Preface

By December 2000 there were 17 538 adult and paediatric patients with AIDS in the UK and 43 774 screened and infected with HIV. Many of those with the virus are well, asymptomatic, and even unaware that they are infected, but others, although they have not yet developed AIDS, have physical, psychological, social, and occupational problems and require as much care as those with AIDS. We therefore need to be concerned not with “a few cases” but with a large number of people infected with the virus, who will be making demands on every part of the health and social services. New infections will occur, and the public health education campaign will need to continue. None of us should feel that the problem of HIV infection and AIDS is unimportant and that it will go away because of the campaign and the possible magic bullet of a cure or vaccine.

We can all hope for these things but it would be a mistake to be lulled into a state of inertia and complacency. All of us will be concerned with AIDS for the rest of our professional lives. This book, originally written as weekly articles for the *BMJ*, attempts to give those doctors and other health care workers, who currently have had little experience of AIDS and HIV, some idea of the clinical, psychological, social and health education problems that they will become increasingly concerned with.

Patients with HIV infection and AIDS spend most of their time out of hospital in the community. Admission is required only when an acute clinical illness supervenes. General practitioners and domiciliary and social services do not always feel skilled and knowledgeable enough to look after them. With the increase in the number of cases, the community services will have to be able and willing to cope. Again, I hope that this book will help to make people feel more skilled and comfortable about caring for patients with HIV and AIDS.

This is the fifth edition of the *ABC of AIDS*; each chapter has been updated or rewritten.

1 Development of the epidemic

Michael W Adler

Box 1.1 Early history of the epidemic

1981	Cases of <i>Pneumocystis carinii</i> pneumonia and Kaposi's sarcoma in the USA
1983	Discovery of the virus. First cases of AIDS in the UK
1984	Development of antibody test

The first recognised cases of the acquired immune deficiency syndrome (AIDS) occurred in the summer of 1981 in America. Reports began to appear of *Pneumocystis carinii* pneumonia and Kaposi's sarcoma in young men, who it was subsequently realised were both homosexual and immunocompromised. Even though the condition became known early on as AIDS, its cause and modes of transmission were not immediately obvious. The virus now known to cause AIDS in a proportion of those infected was discovered in 1983 and given various names. The internationally accepted term is now the human immunodeficiency virus (HIV). Subsequently a new variant has been isolated in patients with West African connections – HIV-2.

The definition of AIDS has changed over the years as a result of an increasing appreciation of the wide spectrum of clinical manifestations of infection with HIV. Currently, AIDS is defined as an illness characterised by one or more indicator diseases. In the absence of another cause of immune deficiency and without laboratory evidence of HIV infection (if the patient has not been tested or the results are inconclusive), certain diseases when definitively diagnosed are indicative of AIDS. Also, regardless of the presence of other causes of immune deficiency, if there is laboratory evidence of HIV infection, other indicator diseases that require a definitive, or in some cases only a presumptive, diagnosis also constitute a diagnosis of AIDS.

In 1993 the Centers for Disease Control (CDC) in the USA extended the definition of AIDS to include all persons who are severely immunosuppressed (a CD4 count $<200 \times 10^6/l$) irrespective of the presence or absence of an indicator disease. For surveillance purposes this definition has not been accepted within the UK and Europe. In these countries AIDS continues to be a clinical diagnosis defined by one or more of the indicator diseases mentioned. The World Health Organisation (WHO) also uses this clinically based definition for surveillance within developed countries. WHO, however, has developed an alternative case definition for use in sub-Saharan Africa (see chapter 10). This is based on clinical signs and does not require laboratory confirmation of infection. Subsequently this definition has been modified to include a positive test for HIV antibody.

Box 1.2 AIDS-defining conditions without laboratory evidence of HIV

- Diseases diagnosed definitively
 - Candidiasis: oesophagus, trachea, bronchi or lungs
 - Cryptococcosis: extrapulmonary
 - Cryptosporidiosis with diarrhoea persisting >1 month
 - Cytomegalovirus disease other than in liver, spleen, nodes
 - Herpes simplex virus (HSV) infection
 - mucocutaneous ulceration lasting >1 month
 - pulmonary, oesophageal involvement
 - Kaposi's sarcoma in patient <60 years of age
 - Primary cerebral lymphoma in patient <60 years of age
 - Lymphoid interstitial pneumonia in child <13 years of age
 - *Mycobacterium avium*: disseminated
 - *Mycobacterium kansasii*: disseminated
 - *Pneumocystis carinii* pneumonia
 - Progressive multifocal leukoencephalopathy
- Cerebral toxoplasmosis

Box 1.3 AIDS-defining conditions with laboratory evidence of HIV

- Diseases diagnosed definitively
 - Recurrent/multiple bacterial infections in child <13 years of age
 - Coccidiomycosis – disseminated
 - HIV encephalopathy
 - Histoplasmosis – disseminated
 - Isosporiasis with diarrhoea persisting >1 month
 - Kaposi's sarcoma at any age
 - Primary cerebral lymphoma at any age
 - Non-Hodgkin's lymphoma: diffuse, undifferentiated B cell type, or unknown phenotype
 - Any disseminated mycobacterial disease other than *M. tuberculosis*
 - Mycobacterial tuberculosis at any site
 - Salmonella septicaemia: recurrent
 - HIV wasting syndrome
 - Recurrent pneumonia within 1 year
 - Invasive cervical cancer
- Diseases diagnosed presumptively
 - Candidiasis: oesophagus
 - Cytomegalovirus retinitis with visual loss
 - Kaposi's sarcoma
 - Mycobacterial disease (acid-fast bacilli; species not identified by culture): disseminated
 - *Pneumocystis carinii* pneumonia
 - Cerebral toxoplasmosis

ABC of AIDS

These case definitions are complex and any clinician who is unfamiliar with diagnosing AIDS should study the documents describing them in detail.

CDC Definition of AIDS

Effective 1 January 1993:
All those with confirmed HIV infection with CD4 T lymphocyte count $<0.2 \times 10^6/l \pm$ indicator disease

Transmission of the virus

HIV has been isolated from semen, cervical secretions, lymphocytes, cell-free plasma, cerebrospinal fluid, tears, saliva, urine, and breast milk. This does not mean, however, that these fluids all transmit infection since the concentration of virus in them varies considerably. Particularly infectious are semen, blood, and possibly cervical secretions. The commonest mode of transmission of the virus throughout the world is by sexual intercourse. Whether this is anal or vaginal is unimportant. Other methods of transmission are through the receipt of infected blood or blood products, donated organs, and semen. Transmission also occurs through the sharing or reuse of contaminated needles by injecting drug users or for therapeutic procedures, and from mother to child. Transmission from mother to child occurs *in utero* and also possibly at birth. Finally, the virus is transmitted through breast milk.

The virus is not spread by casual or social contact. Health care workers can, however, be infected through needlestick injuries, and skin and mucosal exposure to infected blood or body fluids. Prospective studies in health care workers suffering percutaneous exposure to a known HIV seropositive patient indicate a transmission rate of 0.32%. As of December 1999 there have been 96 reported cases of documented seroconversion after occupational exposure in such workers.

The precautions and risks for such groups are covered in detail in chapter 15. Finally, there is no evidence that the virus is spread by mosquitoes, lice, bed bugs, in swimming pools, or by sharing cups, eating and cooking utensils, toilets, and air space with an infected individual. Hence, HIV infection and AIDS are not contagious.

Growth and size of the epidemic

Even though North America and Europe experienced the first impact of the epidemic, infections with HIV are now seen throughout the world, and the major focus of the epidemic is in developing/resource-poor countries.

Worldwide

The joint United Nations programme on AIDS (UNAIDS) has estimated that by the end of 2000 there were 36.1 million people living with HIV/AIDS (34.7 million adults and 1.4 million children <15 years). The new infections during that year were 5.3 million, approximately 16,000 new infections per day.

Box 1.4 Transmission of the Virus

- Sexual intercourse
 - anal and vaginal
- Contaminated needles
 - intravenous drug users
 - needlestick injuries
 - injections
- Mother → child
 - *in utero*
 - at birth
 - breast milk
- Organ/tissue donation
 - semen
 - kidneys
 - skin, bone marrow, corneas, heart valves, tendons etc.

Table 1.1 HIV Transmission: Global Summary

Type of exposure	Percentage of global total
Blood transfusion	3–5
Perinatal	5–10
Sexual intercourse	70–80
(vaginal)	(60–70)
(anal)	(5–10)
Injecting drug use	5–10
(sharing needles, etc.)	
Health care (needlestick injury, etc.)	<0.01

Table 1.2 End-2000 global estimates: children and adults

Categories	Estimate ($\times 10^6$)
People living with HIV/AIDS	36.1
New HIV infections in 2000	5.3
Deaths due to HIV/AIDS in 2000	3.0
Cumulative number of deaths due to HIV/AIDS	21.8

Table 1.3 Regional HIV/AIDS statistics and features, end of 2000

Region	Epidemic started	Adults and children living with HIV/AIDS	Adults and children newly infected with HIV	Adult prevalence rate(*)	% of HIV-positive adults who are women	Main mode(s) of transmission (†) for adults living with HIV/AIDS
Sub-Saharan Africa	late 1970s to early 1980s	25.3 million	3.8 million	8.8%	55%	Hetero
North Africa and Middle East	late 1980s	400 000	80 000	0.2%	40%	Hetero, IDU
South and South-East Asia	late 1980s	5.8 million	780 000	0.56%	35%	Hetero, IDU
East Asia and Pacific	late 1980s	640 000	130 000	0.07%	13%	IDU, hetero, MSM
Latin America	late 1970s to early 1980s	1.4 million	150 000	0.5%	25%	MSM, IDU, hetero
Caribbean	late 1970s to early 1980s	390 000	60 000	2.3%	35%	Hetero, MSM
Eastern Europe and Central Asia	early 1990s	700 000	250 000	0.35%	25%	IDU
Western Europe	late 1970s to early 1980s	540 000	30 000	0.24%	25%	MSM, IDU
North America	late 1970s to early 1980s	920 000	45 000	0.6%	20%	MSM, IDU, hetero
Australia and New Zealand	late 1970s to early 1980s	15 000	500	0.13%	10%	MSM
Total		36.1 million	5.3 million	1.1%	47%	

* The proportion of adults (15–49 years of age) living with HIV/AIDS in 2000, using 2000 population numbers.

† Hetero, heterosexual transmission; IDU, transmission through injecting drug use; MSM, sexual transmission among men who have sex with men.

Currently, 95% of all infections occur in developing countries and continents, the major brunt of the epidemic being seen in sub-Saharan Africa and south-east Asia. It is now recognised that cases of AIDS were first seen in Central Africa in the 1970s even though at that time it was not recognised as such. Current surveys from some African countries show that the prevalence of infection is high amongst certain groups – 50–90% of prostitutes, up to 60–70% of those attending departments for sexually transmitted diseases and antenatal clinics. In the developing world, HIV is spread mainly by heterosexual intercourse.

At a family level, UNAIDS estimated that by the end of 1999 the epidemic had left behind a cumulative total of 13.2 million AIDS orphans (defined as those having lost their mother or both parents to AIDS before reaching the age of 15 years). Many of these maternal orphans have also lost their father. Orphans in Zimbabwe are expected to total 1 million by 2005 and 2 million in South Africa by 2010. Traditional family structures and extended families are breaking down under the strain of HIV. Population growth and death rates are increasingly affected. Life expectancy in countries with adult prevalences of over 10% (for example Botswana, Kenya, Zimbabwe, South Africa, Zambia, Rwanda) are expected to see an average reduction in life expectancy of 17 years by 2010–2015. Young, highly productive adults die at the peak of their output, which has a considerable impact on a country's economy.

Figure 1.1 Prevalence of HIV — different groups

Figure 1.2 Adults and children estimated to be living with HIV/AIDS at end of 2000

ABC of AIDS

USA, UK and Europe

By June 1999, 702 748 adult cases of AIDS had been reported in the USA. In addition there were 8596 paediatric cases (<13 years old). Most of the cases in children (91%) occur because a patient suffered from HIV or belonged to a group at increased risk of HIV; 4% occurred through blood transfusion; 3% in children with haemophilia. Information on risk factors for the remaining 2% of the parents of these children is not complete.

Adult cases in Europe totalled 234 406 by June 2000, and those in the UK 17 151 (December 2000). There are five times more people infected with HIV at any one time than have AIDS. The rate for AIDS cases varies throughout Europe, with particularly high rates in Italy, Portugal, Spain, France and Switzerland, where the commonest mode of infection is through intravenous drug use and the sharing of needles and equipment.

In North America and the UK the first wave of the epidemic occurred in homosexual men. In the UK, proportionally more homosexual men have been notified than in America: 67% of cases compared with 48% respectively. Even though infections amongst men who have sex with men still arise, an increasing proportion of new infections in the USA is occurring amongst intravenous drug users sharing needles and equipment. There is also an increase amongst heterosexuals in both the USA and the UK. Currently in the USA, 16% of cases of AIDS have occurred amongst women, and although the commonest risk factor amongst such women is injecting drug use (42%), the next most common mode of transmission is heterosexual contact (40%).

The nature of the epidemic within the UK is changing with more heterosexual transmission. In the UK 12% of adult cases of AIDS have occurred in women, 70% of which have resulted from heterosexual intercourse. In 2000 there were more new annual infections of HIV than ever before and for the first time more occurring as a result of heterosexual sex than men having sex with men. Most heterosexually acquired infections are seen in men and women who have come from or have spent time in Sub-Saharan Africa.

The advent of an effective antibody test in 1984 has allowed for a clearer understanding of the changing prevalence and natural history of HIV infection. Surveys show that the proportion of individuals infected needs to be high before cases of AIDS start to become apparent. It also underlines the importance of health education campaigns early in the epidemic, when the seroprevalence of HIV is low. Once cases of AIDS start to appear the epidemic drives itself and a much greater effort is required in terms of control and medical care.

Within countries one finds considerable variation in seroprevalence levels for HIV. Over 70% of cases of AIDS and HIV infection within the UK occur and are seen in the Thames regions (London and the surrounding area). Among different groups one also finds geographical differences. For example, the rates among drug users is higher in Edinburgh than London, and for gay men higher in London than anywhere else in the UK. This is also found in the developing world; for example, in Tanzania and Uganda, the urban level of HIV infection in men and women can be five times higher than rural rates.

The use of highly active antiretroviral therapy (HAART) in resource-rich countries has resulted in an increase in life expectancy. This, in combination with the increase in new HIV infections, means that the prevalent pool of those infected, and potentially infectious, is increasing. This presents a continuing challenge for health promotion and a re-statement of the importance of safe sex techniques, particularly condom use (see chapter 16).

Table 1.4 AIDS: adult patient groups in the USA and UK

Patient groups	USA (June 99)		UK (Dec. 00)	
	n	%	n	%
Men who have sex with men	334 073	48	11 345	66
Intravenous drug user	179 228	26	1095	6
Men who have sex with men and IV drug user	45 266	6	307	2
Received blood/haemophilia	13 440	2	828	5
Heterosexual contact	70 582	10	3391	20
Other/undetermined	60 159	8	185	1
Total	702 748	100	17 151	100

UK	68.0	6.5	18.0
Denmark	67.0	8.0	17.0

Figure 1.4 New diagnoses, AIDS cases and deaths reported in the year in which they occurred — United Kingdom

AIDS results in a considerable cost not only in human suffering also to health services. Other costs include time off work and the effect of the deaths of young people on national productivity. AIDS represents a major public health problem in the world. A clear understanding of the epidemiology forms the basis of developing a strategy of control ranging from health education to research.

The data on AIDS/HIV in the UK is reproduced with permission from the Communicable Disease Surveillance Centre (CDSC) and the United Nations AIDS Programme.

Figure 1.5 HIV-infected individuals diagnosed in the UK by exposure category: to December 2000

2 The virus and the tests

PP Mortimer, C Loveday

Introduction

Although it is clear that HIV is the underlying cause of AIDS and AIDS-related disease, its origin remains obscure. There is firm serological evidence of infection on the east and west coasts of the USA from the mid 1970s, and HIV infection in central Africa may have antedated infection in North America. Phylogenetic analysis of the HIV-1 genome has suggested an origin in chimpanzees while, in the case of HIV-2, similarity to the simian immunodeficiency virus (SIV) genome may point to an origin in sooty mangabey monkeys. In both cases the butchery and consumption of these “bush meats” has been incriminated in transmissions to the human host. Like some other RNA viruses, HIV appears to have mutated and shifted its host range and virulence, explaining how a new pathogenic retrovirus could arise in man. Its virulence may since have been amplified as a result of travel, population dislocation and promiscuous sexual contact, with rapid passage of the virus.

Retroviruses are so named because their genomes encode an unusual enzyme, reverse transcriptase, which allows DNA to be transcribed from RNA. Thus, HIV can make copies of its own genome, as DNA, in host cells such as the human CD4 “helper” lymphocyte. The viral DNA becomes integrated in the lymphocyte genome, and this is the basis for chronic HIV infection. Integration of the HIV genome into host cells is a formidable obstacle to any antiviral treatment that would not just suppress but also eradicate the infection. Nevertheless, modern treatment with combinations of nucleoside analogues and protease inhibitors has transformed the prognosis for carriers of HIV, usually achieving a sustained fall in virus concentration in blood and restoration of the main target cell (CD4 lymphocyte) to near normal levels.

By contrast, the inherent variability of the HIV genome and the failure of the human host to produce neutralising antibodies to the virus, as well as technical difficulties and concerns about safety, have continued to frustrate attempts to make an effective vaccine. This must not, however, allow efforts to develop and evaluate candidate vaccines to slacken. A particular concern is that a useful candidate vaccine (probably a recombinant envelope vaccine developed in North America or Europe against the locally prevalent HIV-1 B subtype) would be ineffective in those parts of the world where other subtypes predominate.

WHO estimates that in the year 2000 there are 36 million carriers of HIV worldwide, and only a small fraction of them have access to suppressive treatment. Both their contacts, their dependants and possibly they themselves would have their life prospects transformed by an effective, or even partially effective, vaccine, and successful application of antiviral treatment in developed countries should in no way be allowed to deflect attention from the necessity of developing and delivering an effective vaccine and of promoting “safe sex” behaviour.

Figure 2.1 HIV replication

HIV and related viruses

HIV was discovered by Barré-Sinoussi, Montagnier, and colleagues at the Institut Pasteur, Paris, in 1983 and given the name lymphadenopathy associated virus (LAV). In 1984 Popovic, Gallo, and co-workers described the development of cell lines permanently and productively infected with the virus. In line with two previously described retroviruses, HTLV-I and HTLV-II, they designated this virus HTLV-III. Other virus isolates from patients with AIDS and AIDS-related disease in America, Europe and Central Africa have proved to be all the same virus, now referred to as HIV-1. Eight subtypes of HIV-1, alphabetically designated, have so far been described.

Around 1985 another human retrovirus, different from HIV-1, was recognised in patients from West Africa. This virus, referred to by the Paris investigators as LAV-2 and more recently as HIV-2, is also associated with human AIDS and AIDS-related disease. It is closely related to the simian retrovirus, SIV, carried by healthy African green monkeys, and the cause of an AIDS-like disease in captive rhesus monkeys. Though potentially important worldwide, HIV-2 infections remain uncommon outside West Africa and they have proved far less virulent than HIV-1 infections.

Transmission of HIV infection

HIV-1 and HIV-2, the major and minor human AIDS viruses, are transmitted in ways that are typical for all retroviruses – “vertically” – that is from mother to infant, and “horizontally” through sexual intercourse and through infected blood. The lymphocytes of a healthy carrier of HIV replicate, and eliminate, over one billion virions each day and the circulating virus “load” may exceed ten million virions per millilitre. At these times viraemia can be recognised by measuring the p24 antigen of HIV in blood and quantifying viral DNA or RNA (see below). Transmission also depends on other factors, including the concentration of HIV secreted into body fluids such as semen, secondary infection of the genital tract, the efficiency of epithelial barriers, the presence or absence of cells with receptors for HIV, and perhaps the immune competence of the exposed person. All infections with HIV appear to become chronic and many are continuously productive of virus. The ultimate risk of spread to those repeatedly exposed is therefore high.

The stage of infection is an important determinant of infectivity. High titres of virus are reached early in infection, though this phase is difficult to study because symptoms may be mild or absent and any anti-HIV response undetectable; it is nevertheless a time when an individual is likely to infect contacts. When, much later, the cellular immune response to HIV begins to fail and AIDS supervenes the individual may again become highly infectious. In the interval between, there may be periods when except through massive exposures – for example blood donation – infected individuals are much less infectious. Nevertheless, in the absence of reliable markers of infectivity, all seropositive individuals must be seen as potentially infectious, even those under successful treatment. Effective ways are constantly being sought to protect their contacts and this has led to the development of the concept of “safe sex”. Ideally, this should inform sexual contact between all individuals regardless of whether they are known to be infected with HIV.

ABC of AIDS

Tests for anti-HIV-1 and HIV-2

Anti-HIV tests have transformed our understanding of the epidemiology of AIDS in the years since they were introduced in 1984, and they are still the bedrock of clinical diagnosis and much epidemiological research. Anti-HIV appears three weeks to three months after exposure to HIV and thereafter is invariably detectable in spite of any detrimental effect the virus may have on lymphocyte function and therefore antibody production. Neutralising antibodies to HIV are also measurable, but their titres are low. An inability to mount a neutralising response to HIV antigens together with the mutability of the virus are the most likely reasons why conventional approaches to preparing a vaccine have so far failed.

At first HIV antigen was prepared from infected cell lines. However, antigens can now be made by DNA cloning and expression or by synthesis of viral polypeptides. Several types of anti-HIV test exist, but most use a similar enzyme conjugate and give a colour signal due to the reaction between an enzyme specifically bound onto a polystyrene surface, membrane or inert particles and a substrate that then changes colour. Other tests depend on the binding of a fluorescein or chemiluminescent conjugate, or the visible agglutination of HIV-coated gelatin or latex particles.

Since anti-HIV tests became commercially available in 1985 they have been widely used in diagnostic and transfusion laboratories in the developed world. The accuracy – both sensitivity and specificity – of the antibody assays is continually being improved, and in competent hands the occurrence of false positive and false negative results is less and less frequent. The proportion of true to false positive results depends on the population studied, but even in low risk groups such as volunteer blood donors it is now very high in well conducted laboratories. Human, not test, errors cause most false results, and the key to avoiding these mistakes is continuous review with repeat testing where necessary. All positive reactions should both be confirmed by additional assays and succeeded by a test on a follow-up specimen (see below). The use of several screening tests in parallel on proven positive specimens also acts as a check on the possibility of false negativity in these assays (which it is otherwise difficult to guard against).

More discriminating tests can recognise the components of the antibody response. The serological response to individual HIV proteins can be studied by Western blot, and the immunoglobulin class response to HIV in blood and other fluids can also be investigated. The IgM response slightly precedes the IgG response early in infection and is indicative of recent infection. Other test procedures, which employ both a highly sensitive and a “detuned” assay for anti-HIV are designed to detect infection within the previous few months and may therefore be used epidemiologically to measure incidence. The IgA anti-HIV response is a feature of infection in infancy.

Simple and non-invasive tests, confirmatory tests, follow-up tests

Simple anti-HIV screening tests have been developed for use in clinics, in unfavourable laboratory conditions and close to the patient. When results are needed urgently, for instance before transplantation procedures and to select a blood donor in the field, they are quick and practical. Saliva (oral fluid) and urine can conveniently be used as specimens to investigate for anti-HIV when venepuncture is difficult, hazardous or unacceptable to the patient. These simple rapid and non-invasive tests are attractive options and may lead to developments such as home

Box 2.3 Anti-HIV

- Appears 3 weeks to 3 months after exposure
- Indicative of infection, except in infants of HIV-positive mothers
- Has weak neutralising capacity
- Persists throughout HIV infection

Figure 2.4 The left strip, a Western blot result from a serum specimen collected soon after HIV infection, shows antibody to p24 without other bands being clearly visible. The right strip, a result on a serum sample collected from the same patient 3 months later, shows antibody to many viral proteins, including p15, p24, p31, gp41, and p55

Modern screening kits detect antibody to both HIV-1 and HIV-2. Anti-HIV-2, which is mostly encountered in West Africans and in Europeans who have lived in West Africa, has also been reported in the Indian subcontinent, but it is rare in the Americas. In the UK blood donations and clinical specimens are routinely tested for both infections.

testing. However, few of these tests are quite as accurate as the conventional assays on serum, and follow-up confirmatory tests are essential before a positive diagnosis is made by these means.

