be seen by a surgeon within an hour.

Bloodstained vomit

Bloodstained vomit may be caused by trauma from a feeding tube, swallowed maternal blood, or, most seriously, haemorrhagic disease of the newborn. Trauma caused by a feeding tube may produce a few specks of blood in the vomit. Maternal blood may be swallowed before delivery after premature separation of the placenta or after delivery as the result of bleeding from a cracked nipple. Maternal haemoglobin in the vomit can be recognised in the laboratory.

Haemorrhagic disease of the newborn begins between the second and fourth days of life in the early type or in the third or fourth week in the late type. The first symptom may be haematemesis or melaena and the bleeding can be profuse. An immediate dose of 1 mg vitamin K₁ should be given intramuscularly and a transfusion of fresh blood given urgently if bleeding has been severe or persists after vitamin K treatment.

Figure 12.1 Oesophageal atresia.

Figure 12.2 Erect lateral (left) and anteroposterior (right) radiographs to show fluid levels.

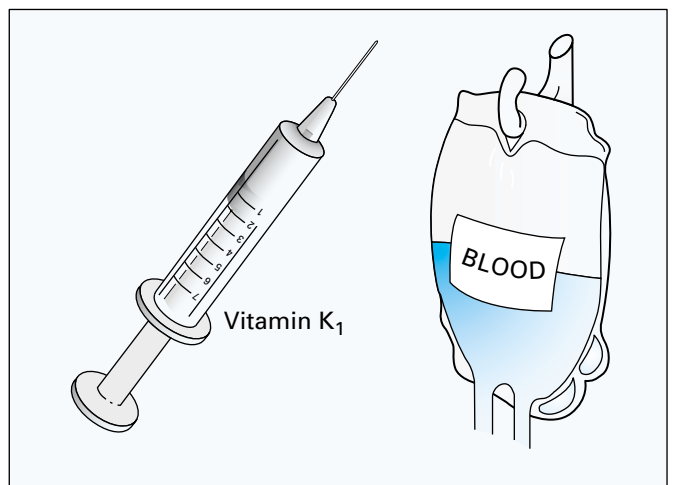

Figure 12.3 Treatment of haemorrhagic disease of the newborn.

Milk

Vomiting of milk may be caused by infections, feeding problems, necrotising enterocolitis, intracranial haemorrhage, or drugs.

Gastroenteritis, urinary tract infection, septicaemia, and meningitis may all be associated with vomiting. A ravenous infant may swallow excessive air at the beginning of the feed and, if not properly “winded”, may later regurgitate milk with air. Larger feeds, more frequent feeds, or a larger hole in the teat is needed.

Necrotising enterocolitis occurs in epidemics in neonatal baby units. Lethargy and refusal of feeds are followed by vomiting and abdominal distension. In the majority of the infants there is blood in the stool. Predisposing factors are prematurity, perinatal hypoxia, hypotension, umbilical vessel catheterisation, and prolonged rupture of the membranes. Embolism or thrombosis of mesenteric vessels is followed by ischaemic changes, which vary from mucosal ulceration to complete necrosis of the gut wall. Bacteria invade the necrotic tissue and healing is followed by scarring and sometimes a stricture. Despite optimal treatment there is a 25% mortality rate and early advice from a paediatric surgeon is advisable.

Raised intracranial pressure due to intracranial haemorrhage may cause vomiting of milk, as may several drugs, especially digoxin.

Figure 12.4 Drops of milk should follow quickly and there should not be a continuous stream.

Vomiting from the first week to the first year: causes

As in the newborn, vomiting in infants older than one week may be a symptom of a feeding problem or an infection such as urinary tract infection, otitis media, gastroenteritis, septicaemia, or meningitis (see p. 90).

If no cause of the vomiting is found and the symptoms are mild, urine should be collected for microscopy and culture and should be examined for protein, bile, and reducing substances.

Pyloric stenosis

Pyloric stenosis must be considered in every infant less than three months of age who vomits. Rarely the vomiting may occur in the first week of life, but it usually begins in the second or third week, though there may be a delay before the infant is seen by a doctor. Usually the vomit is produced forcefully and reaches some distance from the infant. The infant often accepts another feed immediately after vomiting. Stools are infrequent. If the symptoms have been present for more than a few days, there will be a loss of weight due to dehydration and loss of subcutaneous fat. Scanty urine is associated with dehydration.

The essential diagnostic sign is the presence of a pyloric mass palpated during a test feed. Constant practice is needed to appreciate a pyloric mass. Even if no pyloric mass is felt during the first test feed, if the diagnosis of pyloric stenosis is probable the infant should be admitted for rehydration and the examination repeated. Preliminary aspiration and measurement of gastric contents is helpful, particularly if no feed has been given during the preceding four hours. Metabolic alkalosis strongly suggests the diagnosis.

In a small proportion of infants the diagnosis of pyloric stenosis is suspected clinically but no pyloric mass is palpable during a test feed. The diagnosis may be confirmed, preferably by an ultrasound study. A barium study is needed rarely.

Box 12.1 Vomiting after the first week

- Feeding problems
- Infections:
 - Urinary tract infection
 - Septicaemia
 - Meningitis

Figure 12.5 Pyloric stenosis.

Intestinal obstruction

Infants who vomit greenish yellow bile are likely to have intestinal obstruction. They should be admitted immediately and seen by a surgeon within an hour. Abdominal distension is often present and peristalsis may be visible. Duodenal stenosis usually presents during the first few days of life but malrotation of the gut with associated volvulus may produce symptoms at any time during childhood.

An inguinal hernia is more likely to incarcerate in the early months of life than later. Incarceration should be suspected if the hernia is tender or is not reduced easily; immediate surgery is required. The risk of obstruction is always present and early surgical treatment is advisable in every baby with an inguinal hernia. The baby must remain in the ward until the operation is performed.

An intussusception is a partial or complete intestinal obstruction due to invagination of a portion of the gut into a more distal portion. It may occur at any age, although the maximum incidence is at 3–11 months. An intussusception may be easily diagnosed in a child who has all the typical features, but these children are not common. The distinctive feature is the periodicity of the attacks, which may consist of severe screaming, drawing up of the legs, and severe pallor. Some episodes consist of pallor alone. The attack lasts a few minutes and may recur about 20 minutes later, though attacks may be more frequent. There may be vomiting and one or two loose stools may be passed initially, suggesting acute gastroenteritis. Bloodstained mucus may be passed rectally or shown by rectal examination. But some patients pass no blood rectally. Between attacks the infant appears normal and may have no abnormal signs apart from a palpable mass.

It is difficult to examine the abdomen during an attack because the child cries continuously, but between attacks a mass, most commonly over the right upper quadrant, can be felt in 70% of children.

If surgical shock is present, then rapid resuscitation should be carried out and intravenous fluids, including blood, given. Plain radiograph of the abdomen may show evidence of intestinal obstruction or a density in the area of the lesion. Ultrasound may show a doughnut configuration with hypoechogenic rims and a dense central echogenic core. An urgent surgical opinion should be obtained. If the symptoms have been present for less than 48 hours and there are no signs of intestinal perforation, an air or barium enema should be given urgently while the surgeon remains nearby. In over 75% of cases it is possible to reduce the intussusception by the enema. If the intussusception is not reduced, then immediate laparotomy is needed to reduce the lesion manually or to perform an intestinal resection. In about 6% of cases there is a persisting mechanical cause of the intussusception and this will not be detected by the enema.

Gastro-oesophageal reflux

Vomiting due to gastro-oesophageal reflux starts during the first week of life and the vomitus may be blood stained. Aspiration into the lungs may cause recurrent bronchospasm and severe vomiting may cause failure to thrive, dysphagia, or stricture formation. During the first year the lower oesophageal sphincter pressure increases and oesophageal mobility becomes more organised. These factors reduce the regurgitation of gastric contents into the oesophagus when the intra-abdominal pressure rises, for example during crying.

The diagnosis can be confirmed by 24 hour pH monitoring of the lower oesophagus. A probe the size of a

- Stenosis (rare)

ABC of the First Year

nasogastric tube is placed just above the gastro-oesophageal sphincter. The pH recording is analysed by computer. Barium swallow examination is often negative despite typical symptoms.

Vomiting usually resolves by the age of one year without specific treatment. If symptoms are severe, the feeds can be thickened with carob seed flour or ground rice and the infant may be nursed with his head higher than his feet on his side. If the vomiting is persistent and severe, a paediatrician should be consulted. Most paediatricians recommend a trial period with thickened feeds before a pH recording.

Whooping cough

Vomiting may be so severe in infants with whooping cough that the mother is more worried by the vomiting than the cough. During the first five days of the illness (catarrhal phase) there is a short, dry nocturnal cough. Later, bouts of 10–20 short coughs occur day and night. The cough is dry and each cough is on the same high note or goes up in a musical scale. The long attack of coughing is followed by a sharp indrawing of breath, which causes the whoop. Some children with proved pertussis infection never develop the whoop. Feeding often provokes a spasm of coughing and this may culminate in vomiting. Afterwards there is a short refractory period during which the baby can be fed again without provoking more coughing. In uncomplicated cases there are no abnormal signs in the respiratory system.

Adrenogenital syndrome

The adrenogenital syndrome (salt losing type) commonly presents with vomiting as the only symptom in boys. The diagnosis is easier in girls, as virilisation of the external genitalia will have been noticed at birth. Symptoms usually begin between the seventh and tenth days and may be fatal within a few days if extra salt and salt retaining adrenocorticosteroids are not given. Intravenous fluids are essential. The diagnosis is confirmed by raised plasma 17 OH-progesterone concentrations, high plasma potassium, and low plasma sodium concentrations. The plasma electrolyte concentrations are normal at birth and pronounced changes may occur suddenly.

Figure 12.8 Phases of whooping cough.

Figure 12.9 Adrenogenital syndrome.

13 Diarrhoea

Diarrhoea is the passage of loose stools more often than would be expected from the diet and age of the infant. It indicates a change in bowel habit. A stool should be examined personally. A rectal examination is often followed by a fresh stool, which can be examined. When diarrhoea is severe, the stools may be mistaken for urine. When this is a possibility, a urine bag should be placed in position and the infant nursed on a sheet of polyethylene.

The stools of newborn infants vary with their diet. The normal stools of breastfed infants are never formed, may be passed at hourly intervals, may contain mucus, and may be green. When lactation becomes established between the third and fifth days intestinal hurry is common, resulting in frequent stools. Later the stools tend to become less frequent and more pasty and by the age of three weeks they may be passed once every two or three days. No treatment is needed. In contrast, the normal stools of bottlefed infants are formed and do not contain fluid or mucus. With certain cow's milk preparations the stools may be dark green, but this has no sinister meaning.

Acute gastroenteritis

Acute gastroenteritis is an acute infection mainly affecting the small intestine that causes diarrhoea with or without vomiting. The main danger is dehydration and electrolyte imbalance, which may develop rapidly, but the infant may also be very infectious for other infants in a ward or nursery. Gastroenteritis is particularly dangerous to infants aged under two years.

The early signs of dehydration are often difficult to detect, but recent weight loss is often a valuable indicator. Sunken eyes, inelastic skin, and a dry tongue are late signs, but if the infant has not passed urine for several hours severe dehydration is probable. Clinical signs of dehydration are particularly difficult to detect in fat toddlers.

The infant must be examined in detail to exclude any other acute infection.

The rotavirus is the most common cause of gastroenteritis in infants and children throughout the world. It affects every age group and infection easily spreads throughout a family, although the infected adults may have few or no symptoms. Several distinct episodes of diarrhoea can be due to the rotavirus, as there are several serotypes. The incubation period is 24–48 hours and a respiratory illness, including otitis media, precedes the gastrointestinal symptoms in about half the patients. Vomiting which lasts for one to three days is followed by abnormal stools for about five days. Treatment is aimed at keeping infants well hydrated until they recover spontaneously. The frequency of the stools is reduced by dietary treatment, but the abnormal consistency of the stools persists for up to a week.

If infants are given an antibiotic early in the illness (for example, when acute otitis media is suspected as the primary diagnosis) the subsequent diarrhoea may be attributed to the antibiotic rather than to the rotavirus infection. Other drugs (for example, iron) may be associated with diarrhoea.

Management

Clinical signs of severe dehydration or the loss of 5% or more of body weight are definite indications for admission. If infants relapse after treatment or social problems prevent them being

Figure 13.1 Stool of breastfed infant.

- Electrolyte abnormalities
- Cross infection

Figure 13.3 Rotavirus.

treated at home they may need to be admitted. Infants who vomit persistently usually need to be admitted, though mild symptoms may be managed at home by giving small volumes of liquid by mouth every hour.

In mild cases the main principle of management is to stop cow's milk and solids and give a glucose or sucrose solution orally. After 24 hours fruit or vegetable purées may be introduced and then other items from the child's normal diet. Cow's milk and cow's milk products are re-introduced gradually after the first 24 hours of treatment. Vomiting may be reduced by giving small volumes of fluid frequently. The child should be allowed to drink as much as he wants but needs at least the volume shown in Table 13.1.

Rarely, a breastfed infant has gastroenteritis, but the symptoms are usually mild. The appropriate volume of rehydrating fluid is given by bottle or spoon before each breastfeed.

Kaolin should not be prescribed as it deflects the mother's attention from the main treatment. No antibiotics should be given to children with gastroenteritis treated at home.

The ideal oral rehydrating fluid is a glucose–electrolyte mixture, but a 4% sucrose solution is easily available and safe. Single dose sachets of glucose–electrolyte powder (Dioralyte) or glucose–sucrose–electrolyte powder (Rehydrat) are available, which enable mothers to make up the mixture accurately at home. A safe alternative is 4% sucrose solution, which can be made up by the mother using two level teaspoonfuls of granulated sucrose in 200 ml water. *It is dangerous for mothers to add salt to this mixture.*

In severe cases of dehydration or persistent vomiting oral fluids must be replaced with intravenous fluids in infants admitted to hospital. During the next day the fluid requirement should be given as an oral glucose–electrolyte mixture, alternating with full strength cow's milk formula, and fruit and vegetable purées are introduced. Most children are discharged from hospital on normal diets within a few days of admission.

Infants in hospital with diarrhoea must be barrier nursed in a cubicle, which should ideally be in an annexe to the children's ward.

Investigations

Ideally a stool should be sent to the laboratory for detection of pathogens, but this is not necessary for mild cases treated at home. Only a small proportion of children have bacteria such as *Campylobacter*, *Salmonella*, *Shigella*, or pathogenic *Escherichia coli* isolated from their stools. *Cryptosporidium*, a protozoon which can be seen by light microscopy, is a common pathogen. Most cases of gastroenteritis in children are caused by viruses, usually rotavirus, and can be identified by an ELISA slide test.

Children needing intravenous fluids should have their plasma electrolyte, bicarbonate, and urea concentrations measured urgently.

If two or more infants in a ward or nursery have diarrhoea at the same time cross infection should be presumed, even if their stool cultures show no pathogens. Stools from all the infants on the ward should be sent for culture and tests for rotavirus. Admissions to the ward may have to be stopped.

Progress

The infant should be reviewed again by the doctor within 24 hours of starting treatment to ensure that the illness is resolving, the infant is not losing too much weight, and the

mother understands the management. Severe dehydration can occur within a few hours and it is helpful to have a specific policy to ensure adequate follow-up visits.

The main cause of relapse or persistent symptoms is failure to follow a plan of treatment. Social problems may indicate the need for admission to hospital. A few infants aged under two years have temporary mucosal damage and are intolerant to cow's milk or other foods. This causes the diarrhoea to persist for longer than two weeks and is considered on p. 69.

Gastroenteritis in developing countries

In developing countries the continuation of breastfeeding during attacks of gastroenteritis may be essential for survival. Although infants who are completely breastfed rarely have severe gastroenteritis, weaning foods made up with water may infect a breastfed infant. These infants can be managed by continuing the breastfeeding and supplementing the fluid intake to prevent dehydration until the infant spontaneously recovers. Supplements may be given by mouth in mild cases and intravenously in severe cases. An easier method is to give them by continuous intragastric infusion, for which the fluid does not have to be sterile.

Oral rehydrating fluids can be made up using specially designed spoons to measure the sugar and salt. Mothers and older siblings can be taught to use this mixture at the beginning of an episode of diarrhoea rather than wait until the child is dehydrated. Simple slogans such as "a cup of fluid for every stool" are effective.

Box 13.3 Causes of relapse

- Temporary intolerance to cow's milk protein

Figure 13.6 Spoons to measure sugar and salt for rehydration fluid.