In many countries, including the UK, formal procedures have been put in place to secure accurate testing. The most important is that when there is a positive anti-HIV finding the test is repeated and the implicated specimen is tested by other, methodologically independent, anti-HIV assays. Another specimen should then be sought. Although this may cause some delay in confirming a positive finding, anti-HIV testing is as a consequence more precise. A few infected individuals may have little or no detectable anti-HIV when first tested or there may have been technical or clerical mistakes, including specimen misidentifications and transcription errors. Follow-up at an interval of one to four weeks greatly diminishes the chance of either a false negative or a false positive anti-HIV result, and follow-up specimens are the most important element in the accurate laboratory diagnosis of HIV infection. When newly infected individuals are followed up, they show an increase in the titre and range of HIV antibodies. By contrast, persistently weak anti-HIV reactions are usually non-specific. Sometimes PCR (see below) will resolve a difficult-to-confirm antibody reaction. Follow-up procedures also guard against specimen misidentification and transcription errors.

Test for the virus: antigen, viral DNA and RNA, subtypes, mutants

Viral antigens are present in serum, in particular the HIV core antigen, p24. This is only detectable for as long as it is in excess of antibody to p24, typically at the outset of infection. Tests for this HIV antigen are commercially available, and they assist in the diagnosis of early infection and the recognition of infection in infants. In practice, however, tests for HIV antigen have proved of limited value due to lack of sensitivity, although this may be enhanced by preliminary acid or alkali dissociation of immune complexes in the specimen. Viraemia may also be recognised by isolation of HIV from plasma in cultured lymphocytes, but this is time consuming and not especially sensitive. Essentially it has become a research tool.

HIV can also be detected in specimens in the form of genome sequences. Though only rare lymphocytes carry the HIV genome, the polymerase chain reaction (PCR) can be used greatly to amplify chosen HIV genome sequences in those clinical specimens that contain these small numbers of infected lymphocytes. To a large extent, therefore, viral culture has been superseded by PCR amplification of HIV DNA extracted from mononuclear cells in the circulation. Even more commonly, reverse transcription and amplification of HIV RNA is now being used to detect and quantify virus present in blood. While these procedures are no more accurate than anti-HIV assays and much more expensive, they may be useful in diagnosis, for example in infancy when any anti-HIV detected may be of maternal origin. PCR amplification also provides rapid access to the HIV genome and can lead to characterisation of an HIV isolate to strain level. The (semi) quantification of viraemia (i.e. to within about $0.5 \log^{10}$) is an important determinant of the need for, and the effect of treatment. It is especially useful as the choice of antiviral combinations widens. Targets for genome amplification include the genes coding for the main envelope, core and transcriptase proteins. On the basis, particularly, of analysis of the sequences of amplified sections of the envelope gene, HIV-1 has been subtyped – so far from A to K. In some cases the sequences found in the various HIV genes are not concordant, showing that recombination occurs in HIV.

If specimen is anti HIV-positive repeat test using other assay. If HIV-positive take 2nd specimen to confirm.

Figure 2.5 The evolution of plasma laboratory markers of the naturalisation of HIV infection ('x' axis not to scale). The course of HIV may now be modified by combined antiviral treatment which will suppress HIV PCR reactivity but not usually modify the anti-HIV response

ABC of AIDS

Sequencing of PCR “amplicons” is also the basis for proving HIV transmission events in special settings, for example, health care.

The growing use of antiretroviral drugs, especially singly, has encouraged the emergence of resistance. This is usually associated with point mutations in the HIV genome. As the common resistance mutations have become better known, testing for them has begun to be used to guide changes in therapy. There is also growing interest in the epidemiology of those mutations that confer resistance for the obvious reason that a highly transmissible resistant mutant might be untreatable and assume an epidemic character.

Testing of patients and blood donors

Tests for anti-HIV-1 and -2, HIV-1 antigen and HIV-1 genome are widely available in the UK. Anti-HIV tests are carried out daily in most public health laboratories and in blood transfusion centres. The facilities in transfusion centres emphatically do not exist to provide testing for those at risk, however. The primary means by which the blood supply is protected from contamination with HIV is through those individuals at increased risk of HIV infection refraining from volunteering to give blood (see chapter 16). Those who wish to be tested for anti-HIV should instead consult their general practitioner or attend a sexually transmitted diseases (genitourinary medicine) clinic, where the advisability of HIV testing can be discussed. If a decision to test is made the necessary investigations are readily and freely available. In some localities “open access” facilities exist to encourage self-referral for counselling and testing. Other innovations, such as home testing on the patient’s own initiative, are being considered in the USA and might be introduced into the UK.

As testing becomes more common, and as kits with which people can test themselves are now technically feasible and might be introduced in the future, it is important to be aware of the psychological impact of test findings on those who are tested. While the emergence of effective drug treatment for HIV carriers makes testing for anti-HIV desirable for those who think they may have been put at risk, there should remain an element of medical supervision to respond to patients’ questions and anxieties. Telephone helplines have been proposed to provide this support.

Important precautions

The desirability of discussing investigations for HIV infection with patients beforehand and of interpreting the results to them afterwards is discussed in Chapter 13. When patients are tested for anti-HIV in a healthcare setting, permission to collect a sample should always have been sought by the doctor and given by the patient. An exception to this is when serum residues, already irreversibly anonymised, are tested for anti-HIV as part of an epidemiological study. Such studies have become a basis for monitoring the epidemic and predicting future trends and resource needs. They have shown, for instance, that in the UK approximately a third of the HIV-infected population (total about 30 000 in year 2000) are unaware of their infection or have not disclosed it at the time of the medical contact.

Clotted blood for testing should be obtained by careful venepuncture without spillage or risk of inoculation accident. The needle and syringe should be disposed of safely and the blood placed in a leakproof container, properly identified, and sent by a secure route to the laboratory. PCR testing requires a fresh EDTA specimen such as commonly used for

Figure 2.6 Venepuncture to collect a diagnostic specimen. Note the gloved hands and the yellow needleproof container for safe disposal of the needle and syringe.

Box 2.4 Prevalent HIV infection diagnosed/undiagnosed

Heterosexual men/women	49%
Injecting drug users	6%

haematological investigations. Oral fluid can be collected from the gum/tooth margin and anti-HIV detected in this fluid. Anti-HIV can also be detected in urine.

The patient's identity and the suspected diagnosis should not be exposed to public gaze, and use of numbers or codes rather than names may be preferred. However, the risk of misidentification may thereby be increased. Patient information should only be shared over the telephone between individuals who know each other, and written reports should be sent to named members of staff, under confidential cover. Positive results should be checked on a fresh newly-drawn specimen. The consequences of breaches of these well-tried procedures may be very serious for patients and damaging to the reputation of doctors. Because of the implications of positive laboratory findings for the health of the patient and his or her family and contacts, and for the patient's social and professional life, a high level of competence and sensitivity is to be expected from all who are concerned in instigating investigation for HIV infection. Testing patients without their informed consent is unacceptable.

Laboratory tests for HIV have increased understanding of AIDS and greatly facilitated diagnosis, management, treatment and control measures. However, to derive most benefit from them and do least harm, tests must be used wisely, with proper regard to all the possible consequences for those who are being tested. Any changes to what are now well-established procedures must be carefully considered, piloted, evaluated for cost-effectiveness, and, if introduced, periodically audited to ensure that they are yielding the benefits promised.

Figure 2.2 was provided by the late JE Richmond and Figure 2.4 by JP Clewley.

Taking and transporting specimen

Careful venepuncture (clotted blood)

Dispose of syringe and needle safely

Place blood in a leakproof container that has a screw cap with rubber liner
Tighten firmly

Label specimen with patient's number and date of collection

Seal specimen in polythene bag, preferably using heat sealer, with request form attached outside

Send container to laboratory by secure route

Share information only with named staff in confidence

Figure 2.7 Containing and transporting the specimens. Consult the laboratory about appropriate specimens usually clotted blood or blood collected in EDTA

3 Immunology of AIDS

Peter Beverley, Matthew Helbert

Infection with HIV

Many of the clinical features of HIV infection can be ascribed to the profound immune deficit that develops in infected individuals. HIV is immunosuppressive because it infects cells of the immune system and ultimately destroys them. An understanding of this process is helpful in interpreting tests used in monitoring the disease and may explain the failure of immunotherapy and the difficulties in developing vaccines for HIV.

The most obvious target of the virus is a subset of thymus-derived (T) lymphocytes carrying the surface molecule CD4, which has been shown to bind the envelope glycoprotein of HIV (gp120). CD4 is also present on a large proportion of monocytes and macrophages, Langerhans' cells of the skin and dendritic cells of all tissues. More recently it has also become clear that virus entry also requires co-receptors, most of which are members of the seven transmembrane-spanning G protein-coupled receptor family. In the immune system these principally function as receptors for chemokines that orchestrate the migration, differentiation and function of leucocytes during immune responses. Two receptors, CCR5 and CXCR4, are particularly important. CCR5 (R5) is widely expressed on lymphocytes, macrophages, dendritic cells and cells of the rectal, vaginal and cervical mucosae. Virus strains able to infect primary macrophages (macrophage (M) or R5 tropic viruses) use CCR5 as a co-receptor. Only R5 strains are detected early after infection, while both R5 viruses and strains that infect T cells and use CXCR4 (T or X4 tropic viruses) are found late in infection. These data suggest that R5 strains are important for transmission of HIV while X4 variants arise during the course of infection and may be responsible for T-cell loss and disease progression. Even stronger evidence that CCR5-using M tropic viruses transmit infection, comes from the observation that individuals homozygous for a 32 base pair deletion of CCR5 show greatly increased resistance to HIV infection. Several other chemokine receptors have been shown capable of acting as co-receptors *in vitro* and polymorphisms in CCR2 as well as CCR5 and SDF1 (the ligand for CXCR4), are associated with different rates of progression to AIDS.

Immunopathology

CD4 lymphocytes (T helper cells) have been termed "the leader of the immunological orchestra" because of their central role in the immune response, and their destruction accounts at least in part for the immunosuppressive effect of the virus. When these cells are stimulated by contact with an antigen they respond by cell division and the production of lymphokines, such as interferons, interleukins, tumour necrosis factor and the chemoattractant chemokines. Lymphokines act as local hormones controlling the growth, maturation and behaviour of other lymphocytes, particularly the cytotoxic/suppressor (CD8) T-cells and antibody-producing B lymphocytes. Lymphokines also affect the maturation and function of monocytes, tissue macrophages and dendritic cells.

Macrophages and particularly dendritic cells are important antigen-presenting cells for initiating immune responses of lymphocytes. Not only do they act as a reservoir for the virus

Table 3.1 Co-receptors and their ligands. A large number of seven transmembrane-spanning receptors which can act as co-receptors have been identified. In most cases their importance *in vivo* remains to be determined. Many are present on some CD4 cells or macrophages

Figure 3.1 Induction of an immune response

but their antigen-presenting function is impaired, with secondary effects on lymphocytes. Monocytes are the precursors to some glial cells and abnormal lymphokine production after HIV infection may have harmful effects on neural tissue and result in HIV encephalopathy.

Early after HIV infection antibody responses are not impaired; indeed, development of antibodies to the virus envelope and core proteins is the principal evidence for HIV infection and persists until death. In adults, massive activation of B lymphocytes is manifested by a rise in serum immunoglobulin concentration, perhaps due to direct activation of B cells by HIV. This polyclonal activation explains why a variety of false positive serological tests are seen in HIV infection. In young children, the reverse pattern may be seen, with extremely low levels of immunoglobulin sometimes requiring intravenous replacement therapy.

Within days or weeks after infection there may be a transient fall in CD4 lymphocyte numbers and a more sustained rise in the number of CD8 cytotoxic/suppressor cells. Among the CD8 cells, expanded oligoclonal populations are frequently seen and as in other acute virus infections, some of these represent a specific response to HIV. Following this acute reaction, healthy seropositive individuals may have normal numbers of lymphocytes, although the numbers of CD8 cells frequently remain high. Even at this stage, however, *in vitro* testing may show a lowered response to previously encountered (recall) antigens (tetanus toxoid or purified protein derivative, for example). This seems to be due to poor production of the lymphokine interleukin 2. Individuals may remain healthy for long periods, but a hallmark of disease progression, often prior to the development of new clinical symptoms, is a fall in the number of CD4 lymphocytes. In AIDS the number of CD8 lymphocytes also falls.

Biopsy of the lymph nodes in patients with persistent generalised lymphadenopathy shows many enlarged follicles, often infiltrated by CD8 lymphocytes, with depletion of CD4 cells. Even in clinically silent HIV infection, lymph nodes are the site of remarkably active HIV replication. Uninfected cells may also die by apoptosis, initiated by unexplained mechanisms. In the later stages lymph nodes return to normal size and follicles become “burnt out”, with loss of normal architecture and progressive cellular depletion.

Figure 3.2 Mechanisms of CD4 lymphocyte loss in HIV infection

(b)

(c)

Specific immune responses to HIV

In spite of the fact that HIV-infected individuals show the gross abnormalities of immune function described above, they are able to mount a specific immune response to HIV itself. Although serum reactivity to all the viral proteins is detectable, virus neutralising titres are generally low and directed against the immunising virus strain (type specific immunity). Passive transfer of antibody from asymptomatic to symptomatic patients is claimed to be beneficial, but this requires confirmation. Antibodies to HIV may even facilitate infection of cells bearing immunoglobulin (Fc) receptors, such as monocytes. In AIDS a fall in the titre of antibodies to core protein (p24) is often associated with disease progression. p24 antigen, which is detectable in the serum of some patients, may show a rise at the same time and has been used as a marker of disease progression.

CD8 cytotoxic lymphocytes (CTL) capable of killing HIV-infected targets are detected in most HIV-infected individuals and may be beneficial. This is suggested by the observation that viraemia declines at the time that CTL are first detected following infection, and in patients with stable disease, a high frequency of CTL is detectable in the peripheral blood. In addition, in individuals who have been regularly exposed to HIV while remaining seronegative and without detectable virus, HIV-specific CTL have been detected. As well as killing infected cells directly, CD8 lymphocytes may contribute to protection by producing several chemokines and CAF (CD8 T-cell antiviral factor), which strongly inhibit viral replication in CD4 cells. All this has led to the suggestion that CTL are an effective protective mechanism. However, because reverse transcription is an error-prone process, virus mutants arise, which evade the CTL response (escape mutants). These mutants may not only evade recognition themselves but also inhibit recognition of unmutated virus.

There is some evidence to suggest that a minority of patients mount a specific CD4 T-cell response to HIV and that this is associated with effective control of virus replication. In animal experiments CD4 cells have been shown to be important for the maintenance of an effective CTL response, which may explain this association.

Monitoring HIV infection

Counting CD4 lymphocyte numbers (the “CD4 count”) is an important part of monitoring HIV infection. A progressive downward trend in CD4 cells reflects disease progression and decreased life expectancy, even in the absence of symptoms. Epidemiological studies have firmly correlated distinct ranges of CD4 cell counts with risk of particular opportunist infections. Recent data show that monitoring either the absolute CD4 lymphocyte count or the ratio of CD4 to CD8 cells, the 4:8 ratio, are both equally good at monitoring progression in HIV infection. β_2 microglobulin and neopterin are molecules shed from activated lymphocytes; serum levels increase with progressive HIV infection and can be a useful adjunct to CD4 counts in monitoring.

CD4 lymphocyte numbers have a diurnal variation and delays in the sample reaching the immunological laboratory (for example, when a sample is held overnight) also cause profound changes. Because CD4 lymphocyte counting is a lengthy process, most consistent results are obtained when samples are taken at a set time in the morning and sent straight to the lab. In case of unavoidable hold ups, samples should not be refrigerated.

Box 3.1 Positive and negative effects of immune responses

Antibody

Beneficial effects

- Neutralising antibody (demonstrated *in vitro* only) might prevent primary infection and destroy some infectious particles
- Evidence for beneficial effect of passive transfer of antibody in man requires confirmation

Harmful effects

- Antibody may also help the virus to enter cells with Fc receptors
- Immune complexes may cause tissue damage, anemia and neutropenia

Cellular immune responses

Beneficial effects

- A strong CD8 response is correlated with primary resistance in some individuals and with long-term survival
- Cytotoxic T-cells may delay the progress of disease by killing infected cells.
- They produce CD8 T-cell anti-viral factor (CAF) which inhibits viral replication and may be important in slowing disease progression

Harmful effects

- They may kill uninfected cells which take up shed gp120
- Abnormal cytokine secretion may cause immunopathology (perhaps including encephalopathy)

Table 3.2 Protective mechanisms of CD8 T-cells

	Cytotoxic	Non-cytotoxic
Property or mechanism	Death of infected cells	Inhibition of viral replication
Antigen specificity	Specific for epitopes of viral proteins	Non-specific
Cell contact needed?	Yes	No
Mechanism or CAF	Perforin or fas/fas L	CC chemokines
Induction by vaccination?	Yes	Not known

Box 3.2 Causes of CD4 lymphopenia

- HIV infection: seroconversion illness and during disease progression
- Acute viral infections*
- Tuberculosis*
- Sarcoidosis*
- Corticosteroid therapy
- Purine metabolism defects; ADA and PNP deficiency
- SLE

* Reduce CD4 counts when not associated with HIV and can further reduce levels in HIV infection. ADA, Adenosine deaminase; PNP, Putine nucleoside phosphorylase

CD4 counts should never be used as a substitute for an HIV test because low peripheral blood counts are seen in other conditions. The classic examples are sarcoidosis and tuberculosis (without HIV). Used inappropriately in these settings, a CD4 lymphocyte count may incorrectly suggest a diagnosis of HIV infection. CD4 counts may be low during seroconversion illness but usually recover initially during the asymptomatic phase. Hence there is a need to carry out several baseline CD4 counts if subsequent monitoring is to be useful.

Vaccine development

Immunisation against an organism whose target is an important component of the immune system presents particular difficulties. In addition, HIV has already been shown to be perhaps the most variable virus yet discovered, and HIV-2 differs greatly from all HIV-1 isolates. So far, efforts to immunise against the virus have concentrated on the use of cloned gp120 because all strains of virus so far tested use gp120 to bind to the CD4 molecule, implying that a part of the envelope is similar in all strains. In experimental animals gp120 does induce a neutralising antibody response to the virus but restricted to the immunising strain of virus (type specific immunity) and these neutralising sera do not provide reliable protection against virus challenge *in vivo* in animal experiments. More recently it has been shown that gp120 and its anchor gp41 exist in the viral envelope as a trimer of heterodimers. Because of this and because gp120 is heavily glycosylated, much of the antibody response is to the variable V2 and V3 loops. Furthermore, primary isolates have been shown to be less susceptible to neutralisation than the tissue culture-adapted strains, from which the recombinant gp120 used as immunogen in most experiments derives. Thus new immunogens are needed to raise broadly reactive neutralising antibody and a variety of oligomeric and deglycosylated forms of gp120, lacking the V2 and V3 loops, are being tried.

High levels of CTL are seen in the early stages of HIV infection and the demonstration of CTL escape mutants suggests that they play a role in controlling the virus. That individuals exposed to HIV but with no evidence of infection exhibit CTL responses, reinforces the view that this type of response is important in protection. An effective vaccine might therefore contain components able to stimulate both neutralising antibody, CD4 T-cells and strong CTL responses.

A key factor in generating immune responses is the way in which the antigens are presented to the immune system. For the generation of effective CTL responses attenuated live viruses are effective and attenuated (nef deleted) simian immunodeficiency virus (SIV) has been shown able to protect monkeys against challenge with virulent virus. While such a strategy is unlikely to be used in humans because of worries about the safety of such a virus, it suggests that live viral vectors may be an effective means of immunising against HIV. HIV genes have been inserted into several possible vectors (vaccinia, canary pox, adenovirus) and a number of phase I trials are in progress. Alternate means of delivery capable of inducing both antibody and cellular immunity, such as peptides or proteins in novel adjuvants, naked DNA, or the use of different methods of antigen administration in sequence (prime/boost regimes) are under active investigation.

Clearly neither antibody- nor cell-mediated responses prevent the progression of disease in most patients, but they may delay it. However, strong pre-existing humoral and cellular immunity induced by a vaccine might still be protective. Results of vaccination experiments in monkeys and the existence of individuals who appear to be resistant to HIV infection, provide grounds for cautious optimism with regard to the feasibility of

Box 3.3 Strategies for vaccine development

- A good vaccine should induce neutralising antibody, helper T-cells and cytotoxic T-cells.
- Since antibodies bind to three dimensional structures, induction of neutralising antibody requires native envelope. Problem: Native envelope is trimeric.
- T-cells recognise 8–15 amino acid-long peptides bound to Major Histocompatibility Complex (MHC) class I and II molecules. Problem: Antigen needs to enter antigen presenting cells, usually dendritic cells, to be broken down to peptides.
- Peptides with novel adjuvants can generate good T-cell responses. Problem: Different peptides bind to each MHC allele so a large cocktail of different peptides may be needed.
- Adjuvants are needed to induce large responses. Problem: There are very few adjuvants available for unrestricted use in humans. Alum is mainly good for induction of antibody responses.
- DNA immunisation can generate antibody, helper and cytotoxic responses and allows incorporation of adjuvant molecules into the vaccine. Problem: So far DNA vaccination has not proved as effective in man as in experimental animals.
- HIV is very variable and escape variants arise rapidly in infected individuals. Prophylactic immunisation may tip the balance in favour of the host and prevent escape. Some parts of the virus sequence are relatively invariant, these should be targeted if possible.
- In experimental animals immunisation with different immunogens appears promising. DNA vaccination followed by immunisation with antigen in a recombinant viral vector seems particularly effective. This is now under trial in man.

Table 3.3 Immunotherapy for AIDS

Treatment	Outcome
α and γ interferons	Inconclusive
Interleukin-2	Inconclusive

Bone marrow transplantation	Transient improvement in lymphocyte count and skin anergy
Anti-CD3 or IL-2 after HAART	Under investigation

ABC of AIDS

producing HIV vaccines. Adequate testing of an HIV vaccine will be difficult in man, although the SIV model provides a model for vaccine development.

Possibilities for immunotherapy

Attempts at immune reconstitution have been made using interleukin 2, interferons, thymic factors or bone marrow transplantation. These have not been notably successful and remain potentially harmful, since the very factors which activate T-cells will also activate HIV replication. *In vivo*, activation of CD4 cells is caused by stimulation with antigens in the form of micro-organisms or vaccines. This suggests that it is sensible to treat intercurrent infections promptly and provides a rationale for prophylactic chemotherapy for pneumocystis. In some studies, vaccination (for example with influenza vaccine) has been shown to be enough of an antigenic stimulus to increase HIV replication.

The advent of highly active antiretroviral therapy (HAART) has enabled the viral load to be enormously reduced, but the difficulty of maintaining this type of therapy over long periods has led to a search for strategies to complement drug treatment. Two observations are pertinent, the first is that even after 2–3 years of HAART treatment, latent virus can still be detected and the second is that antiviral immune responses decline during treatment. It has therefore been suggested first that latent virus should be “flushed out” by activation of the immune system with anti-CD3 antibody or interleukin 2 while still continuing drug treatment. Secondly vaccination against HIV should be instituted to prevent recrudescence of low level infection. Both strategies are being actively investigated.