14 Mother–infant attachment

There is no specific sensitive period immediately after delivery that is the only time that emotional attachment can form. Any important effects of separation do not persist beyond days or weeks after reunion. Parents who have read obsolete publications may need reassurance that early separation is not followed by permanent damage to mother–infant relationships. A comparison of preterm and term babies indicated that parents find the behaviour of preterm babies less predictable and more frustrating. Though frequent and sustained contact with a sick or preterm baby may increase the degree of parental anxiety, this anxiety induces a feeling of involvement in the care of their baby.

A biological need

Mothers and infants need a close attachment to give the infant the degree of security necessary for optimal emotional and physical development.

Most mothers have strong maternal feelings, which enable them to achieve a firm bond of affection with their babies without difficulty, even after an initial period of separation. The strength of their maternal feelings probably depends on the quality of mothering they received in infancy.

In contrast, a mother may be unable to achieve this attachment without close contact with her baby and even then, it may take a few days before the baby appears to her to be an individual and her own. Failure to form a normal attachment probably accounts for the higher incidence of “battered babies” among preterm infants and among the infants of mothers who were themselves deprived of maternal care.

Forming an attachment

Attachment occurs in five main ways. Firstly, infants can follow the mother’s eyes immediately after birth and this eye to eye contact is an important factor.

Secondly, a mother left with her naked infant touches each part of the baby’s body with her fingertips.

Thirdly, during the first few days after delivery mothers often appear to overprotect their infants and become overanxious about crying and minor difficulties, such as those of feeding.

Fourthly, even in the first days of life babies mimic the facial expressions of others and can, for example, put out their tongues at them, providing “feedback”.

Lastly, physical contact during breastfeeding and the presence of the baby next to the mother throughout the entire 24 hours also promote attachment.

Separation

Separation is sometimes unavoidable if, for example, the infant has to be transferred to another unit for surgery or the mother is receiving heavy sedation for hypertension. The mother is equally separated from her child when she is severely depressed, but this may not appear so obvious.

In the past many babies were separated from their mothers for reasons that would not now be acceptable. Owing to doctors’ anxiety, infants with jaundice were admitted to special care units even though they needed no special care.

Figure 14.1 A newborn infant looking at mother.

Figure 14.2 Maternal feelings are related to the quality of the mother’s own mothering.

Figure 14.3 Factors in attachment.

The number of nursing staff available on individual maternity wards will determine whether it is safe for babies to remain with their mothers, but no infant should be separated from his or her mother without good reason.

A postnatal ward should be staffed with midwives who have special experience in nursing babies of low birthweight. This allows babies needing tube feeding and other forms of special care to remain with their mothers and avoids the separation resulting from admission to the neonatal unit. The care of healthy but low birthweight infants in the same environment as their mothers is called transitional care to indicate that they need more support than normal term infants.

Difficulty in forming attachments

Some aspects of the history may suggest that a mother may have difficulty in forming an attachment to her infant and will need special help from nursing and medical staff. Particularly vulnerable are mothers who had poor maternal care in their own childhood or who have had a request for an abortion rejected or unmarried mothers who have not decided whether they want the infant to be adopted. If a previous infant was stillborn or died in the neonatal period or a close relative has recently died, help may also be needed. Special attention should be given to a mother under 17 or over 35 years of age and having her first baby.

When the baby is born, the mother may refuse to handle or feed him or her and be more concerned with her own minor symptoms than the infant's care. She may feel detached and the infant's problems may appear to her to be more serious than they are. Similar symptoms may be the first indication of a severe depression in the mother and she may need psychiatric help.

Encouraging attachment

To encourage attachment the principle is to avoid unnecessary separation. Unless infants require special nursing they should be given to their mothers in the labour room, even if an abnormality such as Down's syndrome is present. Newborn infants are able to feed moments after birth even if the mother has received sedation and the mother should be encouraged to put the baby to her breast if she intends to breastfeed. Infants should remain with the mother throughout the 24 hours of the day and be taken out at night only if they continually disturb the other mothers in the room. Breastfeeding should be actively encouraged, though this may take time and perseverance by both mothers and nursing staff. Mothers of preterm infants should be encouraged to express their milk and thus feel that they are actively contributing to the infant's welfare.

In neonatal units the atmosphere should make mothers feel that they are welcome at any time and they should be encouraged to look at, touch, change, feed, and later breastfeed their infants. When the mother is about to visit a very sick infant the reasons for the use of special apparatus should be explained beforehand. A mother can usually visit her infant in the neonatal unit the day after a caesarean section by being wheeled in a chair.

If a mother fails to visit her infant for long periods after she has been discharged, an inquiry should be made whether any remediable reason, such as lack of transport, is responsible.

Before the infant is discharged from the unit the mother should remain with her infant in a room on the unit for at

Figure 14.4 Separation may be necessary for medical reasons.

Figure 14.5 Detachment due to depression.

Figure 14.6 Parents should be encouraged to care for their infant in the neonatal unit.

least 24 hours, but longer if possible. This gives her an opportunity to gain confidence in her ability to cope with her baby, who recently appeared to be so fragile and needing expert nursing care to survive.

What the newborn baby can do

Many mothers, especially those having their first baby, believe that newborn babies are blind until they are six weeks old. It is not surprising that these mothers treat their babies like inanimate dolls and feel ashamed when an unexpected visitor catches them talking to the baby. The normal newborn infant can see, hear, and appreciate pain immediately after birth, even if the mother has received heavy sedation. During the hour after birth the infant is often wide awake, looking round for a feed before going to sleep for a few hours.

The distance between the eyes of the mother and the infant when the mother is breastfeeding is the distance at which infants can best focus on an object. This eye to eye contact provides the first means of communication between mother and infant and is probably the reason why mothers find that covering the infant's eyes during phototherapy disturbs them. Mothers of blind infants have difficulty in feeling close to their infants. Newborn infants will become alert, frown, and gradually try to focus on a red object dangled about 30 cm before them. They stare intently at the object and will follow it with short jerking movements of the eyes if it is moved slowly from side to side. Infants are also sensitive to the intensity of light and will shut their eyes tightly and keep them shut if bright light is turned on. They can discriminate shapes and patterns and the arrangements of lines from birth. They prefer patterns to dull or bright solid colours and look longer at stripes and angles than at circular patterns.

Newborn infants can hear. They respond to sound by blinking, jerking their limbs, or drawing in breath. They may stop feeding. Mothers often speak to their infants in a high pitched voice and an infant responds more consistently to his mother's than his father's voice. An infant of three days of age shows preference for sweet and dislike of bitter flavoured fluid. At about the same age he can differentiate smells and distinguish between his own mother's and other mothers' breast pads.

Analysis of sound films shows that both listener and speaker are moving in time to the words of the speaker, creating a type of dance. For example, as the speaker pauses for breath or accentuates a syllable, the infant may raise an eyebrow or lower a foot. The mother notices these changes and this may encourage her to continue speaking. At a few weeks or even a few days after birth the infant may mimic gestures such as tongue protrusion, lip protrusion, or opening the mouth.

If the doctor talks to babies while examining them, mothers will not feel foolish when they do it themselves.

Figure 14.8 Newborn infant looking at the camera.

Figure 14.9 Infant looking at mother's face.

15 Growth and growth charts

Weight and head circumference

The size of the normal infant at birth is determined mainly by the mother's size. The greatest changes to adjust for other hereditary factors take place during the first three months of life. Although children tend to attain a stature between those of their parents, some children take after one parent, grandparent, or an even more remote member of the family. All these children are perfectly healthy. It may be difficult to distinguish these normal adjustments of growth from disease, especially during the first few months of life. Growth charts are therefore essential for diagnosis during this period and helpful in discussions with parents.

Length (or height) is difficult to measure accurately in a very young baby and for some years we have used the head circumference as a reference measurement for comparison with the weight. The use of the head circumference in this way is valuable only in the first two years of life. The head circumference is measured round the occipitofrontal circumference (the largest circumference), which should be determined with a disposable paper tape measure. Linen tape measures stretch and produce inaccurate results.

Normal growth and small normal infants

An infant usually has a similar centile at birth for both head circumference and weight. Children of large parents tend to be towards the 98th centile and those of small parents near the 2nd centile. Most of these children remain on the same centiles for the rest of their lives. Plotting these measurements on a chart in routine clinics helps to confirm that the child is receiving adequate food and is growing normally.

One of the most common problems in paediatric outpatient clinics is short parents who think that their infant does not eat enough. Plotting growth measurements on a chart from measurements already recorded at the local clinic confirms to the doctor and the parents that the child is normal and that the child's final size will be similar to that of the parents (chart A). Charts are better than cards for recording growth.

Figure 15.1 Measuring the head circumference.

Chart A Small normal infant.

Figure 15.2 Growth chart.

Chart B Taking after father.

Chart D Obesity.

Taking after father or mother

Some children are more similar to one parent than the other in final size. If only their weights are recorded, they may appear to be either failing to thrive if the father is small (chart B) or gaining weight excessively if the father is tall (chart C). If both weight and head circumference are plotted on a chart, the weight centile line and head circumference centile line can be seen to be running in parallel. In other words, the whole of the child's size is approaching that of a particular parent.

Getting fat

Growth charts give an early warning of obesity. Chart D shows that at the age of 20 weeks this child's weight centile started deviating upwards although the head circumference centile remained the same. If the mother had been shown the growth chart at the age of 20 weeks she might have been able to prevent the phenomenon seen at 30 weeks.

The standard growth charts are based on data collected when the majority of babies were fed with cow's milk preparations. Some normal breastfed babies gain weight rapidly in the first 10 weeks and then more slowly during the subsequent 20 weeks (chart E). This is a normal growth pattern and is not an indication of obesity.

Chart C Taking after father.

Chart E Normal breastfed infant.

Chart F Poor lactation.

Chart H Catch-up growth in preterm infant.

Poor lactation and failure to thrive

The increased incidence of breastfeeding has resulted in a few infants receiving insufficient milk as a result of their mothers' not recognising poor lactation. This can be detected at an early stage by weighing infants regularly, although normal breastfed infants may not regain their birthweights before the age of two weeks. The onset of full lactation is extremely variable and this must be taken into account when considering the adequacy of weight gain (chart F). Plotting the infant's weight on a growth chart is the first investigation required to diagnose whether failure to thrive is present and also to give a presumptive diagnosis of the cause (chart G).

Preterm

When preterm infants reach home, they may gain weight rapidly, when they will cross the centile lines for both weight and head circumference in parallel (chart H). Preterm infants may have a relatively large head measurement because of the head's discoid shape, but continuing growth on the same centile line shows that the head is normal. Babies of extremely low gestational age, especially below 26 weeks, with chronic lung disease may continue to grow poorly despite feeding well.

Infants whose growth *in utero* has been restricted due to poor nutrition related to placental function may have catch-up growth or may continue to grow poorly postnatally (chart I).

Chart G Coeliac disease.

Chart I Poor weight gain and discoid head in preterm infant.

Chart J Infant of diabetic mother.

Chart K Progressive hydrocephalus.

Infant of diabetic mother

The infant of the diabetic mother may be grossly obese at birth but slims down within a few months of birth (chart J). These infants may not gain any weight at all for the first two months of life and the mother may be accused of starving the infant.

Progressive hydrocephalus

Progressive hydrocephalus can be confirmed by showing a head circumference centile that progressively increases while the weight centile shows no change (chart K). It may occur in association with intraventricular haemorrhage in preterm infants or myelomeningocele. Hydrocephalus can be confirmed by ultrasound examination of the brain if the anterior fontanelle is still open. This condition must be differentiated from familial large head, where the head circumference centile remains constant and is parallel to the weight centile.

16 Feeding and feeding problems

There has been no significant change in the incidence of breastfeeding in Great Britain since 1980. In 1990, 63% of mothers breastfed compared with 64% in 1984 and 65% in 1980. There is a steep gradient in the incidence of breastfeeding among mothers of first babies from 50% in social class V to 89% in social class I. The incidence of breastfeeding among mothers having their first child was 57% for those who left full time education at the age of 16 years or under compared with 93% among mothers who left school at the age of 19. In 1990 one third had stopped breastfeeding by six weeks. The proportion of breastfed babies receiving additional bottles at six weeks has been rising since 1980, when it was 28%, to 34% in 1985 and 39% in 1990.

Full term infants usually regain their birth weight between the seventh and tenth day, and thereafter the infant should gain about 20–40 g/day for the next 100 days. Unmodified milk (“doorstep” milk) should not be given until after the age of one year and should be accompanied by vitamin supplements, particularly vitamin D, until the age of two years. Progress on a growth chart is the best guide to ensuring that an infant is receiving the correct amount of milk.

Breastfeeding

Breastfeeding should be encouraged. Firstly, the fat and protein of human milk are more completely absorbed than those of cow’s milk. The composition of human milk varies during a feed and these subtle changes cannot be mimicked by cow’s milk preparations. The significance of these changes is unknown but may be related to the control of intake by appetite.

Secondly, although the fat composition and therefore the fatty acid composition of breast milk vary during a feed, these changes cannot be replaced exactly by cow’s milk preparations and the differences in body composition resulting from these different milks may have a long term effect.

Thirdly, human milk contains antibodies and iron binding protein (lactoferrin) which may protect the infant against infections. Gastroenteritis is rare in breastfed infants.

Breastfeeding also plays an important part in mother–infant attachment. If the mother is encouraged during the antenatal period to expect to be able to breastfeed her baby and eventually to enjoy it, she is likely to accept early difficulties with patience and understanding. The close contact and intimacy, and often supreme enjoyment, of breastfeeding provide the best “feedback” between the baby and the mother. The mother’s intimate personal relationship with her baby is something that she has to work out for herself. Many feel insecure and inadequate at first and are only too glad to change to bottle feeding whenever the slightest difficulty arises. The attendant should resist such requests and instead use sympathy, understanding, and skill to encourage the mother to gain confidence in handling her own baby.

Latching to the breast

The sensation of the nipple against the palate stimulates the baby to suck. Placing the baby in the correct position encourages successful feeding and avoids damage to the nipple. The baby’s chin must drive into the breast to enable

Figure 16.1 Normal growth chart.

Figure 16.2 Advantages of breastfeeding.

the nipple to reach the palate, so the baby needs to put his head back and up. If the baby's head becomes too flexed, the nipple touches the lower jaw and the tongue and the nose is too close to the breast. Helping the chin to thrust forwards and the head to tilt back is hindered by pressure on the back of the head but improved by supporting the baby's back at shoulder level, with the baby facing the mother, chest to chest.

Rooming in

A normal infant is put to the breast for a few minutes at each side either immediately or a few hours after birth. Only a small amount of colostrum is obtained but sucking by the infant stimulates the production of more milk. Some infants are reluctant to take the nipple initially and the mother needs strong reassurance that this is common.

During the first week, and probably later, most of the feed is obtained within four minutes in some babies. Thus the length of time that the baby is on the breast bears little relation to the amount of milk received by the infant. Some infants take a shorter time and others a longer time to take a full feed.

The most satisfactory method of breastfeeding is "on demand". Babies commonly feed every two or three hours during the first few weeks and these frequent feeds are a powerful stimulus to lactation. This is the main advantage of rooming in, where the infant's cot is by the side of mother's bed and she can pick him up and feed him when he cries. Mothers should be encouraged to do this. Infants initially fed on demand usually settle down to a regular schedule after a few weeks. Most breastfed infants feed three hourly rather than four hourly. After the seventh day, if the infant appears to be hungry after a feed or is progressively losing weight test feeding may be considered.

Test feeding

Test feeding should be avoided whenever possible, as it can create anxiety in some mothers. The infant is weighed, without changing the napkin or clothes, before and after each feed during a 24 hour period. If the feed is deficient, putting the baby to the breast more frequently may stimulate increased lactation in the early days or the deficit may be made up with a bottle feed given after feeding from both breasts (complementary feeding). Fortunately, a well nourished full term infant can tolerate a degree of underfeeding without harm for a few days.

Complementary feeds are rarely necessary in the first five days, and after this they should be used only when absolutely necessary. The feel of the bottle teat is quite different from that of the nipple, and when the infant is accustomed to one it may be difficult to persuade him to take from the other.

Contraindications to breastfeeding

There are few contraindications to breastfeeding. Some women have a revulsion to the idea and it would be a mistake to try to persuade them, but psychiatric illness in the mother may be aggravated if the baby is taken off the breast. Severely cracked nipple is a temporary contraindication to feeding from the affected breast, but the milk should be expressed with a pump. Feeding should continue from a breast with acute mastitis while the mother is receiving an antibiotic; it should also continue if the nipple is only mildly cracked.