Figure 3.4 HAART and Immunotherapy

4 Natural history and management of early HIV infection

Adrian Mindel, Melinda Tenant-Flowers

Introduction

Infection with HIV causes a spectrum of clinical problems beginning at the time of seroconversion (primary HIV) and terminating with AIDS and death. It is now recognised that it may take 10 years or more for AIDS to develop after seroconversion. The Centers for Disease Control (CDC) in the USA developed the most widely used classification for HIV disease based on the presence of clinical symptoms and signs, the presence of certain conditions and investigative findings, the availability of HIV screening and the degree of immunosuppression as measured by the CD4 lymphocyte count. The infection is divided into four groups (Box 4.1):

- Group I Primary HIV infection
- Group II Asymptomatic phase
- Group III Persistent generalised lymphadenopathy
- Group IV Symptomatic infection

Group IV is subdivided into several subgroups and some of these (groups IVA, B, C1 and D) are AIDS-defining conditions (Box 4.1).

In 1993 the CDC included all HIV-infected persons with CD4 lymphocyte counts of <200 cells/mm³ as fulfilling an AIDS defining diagnosis. However, this additional classification is not widely used outside the USA.

A second classification also combines clinical and CD4 count information. Symptoms and clinical findings are graded in severity from A to C₀ and CD4 counts as they fall from 1 to 3 (Table 4.1).

Group I Primary HIV infection

Primary HIV infection (PHI) is also called the seroconversion illness or acute HIV infection. It represents the stage of infection after the acquisition of the virus when antibodies are developing as shown in Figure 4.1. Between 25% and 65% of people have been found to present with symptoms at the time of seroconversion. These can range from a mild, glandular fever-like illness to an encephalopathy. Common symptoms and signs are shown in Box 4.2. The severe symptoms are rare. The differential diagnosis of the mild seroconversion illness is protean and, without a high index of suspicion and a history indicating relevant risk behaviours or factors, the diagnosis may be missed. Investigations that may be useful in reaching a diagnosis are set out in Table 4.2.

The appropriate diagnostic tests for PHI, which should be carried out on serial blood samples, include tests for HIV antibodies and antigen. If these are negative and PHI is suspected, the definitive test is an HIV RNA PCR, which is the most sensitive test for the detection and quantification of the virus. Some of these assays are not routine and the interpretation of investigation results during PHI is difficult, therefore close consultation with colleagues in virology is strongly advised.

At the time of PHI there is sometimes a high rate of viral replication, leading to a transient rise in HIV viral load and concomitant immunosuppression due to a short-lived fall in the CD4 count. This may result in manifestations of HIV disease

Box 4.1 Summary of CDC 1992 classification system for HIV disease

- Group I Primary HIV
- Group II Asymptomatic infection
- Group III Persistent generalised lymphadenopathy
- Group IV Symptomatic infection
- Group IVA HIV wasting syndrome (AIDS) and constitutional disease
- Group IVB HIV encephalopathy (AIDS) and neurological disease
- Group IVC1 Major opportunistic infections specified as AIDS-defining
- Group IVC2 Minor opportunistic infections
- Group IVD Cancers specified as AIDS-defining
- Group IVE Other conditions

Table 4.1 Summary of CDC 1993 classification system for HIV disease

	CD4 lymphocyte count $\times 10^6/l$		
	(1) >500	(2) 200-499	(3) <199
(A) Asymptomatic including Groups I, II and III	A1	A2	A3
(B) Symptomatic not A or C	B1	B2	B3
(C) AIDS-defining conditions	C1	C2	C3

ABC of AIDS

which are normally seen later in the infection, for example oral candida. Diagnostic confusion as to the stage of HIV infection may arise, which can only be resolved by following up the patient for long enough to see the symptoms and signs resolve, HIV antibodies appear, the viral load fall and the CD4 count rise. Treatment should be directed at alleviating any symptoms, and there is considerable interest in the possible use of antiretroviral agents at this time because the virus may be more susceptible due to the relatively low numbers of virus particles which can replicate, the reduced ability of the predominantly non-syncytium-inducing strains of virus to infect a wide variety of cell types and the enhanced immune response seen in PHI.

Such treatment may decrease long-term damage to the immune system and delay or even prevent the development of AIDS. However, if not started within 12–18 months of PHI the theoretical advantage may be lost and, in any case, has to be balanced against the uncertain outcome, drug toxicity, adherence difficulties and the possibility of developing resistant virus, limiting future treatment options.

Group II Asymptomatic infection

After PHI, HIV antibodies continue to be detectable in the blood. The amount of virus in blood and lymphoid tissues falls to very low levels and the rate of HIV replication is slow although it does not cease. CD4 lymphocyte counts are within normal limits or generally above 350 cells/mm³. This phase may persist for 10 years or more (Figure 4.1). The role of antiretroviral therapy during asymptomatic infections is discussed in chapter 9. The decision to treat is made on the basis of the CD4 count and the viral load. The aim of therapy is to maintain immune function by suppressing viral replication to prevent further damage to the immune system. As for PHI treatment, the potential gain of therapy must be weighed against the potential risks and uncertainties.

Group III Persistent generalised lymphadenopathy

Persistent generalised lymphadenopathy may be a presenting feature of HIV infection in a person who is otherwise well. HIV-related lymphadenopathy persists for at least three months, in at least two extra-inguinal sites and is not due to any other cause. The differential diagnosis of this lymphadenopathy is shown in Table 4.3.

A lymph node biopsy in HIV disease is not recommended as a routine procedure as the findings are non-specific and the presence of lymphadenopathy due to HIV alone does not worsen the prognosis. The indications for a biopsy are the same in HIV and non-HIV-related conditions (Box 4.3).

Group IV Symptomatic HIV infection before the development of AIDS

The progression of HIV infection is a result of a decline in immune competence that occurs due to increased replication of HIV from sites where it has been latent. The exact triggers for this reactivation are poorly understood. As the disease progresses, infected persons may suffer from constitutional symptoms, skin and mouth problems and haematological disorders, many of which are easy to treat or alleviate. A decrease in viral load in response to the introduction of antiretroviral therapy often corresponds to a complete or partial resolution of these symptoms.

Box 4.3 Indications for lymph node biopsy

- Constitutional symptoms
- Painful nodes
- Asymmetrical enlargement
- Sudden increase in size
- Hilar lymphadenopathy

Constitutional symptoms

Common constitutional symptoms associated with Group IVA HIV infection include malaise, fevers, night sweats, weight loss and diarrhoea. Serious constitutional symptoms are set out in Box 4.4. The exact criteria for diagnosing the AIDS-defining HIV wasting syndrome are, the combination of 10% weight loss from baseline and one of the other serious symptoms set out in Box 4.4. Many patients find these symptoms worrying and debilitating and they should be investigated to diagnose treatable causes other than HIV. Once other causes have been excluded, symptomatic treatment can include antipyretics, antidiarrhoeal agents and, if all else fails, steroids.

Skin and mouth problems

Many skin problems occur in patients with HIV infection (Box 4.5). These may represent exacerbations of previous skin disease, or a new problem. Identical skin conditions occur in HIV-negative persons. However, in the immunocompromised, these common conditions may be more severe, persistent and difficult to treat. Many minor opportunistic infections (Group IVC2) manifest themselves on the skin and in the mouth. Seborrhoeic dermatitis is frequently seen and usually presents as a red scaly rash affecting the face, scalp and sometimes the whole body. This condition often responds well to 1% hydrocortisone and antifungal cream.

Figure 4.7 Extensive seborrhoeic dermatitis

Figure 4.8 Perianal herpes

Other common dermatoses that respond to antifungal creams (for example Clotrimazole) include tinea cruris and pedis and candidiasis. Folliculitis often responds to 1% hydrocortisone and antifungal cream, impetigo to antibiotics and shingles to aciclovir, valaciclovir or famciclovir. Recurrent perianal or genital herpes may become more troublesome, with recurrences lasting longer and occurring more frequently; if this persists for more than 3 months it is considered an AIDS-defining opportunistic infection (Group IVC1). Treatment with long-term acyclovir, valaciclovir or famciclovir suppression is often required. Genital and perianal warts are common, difficult to treat and frequently recurrent, and high-grade cervical dysplasia is seen more often in HIV-infected women.

Mouth problems are also common, cause considerable distress and when severe may result in difficulty with eating and drinking. Oral candida can be managed with topical or systemic antifungals (eg, nystatin, ketoconazole or fluconazole). If dysphagia develops, oesophageal candidiasis should be suspected

and investigated. Oral hairy leukoplakia can be differentiated from oral candida by its characteristic distribution along the lateral borders of the tongue and the fact that it cannot be scraped off. Although unsightly, this condition which is due to Epstein–Barr virus reactivation is painless and temporary remission can be obtained with acyclovir, valaciclovir or famciclovir. Other oral conditions including dental abscesses, caries, gingivitis and oral ulceration (herpetic or bacterial) may occur. Mouth ulcers may be particularly difficult to treat and expert specialist assessment is recommended. Metronidazole, acyclovir, 0.2% chlorhexidine mouthwashes and analgesic sprays may all be effective depending on the cause and, in extreme cases, thalidomide has been used. Maintenance of good oral hygiene and dental care are important.

HIV and haematological problems

Lymphopenia with depression of the CD4 cell subset is a marker for HIV disease. Mild to moderate neutropenia and a

normochromic, normocytic anaemia of unknown origin are often seen but usually have no adverse effect on HIV-infected individuals. Severe anaemia or neutropenia should be investigated for other underlying causes. Thrombocytopenia is common in HIV disease and, only if persistent, causing bleeding and less than 20×10^9 /litre warrants treatment with antiretrovirals which is usually effective. Many therapies used to treat HIV may be toxic to bone marrow.

Risk of progression and the value of surrogate markers

One of the hardest problems confronting the physician dealing with an asymptomatic patient with HIV infection is predicting how soon that patient will progress to symptomatic disease or AIDS. This issue is important, firstly in terms of counselling and secondly, to decide which patients may benefit from antiretroviral treatment or prophylaxis to prevent opportunistic infections.

Variables associated with rapid disease progression include a symptomatic PHI, older age at diagnosis and receiving a large inoculum of virus, for example via a contaminated transfusion from a donor with a high viral load. The effect of prophylaxis against opportunistic infections (for example cotrimoxazole for pneumocystis and toxoplasmosis) has been to delay the onset of AIDS and to change the pattern of disease represented by the first AIDS-defining illness. Antiretroviral treatment has independently been shown to increase survival before and after AIDS. Some infected individuals do not progress for many years and work is in progress to determine whether this is due to their genetic makeup, amount of viral inoculum, characteristics of the infective virus or their immune system.

Many laboratory indices have been used as prognostic indicators, both to evaluate disease progression and treatment efficacy. The most widely used are the CD4 absolute lymphocyte count or percentage and the viral load. At least two CD4 measurements should be obtained before initiating prophylaxis for opportunistic infections or antiretroviral therapy, as the CD4 count is subject to diurnal and seasonal variation and reduced by intercurrent infection. A fall in CD4 cells is associated with disease progression, particularly if the rate of decline is rapid. Likewise, at least two viral loads, from the same laboratory using the same assay, should be obtained to avoid interassay variation. Some HIV clades are more difficult to monitor with certain assays and the laboratory should be informed of the country of origin of the patient.

Patients who may need close monitoring include individuals whose CD4 count falls below 350 cells/mm^3 , those with a rapidly declining CD4 count, those with a rising viral load and patients who are symptomatic as they may all be candidates for antiretroviral therapy. Patients who present with persistent constitutional symptoms, mouth or skin problems should be considered for antiretroviral therapy irrespective of CD4 count and viral load. These issues are discussed further in the chapters on treatment of infections and antiretroviral agents.

General management of HIV-infected people

One of the most important aspects of dealing with any HIV-infected person is confidentiality (Box 4.6). Maintaining confidentiality might be complicated: for example the patient's family or friends may not know his or her diagnosis or sexual orientation; people at work (or school) may seek medical information (especially if the individual is having time off

Figure 4.9 Vesicles of varicella zoster

Figure 4.10 Cervical intraepithelial neoplasia

Box 4.6 General management of the HIV-infected person

ABC of AIDS

work); or the person may fear that information may inadvertently be given to third parties. Special precautions may be required, firstly to reassure the patient that confidentiality is protected and, secondly, to limit any unwarranted dissemination of confidential information. Issues related to partner notification are discussed in chapter 13.

The routine medical management of these individuals is usually straightforward. They should be seen regularly, for example every three to six months. At each visit the patient's weight should be recorded and special attention given to mouth or skin problems and, if necessary, they should be referred to the appropriate specialist. Screening for STDs and hepatitis viruses should be offered if the individual is at risk and hepatitis A and B vaccines can be safely given. Repeating a full blood count and measuring the CD4 count and viral load every three to six months allows early detection of actual or imminent immune dysfunction. Patients should be advised to reattend if they develop any symptom, especially those suggestive of opportunistic infections or cancers, for example shortness of breath, cough, haemoptysis, pain or difficulty in swallowing, diarrhoea, weight loss, fevers, headaches, fitting, altered consciousness or purple spots on their skin. Other symptoms may indicate increased viral replication and the need to consider treatment.

Psychological and emotional support of the infected individual, the family and friends are a vital aspect of

management (see chapter 13). HIV antibody positive persons should also be advised about reducing the risk of transmitting HIV to others and reducing their own risk of receiving different, possibly drug resistant, strains of HIV. Advice concerning safer sex, safer needle use, pregnancy, breastfeeding and children should also be provided (see chapter 16). Patients should be advised to tell their dentists about their infection, and it may sometimes be necessary to refer them to a dental unit with an interest in HIV-related problems.

The physician may also be asked to advise about insurance, work, immigration, travel passes, housing and disability benefit. Patients should be referred to the relevant legal or benefit agency as soon as possible. Infected individuals will often have considerable difficulty in obtaining life insurance as most insurance companies ask specific questions about the infection and either refuse insurance or charge very high premiums. Finally, patients should be told that being positive is no barrier to employment provided there is no chance of their body fluids entering another person or of them transmitting an opportunistic infection, such as tuberculosis, by coughing. It is worth noting that for notifiable diseases such as TB, standard, confidential public health notification procedures still apply. Because of widespread misconceptions about infectivity which are still prevalent, information about the individual's HIV status should never be divulged to employers without their written consent.

5 Tumours in HIV

Caroline H Bridgewater, Margaret F Spittle

The United States Center for Disease Control recognises three malignancies as AIDS-defining conditions. These are Kaposi's sarcoma, intermediate or high grade B-cell non-Hodgkin's lymphoma (NHL) and cervical carcinoma. Primary central nervous system lymphoma is a rare B-cell NHL that is often considered separately from the other NHLs. Other malignancies are known to have an increased incidence in HIV whilst not being AIDS-defining, for example Hodgkin's disease. All malignancies are more aggressive in HIV positive patients than in the general population and usually present at advanced stages.

The investigation and treatment of suspected malignancy is complicated by unusual presentations and sites of disease, concomitant infections and immunosuppression. Malignancies may occur at different points in the disease process for different individuals and management must be tailored to the patient's overall maximum benefit.

There are many new developments in the understanding of the pathogenesis of AIDS-related malignancies and in the future these will inform new therapies. In the last few years alone highly active antiretroviral therapy (HAART) has had a great impact on the incidence and natural history of some of these malignancies. As opportunistic infections are more easily treated and patients live longer the malignancies are likely to become relatively more common. The incidence of AIDS-related malignancies varies within the different population groups with HIV and as affected groups evolve there will doubtless be a change in the incidence of malignancies seen in the UK. With these rapid changes optimal treatment strategies are controversial and patients should be entered into clinical trials.

Kaposi's sarcoma

Among the first reported illnesses amongst homosexual men in the USA in 1981 was Kaposi's sarcoma (KS), with 20–40% of HIV-infected homosexual men suffering KS. Hitherto KS had been known in three forms. In elderly Jewish or Eastern European patients as “classic” KS, in sub-Saharan Africa as “endemic” KS, and more recently in transplant and other immunosuppressed patients. KS currently remains the most frequent neoplastic condition in AIDS.

Aetiology

The uneven geographical distribution of KS had long suggested that environmental factors were aetiologically important. Epidemiological observations that KS initially occurred in clusters in the HIV population and that it was 20 times more likely in homosexual men than other risk groups suggested a sexually transmitted cofactor. Work in the biological and statistical fields has gone on to establish causality. Whilst no biological pathway has yet been identified, there is now sufficient evidence to state that a DNA virus, Kaposi's sarcoma-associated herpes virus (KSHV) also known as human herpes virus 8 (HHV8), is an essential, although not necessarily a sufficient, cause of KS.

This evidence has primarily come from longitudinal studies showing that KSHV infection precedes KS. This is consistent with analogous evidence of other herpes viruses, for example Epstein–Barr virus (EBV) being oncogenic. KSHV has been

Table 5.1 Risk of malignancies in HIV-positive patients

Malignancy	Relative risk compared to HIV-negative population	Viral co-factor
Kaposi's sarcoma	716–972	KSHV (HHV8)
NHL	71–141	EBV
Primary CNS lymphoma (PCNSL)	~100	EBV
Cervical cancer	?	HPV
Hodgkin's disease	5–9	EBV
Anal cancer	3.5–5	HPV
Testicular germ cell tumours	3	?

Box 5.1 Clinical groups of patients with Kaposi's sarcoma (KS)

- “Epidemic” or AIDS-related KS

Figure 5.1 Classical Kaposi's sarcoma

ABC of AIDS

detected in tissue biopsies taken from patients with African and classical KS as well as AIDS-related cases.

KSHV can be sexually transmitted and seroconversion has been noted following renal transplantation. In endemic areas non-sexual horizontal and vertical spread are the proposed dominant modes of transmission. The evidence for this is the age-dependent increase in KSHV seroprevalence in prepubescent children in studies from Gambia and Uganda and the greater (29% compared to 0%) seropositivity rate in children born to KSHV seropositive women in South Africa.

Histopathology

The tumours have a characteristic appearance, consisting of groups of spindle cells separated by slits giving a sieve pattern. These spindle cells derive from primitive mesenchymal cells. Red cells are often seen in the slits and early lesions may consist almost entirely of bizarre endothelium-lined vascular spaces in the dermis with few spindle cells.

The tumour stains positive for factor VIII and smooth muscle-specific α -actin on immunocytochemistry staining.

The following cytokines have been shown to promote the growth of KS cells *in vitro*: interleukin 6 (IL-6), tumour necrosis factor (TNF), basic fibroblast growth factor (bFGF), vascular endothelial growth factor (VEGF), platelet-derived growth factor (PDGF), Oncostatin M and granulocyte colony-stimulating factor (G-CSF). It may be possible to exploit this therapeutically by inhibiting these cytokines.

Kaposi's sarcoma is a multifocal process rather than a metastatic one.

Clinical presentation

The classic form tends to follow a very indolent course producing large ulcerated plaques on the lower legs. It shows a strong male preponderance and as most affected individuals are elderly their KS causes significant morbidity but not mortality.

Endemic KS follows a more aggressive course in younger adults with more florid skin lesions and lymph node involvement. Death occurs due to widespread systemic involvement. In young children the lymphadenopathic variant is most commonly seen.

In the non-HIV immunosuppressed patient the lesions of KS may improve with reduction or cessation of the immunosuppression.

In the UK these forms are all rare and most cases of KS are AIDS related.

The presentation of KS in AIDS is variable but the disease tends to become increasingly aggressive and may be lethal. Mucocutaneous lesions begin as flat dusky red papules progressing over weeks or months to vary from a few scattered nodular lesions to large plaques. The legs, trunk, arms, face, hard palate and penis are common sites with associated "woody" oedema and ulceration predominantly affecting the lower limbs. KS on the feet make walking difficult and painful. Other mucocutaneous lesions often cause distress because of their disfiguring appearance.

All organs other than the central nervous system may be affected and the presence of visceral disease is predicted by mucocutaneous disease; one third of respiratory "episodes" in patients with cutaneous KS are due to pulmonary KS. The most common visceral lesions are pulmonary and gastrointestinal. Lymph node disease is also common and may cause venous compression resulting in gross peripheral oedema. Presentation of pulmonary KS is usually with exertional dyspnoea but may be with cough or haemoptysis. Chest radiograph changes are often non-specific with interstitial infiltrates, pleural effusions and mediastinal lymphadenopathy. Further information is

Figure 5.2 Classical nodular Kaposi's sarcoma

Figure 5.3 Lymphangioma-like Kaposi's sarcoma

Figure 5.4 Kaposi's sarcoma

gained by bronchoscopy and CT; if possible bronchial biopsy should be avoided as bleeding may be heavy (see chapter 6).

Lesions may occur along the length of the gastrointestinal tract from the palate to the anus and diagnosis is by endoscopy. KS in the oral cavity and oesophagus may cause pain but is usually asymptomatic. Bleeding may occur from lesions throughout the gastrointestinal tract and patients may also suffer protein-losing enteropathy and diarrhoea.

KSHV is also found in two rarer malignancies, primary effusional lymphoma (a subset of B-cell non-Hodgkin's lymphoma) and multicentric Castleman's disease, a lymphoid malignancy which also has an increased incidence in AIDS.

Incidence

KS was the AIDS-defining diagnosis in 30% of patients in the 1980s but this has now fallen. The reduction may be attributed to changes in sexual practices as well as the advent of antiretroviral therapy. KS commonly precedes opportunistic infections and with improvements in treating such infections KS is increasingly common as the cause of death for AIDS patients. Hence whilst the incidence of KS is falling the prevalence is increasing. The deaths of almost 30% of AIDS sufferers are now accounted for by visceral and particularly pulmonary KS.

Treatment

Treatment must be tailored to the site and extent of KS and to the patient's underlying clinical condition. The aim of treatment is resolution of symptoms and prolongation of life. Cure is currently impossible due to the disseminated nature of the condition and its poorly understood pathogenesis as well as the underlying AIDS. HAART has reduced the need for second-line therapies by increasing median time to treatment failure as well as reducing the incidence of KS. There are reports of KS regression with HAART and no other treatment.

Local treatment is important for cosmesis of cutaneous lesions. Superficial radiotherapy is given using 100 kV X-rays applied directly to the skin or palate. A dose of 8 Gy in a single fraction achieves good palliation in 70% of lesions, particularly in early KS with little haemosiderin staining. The area of the lesion is treated with a margin using a lead cutout to protect surrounding tissues. The dose should be given in divided doses on consecutive days (fractionation) to sensitive areas such as the soles or face. Radiotherapy can be repeated if further regression is required or relapse occurs. Alternative treatments include camouflaging with cosmetics and intralesional injection with vinblastine or interferon.

Palatal, bronchial and oesophageal KS can also be treated with radiotherapy. It is particularly useful to stop bleeding.

For extensive mucocutaneous disease or visceral involvement chemotherapy is the preferred option. Several regimens are available and choice of regimen depends on coexistent pathologies and, in some countries, availability and price. Sadly many of the newer treatments with better side-effect profiles are prohibitively expensive for the developing nations where KS is prevalent. In patients with relatively well preserved immune function interferon- α is a useful treatment.

Bleomycin and vincristine in combination was initially the commonest regimen giving a response rate of 50–60% with acceptable side-effects. This has now largely been superseded by the liposomal preparations of doxorubicin and daunorubicin (anthracycline antibiotics) following trials which showed comparable efficacy and reduced toxicity. A liposome is a sphere made of phospholipid bilayers which can be selectively distributed to tumours allowing local drug deposition when the liposome breaks down. Liposomal packaging allows higher doses of these drugs to be delivered with fewer side-effects.

Figure 5.5 Kaposi's sarcoma on the chest

Figure 5.6 Cutaneous Kaposi's sarcoma

Figure 5.7 Palatal Kaposi's sarcoma

ABC of AIDS

Cumulative doses of non-liposomal anthracyclines are limited at 450–550 mg/m² by cardiotoxicity and in a chronic condition like KS long or repeated courses of chemotherapy may be required.

More recently there has been increased interest in the use of antiangiogenics and trials are currently underway on the tyrosine kinase receptor inhibitor SU5416 and thalidomide. This has been fired by studies showing the presence of vascular endothelial growth factor and basic fibroblast growth factor in KS tissues. Paclitaxel, a newer cytotoxic, is also undergoing trials. Common side-effects are those shared with many other cytotoxics including nausea, vomiting, myelosuppression and mucositis. In the AIDS patient, with concomitant diseases and multidrug therapy including HAART, it can be difficult to find the root cause of such symptoms.

Non-Hodgkin's Lymphoma

The occurrence of non-Hodgkin's lymphoma (NHL) was known to complicate immunodeficiency states before the advent of HIV. Up to 20% of HIV positive people may ultimately develop NHLs and it is the presenting diagnosis in 3% of patients. In immunodeficiency NHLs are commonly extranodal.

Aetiology

Both HIV itself and its related opportunistic infections may cause polyclonal B-cell expansion which is probably cytokine and antigen driven. Patients with AIDS have impaired immunity to EBV when compared to HIV negative EBV-infected individuals and EBV is itself likely to cause polyclonal B-cell proliferation. AIDS lymphomas have modified immunoglobulin variable regions which are consistent with antigen drive as an important factor in lymphomagenesis. Macrophages, acting as antigen-presenting cells, also appear to be clonally expanded. When CD4+ T-cell levels fall, antigen levels rise and the risk of lymphomagenesis increases. Such proliferation allows for sequential genetic errors leading to a monoclonal and hence malignant transformation.

Pathology

Systemic lymphomas in AIDS are pathologically diverse. A diffuse small non-cleaved subset is unique to HIV patients and is associated with elevated IL-6 and soluble CD23 levels. It is less frequently associated with EBV than the diffuse immunoblastic or diffuse large cleaved cell subtypes. Histological type does not currently affect prognosis although the different subtypes are clinically separate. All these subtypes are high grade.

Immunohistochemistry reveals positive staining for CD20 in 90% of B-cell lymphomas.

Clinical presentation

NHL can occur at any stage of immunodeficiency with approximately one-third of patients with AIDS-related NHL having a previous AIDS diagnosis. Stage III or IV disease accounts for 70%–80% of cases (see Box 5.3) with a majority of patients presenting with extranodal disease. Common sites are the gastrointestinal tract, liver and bone marrow. Bone marrow involvement occurs in 20%–30% of cases and exacerbates chemotherapy-induced bone marrow toxicity.

NHL is associated with B symptoms of sustained fever greater than 38°C, weight loss (greater than 10% of body weight) and night sweats. All of these symptoms may occur in an HIV positive patient without NHL and so are of limited diagnostic and prognostic use in this clinical setting.

Box 5.2 Summary of malignancies

AIDS-defining malignancies

- Kaposi's sarcoma
- High/intermediate grade non-Hodgkin's lymphoma including primary CNS lymphoma
- Cervical carcinoma

Other malignancies with increased incidence

- Hodgkin's disease
- Ano-genital squamous cell carcinoma
- Testicular germ cell tumours

Figure 5.8 HIV-related non-Hodgkin's lymphoma

Box 5.3 Ann Arbor: classification of lymphoma

Stage I	Single lymph node region +/- local spread to extralymphatic tissue (E)
Stage II	Two or more node regions on same side of diaphragm +/- local spread to extralymphatic tissue (E)
Stage III	Involved nodes both sides of the diaphragm
Stage IV	Diffuse or disseminated involvement of one or more extralymphatic organs

Prognosis is poor with a median survival of 4–6 months in spite of an often good early response to treatment. A previous AIDS-defining illness, a CD4 count $<100 \times 10^6$, bone marrow involvement and poor performance status are all poor prognostic factors. In good prognosis patients the median survival is still only 11–14 months.

Treatment

Treatment of any lymphoma is based on its stage and grade and the patient’s ability to withstand the rigors of treatment. For AIDS patients with their high-stage, high-grade disease this means chemotherapy. When faced with patients who are immunosuppressed and have poor bone marrow reserve before treatment the oncologist must make a balanced choice between reduced doses, which may compromise benefit, and quality of life. CHOP combination chemotherapy giving cyclophosphamide, vincristine and doxorubicin with oral prednisolone is delivered three weekly. Alternatively m-BACOD (methotrexate, Bleomycin, Adriamycin, Cyclophosphamide, Vincristine, Dexamethasone), another combination regimen, can be given. These regimens are toxic to bone marrow and in order to allow second and subsequent courses to be given on time patients may require GCSF. Prophylaxis against *Pneumocystis carinii* pneumonia should be considered. Allopurinol should be given to patients with bulky disease to prevent gout occurring when uric acid levels rise as the tumour breaks down. Patients with positive cytology or EBV DNA detected in their cerebrospinal fluid and those with meningeal or extensive sinus or base of skull disease require concomitant intrathecal methotrexate and cytosine arabinoside. Alternative chemotherapy regimens are undergoing trials but few have proved superior to CHOP and often result in worse immunosuppression and opportunistic infections.

For patients who have poor performance status, low CD4 counts and other AIDS diseases, palliative chemotherapy of vincristine plus prednisolone can be given. Radiotherapy is also useful for the palliation of symptoms caused by bulky disease. In the rare cases where NHL in AIDS presents as Stage I or II disease radiotherapy can be used as first-line treatment, avoiding the toxicity of chemotherapy.

Median survival is better in patients obtaining a complete response initially. In most studies half the patient deaths have been due to the lymphoma with remaining deaths being due to opportunistic infections.

Figure 5.9 Lymphadenopathy due to lymphoma

Figure 5.10 Lymphadenopathy due to lymphoma

Primary cerebral lymphoma

This is a strongly EBV-related process which occurs late in the clinical spectrum and accounts for around 15% of AIDS-related lymphomas. It is pathologically very similar to the post-transplant lymphoproliferative syndromes with EBV-latent gene expression. The presence of EBV DNA in the cerebrospinal fluid is highly predictive for primary central nervous system lymphoma (PCNSL). In the general population it is very rare accounting for only 0.5–1.2% of all intracranial neoplasms which in themselves are rare. The incidence of PCNSL is also increased in other immunosuppressed conditions. PCNSL affected 2–6% of HIV positive individuals in the pre-HAART era. Typically patients have CD4 <50 cells/mm³ and a history of prior opportunistic infections. These lymphomas are always of the diffuse immunoblastic or diffuse large cleaved cell types. Prognosis is even worse than that for systemic lymphoma with median survival being only 1–2 months.

Cerebral lymphoma may be difficult to differentiate from cerebral toxoplasmosis, as both have a variable presentation ranging from subtle personality changes to seizures. Both

Figure 5.11 CNS lymphoma

ABC of AIDS

commonly appear as multiple enhancing lesions on CT or MRI scanning. Initial treatment is usually empirically directed against toxoplasmosis. If this fails PCNSL can only reliably be confirmed by biopsy and many patients are reluctant to undergo such a procedure when life expectancy is limited. Once a definite diagnosis is made treatment is with high dose steroids and radiotherapy. Patients who respond tend to die of opportunistic infections reminding us that the underlying condition is advanced by the time PCNSL occurs.

Cervical carcinoma

For other malignancies in HIV the main predisposing factor is immune deficiency; however, the relationship between squamous cell neoplasia of the cervix and HIV is unique because of common sexual behaviour risk factors.

Viral DNA from high-risk types of the human papilloma virus (HPV16, 18, 31, 33, and 45) is found in 90% of all cervical cancers irrespective of HIV status. Not every woman with HPV infection develops cervical carcinoma and HPV infection alone is not sufficient for tumour development. Persistence of infection is probably important and other risk factors include smoking, oral contraceptive use and early pregnancy. HPV infection in HIV-infected women may represent reactivation of HPV types acquired in the past rather than recent acquisition of new types.

HIV positive women have a high rate of vulvo-vaginal infection which may make screening unreliable, regular Pap smears are therefore critical. Cervical intraepithelial neoplasia (CIN) is more commonly of a higher grade in HIV positive women and if invasive carcinoma ensues it is also more aggressive. A low threshold for referral for colposcopy is essential. Standard treatment strategies of ablation and excision have yielded disappointing levels of recurrence and patients need to be followed up very closely. If invasive disease ensues treatment is as for immunocompetent patients with surgery, radiotherapy and chemotherapy. Unfortunately treatment reactions are often severe with patients suffering severe vaginal mucositis.

Other associated malignancies

Hodgkin's disease

Hodgkin's disease is three to nine times more common in HIV patients compared with the general population. In Spain and Italy there is a high incidence of HIV amongst intravenous drug abusers who suffer more Hodgkin's disease than HIV sufferers in the UK. Research is needed here as in so many areas to discover the relevance of this observation. Hodgkin's disease tends to occur relatively early in HIV infection with a median CD4 cell count of 300/mm³.

As with the non-Hodgkin's lymphomas, presentation is usually with bulky or advanced stage disease and 50% have bone marrow involvement. Most patients have B symptoms. In the HIV negative population Hodgkin's disease is typified by contiguous spread, this is not the case in HIV patients. Histologically tumours are usually high-grade mixed cellularity (41-100%) and lymphocyte-depleted subtypes (20%) and behave aggressively. Between 80% and 100% of Hodgkin's disease tissue from HIV-infected individuals is associated with EBV infection and this is probably relevant in pathogenesis. Treatment is with combination chemotherapy using standard regimens such as ABVD (doxorubicin, bleomycin, vinblastine and dacarbazine) and antiretrovirals. Bone marrow toxicity makes GCSF and dose reductions frequent necessities. If patients can continue their antiretroviral therapy throughout

Figure 5.12 Microscopic and macroscopic appearances of early cervical carcinoma

Figure 5.13 Advanced cervical carcinoma

Figure 5.14 Mediastinal lymphadenopathy

chemotherapy they suffer less immunosuppression. Complete responses following chemotherapy are seen in 45–70%. Median survivals are 12–18 months and whilst not being an AIDS-defining condition 94% of patients progress to AIDS by 2 years. Good prognosis is associated with no prior AIDS diagnosis, CD4 $>250 \times 10^6/l$ and complete response to treatment.

Ano-genital squamous cell carcinoma

Anal cancer like cervical cancer is related to human papillomavirus. HIV positive patients are two to six times more likely than HIV negative persons to have anal human papillomavirus infection. Persistence of infection is inversely related to CD4 count. Low-grade anal intraepithelial neoplasia is more likely to progress to high grade anal intraepithelial neoplasia in HIV positive patients. However it remains unclear whether HIV directly affects the development of anal carcinoma.

There is a threefold increase in incidence in testicular germ cell tumours in homosexual HIV positive men. Seminoma is much more common than teratoma. Lung cancer of all histological types, non-melanomatous skin cancers, angiosarcomas and paediatric leiomyosarcomas may all be increased in HIV infection. Lung cancers occur at an earlier age and have a poorer prognosis in the HIV positive population.

The effect of HAART

With the improved control of HIV replication brought about by combination antiretroviral therapy, the frequency of AIDS-related malignancy is falling. The incidence of KS has dropped by approximately 75%. Sadly there has been a smaller decline in the incidence of NHL, although primary CNS lymphoma has also markedly declined. The lack of change in the incidence of systemic lymphoma reflects a heterogeneous and complex pathophysiology, not as susceptible to the influence of HAART as KS.

The effect on HPV-associated anogenital squamous cell carcinoma has also been disappointing.

This varied response highlights the continued need for innovative treatments, both in terms of chemotherapy and the manipulation of the immune response.

Current research and the future

The rapidly increasing evidence on viral involvement in AIDS-associated malignancies suggests novel molecular targets for drug discovery using drug screening and molecular modelling. Vaccines for cancers occurring in patients with human papilloma viruses associated with cervical and ano-genital carcinoma and EBV in haematological malignancies are currently being researched. Other therapeutic approaches include biological therapy (for example IL-2, IL-12, IFN- α), immune-based therapy (for example antigen-presenting cells and monoclonal antibodies against B-cell targets) and angiogenesis inhibitors.

New assays to detect KSHV are now in use. Further work is needed on the cofactors influencing the progression of KSHV seropositive individuals to the development of KS. The anti-herpes drug cidofovir has activity against KSHV but it remains to be seen as to whether it is an effective treatment for KS.

To improve existing treatments the effects on the underlying HIV infection and the impact on the immune system of anti-tumour therapy need to be identified. As anti-HIV therapies have a clinical effect on tumour incidence, complex issues of drug–drug interactions and overlapping toxicities must be considered.

In the HAART era NHL is likely to become the most common malignancy associated with AIDS — new treatment strategies are urgently needed as treatment is currently extremely disappointing. Possibilities include the exploitation of cytokine networks, as we already know that these patients have low levels of IL-2 and IFN- γ but elevated IL-6. Treatment with low-dose IL-2 is already undergoing trials.

6 AIDS and the lung

Rob Miller

The lungs are commonly affected in patients infected with HIV, with over 60% of patients having at least one respiratory episode during the course of their disease. When immune responses are relatively well preserved in early HIV infection the pattern of respiratory infections is similar to that found in the general population, although they occur with greater frequency. The risk of opportunistic infections and tumours increases as progressive HIV-induced immunosuppression occurs. Over recent years there have been several changes in the pattern of lung disease seen in those infected with HIV. These changes may be accounted for by the widespread availability and uptake of prophylaxis for *Pneumocystis carinii* pneumonia and combination antiretroviral therapy (also known as highly active antiretroviral therapy or HAART).

Investigations

Symptoms of cough and dyspnoea with or without fever and sweats identify the presence of respiratory disease in HIV positive patients, but these are non-specific and symptomatic patients should be investigated.

Non-invasive investigations

These tests should ideally allow a specific diagnosis to be made and a therapeutic response monitored by a quick, cheap and universally available method. Unfortunately, none of these tests fulfils the criteria but they do help to:

- Determine the presence or absence of pulmonary disease.
- Assess disease severity.
- Determine if an invasive test is indicated to make an aetiological diagnosis.

Chest radiology

The chest radiograph may be normal in HIV positive patients with respiratory disease caused by *P. carinii* pneumonia. The most common abnormality seen in patients with pneumocystis pneumonia is bilateral perihilar haze which may be very subtle and easy to miss. More severely unwell patients may have more diffuse interstitial shadowing which may progress to severe consolidation with “white out” throughout both lung fields, with sparing of the apices and costophrenic angles. These radiographic appearances are non-specific and may also be seen in pyogenic bacterial, mycobacterial and fungal infection, and also in Kaposi’s sarcoma and lymphoid interstitial pneumonitis. Between 5% and 10% of patients with pneumocystis pneumonia have atypical chest radiographs showing cystic changes, upper lobe infiltrates mimicking tuberculosis, hilar or mediastinal lymphadenopathy or focal consolidation. The chest radiograph in pneumocystis pneumonia may deteriorate very rapidly from being normal to showing severe abnormality in just a few days. By contrast, radiographic recovery can be slow. Nodular shadowing, adenopathy and pleural effusions on the chest radiograph suggest *Mycobacterium tuberculosis*, Kaposi’s sarcoma or lymphoma.

Figure 6.1 Chest radiograph of patient with early pneumocystis pneumonia

Arterial blood gases and oximetry

Hypoxaemia and a widened alveola–arterial oxygen gradient are very sensitive for the diagnosis of pneumocystis pneumonia but may also occur in other conditions. Exercise-induced arterial desaturation detected by oximetry is also sensitive for the diagnosis of pneumocystis pneumonia; desaturation may persist for several months following recovery from *P. carinii* pneumonia and occur also rarely in cytomegalovirus pneumonitis but is unusual in other respiratory conditions.

Pulmonary function tests

The single breath carbon monoxide transfer factor (TLCO), transfer coefficient (KCO), total lung capacity (TLC) and vital capacity (VC) may all be reduced in patients with pneumocystis pneumonia. Reductions in TLCO to 70% of predicted normal occur in HIV positive patients with pneumocystis and other respiratory disease, including Kaposi's sarcoma and bacterial infections, so this finding is not specific.

Invasive tests

These allow an aetiological diagnosis to be made.

Sputum induced by hypertonic saline

This procedure must be carried out away from other patients and staff in a separate room, ideally with “negative pressure” facilities in order to reduce the risk of nosocomial transmission of infection including tuberculosis. The patient inhales 20–30 ml of 2.7% (3N) saline through an ultrasonic nebuliser. Saline deposits in the peripheral airways and alveoli, causing irritation and inducing bronchial secretion. Fluid is also drawn into the airways from the interstitium, loosening inflammatory exudate and casts from alveoli. These are mobilised by the mucociliary escalator and move centrally where they are coughed out by the patient. Careful preparation of the patient is needed, including starving for several hours before the procedure and rigorous cleansing of the mouth to remove oral debris so that the sputum sample is not contaminated (food debris and squames take up stain and make analysis difficult). Purulent samples of sputum suggest a bacterial cause. *P. carinii* infection is usually found in clear “saliva-like” samples that become viscid on cooling to room temperature. Fungal infection and mycobacterial infection may also be diagnosed by this technique. Many centres do not carry out sputum induction because of the need for special equipment and the low yield when the technique is compared with fiberoptic bronchoscopy, both for the diagnosis of pneumocystis pneumonia and other pathogens. Some patients find sputum induction unpleasant and become nauseated or dyspnoeic. Arterial desaturation may also occur during the procedure.

Fiberoptic bronchoscopy

Bronchoscopy allows inspection of the bronchi to be carried out and lesions of Kaposi's sarcoma may be identified. Bronchoalveolar lavage is routinely carried out from the middle lobe or from the area of maximum abnormality seen on the chest radiograph. Transbronchial biopsies are now rarely done as they add little to the diagnostic yield for *P. carinii* and other diagnoses, and the technique is associated with adverse effects including haemorrhage and pneumothorax. If transbronchial biopsy is not performed a diagnosis of non-specific or lymphocytic interstitial pneumonitis might be missed.

Open lung biopsy

It is rarely necessary to carry out open lung biopsy because of the high yield from bronchoalveolar lavage. This investigation may be necessary if fiberoptic bronchoscopy and lavage fail to

ABC of AIDS

identify a diagnosis or in cases where a patient with a bronchoscopic diagnosis, deteriorates despite specific treatment.

The presenting clinical features and treatment of the common pulmonary manifestations of HIV disease are described below.

Pneumocystis carinii pneumonia

Despite widespread use of anti-pneumocystis prophylaxis and HAART, *P. carinii* pneumonia remains a common AIDS-defining diagnosis in patients who at presentation with pneumonia are unaware of their HIV serostatus or who, despite knowing they have HIV infection, are non-compliant with or intolerant of their prophylaxis and/or HAART.

Patients complain of a non-productive cough and increasing dyspnoea (over two to three weeks or more); they may also have fever and sweats. The chest radiograph may be normal or show interstitial infiltrates: in severe pneumonia there may be widespread alveolar consolidation.

Treatment

It is important to assess the severity of the pneumonia in order to choose appropriate treatment, as some drugs are ineffective in severe disease. High-dose co-trimoxazole remains the “gold standard” treatment. Treatment is for 21 days, given intravenously for the first 10–14 days, diluted in 1 in 25 of 0.9% saline, subsequently, orally. Patients with mild disease may be treated with oral co-trimoxazole from the outset. The principal side-effects are nausea and vomiting, leucopenia and rash. Routine use of folic or folinic acid does not prevent leucopenia and may be associated with increased therapeutic failure. HAART is usually stopped while co-trimoxazole is being given to avoid profound myelosuppression. Conventionally used doses of co-trimoxazole (20 mg/kg/day of the trimethoprim component) may be excessive: dose reduction to 75% of this dose (to maintain serum trimethoprim concentrations at 5–8 µg/ml) has equivalent efficacy and reduced toxicity.

Alternative treatment regimens include:

Clindamycin–primaquine combination (clindamycin 600 mg × 4/day iv or orally and primaquine 15 mg/day orally) has been used in patients intolerant of, or failing to respond to, co-trimoxazole. Principal side-effects are rash, nausea and vomiting, and leuco(neutro)penia.

Dapsone–trimethoprim (100 mg/day dapsone and 20 mg/kg/day trimethoprim) given orally for 21 days is as effective as oral co-trimoxazole in mild to moderate disease and is better tolerated by patients. Side-effects include methaemoglobinaemia and hyperkalaemia, nausea and rash.

Atovaquone suspension (750 mg × 2/day) given orally for 21 days is less effective (and less toxic) than either co-trimoxazole or pentamidine for mild to moderate disease. Absorption from the gut is variable but may be increased if taken with food.

Pentamidine is not often used because of significant toxicity and because other regimens have similar efficacy and less toxicity. It is given at a dose of 4 mg/kg/day (of the isethionate salt) given diluted in 250 mg 5% dextrose by slow intravenous infusion (over 2 hours); it should not be given by intramuscular injection. The major side-effects are hypotension and hypoglycaemia; nephrotoxicity with increases in creatinine and urea concentrations may occur. Dose reduction to 3 mg/kg/day is associated with reduced toxicity but may be less effective. Blood pressure and blood glucose concentrations should be closely monitored. Response to pentamidine (defervescence of fever, reduction in dyspnoea and improvement in blood gases) may take longer (4–7 days) than intravenous co-trimoxazole.

Table 6.1 Grading of severity of *P. carinii* pneumonia

	Mild	Moderate	Severe
Symptoms and rest signs	Increasing exertional dyspnoea, with or without cough and sweats	Dyspnoea on exertion, occasional dyspnoea at rest, fever with or without sweats	Dyspnoea at rest, persistent fever, cough
Blood gas tensions (room air)	P_{aO_2} >11.0 kPa	P_{aO_2} 8.0–11.0 kPa	P_{aO_2} <8.0 kPa
SaO_2 (at rest)	>96%	91–96%	<91%
Chest radiograph	Normal or minor perihilar infiltrates	Diffuse shadowing	Extensive interstitial shadowing with or without diffuse alveolar shadowing

P_{aO_2} = partial pressure of oxygen; SaO_2 = arterial oxygen saturation, measured with a transcutaneous pulse oximeter.

Table 6.2 Treatment of *P. carinii* pneumonia

Choice	Mild	Moderate	Severe
First	Co-trimoxazole	Co-trimoxazole	Co-trimoxazole
Second	Clindamycin and primaquine or Dapsone and trimethoprim or Atovaquone	Clindamycin and primaquine or Dapsone and trimethoprim or Atovaquone	Clindamycin and primaquine or Trimetrexate and folinic acid or Pentamidine iv
Third	Pentamidine iv	Pentamidine iv or Trimetrexate and folinic acid	
Glucocorticoids	Unproven benefit	Of benefit	Of benefit

Box 6.4 Adjuvant glucocorticoids in moderate/severe pneumonia

- Reduce risk of respiratory failure (by 50%)
- Reduce risk of death (by 33%)
- Should be started at same time as specific anti-pneumocystis treatment

Nebulised pentamidine is now no longer used to treat *P. carinii* pneumonia as there are several other more effective therapies and because this form of treatment does not suppress the development of extrapulmonary pneumocystosis.

Adjuvant glucocorticoids for patients with moderate or severe pneumocystis pneumonia reduces the risk of respiratory failure (by up to 50%) and the risk of death (by up to 33%). Glucocorticoids should be started together with specific anti-pneumocystis treatment in any patient presenting with a PaO_2 of

9.3 kPa breathing air. In some patients this will be on the basis of a presumptive diagnosis; clearly there will be a need to confirm the diagnosis rapidly. Treatment is with intravenous methylprednisolone 1 g/day for three days, followed by 0.5 g for two days, followed by oral prednisolone 40 mg daily tailing off over 10 days. Alternatively, prednisolone 40 mg orally twice daily is given for 5 days and then gradually reduced over 21 days (or intravenous methylprednisolone is given at 75% of these doses).

Intensive care

Over 90% of patients respond to treatment and survive their first episode of pneumocystis pneumonia. In those who fail to respond and who develop respiratory failure, mortality is 50%. Transfer to the intensive care unit for mask CPAP ventilation or intubation and mechanical ventilation should be considered in this situation. When considering the appropriateness of intensive care, assess the patient's wishes and those of their partner and relatives as well as the patient's previous and expected quality of life in relation to their HIV disease.