No drugs should be taken by a lactating mother unless there are strong clinical indications. Most drugs that are essential for the mother are secreted in the milk in

Figure 16.3 Breastfeeding.

Figure 16.4 Rooming in.

Figure 16.5 Test feeding.

Box 16.1 Contraindications to breastfeeding

- Maternal dislike
- Severely cracked nipple
- *Rarely*, drugs

insignificant amounts, so breastfeeding should not be stopped unless there is a special reason. Antibiotics are excreted in minute amounts in the milk but there is the theoretical possibility of sensitising the infant. Warfarin, senna, barbiturates, phenytoin, digoxin, steroids, antacids, and occasional doses of paracetamol pass into the milk in unimportant amounts. Kaolin is not absorbed by the mother. Oestrogens in oral contraceptives may reduce lactation, but the progesterone-only pill is an effective contraceptive and has no effect on lactation. A mother receiving carbimazole may continue to breastfeed provided that the infant's plasma thyroxine concentration is monitored.

Mothers receiving radioactive antithyroid treatment or cytotoxic drugs should not breastfeed. Lithium given to the mother may cause hypotonia, hypothermia, and episodes of cyanosis in a breastfed infant.

Problems with breastfeeding

On the fourth or fifth day, when there is a plentiful supply of breast milk, the infant may take up to eight feeds or more a day. Intestinal hurry and frequent loose green stools are common at this stage. Conversely, some normal breastfed infants pass stools only once a week when they reach the age of a few weeks, and this also requires no treatment.

Cracked nipple is usually due to malplacement of the infant on the nipple so that the whole of the pigmented area is not in the infant's mouth. Pulling the infant off the breast abruptly is another cause. If the nipple is slightly cracked, breastfeeding should continue with advice on latching to the breast. If the crack is severe, the infant should be taken off that breast for a day or so and a bland ointment, such as lanolin, placed on the nipple every few hours. A fissure of the nipple occurring after the first few weeks is often aggravated by thrush infection of the baby's mouth and the mother's nipple. It is best treated with miconazole or nystatin gel to both until four days after it appears to be clear.

In acute mastitis there is fever, pain, flushing, and induration in one breast and enlarged axillary lymph nodes. Flucloxacillin or erythromycin is given to the mother for at least a week and feeding continues from both breasts. Fluctuation in the indurated area indicates that an abscess is present and the need for surgical incision and suppression of lactation with bromocryptine.

Feeding on demand usually prevents maternal breast engorgement, which can occur towards the end of the first week of the baby's life. This is easily alleviated by expression after feeding, preferably with a pump. If engorgement has already occurred the help of an experienced midwife is necessary.

During the first feed of the morning milk may spurt quickly from the breast and a ravenous infant may swallow excessive air, which may be regurgitated later with milk. This is often accompanied by severe crying. It can be alleviated by manual expression of the first 30 ml of milk, which can be given to the infant later if necessary.

Bottle feeding

All the cow's milk preparations available in Britain have sodium and protein concentrations similar to those of human milk. The powder should be measured accurately, avoiding heaped or packed scoops. The instructions on each packet must be followed. Ready to feed bottles are used in most obstetric units.

Box 16.2 Problems with breastfeeding

- Breast engorgement: *expression*
- Gulping: *expression*

Figure 16.6 Good placement of the nipple in the infant's mouth.

Figure 16.7 Breast pump.

If feeds are made up for a 24 hour period they should be stored in the refrigerator. Bottles can be sterilised in dilute hypochlorite solution, but processing in an autoclave is the best method in hospitals. Other methods include steam or a special microwave oven kit. Teats should be well washed before sterilisation.

The size of the hole in the teat should allow individual drops of milk to follow each other quickly when the bottle is inverted, and this should be checked each week.

“On demand” feeding

Feeds are usually given “on demand” or three or four hourly. Most infants need to be fed every three hours. The milk must not be made up to a stronger concentration than that recommended on the packet. Few babies can manage without a night feed for the first few months.

A normal full term infant receives 30 ml of milk per kg body weight during the first day of feeding by bottle. Feeds should be increased by 20 ml/kg each day until a maximum of 150 ml/kg is reached on the seventh day of feeding. Underfeeding causes small amounts of green mucus to be passed frequently, but this is more likely to be found with breastfed than with bottlefed infants.

Problems with bottle feeding

If the hole in the teat is too small the infant may swallow excessive air during the feed and regurgitate it later with milk, accompanied by bouts of crying. It is valuable to observe the rate at which the drops of milk are formed when the infant’s bottle is inverted. The drops should follow each other quickly but there should not be a continuous stream. If the hole is too small it may be made larger with a hot needle. If the hole is too large, infants may swallow excessive air as they gulp to avoid choking.

By taking a careful history it is usually possible to determine the likely cause of any symptoms. If growth is poor, infants need more frequent or larger feeds. If the weather is hot and infants are not receiving extra water, they may be thirsty and should have additional water. Mothers tend to use gripe water as a panacea, not realising that it contains bicarbonate, which produces carbon dioxide in the stomach.

Reluctance to feed

In an infant who has fed normally before, reluctance to feed may be a dangerous symptom. It may be due to any severe disease, such as congenital heart disease or a lower respiratory tract infection. On the other hand, when an infant has a mild upper respiratory tract infection the nose may become blocked with mucus making it difficult for the baby to feed. Thrush produces white plaques on the buccal mucosa and tongue, which become sore. It can be treated by a five day course of oral nystatin drops or miconazole oral gel, 1 ml twice a day.

Figure 16.8 Container for sterilising bottles.

Figure 16.9 Drops should follow each other quickly.

Figure 16.10 Infant refusing a feed.

17 Failure to thrive

Mothers become anxious if their infants do not gain weight at the rate that is expected. The majority of these babies are perfectly healthy but the expectations are too high. Initially, it is essential to determine whether the baby is gaining weight normally. If weight gain is abnormal, failure to thrive is present and a cause should be sought. Some of the material in this chapter is also found in Chapter 15.

Normal weight gain

Small parents

An infant usually has a similar centile at birth for both head circumference and weight. Children of large parents tend to be towards the 98th centile and those of small parents near the 2nd centile. Most of these children remain on the same centiles for the rest of their lives. Plotting these measurements on a chart helps to confirm that children are receiving adequate food and are growing normally. A common problem is the infant of short parents who consider that their child does not eat enough. Plotting growth measurements on a chart from measurements already recorded at the local clinic confirms to the doctor and the parents that the child is normal and that his or her final size will be similar to that of the parents. Charts are better than lists of measurements for seeing the trends in growth.

Taking after father or mother

Some children are more similar to one parent than the other in final size. If only their weight is recorded they may appear to be either failing to thrive if the father is small (chart B) or gain in weight excessively if the father is tall (chart C). If both weight and head circumference are plotted on a chart, the

Box 17.1

- Is the weight gain normal?
- If not, what is the cause?

Chart A Normal infant of small parents.

weight centile line and head circumference centile line can be seen to be running in parallel. In other words, the whole of the child's size is approaching that of a particular parent.

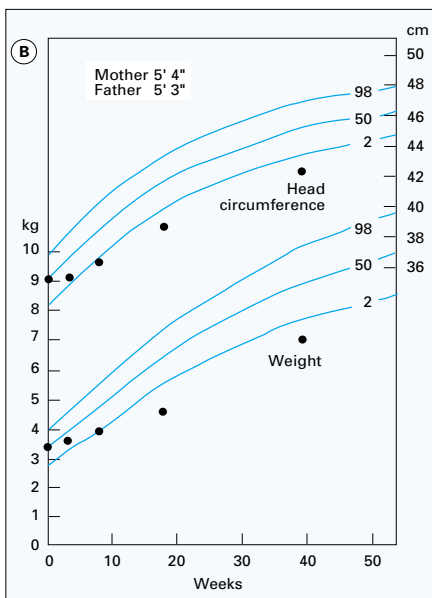

Chart B Taking after father.

Chart C Taking after mother.

Low birthweight

Infants who are of low birthweight may have been born early (preterm) or have experienced intrauterine malnutrition or both. Although some of them have a period of “catch-up” growth during the first few months of life, others remain below the 2nd centile for the whole of their lives. This is considered to be related to the intrauterine malnutrition (see chart D).

Physical causes of failure to thrive

A progressive fall in the weight centile with a constant head circumference centile is the best confirmation of failure to thrive. Measurements on a single occasion may show a weight centile that is below the head circumference and length centile, but these findings may be present in a normal baby whose family has a body shape that is slightly different from the majority. The plotting of serial measurements on a growth chart before starting to take a history often shortens that process.

Deficient intake of food or the excessive loss from malabsorption or metabolic disease cause failure to thrive. Psychiatric and social problems, which are the predominant factor in the majority of the infants with failure to thrive in this country, probably reduce the food intake.

A detailed history is taken, paying particular attention to the family history, birth, feeding, and maternal anxieties. Details of any vomiting, diarrhoea, or abdominal distension are noted. The complete examination includes an assessment of developmental age and evidence of wasting, particularly of the inner aspects of the thighs and buttocks.

Deficient intake

Poor lactation – The high incidence of breastfeeding in some areas has resulted in a few infants receiving insufficient milk as a result of their mothers’ not recognising poor lactation. This can be detected at an early stage by weighing infants regularly (see Chart E), although normal breastfed infants may not regain their birth weights before the age of two weeks. The onset of full lactation is extremely variable and this must be taken into account when considering the adequacy of weight gain (see Chapter 16)

Problems with bottle feeding – Poor tuition may result in deficient milk intake (see Chapter 16)

Cerebral palsy – Infants with cerebral palsy may present with slow feeding and resulting poor milk intake before changes in the motor function in the limbs can be detected. These infants will usually have some evidence of developmental delay.

Congenital heart disease – There may be deficient milk intake due to slow feeding and there is also a high metabolic rate. Central cyanosis, a murmur, or both are usually present.

Urinary infection – A clean catch urine specimen examined promptly in the laboratory is essential for this diagnosis.

Excessive loss

Gastro-oesophageal reflux – Persistent vomiting from birth may result in failure to thrive if the infant does not take in additional milk to compensate for the loss (see p. 51)

Congenital pyloric stenosis – This condition may present at any time until the age of three months. It should be considered in any baby less than that age who vomits persistently (see p. 50)

Malabsorption – In this country the main causes of malabsorption are cow’s milk protein intolerance, cystic

Chart D Low birthweight.

Figure 17.1 Wasting of buttocks.

Figure 17.2 Wasting of thighs.

ABC of the First Year

fibrosis, and coeliac disease (see Chart F). These conditions all cause loose stools that are more frequent than normal but this may not be recognised by a mother with a first child. A detailed history of bowel function should be taken and personal examination of the stool may be helpful.

Diabetes mellitus – This can be excluded by a negative multistix test for glucose in the urine.

Psychiatric and social factors of failure to thrive

A physical cause for failure to thrive may be present in a family with psychiatric and social problems and therefore a physical cause must be excluded for all infants. The exclusion of a physical cause is often helpful in persuading the parents to accept that psychiatric or social factors are the main reason for the problem. Features in the history that may suggest this possibility include maternal depression, marital discord, or a disorganised household. Maternal food preferences may result in the exclusion of certain foods, such as cow's milk, from the diet without reason and without adequate supervision, and may result in a deficient energy intake.

There are more subtle ways in which maternal emotional factors may affect the infant. The mother may be depressed and tense, and this anxiety is transmitted to the child, who does not feed. The mother then reacts by removing the food. In other families the child may be intrinsically less responsive than the average child to food and this may affect the mother's response to the child at mealtimes. In both these examples the amount of food taken by the child falls to a plateau where the infant appears to be satisfied with the amount given. Another possibility is that the mother keeps to a diet herself as she perceives that she is overweight and also gives a diet to the infant in a similar way.

Some infants are deliberately underfed as part of child abuse. Normal weight gain occurs when fostering has been carried out.

Effective management of infants with this diagnosis requires a team approach involving a health visitor, the family doctor, a child psychiatrist, and paediatrician. Regular advice from a health visitor or dietitian often improves the rate of weight gain.

Investigations

Specific investigations are indicated by the history and examination given above, but if there are no pointers to the diagnosis the following investigations are performed: multistix urine test for glucose, full blood count, sweat test, urine microscopy and culture, and plasma creatinine.

Chart E Poor lactation.

Chart F Coeliac disease.

18 Weaning

Weaning is the process of getting babies used to eating foods other than milk, and using a spoon and cup. For the first four months of life babies will need only milk and additional drinks of boiled water. New foods should start to be introduced at about four months. If solid foods are introduced too early babies may become too fat; if they are introduced too late, after seven months, there may be problems with chewing. Once introduced, solid foods should be given regularly and in gradually increasing quantities. As the amount of solid food increases, the number or size of milk feeds should decrease.

In countries where commercially produced infant cow's milk preparations are safe and affordable, they should be used for the first year of life. Advantages are that the protein and calcium concentrations and vitamin content are more appropriate for babies than unmodified cow's milk.

Mothers need a small, wide plastic teaspoon with no sharp edges, a small plastic cup or bowl, a feeding beaker, and a cotton or plastic backed cloth bib. The feeding equipment should be kept in a sterilising solution.

Firstly, babies have to be taught to take food from the spoon rather than just sucking. As solids are increased, the volume of milk should be reduced. The baby should also be given plenty to drink to replace the milk; at least 100–150 ml of cooled boiled water each day. Diluted fruit juices are not necessary. Most fruit *squashes* are unsuitable for babies.

4–6 months

At 4–6 months babies will usually be having breast or bottle feeds at 6–8 am, 10 am, 2 pm, 6 pm, and 10 pm. Solid foods should be introduced to babies before the mid-morning or lunchtime feed – usually a baby cereal or a fruit or vegetable purée.

Mothers should start by using a cereal made from rice and should mix half to one teaspoon of cereal with one to two tablespoonfuls of breast milk, infant formula, or water; it should be given to the baby from the spoon. Sugar, honey or salt should not be added. Wheat based cereals should not be introduced until after the age of six months. At lunchtime babies should be fed with vegetables such as potato or carrot, or fruit such as apple. The vegetables can be fresh or frozen, and the fruit fresh or canned in natural juice. The vegetables should be boiled and the fruit stewed and then liquidised, mashed into purée or sieved. Feeding should start with half or one teaspoonful before or during the lunchtime feed and gradually increased.

At about six months mothers should start to give a wider variety of foods. Banana mashed with a fork is a favourite of many babies. Mashed hard boiled eggs, soups, milk puddings, and strained baby foods should all be tried, with the emphasis on savoury flavours rather than sweet ones. Lightly boiled or scrambled eggs or omelettes should *not* be given, as there is a risk of salmonella infection.

Preparing food

Home prepared foods are best. The mother knows what is in them and can prepare them easily and cheaply, as she can use

Figure 18.1 Equipment for weaning.

Figure 18.2 Feeding with a spoon while sitting on the mother's lap.

Box 18.1 Menu at four to six months

6–8 am	Milk
10 am	Milk

2 pm	Milk
	<i>Fruit or vegetable purée</i>
6 pm	Milk
10 pm	Milk

a small portion of food cooked for the rest of the family. Many families have an electric liquidiser or food processor, but a manual blender is equally effective. A sieve is useful for making fruit and vegetable purées. If there is a deep freeze, time can be saved by preparing puréed food in bulk and storing individual portions for up to three months.

Cans, jars, and packets of baby foods are useful but should not replace home made foods. After opening, jars and cans should be kept in a refrigerator and used within 24 hours.

Iron deficiency is common during weaning but can be prevented by an appropriate diet. Iron from vegetables and cereals is not as well absorbed as that from meat. Sources of iron for vegetarians include breakfast cereals and other cereal products, pulses, green vegetables, and nut purée.

6–8 months

When babies are six months old it is no longer necessary to sterilise equipment for weaning. Bottles and teats should be sterilised until a beaker or cup is used, and that should be introduced at about this age.