Prophylaxis

HIV positive patients, including those receiving HAART should receive primary prophylaxis against *P. carinii* pneumonia if they have a CD4 count <200 cells/ μ l or a history of oral/pharyngeal candidiasis or if they have a CD4 lymphocyte count $<14\%$ of total lymphocyte count, or if they have other AIDS-defining diagnoses, for example Kaposi's sarcoma, regardless of CD4 count. If close monitoring of CD4 counts (at least every three months) is not feasible then prophylaxis should be considered for patients with CD4 counts between 200 and 250 cells/ μ l. Secondary prophylaxis is given to all HIV-infected patients after an episode of *P. carinii* pneumonia, regardless of CD4 count.

The prophylaxis regimen of choice is co-trimoxazole 960 mg once daily. A dose of 480 mg once daily or 960 mg three times a week are also effective and may be better tolerated by the patient. Co-trimoxazole also protects against bacterial infection and reactivation of cerebral toxoplasmosis. In patients who develop mild to moderate adverse reactions to co-trimoxazole, desensitisation may be attempted before changing to alternative therapy. Second-line prophylaxis (for those intolerant of, or unwilling to take, co-trimoxazole) include dapsone, with or without pyrimethamine, atovaquone or monthly nebulised pentamidine (300 mg given using a Respigard II or similar nebuliser). There is a higher relapse rate of pneumocystis pneumonia with this regimen compared with that using co-trimoxazole. Some patients who relapse while receiving nebulised pentamidine have atypical chest radiographs with upper zone infiltrates which mimic tuberculosis. Atovaquone is as effective as dapsone or nebulised pentamidine but is much more expensive.

Stopping prophylaxis

Primary *P. carinii* prophylaxis can be discontinued in HIV-infected patients responding to HAART with an increase in CD4 count from below 200 cells/ μ l to above 200 cells/ μ l and a reduction in HIV-1 viral load, both sustained for 3–6 months. If

Figure 6.4 Transfer to the ICU may be necessary if respiratory failure occurs

Figure 6.5 Chest radiograph mimicking tuberculosis in a patient with pneumocystis pneumonia who had received inhaled pentamidine prophylaxis

Box 6.5 Prophylaxis of *P. carinii* pneumonia

Primary prophylaxis

Any HIV positive patient with a CD4 count of <200 cells/ μ l
Or a history of oral/pharyngeal candidiasis
Or a CD4 count $<14\%$ of total lymphocyte count
Or another AIDS-defining diagnosis, for example Kaposi's sarcoma

Secondary prophylaxis

Any HIV positive patient after an episode of *P. carinii* pneumonia

ABC of AIDS

despite HAART, CD4 counts again fall below 200 cells/ μ l and HIV-1 viral load rises, then the criteria for starting primary prophylaxis should be used. There are insufficient data to support the discontinuation of secondary prophylaxis.

Bacterial infections

Upper respiratory tract infections and pyogenic bacterial infection (sinusitis, bronchitis and pneumonia) occur more often in HIV-infected individuals than in the general population. Bacterial infections are particularly common in HIV positive intravenous drug users. The most commonly isolated organisms are *Streptococcus pneumoniae* and *Haemophilus influenzae*. Severe pneumonia due to *Staphylococcus aureus* or Gram negative bacteria such as *Pseudomonas aeruginosa* also occurs, especially in the later stages of AIDS. Respiratory infection may occur with rapid onset, the patient complaining of a cough with or without sputum and fever with chills; patients are frequently bacteraemic. There is a high rate of complications including intrapulmonary abscess formation and empyema. A rapid response usually occurs to treatment with appropriate antibiotics but relapse may occur. Some groups recommend that all HIV positive patients should be immunised with polyvalent pneumococcal polysaccharide vaccine although not all studies have demonstrated effective antibody responses to this agent, particularly in patients with CD4 counts <200 cells/ μ l.

Kaposi's sarcoma

Pulmonary Kaposi's sarcoma is the commonest non-infectious pulmonary manifestation of AIDS. Almost all patients with pulmonary Kaposi's sarcoma have mucocutaneous or lymph node Kaposi's sarcoma. Palatal Kaposi's sarcoma (with or without mucocutaneous Kaposi's sarcoma) strongly predicts for the presence of pulmonary Kaposi's sarcoma. Pulmonary Kaposi's sarcoma can affect the pulmonary parenchyma, bronchi, pleura and hilar/mediastinal lymph nodes. Chest radiographs most frequently show non-specific features, with bilateral interstitial (often nodular) or alveolar infiltrates; more than 40% of patients have pleural effusion and 25% have mediastinal lymph node enlargement. Routine respiratory function tests show decreased lung volumes (FEV₁ and FVC) and decreased TLCO; airflow obstruction may occur with extensive Kaposi's sarcoma in the airways.

At fiberoptic bronchoscopy 45% of patients with pulmonary Kaposi's sarcoma have visible endotracheal and endobronchial lesions consisting of multiple, red or purple, flat or raised lesions. Biopsy is not routinely done as most patients have the diagnosis made by the presence of cutaneous Kaposi's sarcoma, because of the risk of haemorrhage (up to 30% will have a significant bleed) and the low diagnostic yield (<20%) which occurs because of submucous distribution of the tracheobronchial tumour.

Transbronchial biopsy also has a low yield of less than 20% due to the patchy nature of parenchymal disease. Histological diagnosis is difficult to make at bronchial or transbronchial biopsy as crush artefact and reactive fibrous tissue have similar appearances. Open lung biopsy has a diagnostic yield of >75% but this procedure is very invasive and should probably be avoided as patients with pulmonary Kaposi's sarcoma have a poor prognosis.

Treatment

Chemotherapy most often consists of bleomycin 10 000 units/m² and vincristine 2 mg once every three weeks. Liposomal formulations of daunorubicin and doxorubicin may

Box 6.6 Bacterial infections

- Increased incidence of sinusitis, bronchitis and pneumonia in HIV infected persons, compared to general population
- Bacterial infection especially common in HIV infected IDU

Figure 6.6 Chest radiograph showing lobar pneumonia due to *Streptococcus pneumoniae*

Figure 6.7 Chest radiograph of pulmonary Kaposi's sarcoma showing multiple pulmonary nodules

Figure 6.8 Chest radiograph of pulmonary Kaposi's sarcoma showing bilateral pleural effusions and interstitial infiltrates

also be used as single-agent chemotherapy. Treatment of pleural effusions (which occur secondary to Kaposi's sarcoma on the visceral pleura or to mediastinal glands) is problematical. Chemical pleuradesis is rarely successful and radiotherapy has not been shown to be of value.

Tuberculosis

Unlike opportunistic infections in AIDS tuberculosis is also infectious for healthy individuals. Tuberculosis is a potent stimulator of cell-mediated immunity and so may speed up the natural history of HIV disease. The incidence of tuberculosis is currently increasing in the USA; this is directly attributable to the effects of HIV in certain populations. No increase has occurred yet in Britain but the unpredictable features of the HIV epidemic in heterosexuals, migrants and injecting drug users means careful vigilance is required. Tuberculosis can precede the development of AIDS, be diagnosed at the same time or occur at any time during established AIDS. Tuberculosis in HIV positive patients is AIDS defining and in the USA, the UK and most other European countries is a statutorily notifiable disease.

Over two thirds of cases of tuberculosis in HIV-infected patients present with pulmonary disease. Clinical presentation varies according to the stage of HIV disease. Early on, with relatively well preserved cell-mediated immunity, pulmonary tuberculosis resembles classic adult post-primary disease with upper lobe infiltrates and cavitation; the tuberculin test is usually positive and acid and alcohol fast bacteria (AAFB) are frequently seen when sputum is examined by microscopy. With advanced HIV disease and destroyed cell immunity, presentation is non-specific with fever, weight loss and fatigue, with or without cough. Patients with low CD4 counts $<150 \times 10^6/l$ may also have extrapulmonary disease affecting bone marrow, lymph node, central nervous system or liver. In the chest, the clinical pattern is one of primary infection with hilar and mediastinal adenopathy, diffuse or miliary shadowing; pleural effusions are common. Cavitation occurs rarely and up to 10% of chest radiographs are normal. The tuberculin test is usually negative, sputum (and bronchoalveolar lavage) are often smear negative and culture may also be negative.

As culture and species identification may take up to six weeks, *M. tuberculosis* infection should be assumed if AAFB are found in respiratory sample, an aspirate or biopsy site, or blood, and conventional antituberculous therapy should be started. Treatment can be modified if culture subsequently reveals an atypical mycobacterium and not *M. tuberculosis*.

Treatment

Clinical response to conventional treatment with four-drug regimens is good, but compared with the non-HIV-infected general population, survival is poor. The incidence of adverse reactions to antituberculous drugs, including isoniazid, rifampicin and thiacetazone, is higher in HIV-infected patients than in the general population.

Many of the drugs used to treat tuberculosis share routes of metabolism and elimination or have overlapping toxicities with other medication taken by HIV-infected patients, so there exists the potential for drug-drug interactions. For example, rifampicin renders dapsone, as prophylaxis of *P. carinii* pneumonia, ineffective — by inducing its hepatic metabolism. Clinically important drug-drug interactions occur between rifampicin/rifabutin and antiretroviral therapy particularly protease inhibitors such as zidovudine and non-nucleoside reverse transcriptase inhibitors such as delavirdine.

Compliance with therapy is a problem in some groups and directly observed therapy (DOTS) may be needed.

Tuberculosis may speed up the natural history of HIV disease

Figure 6.9 Chest radiograph in a patient with tuberculosis (and CD4 of $100 \times 10^6/l$) showing hilar lymphadenopathy

Figure 6.10 Tissue stained with Ziehl-Neelsen technique showing red staining of mycobacteria ($\times 400$)

Box 6.7 Treatment of tuberculosis

- Conventional four-drug regimens are associated with good response
- Adverse reactions to anti-tuberculous therapy occur more frequently in HIV infected patients
- Important drug-drug interactions occur between drugs used to treat tuberculosis and drugs used to treat HIV infection

ABC of AIDS

Multi-drug resistant (MDR) tuberculosis

This is tuberculosis resistant to rifampicin and isoniazid with or without resistance to other drugs. Outbreaks of MDR tuberculosis have occurred in the USA, the UK and elsewhere in Europe. Most MDR tuberculosis arises because of inadequate treatment or poor compliance with therapy. Some cases occur in HIV-infected patients who are exogenously re-infected whilst receiving treatment for drug-sensitive disease. Despite treatment, MDR tuberculosis has a poor prognosis in HIV-infected and non-infected patients and healthcare workers who acquire the infection.

Chemoprophylaxis

Some expert groups, for example WHO and International Union Against Tuberculosis and Lung Disease (IUATLD), recommend that HIV-infected patients co-infected with *M. tuberculosis* (but without disease) should receive chemoprophylaxis. There are few data to support this policy. The preferred policy should be close clinical monitoring rather than chemoprophylaxis, because of increasing rates of drug resistance and MDR tuberculosis, difficulties in distinguishing between infection and disease, and concerns that single-drug prophylaxis is associated with the development of resistance.

Once clinical disease is excluded, HIV-infected patients who have had recent contact with a smear-positive index case should receive chemoprophylaxis and life-time follow up should be instituted. Once HIV-infected patients have successfully completed a course of treatment for tuberculosis close clinical monitoring is recommended: such patients do not need to take life-long secondary prophylaxis.

Fungal pneumonia

Infection with *Cryptococcus neoformans*, *Histoplasma capsulatum*, *Aspergillus fumigatus* and other fungi is well recognised in HIV positive patients in the USA and Africa. Infection with these organisms is relatively uncommon in the UK. Cryptococcal pneumonia often occurs as part of a disseminated infection with fungaemia and meningoencephalitis; respiratory symptoms of cough and dyspnoea are non-specific. The chest radiograph may be normal or show diffuse shadowing which may be nodular. Diagnosis is made by culture of bronchoalveolar lavage or transbronchial biopsy specimen (or blood, bone marrow, or cerebrospinal fluid in disseminated infection). Treatment of cryptococcal infection is with fluconazole 400–600 mg/day or intravenous amphotericin B or itraconazole 400 mg twice a day. *Aspergillus* pulmonary infection has a very poor prognosis despite treatment with amphotericin. It occurs almost exclusively in patients with advanced HIV disease who are either neutropenic or who have received broad-spectrum antibiotics.

Lymphoma

Lymphoma occurs more often in HIV positive patients, particularly in those with advanced HIV disease. Most lymphomas are B cell in origin and are of high grade. Intrathoracic disease most frequently occurs in the context of disseminated disease. Symptoms are non-specific. The chest radiograph may show mediastinal lymphadenopathy, pleural lesions or focal parenchymal abnormalities. The prognosis is poor and there is a high relapse rate after treatment. Median survival is <1 year, reflecting the advanced stage of HIV disease.

Box 6.8 Chemoprophylaxis of tuberculosis

- Once active tuberculosis excluded, close clinical monitoring, rather than chemoprophylaxis is preferred policy in patients co-infected with HIV and tuberculosis
- HIV-infected patients in close contact with a smear positive index case should receive chemoprophylaxis and careful follow-up.

Box 6.9

- Cryptococcal pneumonia often part of disseminated infection
- Respiratory symptoms of cough and dyspnoea non-specific
- Chest radiograph may be normal or show diffuse shadowing

Figure 6.11 Chest radiograph showing left pleurally based lymphoma

Lymphocyte interstitial pneumonitis

This condition occurs more commonly in children; it is unusual in HIV-infected adults. Parotid enlargement and lymphocytic infiltration of the liver and bone marrow may accompany pulmonary involvement. Patients often present with slowly progressive dyspnoea and cough, symptoms that cannot be distinguished from infection. Examination of the chest may be normal or reveal fine end inspiratory crackles. The chest radiograph usually shows bilateral reticulonodular infiltrates but may show diffuse shadowing and thus mimic *P. carinii* pneumonia. Diagnosis is made by transbronchial biopsy or open lung biopsy. Some patients have been shown to respond to HAART and others to treatment with prednisolone 60 mg once a day.

Non-specific pneumonitis

This condition is important as patients present with symptoms and chest radiographic appearances similar to those of *P. carinii* pneumonia. It may also occur when the CD4 count is still normal. The diagnosis can only be made by biopsy. Episodes are usually self limiting but prednisolone may be of benefit.

Cytomegalovirus

Cytomegalovirus (CMV) infection in HIV positive patients with advanced disease and low CD4 counts (<100 cells/ μ l) is common and is a well-documented cause of retinitis, colitis, adrenalitis and radiculopathy. In patients with renal allografts and bone marrow transplants, CMV may cause pneumonitis on an immunopathogenic basis and this is frequently fatal.

CMV was originally thought to be an important cause of pneumonitis in patients with AIDS but it is now known that CMV pulmonary infection occurs only rarely in the absence of other pathogens and its presence does not adversely affect outcome and survival. Treatment with specific anti-CMV treatment such as foscarnet (phosphonoformate) does not seem to improve outcome (as would be expected if CMV was causing the pneumonitis).

Lung cancer

Lung cancer in HIV-infected patients presents an earlier age than in the general population and appears to have a poorer outcome, as it is more aggressive. Smoking is strongly associated with the development of lung cancer.

Figure 6.3 is reproduced courtesy of Dr Gabrijela Kocjan; Figures 6.10 and 6.12 are reproduced courtesy of Dr Meryl Griffiths.

Box 6.10 Lymphocytic interstitial pneumonitis

- Commoner in children
- Parotid enlargement and lymphocytic infiltration of liver/bone marrow may also occur
- Presents with slowly progressive dyspnoea/cough
- Treatment is with HAART or prednisolone

7 Gastrointestinal and hepatic manifestations

Ian McGowan, Ian VD Weller

Gastrointestinal symptoms are a common manifestation of HIV infection. Significant clinical problems tend to occur in patients with advanced immunosuppression. The differential diagnosis of gastrointestinal disease is broad and includes opportunistic infection, malignancy, and the effects of medication. Antiviral drugs and antibiotics have gastrointestinal side effects such as nausea, vomiting, and diarrhoea. HIV can be readily detected in mucosal tissue but the direct role of mucosal HIV infection in the cause of clinical disease remains controversial.

This chapter will focus on the differential diagnosis and management of common gastroenterological syndromes associated with HIV infection. Clinical investigation may not always be appropriate in advanced disease. It is important to counsel patients about the risks and benefits of invasive procedures as many “specific” diagnoses may not be treatable.

Oral and oesophageal disease

Oral cavity pain or discomfort are caused by candidiasis, herpetic or aphthous ulceration, periodontal disease, and tumours. Often the diagnosis can be made by simple inspection and appropriate treatment initiated without further investigation. Systemic oral therapy of herpes simplex ulceration and candidiasis is preferred for reasons of efficacy and ease of use. Recurrence is common and if frequent, maintenance therapy may be required rather than the short treatment of each occurrence. Maintenance therapy may be more likely to induce resistance.

About one third of patients develop oesophageal disease. The likelihood of candidiasis is so high that a therapeutic trial with a systemic antifungal agent is indicated before considering further investigation. If symptoms fail to respond, or recur despite adequate maintenance therapy, endoscopy is performed to exclude herpes simplex, cytomegalovirus and other causes of oesophageal ulceration including malignant lesions.

Diarrhoea

Patients with diarrhoea lasting more than two weeks should be investigated. The diagnostic yield is likely to be highest in patients with CD4 counts $<200 \times 10^6/l$. Careful microbiological and parasitological examination of multiple stool specimens is the most cost-effective initial investigation. Endoscopy with collection of tissue from the distal duodenum, ascending and descending colon should be performed to exclude cytomegalovirus and occult parasitic infection.

Bacterial infection with *Campylobacter*, *Salmonella* or *Shigella* spp. may present with severe diarrhoeal symptoms and/or bacteraemia. It is important to exclude toxic megacolon with plain abdominal radiography. Organisms are usually sensitive to conventional therapy but drugs may need to be given parenterally. Evidence of atypical mycobacterial infection is found in 60% of patients with advanced HIV disease at necropsy. Gastrointestinal infection may be associated with fever, weight loss, diarrhoea, and malabsorption. Diagnosis can be made by acid fast staining of the stool or biopsy material and by culture. Positive stool culture alone indicates colonisation only. *Mycobacterium tuberculosis* infection of the bowel does occur but is less common. Antibiotic-associated diarrhoea,

Figure 7.2 Abdominal radiograph of toxic megacolon secondary to *Shigella flexneri* infection

including pseudomembranous colitis due to *Clostridium difficile*, is occasionally seen in patients with HIV infection and is treated with oral metronidazole or vancomycin.

Cryptosporidium spp. is one of the most common pathogens isolated from HIV-infected patients with diarrhoea. The degree of immunosuppression influences patient prognosis and patients with a CD4 count $>200 \times 10^6/l$ may recover spontaneously. Treatment is supportive as no agent has shown convincing efficacy. The organism is heat sensitive and immunosuppressed patients are advised to boil water for drinking purposes.

Microsporidia are also an important cause of diarrhoea as well as being associated with hepatitis, peritonitis, sclerosing cholangitis, sinusitis, and renal failure. Diagnosis is difficult as the spores are only 1–5µm in diameter. A number of centres have reported successful identification of spores in stool using trichrome and fluorescent stains but morphology is best determined using electron microscopy. Albendazole has shown promise in AIDS patients with microsporidiosis but may only be active against *Encephalitozoon intestinalis* and not *Enterocytozoon bienusi*.

Isospora belli is an infrequent cause of diarrhoea in AIDS patients in the USA and Europe but accounts for up to 25% cases of chronic diarrhoea in patients in tropical and subtropical countries. Response to trimethoprim–sulphamethoxazole has been described.

Cyclospora sp. is the most recent protozoan to be associated with diarrhoea in AIDS. It appears to be more common in the developing world and in returning travellers and like *Isospora belli* appears to be sensitive to trimethoprim–sulphamethoxazole.

Other protozoa including *Entamoeba histolytica* are frequently identified in stools from HIV-infected homosexual men but appear not to be pathogenic.

Cytomegalovirus colitis occurs in less than 5% of patients with AIDS. Symptoms include bloody diarrhoea, abdominal pain, and fever. Sigmoidoscopy may show diffuse erythema and mucosal ulceration. Diagnosis is histopathological and is made on the basis of characteristic intranuclear “owl’s-eye” inclusion bodies or detection of CMV antigen with monoclonal antibodies. Treatment is with ganciclovir or foscarnet.

Adenoviruses have been identified by culture and electron microscopy in HIV-infected homosexual men with diarrhoea. No specific treatment is available.

Weight loss and anorexia

Weight loss is a major problem in AIDS and directly influences survival. The causes of weight loss are complex and several factors may coexist in individual patients. Anorexia may occur secondary to drug therapy, opportunistic infection, taste disturbance, or oral discomfort, resulting in inadequate food intake. Malabsorption of fat, lactose, vitamin B12, and bile salts has been demonstrated.

Simple dietary measures such as encouraging smaller, more frequent, meals may be helpful and a wide variety of nutritional supplements are available. Appetite stimulants such as megestrol acetate may be beneficial but weight gain is usually modest. Recombinant human growth hormone, although expensive, may partially reverse HIV-associated weight loss. In patients unable to tolerate oral feeding, enteral and parenteral feeding are alternative forms of nutrition but their efficacy and place in management are still being evaluated. Enteral nutrition offers a safer and cheaper alternative to total parenteral nutrition which is perhaps most useful in patients with severe diarrhoea, nausea, and vomiting, in whom fluid balance and control of symptoms has been difficult.

Hepatitis and cholestasis

Abnormal liver biochemistry and/or hepatomegaly are common clinical problems although frank jaundice is uncommon. With the multiple therapies being used in treatment and prophylaxis, a drug-induced hepatitis must always be considered in a patient with AIDS and abnormal liver function tests. The differential diagnosis is wide and may involve the use of serology, abdominal ultrasound, ERCP, and liver biopsy. These latter two diagnostic procedures are clearly invasive and would not be indicated unless treatment of opportunistic infection, malignancy or biliary strictures was contemplated. In the absence of dilated bile ducts on ultrasound, liver biopsy usually shows a granulomatous hepatitis caused by atypical mycobacteria.

AIDS sclerosing cholangitis presents with right upper quadrant pain, accompanied by a raised alkaline phosphatase. Abdominal ultrasound is abnormal in the majority of patients with biliary tract dilatation. ERCP may demonstrate papillary stenosis, dilatation of the common bile duct and dilatations and strictures with “beading” of the intrahepatic ducts. The disease is commonly associated with cryptosporidiosis, microsporidiosis, or cytomegalovirus infection. Endoscopic sphincterotomy may give pain relief in a proportion of patients with papillary stenosis. Liver function tests do not usually improve, and as it is a late-stage manifestation, the prognosis is poor, with most patients dying from some other HIV-related complication within six months of diagnosis.

HIV infection may alter the natural history of hepatitis B infection in a number of ways. The response rate to hepatitis B vaccination is lower in HIV-infected recipients.

Immunodeficiency may favour the establishment of chronic infection following acute infection and HBV replication is increased with a reduction in the rate of spontaneous loss of HBe antigen. Interferon therapy would appear to be less effective in chronic HBV/HIV dual infection. The immune restoration following the initiation of antiretroviral therapy may lead to a hepatitis “flare” in chronic HBV carriers.

Hepatitis C virus infection is found primarily in intravenous drug users, although it may also be sexually transmitted. HIV can modify the natural history of HCV infection and patients with HIV/HCV dual infection tend to have more aggressive liver disease.

Anorectal disease

Perianal discomfort is often caused by recurrent herpes simplex infection. The diagnosis should be confirmed by viral culture. Patient-initiated intermittent aciclovir can give adequate symptom control in some cases but many patients will require long-term maintenance therapy. Resistance to both aciclovir and ganciclovir has been reported. Foscarnet is then the treatment of choice.

Anal warts are common but rarely cause much in the way of symptoms and should be treated on merit given the absence of any effective antiviral therapy. Anal intraepithelial neoplasia has been described in association with human papillomavirus infection but reports of invasive malignancy are still infrequent.

Patients may present with a mucopurulent proctitis, possible causes of which include recently acquired or long-standing *Neisseria gonorrhoeae* or *Chlamydia trachomatis* infection.

Neoplasia

Kaposi's sarcoma (KS) is commonly seen in the gastrointestinal tract and occurs in homosexual men more frequently than in patients from other risk groups. A new human herpes virus (HHV8) or Kaposi's sarcoma-associated herpes virus (KSHV) has been recently identified as a likely aetiological agent. KS lesions in the gut have the range seen in the skin, from small telangiectatic lesions, not well shown on contrast studies and only seen at endoscopy, to larger nodular or polypoid lesions. Complications from gastrointestinal disease are unusual, but include ulceration, obstruction, haemorrhage, and diarrhoea.

Lymphoma is much less common than KS however, although the incidence of KS has decreased along with the incidence of life-threatening opportunistic infections in association with the introduction of highly active antiretroviral therapy. The incidence of lymphoma has not been affected. HIV-associated lymphomas are usually high grade non-Hodgkin's type, of B-cell origin. Extranodal involvement is typical and the gut is one of the commonest sites involved.

We thank Dr Wilfred Weinstein, UCLA Medical School, Los Angeles for providing the photograph of oesophageal candidiasis and Dr David Casemore, PHLS Glan Clwyd, North Wales for the electronmicrograph of cryptosporidium.

8 Neurological manifestations

Hadi Manji

In patients infected with HIV, the whole neuraxis is vulnerable to damage. Up to 10% of patients may present with a neurological disorder at seroconversion (Box 8.1). The aseptic meningoencephalitis, which is usually self limiting, presents with headache, meningism, cranial nerve palsies and seizures. An acute demyelinating polyradiculoneuropathy (Guillain–Barré syndrome) is identical to that found in non-HIV-infected individuals, clinically and in the response to treatment with intravenous immunoglobulin or plasmapheresis. However, the cerebrospinal fluid shows a pleocytosis of over 20 cells/mm³ which is unusual in non HIV cases. A high index of suspicion is required and HIV should be considered in all such cases.

During the asymptomatic phase of the illness, which may be of variable duration, headache and cranial nerve palsies (especially VIIth nerve – Bell’s palsy) may be the only manifestation of a low-grade chronic meningitis.

The opportunistic infections and tumours as well as the complications ascribed to HIV itself usually develops when the CD4 count drops below 200/mm³ (Box 8.2). Since the introduction of HAART, there has been a significant reduction in the incidence of infections such as toxoplasmosis and CMV.

Clinical approach

The CD4 count is a useful guide to the aetiology of a neurological presentation – toxoplasmosis and cryptococcal meningitis occur at CD4 counts below 200/mm³ whereas CMV complications occur below 50/mm³. Since HIV infection itself results in CSF abnormalities such as a raised white cell count and an elevated protein level, more specific tests are required to diagnose encephalitic and meningitic illnesses. These include the measurement of cryptococcal antigen levels in cases of meningitis due to *C. neoformans* and CSF–VDRL and TPHA if syphilis is a differential. The inflammatory response is impaired and patients with meningitis may present with only mild symptoms of headache and no neck stiffness or photophobia. The threshold for investigating with CT/MRI and lumbar puncture is necessarily low. The measurement of serum antibodies to diagnose, for example toxoplasmosis, is unhelpful since the usual rise in levels of IgM does not occur. Infection with more than one organism occurs not infrequently, for example *Cryptococcus neoformans* and *Mycobacterium tuberculosis* and needs to be considered in cases of non-response or deterioration.

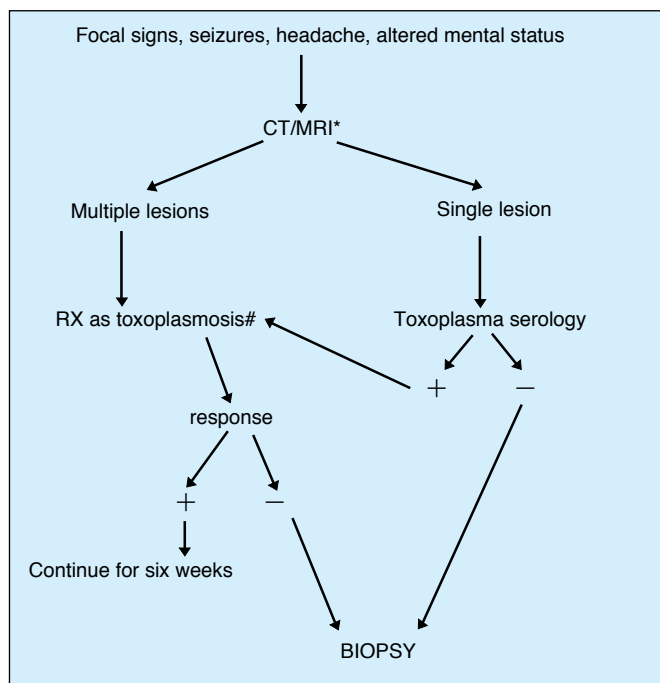

Figure 8.1 Management of mass lesions in HIV infection. * MRI is preferred mode of imaging. # If significant mass effect treat with reducing course of dexamethasone in addition to toxoplasma therapy

Opportunistic infections

Toxoplasma gondii

Toxoplasmosis in HIV infection is usually a reactivation of latent infection in individuals who have been exposed previously to the organism. The clinical presentation is with headache with rapidly evolving focal neurological deficits over one to two weeks which include hemiparesis, dysphasia, visual field deficits, movement disorders (chorea/athetosis, parkinsonism) and seizures. Rarely, toxoplasmosis may affect the spinal cord and present with a myelopathy or a cauda equina syndrome. Blood serology for *T. gondii* is only helpful if negative since this makes the diagnosis less likely. Patients should have their toxoplasma serology documented at the first diagnosis of HIV infection. The risk of developing toxoplasma encephalitis in IgG seropositive patients is between 12% and 30%. These patients should be offered primary prophylaxis with co-trimoxazole at CD4 counts below 200.

CT/MRI shows multiple enhancing lesions with mass effect in the region of the basal ganglia and at the grey/white interface. A response to treatment is seen in 85% by day 7 and in over 90% by day 14. Repeat imaging should be performed after two weeks even if there is clinical improvement in cases of mixed pathology.

In patients with significant mass effect and cerebral oedema who are in danger of coning, additional treatment with dexamethasone will be necessary. A deterioration after this has been tailed off makes it necessary to consider a biopsy.

Cryptococcus neoformans

C. neoformans is a ubiquitous organism acquired by inhalation. Patients with meningitis may present acutely or insidiously over days or weeks with a headache, general malaise, confusion or seizures. The classical signs of meningism – neck stiffness, photophobia and Kernig's sign – are frequently absent.

Brain imaging is usually normal but MRI may reveal small abscesses – cryptococomas. The CSF cell count and protein may be normal and the diagnosis is confirmed by the presence of cryptococcal antigen in the CSF in 95% of cases. India ink staining is positive in 75%. 85% of cases are culture positive – the gold standard. Measurement of the serum cryptococcal antigen is a useful screening tool in patients presenting with headache or fever but should not be considered definitive.

Intracranial hypertension in the absence of mass lesions or hydrocephalus is an important cause of mortality and visual failure in approximately 20%. This is managed by repeated lumbar punctures or by the insertion of a lumbar or ventricular drain.

JC virus

Progressive multifocal leucoencephalopathy (PML) results from reactivation of the JC virus in immunosuppressed individuals. 80% of the general population will have been exposed to this virus as a banal childhood upper respiratory infection and have positive serology.

The presentation is with slowly evolving focal neurological deficits such as a hemiparesis, visual field and language problems and incoordination due to cerebellar involvement. Occasionally patients develop a dementia in association with these focal abnormalities. Symptoms and signs of raised intracranial pressure are absent although headache may be a feature.

Blood serological testing is unhelpful. Cranial CT shows non-enhancing areas of low attenuation in the white matter. MRI shows characteristic scalloping abnormalities at the grey/white interface with no mass effect or enhancement. The diagnosis may be confirmed by isolating JC virus by polymerase

ABC of AIDS

chain reaction (PCR) techniques in the CSF in 75% of cases. If this is negative, a brain biopsy may need to be performed. This typically shows areas of focal demyelination, bizarre enlarged astrocytes and abnormal oligodendrocytes with inclusions which stain for JC viral antigens.

There is at present no specific treatment for PML. Cytosine arabinoside has been shown to be ineffective but trials are underway looking at the efficacy of drugs such as cidofovir (an anti CMV drug) and alpha interferon. Improvement in immune function with HAART has resulted in significantly better survival times.

Cytomegalovirus

Over 90% of HIV-infected individuals have serological evidence of CMV infection. The neurological complications, which occur at CD4 counts below 50/mm³, include retinitis, a cauda equina syndrome, an encephalitis and a mononeuritis multiplex. Apart from retinitis, the other complications occur infrequently.

CMV retinitis

The initial presentation of CMV retinitis depends upon the location – patients may be asymptomatic, complain of floaters, lose peripheral vision or if the lesions are centred around the macula, have poor visual acuity. Patients will often have evidence of CMV disease elsewhere such as colitis and such patients need to be screened for retinitis regularly.

On fundoscopy, there is a perivascular yellow-white infiltrate with retinal haemorrhages. The differential diagnosis includes retinal complications of toxoplasmosis, lymphoma, syphilis, herpes zoster and herpes simplex.

CMV polyradiculopathy

This well-recognised syndrome presents over a period of days with back pain followed by the development of a progressive flaccid weakness of the legs with sensory loss and sphincter disturbance. Imaging studies which are essential to exclude compressive lesions due to, for example, lymphoma are normal or may show thickened nerve roots. The CSF shows a characteristic neutrophil pleocytosis which is unusual in a viral infection. Without treatment there is a progression of the neurological deficits, with death in 2 or 3 months.

CMV encephalitis

Although evidence of CMV infection is often found in the brains of patients dying from AIDS, the clinical correlates are unclear. A CMV encephalitis needs to be considered in patients presenting with a rapidly progressive encephalitis with cranial nerve palsies and seizures. CMV may be isolated from the CSF using PCR.

Primary CNS lymphoma (PCNSL)

PCNSL is the most common cause of mass lesions in children and the second most common in adults after toxoplasmosis. Histologically, this is a high-grade B cell lymphoma. The Epstein-Barr virus can be isolated from tissue specimens and is believed to have a causal role in the development of the lymphoma.

The clinical presentation is similar to that of toxoplasmosis with focal neurological deficits such as hemiparesis and seizures. There are usually signs and symptoms of raised intracranial pressure with increasing headache, vomiting and papilloedema.

Although the isolation of EBV by PCR in the CSF is specific, most patients present with mass lesions and raised intracranial pressure. Lumbar puncture is therefore contraindicated. The CT and MRI findings may be

Box 8.7 Clinical signs and symptoms in PML

- Motor function abnormalities (including hemiparesis)
- Mental status changes
- VIIth cranial nerve palsy
- Cerebellar syndrome
- Language disorders (dysphasia)
- Visual problems (for example hemianopia)
- Seizures

Figure 8.4 Haemorrhagic retinitis due to cytomegalovirus

Figure 8.5 Enhancing right frontal mass lesion due to lymphoma

indistinguishable from those due to toxoplasmosis with multiple enhancing lesions with associated cerebral oedema and mass effect. However, a single lesion on MRI especially if the toxoplasma serology is negative, is more likely to be lymphoma, as are lesions which closely adhere to the ventricular walls.

The diagnosis of PCNSL is usually made by biopsy. This may be performed after failure of treatment with antitoxoplasma therapy for at least two weeks. However, since prognosis is poor even with whole brain radiotherapy, it is reasonable not to proceed with a biopsy unless there is a suspicion that other more treatable pathologies may be identified.

HIV-associated dementia complex (AIDS dementia complex) or HIV dementia

This complication occurs in 15% of AIDS patients usually in patients with a CD4 count below 200/mm³. The early reports of evidence of cognitive abnormalities in HIV positive asymptomatic individuals have been discounted by large cohort studies using clinical, neuropsychological, MRI and neurophysiological methods of assessment. The clinical picture is of a variably progressive dementia with psychomotor slowing and impairment of memory.

The diagnosis is one of exclusion of other infective or neoplastic aetiologies by brain imaging and CSF examination. Although there is a correlation between the CSF HIV RNA viral load and the severity of dementia, there is too much overlap for use as a diagnostic test. A neuropsychological assessment is also helpful. MRI shows cortical atrophy and diffuse or patchy white matter high signal on T2-weighted images.

The underlying pathophysiological mechanisms are unclear but HIV is usually isolated from the microglial cells and astrocytes rather than neuronal cells. Productive infection of the macrophages and microglia with the release of cytokines such as TNF results in neuronal damage.

Since the introduction of zidovudine and subsequently HAART the incidence of HIV-associated dementia has progressively declined. However, more recently there is concern that the CNS may become a sanctuary for HIV, since most of the newer drugs penetrate the CNS poorly.

Peripheral nerve disorders in HIV infection

DSPN is the commonest neurological complication encountered in HIV patients, with 30% of AIDS individuals experiencing symptoms. It is unusual in the asymptomatic stages of HIV infection. Pathologically, this is a length-dependent axonal neuropathy usually sparing the hands. The symptoms and signs are typical of a small fibre neuropathy. Treatment is symptomatic using antidepressant and anticonvulsant drugs.

The neuropathy due to the nucleoside analogue drugs (ddl, ddC and D4T) is similar and therefore difficult to differentiate from DSPN. These drug related neuropathies are dose dependent and reversible. However, patients may continue to deteriorate for 6–8 weeks after stopping the drug – “coasting”.

Box 8.10 Symptoms and signs of DSPN

- Numb, burning feet
- Pins and needles
- Contact hypersensitivity
- Little or no weakness
- Impaired pain and temperature sensation
- Depressed or absent ankle jerks

Box 8.8 Symptoms and signs of HIV dementia

Early

- Poor concentration

- Nerve biopsy may be indicated to exclude an inflammatory neuropathy (vasculitis or demyelination)

9 Treatment of infections and antiviral therapy

Ian VD Weller, IG Williams

The treatment of HIV infection can be largely divided into: (i) specific antiviral agents that inhibit viral replication, (ii) measures that either treat or prevent (prophylaxis) its complications – namely opportunistic infections and tumours. Major advances in the treatment of HIV infection have occurred in the last few years. This has resulted in marked falls in the reported number of new AIDS cases and deaths in the developed world since 1996. Effective antiretroviral therapy regimens which substantially inhibit HIV replication and allow sustained improvements in the immune system are the main reason for this. There are currently three classes of antiretroviral agents: the nucleoside and non-nucleoside reverse transcriptase inhibitors and the protease inhibitors. Improved formulations and new drugs are continuously being evaluated and there is increasing interest in the possible role of immunotherapy combined with antiretroviral therapy to improve specific immune responses.

However, in those who are severely immunosuppressed the treatment and prophylaxis of opportunistic infections remains important. Though it cannot be overemphasised that the most effective way to prevent first episodes or recurrences of opportunistic infections is treatment with antiretroviral drugs. This chapter will cover both antiretroviral therapy and the treatments of the infections previously described in other parts of this book, in an attempt to bring all of these together in a comprehensive manner.

Protozoal infections

***Pneumocystis carinii* pneumonia (PCP)**

Although recently recognised as being more like a fungus, *P. carinii* is considered under protozoa here. Nowadays PCP most commonly occurs in those at risk who fail to take adequate prophylaxis or who are newly diagnosed with HIV infection in advanced disease where it is frequently the presenting illness.

Clinical suspicion is aroused early in patients who are under regular medical supervision, leading to earlier diagnosis. Later diagnosis is associated with more severe disease and poorer treatment outcome. Techniques of diagnosis include sputum induction with nebulised saline; this obviates the need for bronchoscopy but the diagnostic sensitivity is lower. The use of lavage alone at bronchoscopy avoids transbronchial biopsy with its complications of haemorrhage and pneumothorax. Exercise oximetry and alternative imaging techniques with radiolabelled compounds are also being used in diagnosis. Monoclonal antibodies to pneumocystis proteins and sensitive DNA probes have been developed but have yet to reach the bedside. In the absence of a confirmatory test, a presumptive diagnosis may be made based on the clinical presentation and chest x ray appearances in a patient severely immunosuppressed and at risk.

High-dose intravenous co-trimoxazole for two to three weeks remains a standard first-choice regimen for severe PCP, but once fevers and symptoms have settled and blood gas values have improved the drug can be given by mouth. Side-effects are common, typically after 7–10 days. If co-trimoxazole treatment is not tolerated, alternative treatment regimens include either intravenous pentamidine or a combination of clindamycin and primaquine. Pentamidine is as effective as co-trimoxazole but has side-effects that can be life threatening and should be given

Box 9.1 Treatment strategies in HIV disease

- Antiretroviral therapy: suppresses viral replication results in immune reconstitution
- Prophylaxis of opportunistic infections
- Prevent exposure to opportunistic pathogens

Figure 9.1 Chest x ray appearance of *Pneumocystis carinii* pneumonia showing interstitial infiltrates

by slow intravenous infusion with careful monitoring. In patients with moderate or mild PCP a combination of clindamycin and primaquine has proven clinical efficacy and is an alternative first choice for those patients who have a previous history of severe co-trimoxazole hypersensitivity. Side-effects of rash and diarrhoea are frequent.

In patients presenting with severe hypoxaemia high-dose adjunctive corticosteroid therapy is indicated and has been shown in clinical studies to reduce both mortality and morbidity

Alternative second-line therapies include dapsone with trimethoprim, trimetrexate with folinic acid or Atovaquone, a hydroxy-naphthoquinone. The efficacy of atovaquone has only been established in mild to moderate *P. carinii* infection. Like trimetrexate it is probably less effective than co-trimoxazole but it is less toxic. New formulations have improved atovaquone's bioavailability but it still should not be given to patients with malabsorption conditions, previous severe diarrhoea or those not taking oral nutrition. Due to acquired resistance, where possible atovaquone should not be given as single-agent therapy. It is commonly combined with intravenous pentamidine as an effective second-line treatment.

Prophylaxis for PCP pneumonia is essential after a first attack (secondary prophylaxis) but is also recommended for all patients once their CD4 cell counts falls below $200 \times 10^6/l$ (primary prophylaxis). The risk of a first episode PCP below this CD4 count level in patients not on antiretroviral therapy is estimated to be 18% at 12 months for those who are asymptomatic, rising to 44% for those who have early symptomatic disease (for example, oral candida, fever). Co-trimoxazole 960 mg given by mouth daily or three times per week is the most effective agent. In patients who are intolerant, alternative regimens include oral dapsone 100 mg with pyrimethamine 25 mg daily or three times per week, atovaquone 1500 mg daily or nebulised pentamidine. Dose of the latter depends on the nebuliser system: with a Respigard II nebuliser the recommended regimen is 300 mg every four weeks. In patients with more advanced disease and CD4 counts less than $100 \times 10^6/l$, 300 mg given every two weeks should be considered in view of the high failure rate of the monthly regimen.

Figure 9.2 Cysts of *Pneumocystis carinii* in broncho-lavage specimen

Table 9.1 *Pneumocystis carinii* pneumonia treatment

Drug	Duration	Side-effects	Comments
<i>First choice:</i>			
Co-trimoxazole (trimethoprim component 15–20 mg/kg per day p.o./i.v. in divided doses).	21 days	Nausea, vomiting, fever, rash, marrow suppression, raised transaminases	Intolerance common (25–50% of treated patients)
<i>Alternative regimens:</i>			
1. Severe disease:	21 days	Hypotension, hyper- and hypoglycaemia, renal failure, marrow suppression, nausea, vomiting, cardiac arrest	80% of patients will respond to treatment
Pentamidine isethionate 4 mg/kg per day as slow intravenous infusion			
Trimetrexate 45 mg/m ² i.v. and folinic acid 80 mg/m ²	21 days	Marrow suppression, raised transaminases rash, anaphylaxis	Should only be used as third or fourth line treatment
2. Mild to moderate disease:	21 days	Diarrhoea, rash, nausea, vomiting, marrow suppression, methaemoglobinaemia, haemolysis	<i>Clostridium difficile</i> toxin associated diarrhoea is a frequent complication of clindamycin therapy
Clindamycin 600 mg 6 hourly p.o./i.v. and primaquine 15 mg daily p.o.			
Trimethoprim 20 mg per kg/day p.o./i.v. in 2–3 divided doses and dapsone 100 mg daily p.o.	21 days	Rash, nausea, methaemoglobinaemia, marrow suppression	Alternative regimens should be used in patients with G6PD deficiency
Atovaquone suspension 750 mg twice daily	21 days	Rash, raised transaminases and neutropenia	Must be taken with food. Consider combination with i.v. pantamidine as resistance reported with monotherapy
Adjuvant high-dose steroids (for example, prednisolone 40–60 mg daily p.o.)	5 days	tapering over 14–21 days	Indicated in severe disease. Optimal dose not determined

ABC of AIDS

Although clinical trials have shown greater efficacy for co-trimoxazole compared to other regimens, there is a high rate of discontinuation due to side-effects. Desensitisation regimens are used with the aim of reducing the rate of intolerance but there is uncertainty about their efficacy and which regimen is best.

In patients responding to antiretroviral therapy, primary or secondary prophylaxis can be safely discontinued once the CD4 count has increased to levels persistently above $200 \times 10^6/l$.

Toxoplasmosis

Cerebral toxoplasmosis is the commonest manifestation of toxoplasma infection. As toxoplasmosis is the most common cause of ring-enhancing lesions on contrast CT brain scans a presumptive diagnosis is usually made and treatment started. The condition responds well if treatment is started early, and a combination of sulphadiazine 4–6 g/day and pyrimethamine 50–100 mg a day (both by mouth in divided doses with folinic acid 15 mg daily) is the treatment of choice. Side-effects may prevent continued use of sulphadiazine, and clindamycin 600–1200 mg four times a day has been shown to be an effective alternative in controlled studies.

Corticosteroids are sometimes used in addition to first-line treatment to reduce symptomatic cerebral oedema, but a clinical and radiological response seen after two weeks of treatment may be due solely to the corticosteroid effect rather than the anti-toxoplasma treatment. A presumptive diagnosis of toxoplasma may therefore be made, although the underlying lesion may be due to something else, such as lymphoma or another infection. Relapse is common after treatment is stopped, and maintenance treatment is therefore necessary. In patients responding to antiretroviral therapy with sustained increases in CD4 count, discontinuation of prophylaxis is safe but there is limited current data to make definite recommendations.

Atovaquone 750 mg four times a day with or without pyrimethamine may be considered an alternative and the new macrolides clarithromycin 2 g daily and azithromycin, both given with pyrimethamine 75 mg/day, have also been effective in small uncontrolled studies. The most appropriate regimen for secondary prophylaxis has not been determined but treatment doses of either sulphadiazine and pyrimethamine or clindamycin and pyrimethamine are usually halved.

Of patients with positive toxoplasma serology and a CD4 count of less than $100 \times 10^6/l$, approximately 1 in 3 will develop cerebral toxoplasmosis within 12 months without prophylaxis. Primary prophylaxis in patients with positive serology with a CD4 count of less than $100 \times 10^6/l$ is therefore recommended. Co-trimoxazole or dapsone with pyrimethamine have been shown to reduce the incidence of toxoplasmosis compared to patients taking nebulised pentamidine for prophylaxis against PCP. Atovaquone with or without pyrimethamine may also be considered but this is based on more limited data. The macrolides clarithromycin and azithromycin might be anticipated to provide broad-spectrum prophylaxis for toxoplasmosis, atypical mycobacterial and bacterial infections, but bacterial resistance might limit their use in this situation.

Patients who are toxoplasma serology negative should be given advice to prevent exposure in primary infection with toxoplasmosis. They should be advised not to eat raw or undercooked meat and avoid directly handling cats' faeces.