At 6–7 months a greater variety of tastes and textures should be introduced. A little finely minced chicken, lamb, beef, or liver may be given mixed with potato purée. Vegetables should be cooked until soft, then sieved, blended or liquidised until smooth. White fish can be boiled with milk and, after the bones have been removed, mashed in with potato or vegetable purée. Dahls such as chana dahl and dhudhi, lentils and rice can be given at this age, but should not include salt or hot spices (chilli, ginger, cloves), fat or oil. Soup can be made with lentils or soft chick peas and carrots, cauliflower, or potato, which can then be blended, liquidised, or mashed. Grated cheese, cottage cheese, curd cheese, or paneer may be given, mixed in with other foods, and mashed hard boiled egg can be added to mashed potato. Babies often eat yoghurt plain, but they may need to be tempted with added fruit.

At around seven months parents should start changing the texture of foods to encourage chewing. For example, meat and fish should be less finely minced and potatoes and other vegetables can be mashed rather than puréed. Babies should also be given hard foods such as a crust of bread, a piece of chappatti, pieces of apple, carrot, and banana, which they can hold in their hands, and this will encourage them to chew. These foods should always be given *under supervision* to make sure babies do not choke. Babies should not be given rusks or biscuits every day, as these may encourage the taste for sweet foods.

The timetable of feeds should also start to change at this age and the number of milk feeds should fall.

Babies often reject food. This may be because they are not used to a new taste or texture. However, it may also be because they are thirsty or because the food is too hot, or simply because they want to attract attention. Mothers should be told to keep trying with new foods and to give them in different ways. Babies who become constipated should be given more fruit and vegetables and water.

At about eight months the baby can now sit in her high chair at the table with the rest of the family. Two course meals at lunch and teatime should be introduced – for example, a savoury food followed by a fruit purée. The amount of milk will decrease as more solids are taken. Breastfeeding is continued or an infant formula milk should be given until the end of the first year.

Figure 18.3 Electric liquidiser.

Box 18.2 Menu at six to eight months

6 am	Milk feed
9–10 am	Cereal + milk <i>or</i> hard boiled egg Milk feed
1–2 pm	Minced/puréed meat or fish, puréed vegetables and potato, gravy Diluted fruit juice or milk feed
3–4 pm	Diluted fruit juice or water
5–6 pm	Fruit purée/mashed banana Custard or milk pudding Milk feed

Figure 18.4 Sitting in highchair eating with the family.

9–12 months

At this stage babies should be able to eat the same food as the rest of the family, though the food will have to be cut up or mashed. Food should not contain hot spices, particularly chilli, ginger, or cloves, and not too much butter, ghee, or oil. Each day the baby should drink a pint of milk, or less if he or she eats some cheese or yoghurt; two small portions of meat, fish, poultry, or eggs, some fruit, fresh fruit juice, or vegetables; some cereals – for example, a cereal at breakfast and half a slice of bread at tea; and a small amount of butter or margarine. Babies should not be given too many sweet foods, particularly between meals, as they can cause overweight and tooth decay.

Vitamins

Breastfed infants under six months do not need additional vitamins, provided the mother had an adequate vitamin status during pregnancy. From the age of six months infants receiving breast milk as their main drink should be given supplements of vitamins A and D.

Infants receiving 500 ml or more a day of an infant formula milk do not need vitamin supplements. Infants receiving a smaller volume of formula milk or pasteurised whole cow's milk (after the age of one year) should be given vitamin A and D supplements until the age of five years. After the age of one year these supplements may be omitted if the diet has an adequate vitamin content and there is moderate exposure to sunlight.

Box 18.3 Food safety

- Babies should never be left alone when eating, because of the risk of choking.
- Heated foods should be warm but not hot enough to burn a baby's mouth.
- It is not advisable to use a microwave oven to reheat food and drink. This is because "hot spots" can occur in the middle of food if it is not thoroughly stirred after reheating.
- Eggs should be boiled until the white and yolk are solid (about six minutes).
- Peanuts and food containing peanuts or unrefined groundnut oil should not be given to infants from atopic families until they are at least three years of age or to infants who are atopic or allergic to peanuts.
- Whole nuts should not be given to children less than 4–5 years of age because of the risk of choking. However, smooth peanut butter or finely milled nuts are suitable.

19 Review at six weeks

For many years, infants nursed in neonatal units have been routinely assessed at regular intervals as have those who were placed on “at risk” registers for handicaps. Total population screening was introduced when it was realised that many children later found to have disabilities were not on registers or being seen after discharge from neonatal units.

Examination of all infants at specific ages allows abnormalities to be detected at an early stage, provides mothers with a chance to discuss their anxieties, and gives opportunities for education in preventive health.

Developmental examinations should be considered on two levels: the surveillance of an apparently healthy population and the detailed assessment of infants referred from primary examinations because of suspected abnormalities. Primary examinations, which should cover all infants in the district, are best performed by the family doctor. In some districts specially trained health visitors do this work, especially for infants whose parents will not visit the surgery or clinic. Nevertheless, this system is not ideal since health visitors may consider up to 20% of infants abnormal and refer them to an assessment clinic, with all the anxiety that this entails. Some clinics are run jointly by a family doctor and health visitor, who often has wide experience of managing feeding and behaviour problems.

Infants found to be abnormal at the primary examination need to be referred to a doctor with a special interest in developmental assessment. This may be the community or the hospital paediatrician. The more detailed examination performed at this stage will probably need a team of paramedical staff.

A mother who considers that her infant has an abnormality of hearing, sight, or development must be sent straight to the specialist because she cannot be reassured until a detailed assessment has been performed, which usually needs several members of the team. The mother is likely to be right.

Primary examination

Infants in the normal population should be assessed within 48 hours of birth, at six weeks, and again at seven or eight months. Preterm infants should be examined about six weeks after the expected date of delivery, when their development should be the same as that of a six week infant born at term.

The examination should take no more than about 15 minutes and should be confined to items that have prognostic significance.

Many districts use a “parent held” manual record that, if completed correctly by professionals and parents, is a complete record of a child’s health. All child health surveillance data, the dates of immunisations, and outcomes of visits to general practitioners and hospitals, and contacts with other health professionals can be recorded. Some health advice is also included throughout this record. In addition, the Health Education Authority’s book *Birth to Five Years*, which is issued to all first-time mothers, is an excellent manual on child health for all parents (and junior doctors).

The six week examination should include a physical examination and assessment of alertness, vision, and motor function. The checks should be carried out as part of clinical care and not be regarded as pass or fail examinations. A simple form is useful for recording the information quickly. Screening

Figure 19.3

for hearing defects is not usually done until seven or eight months (see page 80), and other abilities are assessed more sporadically, depending on whether the mother takes the child to a local clinic or to the general practitioner's special baby clinic.

Of greatest importance is the child's alertness, interest in his surroundings, responsiveness, and ability to concentrate.

The physical examination of the infant should always include measurement of weight and head circumference. These values, plotted on a growth chart, will show at a glance whether the infant's growth is normal.

Weighing and measuring

Being undressed and weighed is often the most worrying part of the visit to the child. Weighing the child in vest and napkin reduces upset and time taken. Weights of the vest and napkin should be subtracted from the total weight. Suitable scales that are checked regularly are an essential piece of equipment.

In very young infants it is easier to measure head circumference than length. The measurement should be made, using a paper tape measure, around the occipitofrontal circumference (the largest circumference). Measurements can then be plotted on a growth chart together with weights.

The length of infants aged under two years is measured on a special measuring board and accurate results can be obtained only when there are two dedicated measurers present. One has to hold the infant's head against the top board while the other brings the footboard up to the child's feet while stretching him or her out. When the child is old enough to stand a special stadiometer can be used to measure height, but careful attention to detail is necessary for reproducible results.

Vision and squint

The infant's visual attention is engaged by the examiner crouching about 60 cm in front of the infant so that their eyes are on the same level. When the examiner slowly moves his head a short distance to one side then the other, the normal infant will continue to hold his gaze. Failure to do so is abnormal but may be due to something distracting the infant. Infants who fail to follow must be examined again two weeks later. Possible causes include lack of stimulation at home, delay in development, or blindness.

The second routine test at this age is the detection of the red reflex. If a bright ophthalmoscope is held about 45 cm away from an infant's eye, with the observer looking down the beam of light, a bright red reflex is normally seen in a fair skinned infant and a dark red or grey reflex in an infant with a dark skin. Absence of the reflex indicates an abnormality of the refractive media and requires urgent referral to an ophthalmologist.

An infant who does not fixate on the examiner's face at the second visit should be referred to a developmental specialist. At that stage additional tests will include an attempt to determine whether the infant can see at all by showing him a revolving Catford drum. This induces opticokinetic nystagmus – an involuntary movement of the eyes, which occurs even if the infant does not concentrate well.

In a young infant a squint can be noticed by observing the position of the light reflex on each cornea when a torch is shone into the eyes. Normally the reflex should be in the centre of each pupil or at a corresponding point on each cornea. If there is a possibility of a squint, movements of the eyes should be assessed and the cornea, lens, and fundi should

be examined. An infant with a squint needs to be referred to an ophthalmologist.

Motor function

The baby should be placed prone on a couch; normally he will lift his head for a few seconds, though some infants may take a few minutes to do so. Infants who usually sleep prone are more advanced in lifting their heads than others. If the infant does not eventually lift his head he needs to be re-examined two weeks later.

When the infant is held in the prone position, his head rises to the same plane as his trunk and his legs do *not* fall vertically.

Figure 19.6 Lifting the head.

Other assessments

The testes and hips should be examined by the methods described for the newborn infant. It is difficult to detect an abnormal hip at the age of six weeks and ideally the condition should have been detected in the newborn infant.

Cardiac murmurs should be sought for and the femoral pulses checked. Though hearing is not tested at six weeks, the normal infant will respond to sounds by stopping crying, opening his eyes widely or by a startle reflex, depending on the intensity of the sound.

Figure 19.7 Examination of the hips.

Patterns of development in childhood

Progress in a particular field does not occur gradually but in spurts, and when one skill is advancing quickly others tend to go into abeyance.

There is considerable variation in the range of normal development, but among the children who fall outside the normal range there are some who later turn out to be normal. The children who fall into this group need examining more closely and more often to determine which are definitely abnormal. They should be referred to developmental specialists.

Lack of appropriate stimulation may cause delay in physical, intellectual, or social development. This factor must be taken into account if the child has been cared for in an institution or if the mother has a learning disability or has had puerperal depression. These children advance rapidly when the mother is given advice on handling them or they are placed in a better environment. Delayed speech development, probably the commonest disability of childhood, may be prevented by encouraging mothers to talk to their infants from birth.

No child has impaired intelligence if development is delayed in a single field and normal in all others. A child who is slow at learning will be delayed in all fields, except sometimes in walking. Intelligence cannot be assessed accurately until the age of about $4\frac{1}{2}$ years and before that age it is best to use the term developmental delay.

Equipment for examining children

Most of the equipment needed for examining and assessing children is cheap, but its use would greatly improve the quality of care: scales, disposable paper tape measures, measuring rod, torch, auriscope, spatulas, centile charts, one inch cubes, Nuffield rattle, Ladybird first reading books, miniature cups and saucers, small table and chair, pictures on the ceiling, toys (including wooden puzzles, pencils and paper), disposable napkins, urine bags, heel prick equipment, including lancet and Steriswab, and ophthalmoscope.

Fig. 19.9 Essential equipment: (1) scales, (2) disposable paper tape, (3) urine bag, (4) building blocks, (5) Nuffield rattle, (6) ophthalmoscope, (7) picture on ceiling, (8) auriscope.

20 Review at eight months

Mothers are asked whether they have any problems and whether the infants have had any illnesses since the last examination. They are also asked whether the infants are making sounds and the details of their diet, in particular whether they are chewing solids.

As at six weeks, the infant's alertness and interest are checked. Head circumference and weight should be measured and plotted on the growth chart.

Vision

Eye movements should be noted. If a squint is suspected, the position of the light reflex in each cornea should be observed; if there is a squint, the reflex will be in a different position in each eye. While the infant looks at an object one eye is covered with the doctor's hand. If the eye that is not being covered moves to fixate the object, that eye has an overt squint. The covering hand is slowly removed and if that eye moves to fixate the object, there is a latent squint. If a squint is seen or suspected at any time the infant should be seen by an ophthalmologist.

Near vision may be tested by placing a raisin or pellet of paper about 20 cm in front of an infant and watching whether he reaches out to grab it. Testing distant vision is time consuming at this age and is usually performed only at specialist clinics.

Motor development

From the prone position infants should get up on their wrists. When pulled from the supine position they should be able to sit spontaneously for a minute or two. Normal children can sit without help by the age of eight months. Infants should also be able to take their weight on their legs when they are held standing.

If a cube is placed in front of the infant he should grab it with his whole hand. This test should be tried for both the right and the left hand, and the infant should transfer the object from one hand to the other. Infants who perform all these tests normally but are not sitting spontaneously should be seen again two months later.

A dislocated hip will show reduction of abduction and a proximal displacement of the lower buttock crease. Bilateral dislocation is hard to detect clinically but radiographs of the hips will confirm the diagnosis at this age.

Hearing

The distraction method is the hearing test used at this age. The distractor holds the infant's attention while the tester produces a sound. Careful attention to detail is essential to produce reliable results. The mother is requested to position the infant at the edge of her lap and not to react to the sounds. The distractor sits at the level of the infant's face and holds the infant's attention with a toy that produces no noise. Eye contact is avoided. The toy is withdrawn from sight and immediately afterwards the tester produces the test sound at a distance of 45 cm from the infant's ear, on a level with the ear,

Figure 20.4

Figure 20.5 Testing hips.

but slightly behind it so that the infant does not see the test object or the tester's shadow. The distractor detects whether the infant turns the head or eyes abruptly towards the sound. The speed with which the infant responds to the sound is a useful indication of his alertness. The test sounds should include those with a known pitch and intensity such as a warbler. Voice sounds at minimal intensity should include "psss", "phth" (for high tones), or "oo" (for low tones). If an infant fails to turn to the sound, the ability to turn the head to each side should be assessed. If the infant responds to sounds on two out of three tests performed on one ear, hearing is considered normal in that ear. If the infant fails to respond, the ears should be examined with an auriroscope.

The room where the test is performed must be quiet. It should ideally have a carpet and be removed from the waiting area and sounds of traffic. The commonest reasons for a child failing to respond to the test sounds are lack of interest, tiredness, distraction, wax blocking the external meatus, otitis media, and lack of familiarity with the test sounds. It is important to explain to the mother that these are far more likely reasons for lack of response than deafness and that the test will be repeated by the same person one month later. Infants who fail to respond at the second visit should be seen by an audiologist.

High tone deafness cannot be excluded by these tests and if there is a high suspicion of deafness – for example, if the infant had a very high plasma bilirubin concentration in the neonatal period, has congenital rubella syndrome, or has a family history of deafness – the infant should be seen by an audiologist even if the results of these simple tests appear normal. Pure tone audiology may be needed and the audiologist may have to see the child several times before a hearing defect can be completely excluded.

Pattern of development

Most normal children sit unaided by the age of eight months. African children tend to advance in most aspects of motor development faster than other children up to the age of about seven months. In some families one aspect of development – for example, sitting, walking, or speech – may be unusually early or late, the development in all other fields being normal.

Finding that an infant is not sitting by a certain age does not necessarily mean that he is abnormal, as he may have a variation of normal development. These children fall into a group who are late in reaching a developmental milestone and it is reasonable that they should be referred for further examination to exclude more sinister problems.

Figure 20.6 Distraction test.

Figure 20.7 High-pitched rattle.

Figure 20.8 Indications for direct referral to the audiologist in the neonatal period.

21 Respiratory infections in the older infant

Infection of the respiratory tract is a common cause of illness of infants. Although pathogens are often not confined to anatomical boundaries, the infections may be classified as: (a) upper respiratory tract – common cold, tonsillitis, and otitis media; (b) middle respiratory tract – acute laryngitis and epiglottitis; (c) lower respiratory tract – bronchitis, bronchiolitis, and pneumonia.

Upper respiratory tract infection is usually the least serious condition but blockage of the nose by mucus may completely obstruct the airway in those infants who cannot breathe through their mouths. Middle respiratory tract infection may totally obstruct airflow at the narrowest part of the airway. Lower respiratory tract infection produces trivial signs initially but may be lethal within a few hours.

Viruses, which cause most respiratory tract infections, and bacterial infections produce similar clinical illness. Different viruses may produce an identical clinical picture or the same virus may cause different clinical syndromes. Clinically it may not be possible to determine whether the infection is due to viruses, bacteria, or both. If the infection is suspected of being bacterial, it is safest to prescribe an antibiotic, as the results of virus studies are often received after the acute symptoms have passed. The commonest bacterial pathogens are pneumococci, *Haemophilus influenzae*, group A β -haemolytic streptococci, and *Staphylococcus aureus*. Group B streptococci, Gram negative bacteria, and anaerobic bacteria are less common.

Figure 21.1 Sites of infection in the upper respiratory tract.

Common cold (coryza)

Preschool children have at least 3–6 colds each year. The main symptoms are sneezing, nasal discharge, cough, and, rarely, fever. Nasal obstruction in infants who cannot breathe through their mouths may cause feeding difficulties and, rarely, brief periods of apnoea. Similar symptoms may occur in the early phases of infection with rotavirus and be followed by vomiting and diarrhoea. Postnasal discharge may produce coughing. The commonest complication is acute otitis media, but secondary bacterial infection of the lower respiratory tract sometimes occurs.

There is no specific treatment for the common cold and antibiotics should be avoided. If an infant is not able to feed due to nasal obstruction from mucus, two drops of 0.9% sodium chloride solution can be instilled into each nostril before feeds three times daily. This will wash the mucus into the back of the pharynx and relieve the obstruction. There is a danger with nasal drops that they will run down into the lower respiratory tract and carry the infection there.

Tonsillitis and pharyngitis

In children aged under three years the commonest presenting features of tonsillitis are fever and refusal to eat, but a febrile convulsion may occur at the onset. Older children may complain of a sore throat or enlarged cervical lymph nodes, which may or may not be painful. Viral and bacterial causes cannot be distinguished clinically as a purulent follicular exudate may be present in both. Ideally, a throat swab should be sent to the laboratory before starting treatment, to determine a bacterial cause for the symptoms and to help to

Box 21.1 Main symptoms of common cold

- Sneezing

- Cough
- Fever (rare)

Figure 21.2 Picture of child in highchair pushing food off the table.

indicate the pathogens currently in the community. There has been a recurrence of group A haemolytic streptococci in outbreaks of sore throat and a more liberal use of penicillin is justified. As this organism is the only important bacterium causing tonsillitis, penicillin is the drug of choice and the only justification for using another antibiotic is a convincing history of hypersensitivity to penicillin. In that case the alternative is erythromycin. In the absence of an outbreak of group A streptococcus infection the indication for oral penicillin is fever or severe systemic symptoms. The drug should be continued for at least 10 days if a streptococcal infection is confirmed. Parents often stop the drug after a few days as the symptoms have often abated and the medicine is unpalatable. The organism is not eradicated unless a full 10-day course is given.

Viral infections often produce two peaks on the temperature chart.

An extensive thick white shaggy exudate on the tonsils (sometimes invading the pharynx) suggests infectious mononucleosis and a full blood count, examination of the blood film, and a Monospot test are indicated. Although rare in Britain, a membranous exudate on the tonsils suggests diphtheria and an urgent expert opinion should be sought.

Fluids can be given while there is dysphagia and regular paracetamol during the first 24–48 hours reduces fever and discomfort.

A peritonsillar abscess (quinsy) is now extremely rare. It displaces the tonsil medially so that the swollen soft palate obscures the tonsil and the uvula is displaced across the midline. The advice of an otolaryngology surgeon is needed urgently.

Otitis media

Pain is the main symptom of acute otitis media and is one of the few causes of a fretful infant who cries all night. The pain is relieved if the media drum ruptures. Viruses probably cause over half the cases of acute otitis, but a viral or bacterial origin cannot be distinguished clinically. The commonest bacteria are pneumococci, group A β -haemolytic streptococci, and *H. influenzae*.

Children are often fascinated by the light of the auriscope and the auriscope speculum can be placed on a doll or the child's forearm for reassurance. Gentleness is essential and the speculum should never be pushed too far into the external meatus because this causes pain. If the pinna is pulled gently outwards and downwards to open the meatal canal, the tympanic membrane is visible with the tip of the speculum in the outer end of the meatus. In early cases of otitis media there are dilated vessels over the upper and posterior part of the drum. Later, the tympanic membrane becomes red, congested, and bulging and the light reflex is lost. Swelling or tenderness behind the pinna should always be sought, as mastoiditis can be easily missed.

The choice of initial treatment lies between amoxicillin and erythromycin. If there is no improvement in the drums after two or three days, another antibiotic should be substituted. Cefaclor or amoxicillin with clavulanic acid may be included in the second line drugs. The duration of the course of antibiotics is controversial. The most common view is that antibiotics should be given for seven days and the ears examined again before the course is stopped. There is some evidence that short courses of 3–5 days of antibiotics given at high doses may be as effective as the longer courses. Ideally, a hearing test should be performed three months after each attack of acute otitis media to detect residual deafness and

Figure 21.3 Antibiotics should be taken regularly.

Figure 21.4 Temperature chart in a viral infection.

“glue ear”. One study showed that after the first attack of acute otitis media in infants, which was treated with antimicrobial agents, 40% of patients had no middle ear effusion after one month and 90% after three months.

Stridor

Stridor is noisy breathing caused by obstruction in the pharynx, larynx, or trachea. It may be distinguished from partial obstruction of the bronchi by the absence of rhonchi. Although most cases are due to acute laryngitis and may resolve with the minimum of care, similar features may be due to a foreign body and may cause sudden death.

Stridor is recognised as one of the most ominous signs in childhood. Any doctor should be able to recognise the sound over the telephone and arrange to see the child immediately. Examination of the throat may precipitate total obstruction of the airway and should be attempted only in the presence of an anaesthetist and facilities for intubation.

A glance at the child will show whether urgent treatment is needed or whether there is time for a detailed history to be taken. The doctor needs to know when the symptoms started and whether there is nasal discharge or cough. Choking over food, especially peanuts, or the abrupt onset of symptoms after playing alone with small objects suggests that a foreign body is present.

During the taking of the history and the examination mothers should remain near their children and be encouraged to hold them and to talk to them. All unpleasant procedures, such as venepuncture, should be avoided. This reduces the possibility of struggling, which may precipitate complete airway obstruction. Agitation and struggling raise the peak flow rate and move secretions, which results in increased hypoxia and the production of more secretions.

Acute laryngotracheitis

Acute laryngitis causes partial obstruction of the larynx. It is characterised by inspiratory and expiratory stridor (noisy breathing), cough, and hoarseness. The laryngeal obstruction is due to oedema, spasm, and secretions. Affected children are usually aged six months to three years, and the symptoms are most severe in the early hours of the morning. Recession of the intercostal spaces indicates significant obstruction and cyanosis or drowsiness shows that total obstruction of the airway is imminent.

A child often improves considerably after inhaling steam, which is provided easily by turning on the hot taps in the bathroom. Mild cases may be treated successfully at home using this method, but children must be visited every few hours to determine whether they are deteriorating and need to be admitted to hospital. Continuous stridor or recession demands urgent hospital admission. Hypoxaemia or thirst may cause restlessness and should be corrected and sedatives avoided. Nebulised adrenaline or betamethasone may produce considerable improvement in symptoms within an hour. Rarely, the obstruction needs to be relieved by passing an endotracheal tube or performing a tracheostomy.

Acute laryngotracheitis is usually caused by a viral infection and therefore infants with mild symptoms do not need antibiotics. In a few cases *Staph. aureus* or *H. influenzae* is present and the associated septicaemia makes the child appear very ill. Bacterial infection is characterised by plaques of debris and pus on the surface of the trachea, partially obstructing it, just below the vocal cords. Acute epiglottitis and acute

- fear

laryngitis may be indistinguishable clinically since stridor and progressive upper airway obstruction are the main features of both. If bacterial infection is suspected cefotaxime is given intravenously. Some paediatricians give steroids as well. The dose of hydrocortisone is 100 mg intramuscularly or intravenously repeated once after two hours. No effect is seen for at least two hours. Later, betamethasone should be given at a dose of 3 mg intravenously every six hours but only until signs of improvement appear. Children with severe symptoms should be managed in the intensive care unit.

Children with epiglottitis are usually aged over 2 years; drooling and dysphagia are common, and the child usually wants to sit upright. When the obstruction is very severe, the stridor becomes ominously quieter. There is usually an associated septicaemia with *H. influenzae*. Epiglottitis is now rare due to the Hib vaccine.

Other causes of stridor

Even if the symptoms have settled and there are no abnormal signs, a history of the onset of sudden choking or coughing can never be ignored. A radiograph of the neck and chest should be taken and may show a hypertranslucent lung obstructed by a foreign body, a shift of the mediastinum, or, less commonly, collapse of part of the lung or a radio-opaque foreign body. The radiograph may be considered normal. Bronchoscopy may be needed to exclude a foreign body even if the chest radiograph appears to be normal. Stridor in a child who has had scalds or burns or has inhaled steam from a kettle suggests that intubation or tracheostomy may be needed urgently.

If the cause of stridor is likely to be a foreign body below the larynx, the object should be removed immediately by a thoracic surgeon in the main or accident and emergency operating theatre. If the object is above the larynx and if an ENT surgeon or anaesthetist is not immediately available and the child is deteriorating, the safest treatment is to insert a wide needle, such as Medicut size 14, into the trachea in the midline just below the thyroid cartilage. It may be preferable to insert two needles. No attempt should be made to look at the mouth or throat or remove the object, as the struggling that may follow may impact the object and prove fatal. A first aid measure usually performed before arrival is to slap the infant's back between the shoulder blades while holding the infant upside down by the legs. The child should remain in the position he or she finds most comfortable, which is usually upright. Forceful attempts to make the child lie flat – for example, for a radiograph – may result in complete airway obstruction.

Infants with congenital laryngeal stridor, which is due to loose aryepiglottic folds, usually have inspiratory stridor only. The symptoms begin during the first few weeks of life and usually persist for several months, becoming more severe during episodes of upper respiratory tract infections or while crying, but subsiding in sleep.

Acute bronchitis

Acute bronchitis often follows a viral upper respiratory tract infection; there is always a cough, which may be accompanied by wheezing. There is no fever or difficulty with feeding. The respiratory rate is normal and the symptoms resolve within a week. The only signs, which are not always present continuously, are rhonchi. Since bronchitis is usually due to a virus, antibiotics are indicated only if secondary bacterial infection is suspected.

Box 21.4 Upper limit for normal respiratory rate related to age

< 2 months	60/min
2–11 months	50/min
12–60 months	40/min

Acute bronchiolitis

Acute bronchiolitis is an acute infection that occurs in winter epidemics in infants aged under one year. For the first few days there may be only a rasping cough but deterioration may occur within a few hours, causing a raised respiratory rate, indrawing of the intercostal spaces, cyanosis, drowsiness, and apparent enlargement of the liver. The respiratory syncytial virus is found in over 70% of cases. During epidemics the disease may be recognised at an early stage, but at the beginning of epidemics the condition may be recognised only when the infant is moribund. Signs in the chest vary at different stages of the illness and there may be no adventitious sounds. The chest radiograph may appear normal even in severely ill infants. In units with ELISA or immunofluorescence techniques for diagnosing respiratory syncytial virus, results are available the same day, treatment can be planned, and cross infection avoided. Oxygen is the most important aspect of treatment and is efficiently given by a nasal cannula with a special low flow regulator. Most infants need intragastric tube feeding or intravenous fluids for a few days. Where a viral cause can be confirmed immediately, antibiotics can be avoided but they should not be withheld from severely ill infants, as there is a possibility of additional bacterial infection. A few infants develop progressive respiratory distress and intermittent positive pressure ventilation may have to be considered.

The infant is discharged from hospital when feeding is normal. The cough may persist for six weeks, but if there is no improvement after three weeks, a sweat test should be performed to exclude cystic fibrosis.

Figure 21.11 Oxygen given by a nasal cannula.

Bronchopneumonia and segmental pneumonia

Pneumonia is acute inflammation of the lung alveoli. In bronchopneumonia the infection is spread throughout the bronchial tree whereas in segmental pneumonia it is confined to the alveoli in one segment or lobe. A raised respiratory rate at rest or indrawing of the intercostal spaces distinguishes pneumonia from bronchitis. The upper limit for a normal respiratory rate is related to age (see Box 21.4). Cough, fever, and flaring of the alae nasi are usually present and there may be reduced breath sounds over the affected area as well as crepitations. A chest radiograph, which is needed for every child with suspected pneumonia, may show extensive changes when there are no localising signs in the chest. The radiograph may show an opacity confined to a single segment or lobe, but there may be bilateral patchy changes. Bacterial cultures of throat swabs and blood should be performed before treatment is started. Ideally, nasopharyngeal secretions should be studied virologically and virus antibody titres of serum collected in the acute and convalescent phases should be measured.

Children with pneumonia are best treated in hospital, as they may need oxygen treatment. Antibiotics should be prescribed for all cases of pneumonia, although a viral cause may be discovered later. If the child is not vomiting and not severely ill, oral erythromycin or amoxycillin is given. Cefotaxime is given intravenously if the symptoms are severe, and erythromycin is added when failure to improve promptly suggests infection with mycoplasma or chlamydia. Antibiotic treatment can be modified when the results of bacterial cultures are available. Intravenous fluids may be needed.

The chest radiograph of a child with segmental or lobar pneumonia should be repeated after one month.

Figure 21.12 Chest radiograph showing pneumonia in the right lung.

Recurrent respiratory infections

Although all doctors concerned with children are familiar with the catarrhal child, the exact pathology of the condition is unknown and it is called by many names – postnasal discharge, perennial rhinitis, or recurrent bronchitis. These children have an increased incidence of colds, tonsillitis, and acute otitis media. Recurrent episodes of symptoms such as fever, nasal discharge, and cough are most common during the second half of the first year of life, the first two years at nursery school, and the first two years at primary school. Recurrent viral or bacterial infections contracted from siblings or fellow pupils may be important, but the considerable differences between the behaviour of children in the same family suggest the possibility of a temporary immunological defect.

Various treatments including nasal drops and oral preparations of antihistamines are given with little effect. A chest radiograph should be performed to exclude persistent segmental or lobar collapse. A sweat test should be carried out to exclude cystic fibrosis and plasma immunoglobulin studies should be conducted to exclude rare syndromes.

Recurrent bronchitis

Two separate episodes of acute bronchitis may occur in a normal child in a year. If attacks are more frequent at any age, bronchial asthma should be considered. Viruses cause the majority of attacks of bronchitis and will precipitate most attacks of bronchial asthma. Some paediatricians have reverted recently to the older terms recurrent or wheezy bronchitis, as most children with these features become free of symptoms by the age of five. Although the pathological processes and prognosis may differ between recurrent bronchitis and bronchial asthma, there is no clinical or laboratory method of distinguishing between them and treatment is the same.

After an episode of severe symptoms during an infection with respiratory syncytial virus (bronchiolitis), many children have recurrent episodes of cough and wheezing during the subsequent four years. It is not known whether the respiratory syncytial virus predisposes the child to recurrent respiratory symptoms or whether the child has a predisposition to produce severe symptoms with viral respiratory infections.

If there is a persistent or recurrent cough, a chest radiograph should be performed to exclude persistent segmental or lobar collapse. A Mantoux test for tuberculosis and a sweat test to exclude cystic fibrosis should be performed and plasma concentrations of immunoglobulins and IgG subclasses should be measured to exclude transient or permanent immune deficiencies.

The management of recurrent bronchitis or bronchial asthma is the same. For infants with mild symptoms an oral bronchodilator, for example salbutamol, can be given at the beginning of an episode and continued for a week. If this is not effective, a bronchodilator can be given by a *small* spacer device with a face mask or by air pump and nebuliser. Infants with severe or frequent episodes can be given an inhaled steroid as a prophylactic drug for six weeks and the course can be extended to six months if there is an improvement in symptoms.

Prophylactic drugs can be given with a small spacer device or by an air pump and nebuliser. If infants are receiving both a bronchodilator and a prophylactic drug, the dose of bronchodilator should be given just before the prophylactic drug.

22 Whooping cough

Young infants receive no protective immunity to whooping cough from their mothers and have the highest incidence of complications. Immunisation is directed at increasing herd immunity and reducing the exposure of infants to older children who have the disease. Recent changes in advice on contraindications to whooping cough vaccine have been associated with the increased use of this vaccine.

Contraindications to immunisation

Convulsions and encephalopathy have been reported as rare complications, but these conditions may arise from other causes and be falsely attributed to the vaccine. Neurological complications after whooping cough itself are considerably more common than after the vaccine.

As with any other elective immunisation procedure, if a child is suffering from any acute illness then vaccination should be postponed until the child has fully recovered. Minor infections without fever or systemic upset, however, are not reasons to delay immunisation. Vaccination should not be carried out in children who have a history of a severe local or general reaction to a preceding dose; the following reactions should be regarded as severe.