Cryptosporidiosis and other protozoa

In patients with less advanced HIV disease (CD4 counts $>200 \times 10^6/l$) cryptosporidial infection usually causes a self-limiting gastrointestinal illness and symptomatic treatment with

anti-diarrhoeal agents is all that maybe needed. In those with more severe immunosuppression and persistent symptoms treatment is more difficult and reported successes with a variety of agents are still anecdotal. Symptoms and excretion of cysts may be intermittent. Responses have been described after treatment with a variety of agents, including spiramycin, erythromycin, diclazuril, letrazuril, hyperimmune bovine colostrum, paromamycin, azithromycin and subcutaneous somatostatin.

Symptomatic treatment with antidiarrhoeal and antiemetic agents together with fluid, electrolyte and nutritional support should be provided. Case reports suggest that immune reconstitution is likely to result in improvement and resolution of both symptoms and infection. Thus in the absence of an effective specific treatment against cryptosporidium, infected patients should be started on antiretroviral therapy to increase the CD4 count.

Patients at risk of infection should be advised to avoid possible exposure in water supplies particularly at times of documented outbreaks. Although unproven, measures that may be considered for patients with CD4 counts less than $200 \times 10^6/l$ include using bottled water, point of use filters or boiling water for more than one minute.

For microsporidiosis there have been anecdotal reports of symptomatic improvement with albendazole 400 mg twice a day or metronidazole 500 mg three times a day.

Isosporiasis is less common and appears to respond to co-trimoxazole 960 mg four times a day, but relapses occur in half of all cases.

Diarrhoea often occurs in the absence of recognised pathogens in the stool, and metronidazole has relieved symptoms in some cases.

Figure 9.5 Cryptosporidium

Table 9.2 Viral opportunistic infections

Infection	Drug	Duration	Side-effects	Comments
<i>Herpes simplex</i>				
Treatment	Aciclovir 200 mg 5 × a day orally or 10 mg/kg 8 hourly i.v.	5–7 days		Duration may be extended in severe infections
Prophylaxis	Aciclovir 200 mg 4 × a day or 400 mg 2 x day	Indefinite		
<i>Cytomegalovirus</i>				
Treatment	Ganciclovir 5 mg/kg twice a day i.v.	14–21 days	Neutropenia, anaemia	GCSF support may be required
	Cidofovir 5 mg/kg i.v. once a week	2 weeks	Nephrotoxicity: impaired creatine clearance, proteinuria, hypophosphataemia Neutropenia Ocular toxicity	Co-administer with probenecid and adequate hydration to reduce risk of nephrotoxicity
	Foscarnet 180 mg/kg daily i.v.	14–21 days	Nephrotoxicity, hypomagnesaemia, hyper- and hypocalcaemia, hyper- and hypophosphataemia, hypokalaemia, nausea vomiting, genital ulceration	Dose must be adjusted according to renal function
Maintenance ganciclovir	Ganciclovir 3gr daily orally	Until CD4 count > $100 \times 10^6/l$ on HAART	As above	May be combined with intraocular implants Avoid in patients with diarrhoea Increases levels of didanosine
	Cidofovir 5 mg/kg once every 2 weeks	Until CD4 count > $100 \times 10^6/l$ on HAART	As above	As above
Alternative secondary prophylaxis regimens include daily intravenous foscarnet or ganciclovir, intravitreal injections of ganciclovir or foscarnet and intraocular ganciclovir implants				

Viral infections

Severe mucocutaneous and systemic infections with herpes simplex virus are best treated with aciclovir. Prophylaxis is used after severe infection and in patients with increasing severity and frequency of recurrences. These recurrences can be a prelude to the chronic persistent mucocutaneous ulceration characteristic of AIDS.

Varicella zoster virus infections are usually treated with high-dose aciclovir given by mouth. However, dissemination of infection from dermatomal zoster is unusual even without treatment.

Valaciclovir is a pro-drug of aciclovir which is used in the treatment of herpes zoster and herpes simplex infections of skin and mucous membranes. Valaciclovir is a L-valine ester of aciclovir that is rapidly converted to aciclovir after oral administration. The antiviral spectrum and mode of action is therefore the same as aciclovir. Aciclovir has, however, a low oral bioavailability (about 15–20%). Valaciclovir has three or four times the oral bioavailability of aciclovir.

Famciclovir is a diacetyl ester of 6-deoxy penciclovir which has been used in the treatment of herpes zoster and genital herpes infections. Famciclovir is metabolised to penciclovir in the intestinal wall and liver. Penciclovir and aciclovir have similar antiviral spectrum.

Aciclovir resistant herpes simplex infections can occur, particularly in patients with advanced disease and severe immunosuppression. Alternative agents to treat resistant infections include foscarnet and cidofovir.

Reactivation of cytomegalovirus with viraemia and end-organ disease tends to occur when CD4 cell counts are persistently below $50 \times 10^6/l$. Ganciclovir (an acyclic analogue of deoxyguanosine), foscarnet phosphonoformate (a pyrophosphate analogue, which inhibits polymerase enzymes) and cidofovir (a nucleoside analogue with potent *in vitro* activity against viruses) are used for the treatment of cytomegalovirus retinopathy, gastrointestinal and neurological disease. Treatment arrests progression retinitis in most patients, and maintenance therapy is required in those patients who continue to be severely immunosuppressed to delay the time to further relapse. There is little comparative data to guide initial choice of treatment. A study comparing ganciclovir with foscarnet for treatment of CMV retinitis found no difference between the drugs in their ability to delay progression of disease, but there was a survival advantage in those patients treated with foscarnet. However, foscarnet is not as well tolerated as ganciclovir, as it produces reversible renal failure and electrolyte disturbances. Careful and frequent monitoring is required which complicates outpatient management. The major side-effect of ganciclovir is bone marrow suppression, particularly neutropenia. Support therapy with granulocyte colony stimulating factor (G-CSF) maybe required.

The detection of mutations in the CMV UL97 gene is associated with an increase in CMV DNA levels in blood and clinical progression of CMV retinitis during ganciclovir therapy. High-level resistance to ganciclovir results in cross-resistance to cidofovir. Resistance to foscarnet can occur but the mechanism is different.

Cidofovir has been shown to be effective however in delaying progression and time to relapse in patients who have experienced therapy failure on ganciclovir and foscarnet. The dosing schedule of cidofovir is convenient and more suitable to outpatient care than with either intravenous ganciclovir or foscarnet. It is given once weekly (5 mg/kg) for two weeks as induction therapy and then at the same dose every two weeks thereafter as maintenance therapy. The main side-effect is

Box 9.3 Management of CMV disease: key points

- Population at highest risk of clinical disease: CD4 $< 50 \times 10^6/l$ positive CMV viraemia
- Diagnostic criteria: combination of clinical presentation +/- histopathology +/- virus isolation (culture or antigen detection)
- Choice of first line therapy dependent upon renal function, haematological indices and risk of toxicity
- Where possible all patients should be started on an effective HAART regimen to increase the CD4 count to above $100 \times 10^6/l$
- Secondary prophylaxis maybe discontinued once the CD4 count has risen and remains above $100 \times 10^6/l$

Table 9.3 Opportunistic infections: recommendations for initiation of primary prophylaxis

Opportunistic infection	Recommendations
<i>Pneumocystis carinii</i> pneumonia	CD4 count $< 200 \times 10^6/l$
Cerebral toxoplasmosis	CD4 count $< 100 \times 10^6/l$ and positive Ig G toxoplasma serology
Mycobacterium avium complex	CD4 count $< 50 \times 10^6/l$
CMV disease	under evaluation: may consider if CD4 $< 50 \times 10^6/l$ and positive CMV viraemia
Tuberculosis	If recent close contact of smear positive index patient and no evidence of active clinical disease National Guidelines for use of Tuberculin skin testing for screening varies.

Figure 9.6 Penile ulceration caused by intravenous foscarnet therapy.

nephrotoxicity. The dose needs to be adjusted or treatment delayed or discontinued if there is evidence of renal tubular dysfunction, for example proteinuria, hypophosphataemia and impaired creatinine clearance.

The choice of initial treatment is therefore dependent on the preferred dosing schedule, the risk of drug-associated toxicity and previous anti-CMV treatment history. Alternative treatment strategies include combination regimens of foscarnet and ganciclovir, intravitreal injections of ganciclovir or foscarnet and intraocular implants of ganciclovir. The latter effectively prevents relapse in the treated eye for up to three months but there is an increased risk of early retinal detachment. There is a risk of CMV disease occurring in the contralateral eye or elsewhere, and thus concomitant oral ganciclovir is indicated.

Following induction therapy, secondary prophylaxis is required but can be safely discontinued without risk of relapse of retinopathy in patients who have responded to highly active antiretroviral therapy (HAART). Improved cytotoxic T-lymphocyte responses to CMV and suppression of CMV viraemia is seen in those patients with advanced disease who sustain a rise in CD4 count on HAART. Effective antiretroviral therapy has resulted in dramatic falls in the incidence of new episodes of CMV disease and of relapse. However, in patients who remain severely immunosuppressed and at risk of CMV disease and relapse, secondary prophylaxis is required. Daily intravenous foscarnet or ganciclovir regimens require an indwelling intravenous catheter which is inconvenient and complicated by the risk of bacterial infections. Either daily oral ganciclovir or two-weekly intravenous cidofovir are preferable. Although ganciclovir is poorly absorbed, the oral preparation at a daily dose of 3 g has similar efficacy to intravenous regimens in preventing progression of retinitis. Combinations of ganciclovir with greater oral bioavailability are under evaluation.

Primary prophylaxis against CMV retinitis with oral ganciclovir has been investigated, but the results of two large clinical trials are conflicting, and in view of the high cost has not gained acceptance in routine clinical practice. Immune preservation or reconstitution as a result of HAART is the best prophylaxis (both primary and secondary) against CMV end-organ disease and other major opportunistic infections.

Table 9.4 Fungal opportunistic infections

Infection	Drug	Duration	Side-effects	Comments
<i>Candidiasis</i>				
Local treatment	Nystatin oral suspension or pastilles, miconazole oral gel or amphotericin lozenges all 4–6 times a day	As required		Systemic therapy is commonly required
Systemic treatment	Ketoconazole 200 mg a day (p.o.)	1–2 weeks	Nausea (less if taken with food), abnormal liver function tests, hepatitis thrombocytopenia, rash	In patients who remain severely immunosuppressed, relapse is common and maintenance therapy is required
	Fluconazole 50–200 mg a day (p.o.)		1–2 weeks	Nausea, abnormal liver function tests
	Itraconazole capsules or solution 200 mg/day (p.o.)	1–2 weeks	Nausea, abnormal liver function tests	As above
<i>Cryptococcosis</i>				
Treatment	Amphotericin B 0.7–1.0 mg/kg/day (i.v.) ± flucytosine 75–100 mg/kg/day in 3–4 divided doses		Nausea, vomiting, rash, bone marrow suppression, renal impairment, hypocalcaemia	In patients who remain severely immunosuppressed, relapse is common and maintenance therapy is required
	or Fluconazole 800 mg daily 1–3 days 600 mg daily thereafter (p.o. or i.v.)		As above	Liposomal preparations of amphotericin reduces risk of nephrotoxicity

Fungal infections

Dermatophytic fungal infections respond well to imidazole creams. Oral candida is often asymptomatic in its early stages and may not require treatment. In more severe infections local treatment with frequent nystatin suspension, or pastilles, or amphotericin lozenges can be used. Systemic treatment with oral ketoconazole or fluconazole daily is required for more severe oropharyngeal and oesophageal candidiasis. Long-term maintenance treatment may be required to prevent recurrences, and liver function tests should be monitored. Clinical resistance to treatment can occur and in the case of fluconazole may be related to emerging candida species that are less sensitive to fluconazole or to *Candida albicans*-resistant strains. Intermittent therapy rather than maintenance may be a more appropriate strategy to reduce this risk but has yet to be assessed in a large controlled trial. Itraconazole solution has been found to be useful in cases of clinical resistance and this may be related to its topical action, better absorption and greater spectrum of activity.

Vulvovaginal candidiasis can be a recurrent problem in women and should be treated either with topical agents (clotrimazole or miconazole pessaries and cream) or single high dose fluconazole.

Cryptococcal meningitis is treated with either fluconazole or amphotericin B with or without flucytosine. A large comparative study has shown that the overall mortality was similar in both treatment groups. However, there were more early deaths in the fluconazole group, and amphotericin sterilised the cerebrospinal fluid more rapidly but fluconazole was better tolerated. There was a 20% mortality and the factors predictive of death were an abnormal mental state, a cryptococcal antigen titre above 1 024 and a white cell count below $0.02 \times 10^9/l$ in the cerebrospinal fluid. Physicians will probably therefore prefer to treat patients with these poor prognostic markers with amphotericin rather than fluconazole. With a 20% mortality irrespective of what treatment is used it is clear that improvements in treatment are required.

Maintenance treatment is required in those who remain severely immunosuppressed, as relapse is common. Fluconazole (200 mg/day) was more effective than amphotericin B (1 mg/kg/week) in a large randomised study. The comparative efficacy of higher doses of amphotericin maintenance treatment is unknown. Liposomal preparations of amphotericin B may be useful, particularly in patients at risk of renal toxicity. Controlled studies of high doses of fluconazole suggest greater efficacy. As with other severe opportunistic infections, immune reconstitution following HAART will allow safe discontinuation of secondary prophylaxis regimens.

Amphotericin B is still the mainstay of treatment of other systemic fungal infections. Itraconazole has shown to be effective in induction and maintenance treatment of disseminated histoplasmosis.

Bacterial infections

Tuberculosis in HIV infection is treated in the standard way with isoniazid and rifampicin plus either pyrazinamide or ethambutol. Rifampicin is a potent enzyme inducer and increases the metabolism of drugs such as oral contraceptives, dapsone, fluconazole, ketoconazole and anticonvulsants. Clinicians should also be aware of drug interactions between rifamycins (rifampicin and rifabutin) and antiretroviral drugs, particularly the protease inhibitors (PIs) and the non-nucleoside reverse transcriptase inhibitors (NNRTIs). Certain combinations of each are contraindicated or require dose adjustment to

Ethambutol 15 mg/kg/day daily
+
Either Rifabutin 450–600 mg daily
Rifampicin 450–600 mg daily
Ciprofloxacin 500 mg twice daily
Clofazimine 100 mg daily
3 or 4 drug regimens are recommended

maintain therapeutic levels. Knowledge of these potential interactions is essential to avoid loss of clinical efficacy or increased risk of drug toxicity.

Although extrapulmonary disease is more common in HIV seropositive patients than in uninfected controls, the responses to treatment appear similar in the developed world if patients are compliant. Over the last few years there have been several outbreaks of tuberculosis with multiple drug-resistance (MDR) in the USA and Europe including the UK. Transmission of drug-resistant strains has occurred between patients and from patients to family members, healthcare workers and prison guards. Mortality from drug-resistant tuberculosis in this setting is high, around 70–90%. To reduce the risk of MDR TB it is essential to ensure adherence to antituberculosis therapy by patients and for healthcare facilities to have in place procedures and facilities to reduce the risk of nosocomial transmission.

Disseminated infection with *Mycobacterium avium* complex (MAC) causes considerable morbidity and mortality in the later stages of HIV infection (when CD4 counts are persistently below $50 \times 10^6/l$). Various combinations of drugs have been shown to decrease mycobacteraemia and improve symptoms in uncontrolled studies. Four, three and two drug regimens have and are being assessed in clinical trials. A commonly used regimen in clinical practice is rifampicin or rifabutin (450–600 mg/day), ethambutol (15 mg/kg, max 1 g/day) and clarithromycin (500 mg twice a day). Other drugs that have been studied and may be considered include: clofazimine (100 mg/day), ciprofloxacin (500–75 mg twice a day), parental amikacin (7.5–15 mg daily for 2–4 weeks) and another macrolide azithromycin.

Primary prophylaxis has been shown to significantly reduce the incidence of M.avium complex bacteraemia and should be considered in patients whose CD4 counts are less than $75 \times 10^6/l$. A variety of agents have been shown to be effective including rifabutin 300 mg daily, clarithromycin 500 mg twice daily or azithromycin 1200 mg once weekly. Resistant strains on clarithromycin and azithromycin prophylaxis can occur in those who develop breakthrough bacteraemia, and there is cross-resistance. A combination of once weekly azithromycin and once daily rifabutin is probably the most effective prophylaxis regimen and may also provide additional prophylaxis against PCP.

Salmonella infections are treated with either co-trimoxazole or ciprofloxacin and campylobacter with ciprofloxacin. In salmonella infections relapses of enteritis or bacteraemia are common.

Antiretroviral drugs

The clinical effectiveness of antiretroviral therapy has improved markedly over the last few years. Since 1996 in the developed world there have been dramatic falls in the incidence of new AIDS cases and AIDS-associated deaths. Published data in the late 1990s estimated the mortality rate in patients with CD4 counts of less than $100 \times 10^6/l$ had fallen by nearly two-thirds to <8 per patient years. Although the long-term clinical efficacy of the current antiretroviral treatment regimens remains uncertain, the biological rationale for maintaining a clinical response has been established. Sustained inhibition of viral replication results in partial reconstitution of the immune system in most patients, substantially reducing the risk of clinical disease progression and death. Reservoirs of HIV in latently infected resting T-lymphocytes and other long-lived cell populations makes it unlikely that HIV can be eradicated by antiretroviral therapy alone. Strategies to sustain suppression of viral replication in the long-term will be necessary.

Figure 9.9 Immune reconstitution of disease: MAC lymphadenitis in a patient recently starting HAART

Table 9.5 Targets for antiretroviral therapy

Target	Treatment
Virus receptor and entry	Fusion inhibitors, chemokine receptor blockers
Reverse transcriptase	Inhibitor/DNA chain terminators
RNAase	Inhibitors
Integration	Viral integrase inhibitors
Viral gene expression	Inhibitors of HIV regulatory genes and their products
Viral proteins synthesis	Enzyme inhibitors, for example, protease inhibitors
Viral budding	Interferons (also act at other sites of replication cycle) antibodies and ligands

Antiretroviral regimens for the initial treatment of chronic infection in adults (2001). Choice would depend upon efficacy, tolerability, adherence and resistance profile of the regimen. Treatment guidelines are constantly reviewed and updated.

ABC of AIDS

There are several potential targets for antiretroviral drugs in the viral replication cycle. Three classes of antiretroviral drugs are currently used in combination for the treatment of HIV infection, which target the activity of two viral enzymes. New therapeutic agents are constantly being evaluated.

Reverse transcriptase inhibitors

The first drugs made available for clinical use were inhibitors of the HIV reverse transcriptase enzyme. Before the virus can be integrated into the host cell genome DNA, a copy of the viral RNA has to be formed (pro-viral DNA). This is regulated by the specific HIV DNA polymerase: reverse transcriptase (RT). If a DNA copy is not formed, the viral RNA genome becomes susceptible to destruction by cellular enzymes.

The nucleoside reverse transcriptase inhibitors (NRTIs) are both competitive inhibitors of RT and DNA chain terminators. The normal 2' deoxynucleosides which are substrates for DNA synthesis link to form a chain by phosphodiester linkages bridging the 5' and 3' positions on the five carbon sugar molecule. The 2', 3'-dideoxynucleosides analogues are formed by the replacement of the 3'-hydroxy group by an azido (zidovudine), hydrogen or other group. These nucleoside analogues as substrates will bind to the active site of the HIV RT enzyme and will be added to the growing HIV proviral DNA chain. However, once inserted, the normal 5' to 3' links will not occur resulting in HIV proviral DNA chain termination.

Genotypic mutations at various codons in the RT gene result in decreased susceptibility of HIV to inhibition by the NRTIs. Several NRTIs are currently licensed for the treatment of HIV infection in combination regimens and newer agents with better tolerability and resistance profiles are under evaluation.

The non-nucleoside reverse transcriptase inhibitors (NNRTIs) are a group of structurally diverse agents which bind to RT at a site distant to the active site resulting in conformational changes at the active site and inhibition of enzyme activity. These agents show high antiviral activity *in vitro* and have relatively low toxicity. They are also highly specific, inhibiting the reverse transcriptase of HIV-1 but not HIV-2. As monotherapy, rapid emergence of resistant strains associated with single point mutations of the RT gene, high-level phenotype resistance and loss of antiviral effect occurs. The drugs therefore need to be combined with other antiretroviral agents, usually two NRTIs, to achieve and maintain an effective long-term treatment response.

Protease inhibitors

The protease inhibitors bind competitively to the substrate site of the viral protease enzyme. This enzyme is responsible for the post-translational processing and cleavage of a large structural core protein during budding from the infected cell. Inhibition results in the production of immature virus particles. Their potent anti-HIV activity and introduction to clinical use from 1996 was one of the main reasons for the observed substantial falls in morbidity and mortality associated with HIV infection in the developed world. However, tolerability, relatively high pill burden and poor adherence were frequent problems with the initial protease inhibitor containing regimens. Specific genotypic mutations in the protease gene can result in high levels of phenotype resistance to individual protease inhibitors and cross-resistance. New protease inhibitors are under evaluation.

Figure 9.10 Mechanism of action of nucleoside reverse transcriptase inhibitors

Figure 9.11 MAC infection causing multiple cutaneous pustular lesions in a severely immunosuppressed patient after initiating HAART

Treatment of chronic adult infection

In the mid 1990s, several large clinical endpoint studies demonstrated a strong association between falls in plasma HIV RNA levels (plasma viral load) in the first few weeks on therapy and clinical outcome at one year. It is now accepted that falls in plasma viral load combined with increases in CD4 count are predictive of the clinical treatment response on different combination regimens at 1–2 years, although changes in the markers probably do not fully predict the observed clinical effect.

Studies have also shown an association between the plasma viral load nadir on therapy and both the risk of subsequent viral load rebound, and the emergence of viral genotypic mutations associated with reduced drug susceptibility. Where possible an objective of antiretroviral therapy is to reduce and sustain plasma viral load levels to below the level of detectability of the current ultra-sensitive viral load assays (< 50 copies/ml). If patients are adherent to therapy, the likelihood of a viral load rebound and drug resistance is minimal. Despite inhibition of viral replication in plasma, lymph nodes and at other sites, reservoirs of HIV infection in latently infected resting T-lymphocytes remain. Continued activation of these cells will theoretically result in the reduction of this reservoir, however new cells probably continue to be infected either as a result of localised small bursts of viral replication or loss of the antiretroviral effect of the treatment regimen. Even in patients who have sustained, undetectable levels of plasma viral load (< 50 copies/ml) for three years or more, discontinuation of antiretroviral therapy results in rapid rebound of plasma viral load to pretreatment levels.

Sustained inhibition of viral replication does however result in substantial immune reconstitution, even in those patients with advanced disease who start antiretroviral therapy at very low CD4 counts. Reduction in immune activation markers, increases in both memory and naïve CD4 and CD8 T cells and development of improved lymphoproliferative responses to antigens such as CMV and mycobacteria occur in patients on HAART. Immune responses to HIV are generally not regained, and it remains uncertain what levels of immune reconstitution can be achieved over time. This may depend on any residual thymic function or the ability of extrathymic pathways to facilitate immune reconstitution.

To achieve sustained falls in plasma viral load it is standard of care in patients starting antiretroviral therapy for the first time to use a triple drug regimen containing two NRTIs in combination with either one NNRTI or one or two protease inhibitors. In clinical trials, a combination of two NRTIs and a protease inhibitor has been shown to reduce the risk of progression to AIDS or death compared to treatment with two NRTIs alone. There is no similar clinical endpoint data for NNRTI-containing combinations, however randomised trials have shown that treatment with a combination of two NRTIs and one NNRTI results in similar falls in plasma viral load and increases in CD4 count after one year to treatment with two NRTIs and a protease inhibitor. On the basis of these results, it is recommended to initiate therapy with either a PI or an NNRTI containing triple combination. Large randomised trials are under way to evaluate which starting regimen is better in the long term.