Local – an extensive area of redness and swelling, which becomes indurated and covers most of the anterolateral surface of the thigh or a major part of the circumference of the upper arm.

General – fever (a temperature of 39.5°C or higher) within 48 hours of vaccination, anaphylaxis, bronchospasm, laryngeal oedema, generalised collapse, prolonged unresponsiveness, prolonged inconsolable screaming, and convulsions occurring within 72 hours.

A personal or family history of allergy is *not* a contraindication to immunisation against whooping cough; nor are stable neurological conditions such as cerebral palsy or spina bifida.

Children with problem histories

When there is a personal or family history of *febrile* convulsions then there is an increased risk of these occurring after pertussis immunisation. In such children immunisation is *recommended*, but advice on the *prevention of fever* (see Box 22.2) should be given at the time of immunisation.

In a recent British study, children with a family history of epilepsy were immunised with pertussis vaccine without any appreciable adverse events. These children's developmental progress has been normal. In children who have a close (first degree) relative with *idiopathic epilepsy* there may be a risk of developing a similar condition, irrespective of whether they are vaccinated. Immunisation is *recommended* for these children.

When there is a *still evolving neurological problem* immunisation should be *deferred* until the condition is stable. When there has been a documented history of *cerebral damage in the neonatal period* immunisation *should be carried out unless there is evidence of an evolving neurological abnormality*. If immunisation is to be deferred, this should be stated on the neonatal discharge summary. When there is doubt, appropriate advice should be sought from a consultant paediatrician, district immunisation coordinator, or consultant in public health medicine *rather than withholding the vaccine*.

Has the baby, or anyone in the immediate family, ever had fits or convulsions? YES/NO
Is the baby developing normally? YES/NO

Box 22.2 Post-immunisation fever

The doctor should advise the parent that if fever develops after immunisation the child may be given a dose of paracetamol followed, if necessary, by a second dose 4–6 hours later. The dose of paracetamol for post-immunisation fever for an infant aged 2–3 months is 60 mg; an oral syringe can be obtained from any pharmacy to give the small volume required. The doctor should warn the parent that medical advice should be sought if the fever persists after the second dose.

Diagnosis

Whooping cough is difficult to diagnose during the first 7–14 days of the illness (catarrhal phase), when there is a short dry cough at night. Later, bouts of 10–20 short dry coughs occur day and night; each is on the same high note or rises in pitch. A long attack of coughing is followed by a sharp indrawing of breath, which may produce the crowing sound or whoop. Some children, especially babies, with *Bordetella pertussis* infection never develop the whoop. Feeding with crumbly food often provokes a coughing spasm, which may culminate in vomiting. Afterwards there is a short period when the child can be fed again without provoking coughing. In uncomplicated cases there are no abnormal respiratory signs.

The most important differential diagnosis in infants is bronchiolitis; this is usually due to the respiratory syncytial virus, which produces epidemics of winter cough in infants under one year. For the first few days there may be only bouts of vibratory rasping cough, which never produce a whoop. Later, rhonchi or crepitations are heard in the chest and the infant either deteriorates or improves rapidly within a few days. Older siblings infected with the virus may have a milder illness. Other viruses may cause acute bronchitis with coughing but there are seldom more than two coughs at a time.

A properly taken pernasal swab plated promptly on a specific medium should reveal *B. pertussis* in most patients during the first few weeks of the illness. A blood lymphocyte count of $10 \times 10^9/l$ or more with normal erythrocyte sedimentation rate suggests whooping cough.

Management

If the diagnosis is suspected in the catarrhal phase (usually because a sibling has had recognisable whooping cough) a 10-day course of erythromycin may be given to the child and to other children in the home. Parents must be warned that an antibiotic may shorten the course of the disease only in the early stages and is unlikely to affect established illness. Vomiting can be treated by giving soft, not crumbly, food or small amounts of fluid hourly.

No medicine reliably reduces the cough. Oral salbutamol has been used in a dosage of 0.3 mg/kg/24 hours divided into three doses. When sleep is disturbed some authorities recommend that the child should be given a bedtime dose of 3–5 mg/kg of phenobarbitone. In severe cases mothers can be taught to give physiotherapy, which may help to clear secretions, especially before the infant goes to sleep. An attack may be stopped by a gentle slap on the back.

The threshold for admission to hospital should be lower for children aged under six months. Convulsions and cyanosis during coughing attacks are absolute indications for admission to an isolation cubicle. Parents often become exhausted by sleep loss and arranging for different members of the family to sleep with the child will give the mother a respite. The cough usually lasts for 8–12 weeks and may recur when the child has any new viral respiratory infection during the subsequent year. If the child is generally ill or the cough has not improved after six weeks, a chest radiograph should be performed to exclude bronchopneumonia or lobar collapse, which need treatment with physiotherapy and antibiotics. Long term effects on the lung, such as bronchiectasis, are rare in developed countries.

The infant will not be infective for other children after about four weeks from the beginning of the illness or about two days after erythromycin is started. The incubation period is about seven days and contacts who have no symptoms two weeks after exposure have usually escaped infection.

Figure 22.4 Normal radiograph.

23 Fever in the older infant

Examining an ill child

Infants should be allowed to adopt whatever position they like (usually on their mother's knee) where they can be observed. The history taken from the mother must contain enough detail to provide a differential diagnosis before the physical examination begins.

A systematic examination may prove impossible in a protesting infant, so the most relevant system should be examined first. If the infant objects to being fully undressed, only the part being examined need be exposed. The examiner needs warm hands and should talk to the infant continuously to soothe him. Patience and gentleness at this stage are often rewarded by the infant accepting a full examination without protest.

The baby's abdomen is best examined as the infant lies on his mother's knees during a feed. Abdominal breathing is normal and the edge of the liver is easily palpable. Even the newborn will show abdominal tenderness by grimacing or crying. Rectal examination may be performed with the little finger.

Instruments such as auriscopes and stethoscopes should be shown to the infant first and rested on his forearm so that he can see what they are. The auriscope must be used gently and the speculum not pushed too far into the external meatus. When the pinna is pulled gently outwards and downwards, the tympanic membrane can be seen with the tip of the speculum in the outer end of the meatus.

Examination of the throat, which is the most disliked procedure, should be left until last. It should never be performed in an infant with stridor unless the examiner has the facilities to intubate the infant immediately.

The infant should be examined again no longer than 24 hours later and the initiative for this review should not be left to the parents, who may not appreciate the danger of features that have developed.

The normal oral or rectal temperature is about 37.5°C (99.5°F) and the normal axillary (skin) temperature 37.0°C (98.4°F). If the temperature is 0.5°C above these levels, the infant has a fever. In the prodromal period of any infectious disease of childhood, fever may be the only symptom.

Specific causes

Tonsillitis – There may be small areas of pus on the tonsils or the throat may be generally red. The presence of pus does not help to distinguish between bacterial infection due to group A streptococcus (*Streptococcus pyogenes*) and a viral infection. Petechiae on the soft palate usually indicate a viral infection. A throat swab should be taken and a 10-day course of oral penicillin given (see p. 82).

Acute otitis media – An early sign is an increase in the size of the vessels of the upper posterior part of the drum. Later the drum becomes dull pink or red and in severe cases there is bulging. Ear drums can be examined efficiently only if the auriscope has a magnifying lens. It is important to look for swelling or tenderness over the mastoids. The first choice of drugs is oral amoxycillin or erythromycin. If these are not effective, amoxycillin with clavulanic acid or cefalexin is given. The drum should be examined again after two days and if there is no improvement the antibiotic should be changed.

Figure 23.1 Throat examination.

Figure 23.2 Ear examination.

Figure 23.3 Auriscope.

carried out during the acute phase, cystourethrography is performed when the urine is sterile, and isotope (^{90m}Tc dimercaptosuccinic acid (DMSA)) scanning is carried out at least six weeks after the acute phase. DMSA scanning detects scars, ultrasound examination shows obstructive lesions, and cystourethrography detects vesicoureteric reflux and should be performed under the protection of a suitable antibiotic.

Regular urine cultures are advisable at three monthly intervals as well as at times of fever or recurrence of symptoms. The urine should be cultured regularly while vesicoureteric reflux persists and in children with renal damage at least until the age of five years. The child's growth and blood pressure should be measured regularly.

Pneumonia – A raised respiratory rate at rest and fever may be the only signs of pneumonia and a chest radiograph may be necessary to show consolidation. The upper limit for the normal respiratory rate is 60 per minute for infants less than two months of age and 50 per minute between two and 12 months. Movements of the alae nasi and indrawing of the chest wall between the ribs are confirmatory signs.

Osteomyelitis or septic arthritis may present with fever. In the early stages the only helpful sign may be the infant's reluctance to move a limb and radiographs are often normal. Later there is redness, swelling, and tenderness at the site of the osteomyelitis, which usually affects the maxilla, long bones, or vertebrae in infants. Early blood culture and radioisotope bone scans are helpful in the diagnosis.

Malaria – If within the previous two years the child has been in an area where malaria is endemic, blood films should be examined immediately for malarial parasites. The parasites are most numerous during fever but may be found at any time.

Pyrexia of undetermined origin

Infants have no localising symptoms or signs. If they simply have fever, they should be seen again within a few hours or admitted to a cubicle on a children's ward for observation. Usually these children will have a full blood count, urine microscopy, and culture and sometimes blood culture and CSF examination.

Persistent fever lasting more than a few days should prompt the consideration of Kawasaki disease. Features include conjunctivitis, cracked lips, red throat, cervical lymphadenopathy, blotchy rash, oedema of the hands and feet, and reddening of the palms and soles. In the second week there may be peeling of the skin of the finger tips and toes. Prompt admission for intravenous gammaglobulin reduces the risk of coronary artery aneurysms.

Figure 23.10 Urine examination.

24 Convulsions in the older infant

In infants between the ages of one month and one year convulsions are usually associated with fever. If there is no fever, epilepsy should be considered.

Fits can be divided into generalised or partial seizures. Generalised seizures include tonic-clonic and myoclonic fits. Partial seizures include focal and temporal lobe fits. During some episodes partial seizures may be followed by generalised seizures.

Generalised tonic-clonic fits are the most common type. The child may appear irritable or show other unusual behaviour for a few minutes before an attack. Sudden loss of consciousness occurs during the tonic phase, which lasts 20–30 seconds and is accompanied by temporary cessation of respiratory movements and central cyanosis. The clonic phase follows and there are jerky movements of the limbs and face. The movements gradually stop and the child may sleep for a few minutes before waking confused and irritable.

Although a typical tonic-clonic attack is easily recognised, other forms of fits may be difficult to diagnose from the mother's history. Infantile spasms may begin with momentary episodes of loss of tone, which can occur in bouts and be followed by fits in which the head may suddenly drop forward or the whole infant may move momentarily like a frog. Recurrent episodes with similar features, whether they are changes in the level of consciousness or involuntary movements, should raise the possibility of fits.

Differential diagnosis

Convulsions must be differentiated from blue breath holding attacks, which usually begin at 9–18 months. Immediately after a frustrating or painful experience infants cry vigorously and suddenly hold their breath, become cyanosed, and in the most severe cases lose consciousness. Rarely, their limbs become rigid and there may be a few clonic movements lasting a few seconds. Respiratory movements begin again and infants gain consciousness immediately. The attacks diminish with age with no specific treatment. The mother may be helped to manage these extremely frightening episodes by being told that the child will not die and that she should handle each attack consistently by putting the child on his side.

Rigors may occur in any acute febrile illness, but there is no loss of consciousness.

Febrile convulsions

A febrile convulsion is a fit occurring in a child aged from six months to five years, precipitated by fever arising from infection outside the nervous system in a child who is otherwise neurologically normal.

Convulsions with fever include any convulsion in a child of any age with fever of any cause. Among children who have convulsions with fever are those with pyogenic or viral meningitis, encephalitis, or cerebral palsy with intercurrent infections. Children who have a prolonged fit or who have not completely recovered within one hour should be suspected of having one of these conditions.

Most of the fits that occur between the ages of six months and five years are simple febrile convulsions and have an excellent prognosis.

Box 24.4 Simple febrile convulsions

All the following:

- < 20 minutes
- No focal features
- Six months to five years
- No developmental or neurological abnormalities
- Not repeated in the same episode
- Complete recovery within one hour

By arbitrary definition, in simple febrile convulsions the fit lasts less than 20 minutes, there are no focal features, and the child is aged between six months and five years and has been developing normally.

Often fever is recognised only when a convulsion has already occurred. Febrile convulsions are usually of the tonic-clonic type. The objective of emergency treatment is the prevention of a prolonged fit (lasting over 20 minutes), which may be followed by permanent brain damage, epilepsy, and developmental delay.

An electroencephalogram (EEG) is not a guide to diagnosis, treatment, or prognosis.

Emergency treatment

A child who has fever should have all his clothes removed and should be covered with a sheet only. He should be nursed on his side or prone with his head to one side because vomiting with aspiration is a constant hazard.

Rectal diazepam (0.5 mg/kg) produces an effective blood concentration of anticonvulsant within 10 minutes. The most convenient preparation resembles a toothpaste tube (Stesolid). Early admission to hospital or transfer to the intensive care unit should be considered if a second dose of anticonvulsant is needed.

All children who have had a first febrile convulsion should be admitted to hospital to exclude meningitis and to educate the parents, as many fear that their child is dying during the fit. Physical examination at this stage usually does not show a cause for the fever, but a specimen of urine should be examined in the laboratory to exclude infection and a blood glucose test should be performed. Blood should be taken for blood culture and plasma glucose and calcium estimations. Most of these children have a generalised viral infection with viraemia. A febrile convulsion may occur in roseola at the onset and three days later the rash appears. Occasionally, acute otitis media is present, in which case an antibiotic is indicated, but most children with febrile convulsions do not need an antibiotic. A pupuric rash suggests meningococcal septicaemia and the need for penicillin to be given immediately either intravenously or intramuscularly (see p. 91).

Lumbar puncture – A lumbar puncture should be performed if the child is under 18 months old or any of the following are present:

- signs of meningism such as neck stiffness
- drowsiness, irritability, or systemic illness
- complex convulsion that contains any feature that does not conform with the definitions of a simple convulsion.

Ideally, the decision should be taken by an experienced doctor, who may decide on clinical grounds that lumbar puncture is unnecessary even in a younger child, but when in doubt the investigation should be performed. The doctor deciding not to undertake a lumbar puncture should review the patient personally within a few hours. Children less than two years of age may have meningitis with *no* neck stiffness or other specific signs.

A child who has had severe vomiting or is in coma must be examined by an experienced doctor before lumbar puncture because of the risk of coning.

Management of fever – There is no evidence that antipyretic treatment influences the recurrence of febrile convulsions, but fever should be treated to promote the comfort of the child and to prevent dehydration. The child's clothes should be taken off and he should be covered with a sheet only.

Figure 24.1 Position should be on the side or prone with the head to one side.

Figure 24.2 Rectal diazepam tube.

Figure 24.3 Repeated similar movements indicate a convulsion.

Paracetamol is the preferred antipyretic and adequate fluid should be given.

Failure to respond to paracetamol is an indication to add ibuprofen to the paracetamol or to give ibuprofen alone.

Anticonvulsant drugs – Rectal diazepam should be used as soon as possible after the onset of the convulsion. The parents should be advised not to give it if the convulsion has stopped.

The indications for long term anticonvulsant prophylaxis have changed and the sole indication – frequent recurrences, which should be treated with phenobarbitone – is rare. There is no evidence that in the minority of children who later develop epilepsy the prophylactic use of anticonvulsant drugs would have prevented it.

Immunisation

As routine immunisation is given to children 2–4 months old, this schedule is usually completed before febrile convulsions occur. Babies having convulsions with fever aged under six months should be assessed by a paediatrician. Children who have febrile convulsions before immunisation against diphtheria, pertussis, and tetanus because the immunisation has been delayed should be immunised after their parents have been instructed about the management of fever and the use of rectal diazepam.

Measles, mumps, and rubella immunisation should be given as usual to children who have had febrile convulsions, with advice about the management of fever to the parents. Rectal diazepam should be made available for use should a convulsion occur.

Prognosis

Unless there is clinical doubt about the child's current developmental or neurological state, parents should be told that prognosis for development is excellent. The risk of subsequent epilepsy after a single febrile convulsion with no complex features is about 1%. With each additional complex feature the risk rises to 13% in those children with two or more complex features. Only about 1% of children with febrile convulsions are in this group.

The risk of having further febrile convulsions is about 30%. This risk increases in younger infants and is about 50% in infants aged under one year at the time of their first convulsion. A history of febrile convulsions in a first degree relative is also associated with a risk of recurrence of about 50%. A complex convulsion or a family history of epilepsy is probably associated with an increase in the risk of further febrile convulsions.

Information for parents

Information for parents should include:

- an explanation of the nature of febrile convulsions, including information about the prevalence and prognosis
- instructions about the management of fever, the management of a convulsion, and the use of rectal diazepam
- reassurance.

Verbal and written advice should be given (see p. 96).

Basic life support in the community

Basic life support (BLS) should be given immediately whenever an infant stops breathing, even if no specialised equipment is available. It may be life saving.

Figure 24.4 Paracetamol is the preferred antipyretic.

Advice to parents: Febrile convulsions

Your child has had a febrile convulsion. We know it was a very frightening experience for you. You may have thought that your child was dead or dying, as many parents think that when they first see a febrile convulsion. Febrile convulsions are not as serious as they appear.

What is a febrile convulsion?

It is an attack brought on by fever in a child aged between six months and five years.

What is a convulsion?

A convulsion is an attack in which the child becomes unconscious and usually stiff, with jerking of the arms and legs. It is caused by unusual electrical activity of the brain. The words convulsion, fit, and seizure have the same meaning.

What shall I do if my child has another convulsion?

Lay him on his side, with his head on the same level or slightly lower than the body. Note the time. Do not try to force anything into his mouth. Do not slap or shake the child.

The hospital may give you medicine to insert into your child's bottom. This is called rectal diazepam. If the convulsion has not stopped by the time that you have found the tube, insert it into the child's bottom and express the contents of the tube. This treatment should stop the convulsion within 10 minutes. If it does not, take your child to the hospital. You may need to dial 999 to obtain an ambulance. Let your doctor know what has happened.

About one child in 30 will have had a febrile convulsion by the age of five years.

Is it epilepsy?

No. The word epilepsy is applied to fits without fever, usually in older children and adults.

Do febrile convulsions lead to epilepsy?

Rarely; 99 out of 100 children with febrile convulsions never have convulsions after they reach school age, and never have fits without fever.

Do febrile convulsions cause permanent brain damage?

Almost never. Very rarely, a child who has a very prolonged febrile convulsion lasting half an hour or more may suffer permanent damage from it.

What starts febrile convulsions?

Any illness that causes a high temperature, usually a cold or other virus infection

Will it happen again?

Three out of 10 children who have a febrile convulsion will have another one. The risk of having another febrile convulsion falls rapidly after the age of three years.

Does the child suffer discomfort or pain during a convulsion?

No. The child is unconscious and unaware of what is happening.

What shall I do if my child has fever?

You can take the child's temperature by placing the bulb of the thermometer under his armpit for three minutes with his arm held against his side. Keep him cool by taking off his clothes and reducing the room temperature. Give plenty of fluids to drink. Give children's paracetamol medicine to reduce the temperature. The following doses should be given:

Up to 1 year old	one 5 ml spoonful (120 mg)
Aged 1 to 3 years	two 5 ml spoonfuls (240 mg)
Aged 4 years and over	three 5 ml spoonfuls (360 mg).

Repeat the dose every four hours until the temperature falls to normal, and then every six hours for the next 24 hours.

If the child seems ill or has ear ache or sore throat, let your doctor see him or her in case any other treatment, such as an antibiotic, is needed. Antibiotics are not necessary for most children with fever due to virus infections.

Is regular treatment with tablets or medicine necessary?

Usually not. The doctor will explain to you if your child needs regular medicine.

Adapted from a pamphlet produced by the British Paediatric Association

Assessment of condition

The level of consciousness of the infant should be quickly assessed by gentle pressure on the shoulders or limbs together with a verbal command. Even young infants may open their eyes or move in response to sound if they are not unconscious. Young infants should not be shaken as this may result in brain haemorrhage from trauma caused by the mobile brain hitting the inside of the skull. If the infant is not responsive, then the ABC of basic life support should be followed.

Airway

The rescuer can assess whether the infant is breathing by placing their face closely above the infant's face in order to look, listen, and feel for breathing and chest movement. If the infant is not breathing, the head of the infant should be maintained in the neutral position (head in line with body) by gentle pressure with one of the rescuer's hands on the forehead and chin lift or jaw thrust under the angles of the mandible with the other hand. Flexion or overextension of the neck of an infant may cause obstruction of the upper airway by the tongue blocking the pharynx. Attempts to improve an obstructed airway with the rescuer's finger are not recommended and may be dangerous.

Box 24.7 Sequence of basic life support

- Call for help
- Check environment is safe
- Assess condition
- **Airway**
- **Breathing**
- **Circulation**

Breathing

The rescuer should give five exhaled breaths, each lasting approximately one second into the infant's mouth or mouth and nose. The chest of the infant should be seen to expand with each breath or else the airway is not clear and airway opening manoeuvres should be repeated.

Circulation

After five initial breaths, the pulse should be assessed by palpation of the brachial artery in the medial aspect of the antecubital fossa or femoral artery in the groin. The carotid artery is difficult to palpate in infants because the neck is often short and fat. If the pulse is absent or < 60 beats per minute as assessed over 10 seconds, then external cardiac compressions should be commenced.

External cardiac compression

Cardiac compressions should be applied with the infant lying flat on the back on a firm surface. There are two methods of compressions in small infants.

- Hands encircling the thorax with the thumbs compressing the sternum one finger breadth below an imaginary line drawn between the nipples. This method is only possible in very small infants and is difficult for a lone rescuer to perform along with mouth to mouth with or without nose breaths.
- Two finger technique with the ball (not tips) of two fingers compressing the chest with the fingers again placed one finger breadth below the imaginary line between the nipples.

Whichever method is used, the chest should be compressed by about one-third depth in order to propel blood to the coronary arteries.

Continue CPR

Cardiopulmonary resuscitation (CPR) should be continued with a ratio of five chest compressions to one breath for approximately one minute (20 cycles) before reassessment. It is not necessary to simulate the heart rate of a normally breathing infant and, indeed, it may not be possible to do so in an effective manner. The rescuer should continue CPR until the emergency services arrive and take over resuscitation or if no help has arrived within a few minutes, the infant should be carried quickly to where help can be summoned.

Figure 24.6c External cardiac compression.

Figure 24.6d External cardiac compression.

25 Crying babies

Apart from the subtle method of eye to eye communication, babies have no other way of signalling their needs to their mothers than by crying. Babies who are quiet or “good” may be abnormal or ill. As crying is a non-specific call for help, obvious needs should be investigated. In most cases no remediable cause is found and the problem may resolve spontaneously when infants are about three months old. By then, however, parents may have become exhausted from lack of sleep and marital discord may follow while the infant remains fresh. As well as suggesting any appropriate management, the family doctor should encourage parents to take one or two evenings off together each week to visit friends or go to a film. Parents often worry that the infant is suffering from lack of sleep and wrongly ascribe poor appetite or frequent colds to this cause.

Sound spectrography has confirmed the clinical impression that cries of cerebral irritability, pain, and hunger are different in quality, but this method is not available to most clinicians. During the first month infants do not shed tears when they cry and even after the age of about six months many infants cry at night without shedding tears.

The doctor needs to take a full history, including details of the pattern of crying, when the problem began, and measures taken to resolve it. It should be possible to determine whether the infant has always needed little sleep or whether he has developed a habit of crying in order to get into his parents’ comfortable bed. The doctor should also explore the reason why the parents have sought advice at this stage. The mother should be asked about any change in the house, where the infant sleeps, and who looks after him during the day. Illnesses in the child or family and marital and social backgrounds also need considering. A physical examination usually shows no abnormality, but occasionally there may be signs of acute otitis media.

Difficulty in getting to sleep may be avoided by starting a bedtime ritual in infancy. A warm bath followed by being wrapped in particular blankets may later be replaced by the mother or father reading from a book or singing nursery rhymes before the light is turned out. A soft cuddly toy of any type can lie next to the infant from shortly after birth, and seeing this familiar toy again may help to induce sleep.

The parents should be told that during the night babies often open their eyes and move their limbs and heads. They should be asked to resist getting up to see their baby, as the noise of getting out of bed may wake him and he may then remain awake. Babies who do wake may be pacified with a drink and may then fall asleep. The drink is to provide comfort rather than to assuage any thirst.

Parents whose young children sleep a great deal during the day can discourage them from doing this by taking them out shopping or giving them other diversions, and they may then sleep well at night.

Sleep disturbance is a common reaction to the trauma of admission to hospital or moving house, and taking the child into the parents’ room for a few weeks may help to reassure the infant that he has not been abandoned.

If the infant is prepared to go to sleep at a certain time but the parents would like to advance it by an hour, they can put him to bed five minutes earlier each night until the planned bedtime is achieved.

Figure 25.1 Crying signals needs.

Figure 25.2 A bath is a bedtime ritual.

Figure 25.3 Father reading from a book.

Hunger and thirst

Babies often cry and become restless just before a feed is due and in the early weeks of life the infant may demand to be fed three hourly or even two hourly. This is perfectly normal. Preterm infants need particularly high milk intakes for “catch-up” growth and they may become less demanding when they reached their final centiles for weight.

The volumes of bottled milk recommended are only average amounts and many infants will therefore need more to prevent excessive hunger. Regular weighing and use of a growth chart to plot the results are the only ways of ensuring that the infant is obtaining the correct amount of feeds. Feeding at regular intervals is apt to cause crying in many babies and demand feeding is preferable. Some infants scream when they approach the breast and the help of an experienced midwife is needed to overcome this problem.

The age at which infants sleep through the night and do not require a night feed varies greatly. It usually occurs when infants weigh about 5 kg and parents may be worried because their neighbour’s child of a similar age has already omitted the night feed. Similar competition between mothers over which baby first manages three meals a day may also lead to inadequate feeding, followed by crying.

It is impossible to determine the difference between a cry due to hunger and a cry due to thirst. The only way of solving this problem is to offer infants water twice daily. This can easily be given mid-morning or mid-afternoon. Some infants dislike the taste of boiled tap water so a little fruit juice or half a teaspoon of sugar can be added to 100 ml of water.

Even newborn infants cry to obtain physical contact and the crying stops as soon as they are picked up. It does not spoil babies to pick them up when they want contact. Once they are a few weeks old infants begin to have periods of waking and some will not tolerate being left in a pram or cot by themselves. A harness that allows them to remain in contact with their mother’s body will often satisfy these infants. Alternatively, a canvas chair can be used even as early as one month and can be placed in a safe position in the kitchen or wherever the mother is working.

If babies do not stop crying when held, walking with them, rocking them, or taking them for a car ride may stop the crying.

Wrapping infants in a blanket and putting them firmly into a carrycot or a very small cot may also provide contact, although by an impersonal method.

Non-nutritive sucking stops crying, provided babies are not hungry. Putting a dummy into the mouth of a crying baby who is not hungry may be effective as a temporary measure.

Three months’ colic and feeding problems

Three months’ colic is the name given to a syndrome that usually begins at about two weeks of age and has usually stopped by four months. The infant screams, draws up his legs, and cannot be comforted by milk, being picked up, or having his napkin changed. This usually occurs in the early evening, when the mother is busy getting supper ready, has less time to play with the baby, and may be anxious. Breastfeeding mothers may have less milk at that time of the day.

Some babies swallow excessive air during feeding as a result of milk spurting from the breast or a very small hole in the teat of the bottle. Mothers usually complain that these infants gulp at the beginning of the feed and they have particular difficulty in bringing up the wind. This problem does not occur in

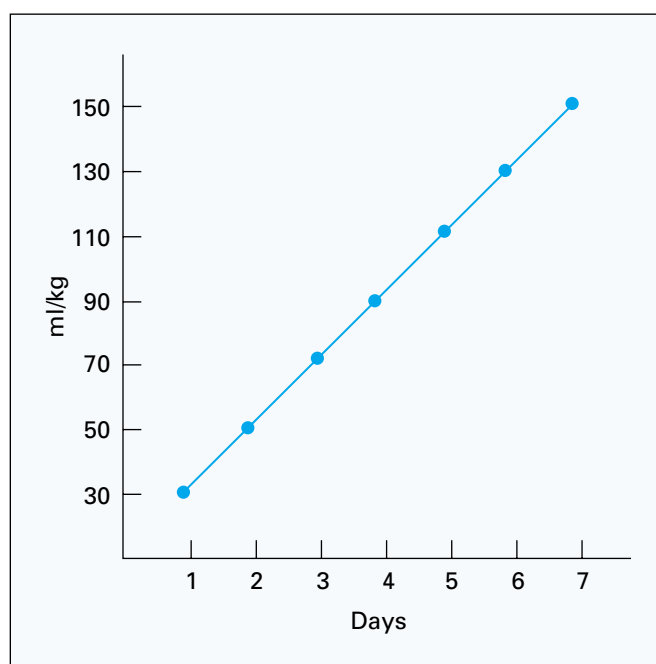

Figure 25.4 Milk intake increases with age.

Figure 25.5 Close contact often stops crying.

societies where babies are held on the mothers' backs for most of the day. The infant's abdomen is pressed against the mother's back and the infant is kept upright, which is the best position for releasing excessive gastric air.

If the milk spurts from the breast, the first 25 ml or so should be expressed manually and given to the infant later if necessary. If the baby is fed by bottle, the size of the hole in the bottle teat should be checked and made larger with a hot needle if necessary. The infant can be winded most easily by putting him prone with his head higher than his feet, but he must be observed constantly while in this position.

Teeth and teething

Although mothers consider that the eruption of the first tooth is a milestone in development, the age at which this occurs is of no practical importance. The first teeth to appear, at 6–12 months, are the lower incisors.

From the age of a few weeks infants normally put their fingers, and later anything else that comes to hand, into their mouths and mothers often wrongly ascribe this to teething.

Teething produces only teeth. It does not, contrary to common belief, cause convulsions, bronchitis, or napkin rash. Some mothers insist their infants are particularly irritable when they are teething, but it is important to examine the infant to exclude disease such as otitis media or meningitis before accepting the mother's explanation.

Dummies temporarily affect the growth of the mouth but there are no objections to using them. They should not be dipped in honey. Severe dental caries also follows the use of "comforters" or "dinky-feeders", which are filled with fluid containing sugar.

Tetracycline or its derivatives should never be given to children less than eight years of age, as permanent brownish yellow staining of the teeth may occur.

Other causes

Illness – If the infant starts crying persistently, especially if he has not cried like this before, disease should be suspected. Acute otitis media often causes persistent crying at night, but meningitis or a urinary tract infection may have no specific signs. An intussusception is an invagination of a proximal part of the gut into a more distal portion and may result in partial or complete intestinal obstruction. The infant has sudden attacks of screaming and pallor that last for a few minutes and recur every 10–20 minutes. Between attacks the infant appears normal. Bloodstained mucus may be passed rectally. The abdomen is tender only during attacks, but often there is a mass over the course of the colon. If intussusception is suspected the infant should be admitted to hospital (see p. 51).

Mechanical problems – Babies do not seem distressed when their napkins are wet or soiled, though some cry when they are being undressed or changed. An open safety pin is an extremely rare cause of crying.

Fatigue – When young infants have been on a long journey or have been stimulated more than usual by playing with relatives, they may become irritable and not keen to sleep.

Failure of mother–infant adjustment – Crying may be a sign of this failure, which may be related to the character of the infant as much as the response of the mother. The crying may represent the difficulties of each adjusting to the other. If an infant has been crying persistently for several weeks the possibility of severe depression in the mother should be

Figure 25.6 Evening colic begins about 5 pm.

Figure 25.7 Severe discoloration due to tetracycline.

Figure 25.8 Non-accidental injury behind the ear.

considered. This depression could be the cause or the result of the crying. The mother is exhausted by lack of sleep and particularly liable to injure her infant, and both mother and infant may need to be admitted to hospital for diagnosis and management.

For most infants none of the above reasons for crying are present. The parents need reassuring strongly after examination that their infant is healthy and that the problem will resolve spontaneously. Sedation of the infant with chloral hydrate for a week during a difficult period may enable the mother to regain some of her strength. The drug should not be used for longer, since it loses its effect. Only a few doses should be prescribed, as the mother may take them herself or give too many to her infant in a depressive episode.

Special problems after the age of three months

Loneliness is probably the commonest cause of crying after the age of three months. While they are awake during the day some infants will not tolerate being left alone but are happy if they are left in the room where the mother is working. These infants are extremely interested in their surroundings and need the stimulation of things going on around them. Similarly, infants need to be propped up when out in their prams and when they begin to reach out they need simple toys to play with.

Separation from the mother during admission to hospital or when parents go on holiday by themselves may be followed by bouts of crying. An infant can relate to only two or three adults at a time and frequent changes in caretaker may be associated with crying.

After about five months infants may cry when a stranger approaches them or when they sleep in a different room. They may wake suddenly and appear terrified, which might be due to a nightmare, although there is no method of proving this.

Infants who do not sleep after three months

During the first few weeks of life some babies sleep almost continuously for the 24 hours whereas others sleep for only about 12 hours. Many mothers consider that a newborn baby should sleep continuously and do not realise that babies take an interest in what is going on around them. Infants who need little sleep may wake regularly at 2 or 4 am and remain awake for two or three hours. Some are settled by a drink, but others cry persistently after this and the mother may take the infant into her own bed before they go to sleep. Some infants wake in a similar way but are then content to remain awake looking at mobiles above their cots or playing with toys left in the cot.

Behaviour modification and drugs

When infants wake frequently during the night and cry persistently until they are taken into their parents' bed, a plan of action is needed. If there is an obvious cause, such as acute illness or recent admission to hospital, the problem may resolve itself within a few weeks, and at first there need be no change in management. If there is no obvious cause, the parents are asked to keep a record of the infant's sleep pattern for two weeks (see Figure 24.10). This helps to determine where the main problem lies and can be used as a comparison with treatment.

Both parents are seen at the next visit; both need to accept that they must be firm and follow the plan exactly. Behaviour

Figure 25.9 A chair in the kitchen reduces loneliness.

Figure 25.10 Playing with toys suspended across the cot.

Figure 25.11 Record of sleep pattern.

ABC of the First Year

modification is the only method that produces long term improvement, but it can be combined with drugs initially if the mother is at breaking point.

Behaviour modification separates the mother from the child gradually or abruptly, depending on the parents' and doctor's philosophy. The slow method starts with the mother giving a drink and staying with the child for decreasing lengths of time. In the next stage no drink is given. Then she speaks to the child through the closed door and, finally, does not go to the child at all. The abrupt method consists of letting the child cry it out; he stops after three or four nights. There are an infinite number of variations between these extremes and the temperament of the parents, child, and doctor will determine what is acceptable.

Another approach is to increase the waiting time before going to the infant. In severe cases a written programme of several small changes can be given to the mother and she can be seen again by the health visitor or family doctor after each step has been achieved. The mother will need to be reassured that the infant will not develop a hernia from crying or vomit or choke, and neighbours may be pacified by being told that the child will soon be cured.

Many sleep problems can be resolved without drugs, but some mothers are so exhausted by loss of sleep that they cannot manage a programme of behaviour modification unless the infant receives some preliminary sedation. The most satisfactory drug for this age group is chloral hydrate 30 mg/kg body weight given one hour before going to bed. The full dose is given for two weeks, followed by a half dose for a week; the drug is then given on alternate nights for a week. The objective is to change the pattern of sleeping. A behaviour modification plan is needed during the third and subsequent weeks.

26 Non-accidental injury and selected drugs

Non-accidental injury

This section has been restricted to physical abuse, as sexual abuse is rare in infants less than a year of age.

Non-accidental injury inflicted by adults on children is often hard to detect. Symptoms that are difficult to explain may be the result of inflicted injury. In Britain as many as 100 children a year may die from non-accidental injuries.

Non-accidental injury should be suspected, especially in a child aged under three, whenever: (a) there has been a delay between the accident occurring and the parents seeking medical help; (b) the explanation of the injury is inadequate, discrepant, or too plausible; (c) the child or sibling has a history of non-accidental or suspicious injury; (d) there is evidence of earlier injury; (e) the child has often been brought to the family doctor or accident department for little apparent reason; (f) the parents show disturbed behaviour or unusual reactions to the child's injuries or have a history of psychiatric illness; (g) the child shows obvious neglect or failure to thrive.

Typical initial injuries are: (a) burns, abrasions, or small bruises on the face; (b) injuries to the mouth or torn fraenum of the tongue; (c) bruises caused by shaking or rough handling, including finger-shaped bruises; (d) subconjunctival or retinal haemorrhages. If the doctor suspects non-accidental injury, the child should be undressed completely and examined fully, with all signs of injury noted. If the doctor's suspicions are not allayed, he or she should ensure the immediate examination of the child by a consultant paediatrician. The family doctor should, if possible, not mention any suspicions to the parents, as they may refuse to allow this examination and it may impair his relationship with them.

If parents refuse to allow their child to be seen or want to remove the child from hospital too soon, the social services department, the police or National Society for the Prevention of Cruelty to Children may seek an emergency protection order, which allows the child to be kept in hospital for eight days.

Children with genuinely accidental injuries will occasionally be admitted unnecessarily, but this should not deter any doctor from admitting a child when there is reasonable doubt about the cause of an injury.

Preventable causes of death

Six preparations of drugs are especially associated with avoidable deaths in children.

Ampoules of digoxin for use in adults should never be supplied to children's wards. Ampoules of digoxin made especially for children ensure that a fatal overdose cannot be given.

Penicillin given intrathecally has no therapeutic value. Errors are often made in dispensing the correct dose of penicillin for intrathecal use, with fatal results. This route should therefore never be used for penicillin.

Excessive doses of chloramphenicol can easily be given if the special infant preparation is not used.

Intravenous glucose solution should never be given at a concentration higher than 20%. Sodium bicarbonate solution should never be given intravenously at a concentration higher than 4.2%. Higher concentrations of either of these solutions

Figure 26.1 Non-accidental injury.

Figure 26.2 Non-accidental injury behind ear.

Box 26.1 Drugs which are potentially dangerous

- Digoxin
- Penicillin intrathecally
- Chloramphenicol
- Glucose > 20%
- Sodium bicarbonate > 4.2%
- Potassium chloride solution

are severely hypertonic and may be followed by sudden death or permanent brain damage.

A bag of intravenous fluid to which potassium chloride solution has been added should be shaken thoroughly to avoid giving a bolus of potassium chloride solution, which may cause a fatal arrhythmia.

Selected drugs in the newborn

Intestinal absorption is variable and regurgitation of antibiotics common, so the intramuscular or intravenous route should usually be used initially. Intramuscular injections are given into the upper lateral aspect of the thigh. Schemes for rotation of sites are essential to prevent local necrosis and to avoid further injections being given into a relatively avascular area. Drugs are usually given intramuscularly or orally every eight hours and intravenously by slow bolus injection every 12 hours. In preterm infants an adjustment of dose and frequency of administration may be needed and specific texts should be consulted.

Amoxicillin	(oral, IM, or IV)	50–100 mg/kg/24 h
Ampicillin	(oral, IM, or IV)	50–100 mg/kg/24 h
Ceftazidime	(IM or IV)	60–100 mg/kg/24 h
Chloral hydrate	(oral)	30–50 mg/kg per dose
Diazepam	(IM or IV)	200–300 microgram/kg per dose
Flucloxacillin	(oral, IM, or IV)	50–100 mg/kg/24 h
Gentamicin	(IM or IV)	7 mg/kg/24 h (12–18 hourly). Blood concentration <i>must</i> be checked
Miconazole gel	(oral)	2.5 ml twice daily
Naloxone	(IM)	60 microgram/kg per dose
Nystatin	(oral)	100 000 units/dose (after feeds)
Paraldehyde	(IM)	0.1–0.2 ml/kg per dose
Benzylpenicillin	(IM or IV)	50–100 mg/kg/24 h
Phenobarbitone	(IM or IV)	15 mg/kg once only followed by 3 mg/kg per dose 12 hourly
Phenytoin	(IV)	15 mg/kg per dose slowly once followed by 3 mg/kg per dose 12 hourly
	(oral)	5 mg/kg/24 h
Sodium ironedetate	(oral)	1 ml twice daily
Triclofos	(oral)	50 mg/kg per dose
Trimethoprim	(oral)	4 mg/kg/24 h

Figure 26.3 Wrapping the infant may prevent spillage of medicine.

Figure 26.4 Special medicine syringes (which have no needles) can be used to measure and give small volumes accurately.

Selected drugs in older infants

Infants treated at home and most of those in hospital need oral drugs three times a day. The drugs should be given before feeds and the infant need not be woken specially for them. Some preparations, particularly the penicillins, have an unpleasant taste and the medicine should not be mixed with food as the infant may then hate both. Syrup, which is a sucrose solution that forms the base of most elixirs, may cause dental caries if it is given regularly for a long time. If only one adult is present to give the medicine, wrapping the infant securely in a blanket may prevent spillage. Special medicine syringes (which have no needles) can be used to measure and give small volumes accurately.

Amoxycillin	50–100 mg/kg/24 h
Ampicillin	100 mg/kg/24 h
Betamethasone	3 mg per dose intramuscularly or intravenously = 100 mg hydrocortisone
Cefaclor	40 mg/kg/24 h
Cefotaxime	100 mg/kg/24 h intramuscularly or intravenously (12 hourly)
Chloral hydrate	30–50 mg/kg/per dose

Diazepam	200–300 microgram/kg orally per dose or slowly intravenously
Erythromycin	30–50 mg/kg/24 h
Flucloxacillin	50–100 mg/kg/24 h
Gentamicin	7 mg/kg/24 h intramuscularly or intravenously
Hydrocortisone	100 mg per dose intramuscularly or intravenously
Nystatin	100 000 units per dose (four hourly)
Paracetamol	75 mg/kg/24 h
Paraldehyde	0.15 ml/kg per dose intramuscularly (intramuscularly or intravenously)
Benzylpenicillin	100 mg/kg/24 h
Phenoxymethylpenicillin	60 mg/kg/24 h
Phenobarbitone	5 mg/kg/24 h
Phenytoin	5 mg/kg/24 h
Trimethoprim	1–2 mg/kg single daily prophylactic dose 8 mg/kg/24 h
Trimeprazine tartrate	3 mg/kg per dose once daily

Acknowledgements

We thank Blackwell Scientific Publications for allowing us to adapt liberally material that has appeared in *Practical Management of the Newborn*, *Accident and Emergency Paediatrics*, and *Paediatric Therapeutics* and use the two photographs of resuscitating a newborn.

We also thank Susan Thomason, Maire Sullivan, Richard Bowlby, Joanna Fairclough, Brian Pashley, Jeanette McKenzie, Derek De Witt, and Ann Shields of the department of medical illustration at Northwick Park Hospital for taking most of the photographs. The remaining photographs were supplied as follows:

Early prenatal diagnosis: ultrasound scans Dr H B Meire and Sujata Patel.

Breathing difficulties in the newborn: micrograph of respiratory distress syndrome, Dr G Slavin; apnoea monitor, Graesby.

Some congenital abnormalities: cleft lip, Mr R Saunders.

Routine examination of the newborn: cardiac ultrasound, Miss Varrela Gooch.

Dislocated and dislocatable hips in the newborn: the ultrasound scans were provided by Dr Dennis Remedios and the photograph of the Pavlik harness by Mr L Freedman.

For all photographs apart from those mentioned specifically above, Dr H B Valman and Dr R M Thomas retain the copyright. We thank Mr R Lamont for providing extensive new material for the chapter on prenatal assessment. We are indebted to the Child Growth Foundation for allowing the use of data to construct the growth chart on p.66, and Dr Judith Wilson for the Harrow version of the personal health record which is used for recording health surveillance data.

 respiratory problems 12, 17
 very low gestational age 62
 weight gain 69
 progesterone 42, 52
 progesterone-only pill 66
 proteinuria 91
 pulmonary hypoplasia 6
 pulmonary surfactant 13
 pulse, brachial 97
 pupils 19, 27, 76
 pure tone audiology 81
 pyloric stenosis 50, 69
 pyrexia *see* fever
- quinsy 83
- rash 94
 meningococcal **91**
 napkin 40–1
 purpuric 94
 rattle **78**
 red cell enzyme defect 43, 44
 red cell incompatibility 42
 red reflex 27, 76
 regurgitation 17, 49, 50, 67
 renal failure 39
 renal isotope scan 3
 renal pelvis, dilatation 3, 92
 renal scars 39
 renal tract anomalies 3
 respiratory distress syndrome 3, 10, 13–15
 causes 13
 clinical features 13–14
 complications 15
 management 14–15
 respiratory rate 24, 92
 upper limit 85, 86
 respiratory syncytial virus 86, 87
 respiratory tract infections 37–8, 82–7
 lower tract 67, 85–7
 middle tract 84–5
 recurrent 87
 upper tract 82–4
 resuscitation (basic life support) 95–7
 resuscitation of the newborn 4–9
 assessment 4
 death of infant 8–9
 discussion with parents 8
 drugs 6–7
 failure to improve 6
 procedure 4–6
 vitamin K 8
 when not to start 7–8
 when to stop 7
 resuscitation trolley **7**
 review at eight months
 hearing 79, 81
 motor function 79
 patterns of development 81
 record form **80**
 vision 79
 review at six weeks 74, 76
 motor function 77
 patterns of development 77
 record form **75**
 vision and squint 76–7
 weighing and measuring 76
 rhesus incompatibility 1, 43
 rhonchi 84, 85, 89
 roseola 91, 94
 rotavirus infections 37, 53
 rubella 81
- salbutamol 87, 89
 salicylic acid shampoo 41
 salmonella infections 54, 71
 salt intake 31, 72
 salt loss 52
 scales **78**
 seborrhoeic dermatitis **40**, 41
 sedation 101, 102, 104, 105
 seizures 93
 senna 66
 separation, mother and baby 56–7, 101
 septicaemia 36, 37, 50, 84
 antibiotics 39
 jaundice 42
 meningococcal 91, 94
 Shigella 54
 shock 7
 siblings
 cot death 31
 death of newborn baby 9
 sickle cell trait 1
 sitting up 79, 81
 skin
 lesions 23
 napkin rashes 40–1
 rashes **91**, 94
 sepsis 37
 spread of jaundice 42, **43**
 sleeping position 28–9
 sleeping problems 98
 after three months 101
 bedtime rituals 98
 behaviour modification 101–2
 small for gestational age *see* light for dates infant
 smoking 12, 29
 sodium 31, 52
 sodium bicarbonate 7, 103
 sodium chloride 7, 82
 sodium ironedetate 104
 spasms, infantile 93
 specialist referrals 12, 74, 81
 speech
 delayed development 77
 milestones **76**
 spina bifida 88

Index

- spinal defects 1, 20, 63, 88
- spine, midline pit 23
- squint 76–7, 79
- stadiometer 76
- staphylococcal infections 37–8, 41
 - Staphylococcus aureus* 37, 84
 - Staphylococcus epidermis* 37
- sternomastoid “tumour” 19
- steroids 7, 66, 87
- stethoscope 90
- stools 53
 - bloodstained mucus 51
 - culture 54
 - mucus in 65, 67, 100
 - pale 45
- strawberry naevus 23
- streptococcal infections
 - group A 83, 90
 - group B 15, 17, 36, 39
- Streptococcus pyrogenes* 90
- stridor 84, 84–5, 90
- subarachnoid haemorrhage 48
- subconjunctival haemorrhage 19
- subdural haemorrhage 48
- substernal recession 13, 84
- sucking 99
- sucking reflex 11, 64–5
- sucrose solution 54
- sudden infant death *see* cot death
- sunburn 31
- support organisations 9
- suprapubic bladder puncture 38, 91
- swaddler 10
- sweat test 86, 87

- tachypnoea, transient 16
- talking to babies 58
- tape measures 59, 76, 78
- tear ducts 27
- tears 98
- teething 100
- temperature
 - axillary 90
 - newborn 10–11
 - optimum for baby 29
 - oral/rectal 90
 - roseola 91
 - viral infections 83
- tentorium cerebelli 18–19
- testis, undescended 25
- tetanus immunisation 95
- tetracycline 100
 - eye ointment 37
- thirst 67, 99
- throat
 - examination 90
 - sore 82–3
- thrush 38, 67
- thyroid stimulating hormone 43, 44
- thyroxine, plasma 43, 44, 66
- tonic-clonic convulsions 93
- tonsillitis 82–3, 87, 90
- torticollis 19
- total parenteral nutrition 15
- toxoplasmosis 20
- toys 101

- tracheo-oesophageal fistula 49
- tracheostomy 84, 85
- travel
 - car seats 29