The efficacy of antiretroviral therapy has improved over the last few years, however only approximately 50–70% of patients will have sustained plasma viral loads to <50 copies/ml at one year. An important factor associated with treatment success is adherence. Patients who are able to tolerate and adhere to their treatment regimen are more likely to achieve and sustain

Box 9.6 Factors associated with virological treatment failure

- poor adherence
- drug intolerance and toxicity
- drug–drug interactions resulting in sub-optimal drug levels
- development of genotypic mutations associated with reduced drug susceptibility
- pharmacological resistance resulting in decreased intracellular drug levels

ABC of AIDS

suppression of plasma viral load than those who do not. Few patients experience virological treatment failure as a result of poor antiviral potency. The ability of a patient to adhere to a treatment regimen is important in determining the choice of treatment regimen. The dosing schedule, pill burden, the requirement or not for dietary restrictions, risk of side-effects and patient motivation are important in determining adherence. Other factors which contribute to the initial treatment choice are baseline viral load, resistance profile of the drug, future options for treatment, known efficacy of the treatment regimen, the potential for drug to drug interactions and the presence of drug resistance at baseline.

The optimal time to initiate therapy with the current antiretroviral drugs has not been established in clinical studies. CD4 count and plasma viral load are predictors of the estimated risk of progression to AIDS which is a factor in determining when to start treatment. The motivation of a patient to start and adhere to therapy and the known effectiveness of current regimens are also important. Clinical practice across Europe and North America varies, but most clinicians would consider initiating therapy at some point between a CD4 count of $200\text{--}500 \times 10^6/l$ and in all patients who are symptomatic. Even in patients who initiate therapy with CD4 counts of $<100 \times 10^6/l$, substantial increases in CD4 count and clinical benefit can be achieved. Patients on therapy should have CD4 count and plasma viral load levels monitored at regular intervals. On effective therapy, plasma viral load falls rapidly as viral replication is inhibited. By four weeks a fall of greater than 1 log and by 3–6 months a fall to <50 copies/ml should be expected.

Apart from drug intolerance, indications to change therapy have not yet been fully defined and evaluated. Physicians, however will use evidence of clinical progression, a fall in CD4 count and a rise in plasma viral load as markers of therapy failure, and consider changing therapy. When to switch therapy will also depend on available treatment options, patient adherence and the emergence of drug resistance and the potential for cross-resistance to other drugs.

In the antiretroviral experienced patient, the objective of therapy remains similar to that in patients starting treatment for the first time. Therapeutic options, however, are more limited because of previous drug toxicity and the presence of genotypic mutations conferring drug resistance.

Treatment of primary infection

It remains uncertain whether patients who present with acute primary HIV infection should be started on antiretroviral combination therapy. It is likely that the quality and breadth of cytotoxic T lymphocyte-cell (CTL) responses to different HIV antigens at the time of primary infection determines how well the immune system controls HIV replication over time. Studies have also shown that specific T-helper cell responses to HIV antigens are rapidly lost during primary infection, disabling the immune response to HIV. In patients who start antiretroviral therapy within the first few weeks of initial infection, specific T-helper cell responses to HIV are preserved, and CD4 cell counts are higher compared to the levels in patients who do not start therapy. The relevance of this immunological benefit is uncertain, or whether there is any long-term clinical advantage compared to patients who initiate effective antiretroviral therapy at some point during established chronic infection. Even after 2–3 years of sustained reduction in plasma viral load, discontinuation of therapy results in rapid viral rebound. Whether specific immune responses to HIV are more likely to be preserved and the level of viral load on discontinuation of

Figure 9.13 Changes in CD4 count and plasma HIV RNA levels (viral load) in patients treated with HAART

Box 9.7 Factors determining when to start and choice of therapy

- Risk of clinical disease progression (CD4 count, viral load)
- Willingness of patient to start therapy
- Clinical effectiveness of combination regimen
- Ability and motivation of patient to adhere to therapy
- Drug toxicity profile
- Pill burden and dosing schedule
- Transmitted drug resistance
- Future therapy options
- Likelihood of drug resistance
- Drug–drug interactions

Box 9.8 Treatment of primary HIV infection

Pros:

- Preserve immune function including specific T helper cell responses to HIV
- Decrease magnitude of virus dissemination and establishment of viral reservoirs
- Potentially alters viral set-point in favour of slower disease progression on discontinuation of HAART

Cons:

- Longterm toxicity associated with drug treatment, potential for therapy failure and emergence of drug resistance
- Uncertainty of improved longterm clinical benefit compared to initiating treatment during established chronic HIV infection
- Probably need to treat within a few weeks of exposure to HIV infection to gain immunological benefit.

therapy is lower than might have occurred in patients who were not treated during primary infection is not known. Antiretroviral therapy should be considered in patients presenting with acute primary HIV infection, however the immunological arguments need to be balanced against the unknown long-term efficacy of such a strategy, the risk of drug toxicity over time and the development of drug resistance.

Drug resistance

Soon after the introduction of zidovudine into clinical practice it was recognised that viral isolates taken from patients six months after therapy were less susceptible to zidovudine than at baseline. The emergence of genotypic mutations in the reverse transcriptase gene was associated with reduced susceptibility. Genotypic and phenotypic resistance can develop against all currently antiretroviral drugs and is a major factor contributing to therapy failure. Multiple mutations in the RT and the protease genes have now been identified to be associated with reduced drug susceptibility. The pattern and number of mutations which emerge and whether they confer cross-resistance within the class differs between each drug and regimen. For certain drugs, for example, lamivudine, nevirapine or efavirenz, the emergence of a single point mutation within the RT gene confers a very high fold decrease in susceptibility. For other drugs the fold decrease in susceptibility is much lower and multiple mutations may be needed to confer high-level drug resistance. Cross-resistance within a class can occur particularly with the NNRTIs and the protease inhibitors. For the NNRTIs this requires single genotypic mutation only, while for the protease inhibitors this usually requires a primary mutation plus four or five other secondary mutations. The emergence of resistance to all drugs does not always occur with a combination in a patient who experiences virological rebound on therapy. Some patients do not develop any genotypic mutations on treatment failure and this may reflect poor adherence and low drug selection pressure. Patients who achieve sustained falls in plasma viral load to less than 400 copies per ml are less likely to develop genotypic mutations associated with drug resistance than those who do not. Drug-resistant viruses can be transmitted and various recent studies have shown that 10–15% of patients presenting with primary HIV infection have genotypic mutations associated with drug resistance particularly in the RT gene. Drug-associated genotypic mutations usually fade on withdrawal of drug therapy but frequently rapidly re-emerge if the same drugs are taken again in combination.

The presence of drug resistance may affect the choice and efficacy of therapy in patients who have previously failed one, two or more combination regimens. Genotypic and phenotypic resistance assays are available in clinical practice and early randomised studies suggest that their utility in helping with the choice of therapy may result in greater falls in viral load in the short term. There are larger randomised studies ongoing and the exact role of these assays in clinical practice is yet to be established. The usefulness of these assays may depend upon the availability of alternative effective antiretroviral agents in a treatment experienced patient.

Drug toxicities

The tolerability and side-effects of a combination regimen is very important in determining the antiviral response. In clinical practice 40–50% of patients will not have sustained falls in plasma viral load by one year of therapy and a major factor contributing to this is poor tolerability. Drug-specific side-effects are listed in Table 9.6.

Table 9.7 Common Primary Genotypic Mutations associated with reduced drug susceptibility in-vivo

NRTIs	Codon
Zidovudine	K70N, T215Y
Abacavir	K65R, L74V, M184V
Didanosine	L74V
Lamivudine	M184V
Zalcitabine	K65R, T69D, L74V
Stavudine	T215Y + other TAMS ¹
Multi nucleoside resistance	Q151M, T69S-SS
NNRTIs	
Nevirapine	K103N, V106A, Y181C, G190A, Y188C/L/H
Efavirenz	K103N, G190A, Y188C/L/H
PIs	
Saquinavir	G48V, L90M
Ritonavir	V82A/T/F
Indinavir	M46I/L, V82A/T/F
Nelfinavir	D30N, L90M
Amprenavir	I50V, I54L/M, I84V

1. TAMS: Thymidine analogue mutations
2. Resistance profile of lopinavir/r in-vivo is uncertain

Clinically relevant phenotypic resistance may require only a single primary mutation or 2 or more primary and secondary mutations. Interpretation of a genotypic test is complex and requires expert advice.

Box 9.9 Role of resistance testing

- detection of transmitted resistance in primary infection
- detection of resistance prior to starting treatment for the first time
- guide choice of new treatment regimen in patients experiencing virological treatment failure on first or subsequent regimens
- guide treatment choice in pregnant mothers for prevention of vertical transmission

The utility of genotypic and phenotypic resistance tests are continuing to be evaluated.

ABC of AIDS

In the last two to three years abnormalities of fat redistribution have been observed in patients on combination regimen. Observational cohort studies suggest that lipodystrophy may occur in up to 50–60% of patients after one to two years on therapy. Patients either present with peripheral fat wasting affecting the buttocks, limbs and face or fat accumulation round internal viscera in the abdomen resulting in a distended abdomen and bloating. The exact pathogenesis of these fat distribution syndromes is unknown but age of patient, antiretroviral drug therapy and time on therapy may all be implicated. They have been reported in both protease inhibitor and NRTI-containing combination regimens, and it is likely that it is a mixed syndrome with a multifactorial cause. The occurrence of lipodystrophy can affect the psychological well being of the patient but as yet we do not know how it is best managed.

It has recently been suggested that mitochondrial toxicity may account for some of the toxicities associated with the NRTIs as a result of inhibition of mitochondrial gamma DNA polymerase. Severe lactic acidosis is a rare complication of NRTI therapy.

Future agents

For the reasons of poor tolerability, suboptimal antiviral potency and long-term drug toxicity, it is important that new antiretroviral agents and therapeutic strategies are developed and evaluated. New formulations of current drugs which improve tolerability and reduce pill burden will help to improve adherence in patients. New protease and reverse transcriptase inhibitors are currently undergoing clinical trials which *in vitro* appear to be effective against viral isolates which are resistant to different drugs. Whether these agents will prove to be clinically effective will be important in treating those patients who have previously failed combination therapies.

New classes of drugs are also being developed. Fusion inhibitors which block the activity of the GP41 viral transmembrane protein are in Phase III clinical trials and are likely to be the first new class of drug to reach the bedside.

As well as specific drugs that inhibit targets in the viral replication cycle, immunotherapeutic approaches are so being assessed. Treatment with cycles of the cytokine interleukin 2 results in substantial increase in CD4 counts but has little effect on plasma viral load levels. Interleukin 2 may also improve immune responses to HIV and a large randomised international trial is underway to assess its efficacy in combination with effective antiretroviral combination regimens. Therapeutic vaccines are also under evaluation which might improve specific immune responses and assist immunological control of HIV replication. Their clinical effectiveness remains uncertain.

Few areas of medicine have seen such dramatic changes in treatment with a resulting reduction in morbidity and mortality as there has been in patients with HIV infection. It is very likely that therapeutic options will continue to improve, although the long-term efficacy of treatment over many years still remains uncertain.

Table 9.8 Drug toxicities

Drug	Toxicity
<i>NRTIs</i>	
Class associated	Lactic acidosis Hepatic steatosis Lipodystrophy (peripheral fat wasting)
Drug specific	
Zidovudine	Bone marrow suppression, nausea, vomiting, myopathy
Stavudine	Peripheral neuropathy, hepatitis
Zalcitabine	Peripheral neuropathy, mouth ulcers
Didanosine	Pancreatitis, dry mouth, peripheral neuropathy
Lamivudine	Few side-effects
Abacavir	Hypersensitivity reaction, nausea
<i>NNRTIs</i>	
Nevirapine	Rash, hepatitis, Steven–Johnson syndrome
Efavirenz	Rash, dysphoria, mood changes, vivid dreams, hypercholesterolaemia, hepatitis
<i>PIs</i>	
Class specific	Lipodystrophy (fat wasting or accumulation) Hyperlipidaemia, diabetes mellitus
Drug specific	
Nelfinavir	Diarrhoea, rash
Saquinavir	Few side-effects
Indinavir	Hyperbilirubinaemia, nephrolithiasis, nail changes, dry skin
Ritonavir	Perioral dysaesthesia, flushing, hepatitis, diarrhoea, nausea, vomiting
Amprenavir	Rash, nausea, diarrhoea
Lopinavir	Diarrhoea

10 HIV infection and AIDS in the developing world

Alison D Grant, Kevin M De Cock

Epidemiology of HIV-1 and HIV-2 infections in developing countries

The epidemiology and burden of HIV in the developing world are discussed earlier (see chapter 1). Two distinct viruses, HIV types 1 and 2 (HIV-1/HIV-2), cause AIDS. HIV-1 is responsible for the great majority of infections globally, HIV-2 being very rare outside of West Africa. Individual cases of HIV-2 infection have been described in other parts of Africa, Europe, the Americas and Asia (India), but most people with HIV-2 infection have some epidemiological link to West Africa.

The routes of transmission of HIV-1 and HIV-2 (as described in chapter 1) are the same worldwide, but the relative importance of different modes of transmission differs according to region. In most developing countries, heterosexual transmission is the dominant mode of spread, and mother-to-child transmission of HIV is much more common than in industrialised countries. Homosexual transmission is rare in Africa, but is more common in south-east Asia and central and south America. Transmission associated with injecting drug use is particularly frequent in parts of south and south-east Asia and central and south America. Acquisition of infection from contaminated blood remains a problem, especially in parts of sub-Saharan Africa and south Asia; in some countries commercial blood donation acts to amplify the spread of transfusion-transmitted HIV infection, both to the recipients of blood as well as to donors who may become infected through exposure to unsterile equipment. Women and children are at especially high risk for transfusion-transmitted HIV infection, the former because of the high incidence of anaemia and haemorrhage associated with pregnancy and childbirth, and the latter because of malarial anaemia.

The transmission of HIV-2 infection is less efficient than that of HIV-1; this applies particularly to mother-to-child transmission, with only about 1% of HIV-2 infected mothers passing the infection on to their offspring. By comparison, up to 42% of HIV-1 infected mothers pass the infection to their children by all routes (intrauterine, puerperal and breast milk). Sexual transmission of HIV-2 is also less efficient, especially before the development of end-stage immune deficiency. Postnatal transmission of HIV-1 by breast milk is more important than previously believed and approximately doubles the risk of mother-to-child transmission.

Natural history of HIV-1 and HIV-2 infections in developing countries

There is still relatively little information available about the natural history of HIV-1 and HIV-2 infections in the developing world. Prospective studies from industrialised countries before highly active antiretroviral therapy (HAART) was widely used suggest that after 10 years of infection with HIV-1, approximately 50% of people will have developed AIDS. There has been a widespread belief that HIV-1 disease progresses more rapidly in developing countries, but more recent evidence suggests that the rate of progression from infection to severe immunosuppression may be little different from that documented in industrialised countries in the pre-HAART era.

Figure 10.1 UNAIDS estimates that 95% of people living with HIV/AIDS are in developing countries

Figure 10.2 A common clinical presentation of advanced HIV disease in African countries is with marked wasting, known in Uganda as “slim” disease (courtesy of Professor Sebastian Lucas)

Figure 10.3 Pruriginous dermatitis. This may be an early manifestation of HIV infection

ABC of AIDS

Because bacterial diseases such as pneumococcal disease and tuberculosis are prevalent in developing countries and may occur at relatively high CD4+ lymphocyte (CD4) counts, some HIV-infected persons may appear to become symptomatic earlier. In addition, outcome may be worse in developing countries than in the industrialised world because of lack of access to care: this is almost certainly the main explanation for the reduced survival following the development of an AIDS-defining illness in developing countries, generally around six to nine months.

Progression from infection to disease is substantially slower for HIV-2 infection compared with HIV-1. Evidence for this includes individual reports of long survival with HIV-2 infection, higher levels of CD4 counts in HIV-2- than in HIV-1-infected people in cross-sectional studies, and a lower incidence of CD4 decline and AIDS in cohort studies comparing HIV-1- and HIV-2-infected people. Nonetheless, HIV-2 may eventually cause severe immunosuppression, accompanied by disease which is clinically indistinguishable from that caused by HIV-1.

Clinical aspects of HIV disease in developing countries

As in industrialised countries, the spectrum of clinical manifestations associated with HIV infection is wide, ranging, as the CD4 count falls, from an asymptomatic state, through symptomatic disease, to fatal illness characterised by opportunistic infections, malignancies, neurological disease and wasting. Initial acquisition of HIV infection (“acute HIV infection” or “seroconversion illness”) may be complicated by a syndrome resembling infectious mononucleosis, or a wide range of other manifestations as described in chapter 4. However, since this syndrome is not specific, it is rarely recognised even when clinically apparent.

Early manifestations of HIV disease

Common early symptoms and signs are weight loss, fever, night sweats and diarrhoea. Skin disorders are frequent early manifestations, especially varicella zoster, fungal infections and pruriginous dermatitis, an itchy rash consisting initially of papules which become shallow ulcers due to scratching, and finally heal, leaving pigmented macules.

Tuberculosis

Tuberculosis is unquestionably the most important opportunistic infection complicating HIV infection in developing countries, and may present at any stage in the course of immunodeficiency. In early HIV disease, pulmonary tuberculosis is similar to that found in HIV-negative people. In advanced immunodeficiency, tuberculosis is often disseminated and multibacillary in nature. Nocardiosis, while much less common, is a differential diagnosis in some areas.

Bacterial septicaemia

An inadequately recognised manifestation of HIV disease in developing countries has been bacterial septicaemia. Gram-negative organisms are the most common pathogens identified, especially non-typhoid *Salmonella* spp. Invasive pneumococcal disease is also frequent, and may occur earlier than Gram-negative infections. In some patients with advanced HIV disease, mycobacteraemia is detectable; this is much more frequently due to *Mycobacterium tuberculosis* than *Mycobacterium avium intracellulare* complex.

Figure 10.4 Chest radiograph showing upper lobe cavitation typical of pulmonary tuberculosis. Appearances may also be atypical (see chapter 6)

Figure 10.5 Post-mortem lung showing miliary tuberculosis (courtesy of Professor Sebastian Lucas)

Figure 10.6 Tuberculosis may be multibacillary in HIV-infected patients: non-reactive tuberculous infection of the pericardium, showing abundant acid-fast bacilli (courtesy of Professor Sebastian Lucas)

Diarrhoeal disease and HIV wasting syndrome

The best known clinical picture of AIDS in Africa is “slim”, the term given by people in rural Uganda to the HIV wasting syndrome. Profound wasting, chronic diarrhoea and fever are the typical features. About half the time no specific aetiology can be found for the diarrhoea; among identified causes, the most common are cryptosporidiosis, microsporidiosis, isosporiasis and bacterial infections. The commonest autopsy finding in African patients with HIV wasting syndrome is disseminated tuberculosis, and undue emphasis may have been put on searching for a primary gastrointestinal cause of this whole syndrome. As with all medical causes of wasting, an important contributing factor to the HIV wasting syndrome is reduced food intake.

Neurological disease

Cerebral toxoplasmosis and cryptococcal meningitis are probably more frequent causes of severe HIV-related disease in developing than industrialised countries, and their prevalence may vary by geographical region. Cerebral toxoplasmosis most often presents as a space-occupying lesion of the brain, and cryptococcosis as a chronic meningitis.

Regional variation in disease spectrum

Tuberculosis and bacterial infections, particularly pneumococcal disease, are common HIV-related diseases in developing countries worldwide. Other HIV-related diseases show regional variation. Pneumocystosis, cytomegalovirus disease and disease due to atypical mycobacteria such as *Mycobacterium avium intracellulare*, common in industrialised countries, are unusual in adults in many African countries (although *Pneumocystis carinii* pneumonia is common in HIV-infected African infants). The reasons for this are uncertain, but may include development of diseases such as tuberculosis at higher levels of CD4 counts, and shorter survival once the stage of profound immunodeficiency has been reached. Endemic Kaposi’s sarcoma is more common in Central and East than in West Africa, and this is probably also true for the AIDS-associated form.

Some HIV-related diseases are limited to specific geographic areas, such as disease due to the fungus *Penicillium marneffei*, which is confined to south-east Asia. Penicilliosis causes disseminated disease in patients with advanced immune deficiency, with nodular skin lesions as the most obvious manifestation. Tuberculosis, salmonellosis and cryptococcosis are other frequent AIDS-defining conditions in south and south-east Asia. Tuberculosis is frequent in Latin America, where the spectrum of disease is otherwise similar to that in the industrialised world.

Association with endemic tropical diseases

The association between endemic tropical diseases and HIV infection has only been studied to a limited degree. Theoretically, HIV infection could increase the incidence of tropical diseases, and alter their natural history, clinical expression, or response to treatment. Malaria is indirectly linked to HIV infection by causing anaemia in children, who may then be at risk for HIV infection transmitted through blood transfusion. HIV-infected pregnant women experience greater frequency and severity of malarial parasitaemia, and increased frequency of placental malaria compared with HIV negative women. HIV-infected people with *Schistosoma mansoni* excrete fewer eggs than those who are HIV negative, but it is not known whether the severity of schistosomiasis is affected by HIV infection, and response to treatment seems to be unaffected by HIV status. Amoebiasis and strongyloidiasis might be expected to be more frequent in HIV disease, but are not; on the basis of

Figure 10.7 *Isospora belli*, a treatable cause of diarrhoea in HIV-infected people

Figure 10.8 India ink stain of cerebrospinal fluid showing *Cryptococcus neoformans*, a common cause of meningitis (courtesy of Professor Sebastian Lucas)

Figure 10.9 Cerebral toxoplasmosis: haemorrhagic and necrotic mass in the occipital lobe (courtesy of Professor Sebastian Lucas)

ABC of AIDS

limited data, the same seems to be true of trypanosomiasis and leprosy. Little information is available concerning the influence of HIV infection on filariasis. Visceral leishmaniasis, often disseminated, appears to be increased in incidence in HIV-infected persons, although most reports have been from southern Europe rather than sub-Saharan Africa or South America. HIV-infected persons with leishmaniasis require maintenance treatment as relapse is otherwise likely.

AIDS case definitions and staging of HIV disease

Case definitions of AIDS for epidemiological surveillance

For epidemiological surveillance, a practical case definition of severe HIV-related disease is needed. The Centers for Disease Control (CDC) AIDS surveillance case definition is used in many industrialised countries (see chapter 1), but cannot be used in most developing countries because it requires access to sophisticated laboratory investigations. For this reason, the World Health Organisation (WHO) introduced a clinical case definition that could be used in settings where laboratory facilities are inaccessible (Box 10.1). In 1994, this definition was expanded to incorporate HIV serology (thus increasing specificity) and to take account of revisions of the CDC case definition (Box 10.2). If serological testing is unavailable or inaccessible, the clinical case definition should be used; if serological testing is available, the expanded case definition should be used.

Diagnosis and clinical staging of HIV disease in resource poor settings

Although advanced HIV disease may be easy to diagnose clinically, it is desirable to have HIV serology on patients with suspected HIV disease, particularly since HIV negative tuberculosis may be clinically indistinguishable from advanced HIV disease.

The case definitions in Boxes 10.1 and 10.2 were developed for epidemiological surveillance, and are not intended to be used for clinical staging of patients, for which they are neither sensitive nor specific. In order to estimate prognosis in individual patients, a clinical staging system is more useful than a case definition. Box 10.3 overleaf outlines the WHO proposed staging system for HIV infection and disease, using clinical and laboratory data, which can be used in developing countries.

This system categorises patients into four stages based on clinical features of prognostic significance. The stages are interpreted as:

Stage 1: asymptomatic infection.

Stage 2: early (mild) disease.

Stage 3: intermediate (moderate) disease.

Stage 4: late (severe) disease.

The system can be refined using a laboratory axis: the CD4 count is the most useful laboratory marker for clinical staging, but is rarely available in developing countries. The total lymphocyte count can be used as a surrogate, although this is not ideal. Manifestations of HIV disease are rare at CD4 counts above $500 \times 10^6/l$ and severe illness and death are rare in patients with counts above $200 \times 10^6/l$. Tuberculosis and pneumococcal disease may occur at higher as well as lower CD4 counts. Once patients in developing countries have developed advanced HIV disease, they die with higher CD4 levels than in industrialised countries because of lack of access to high quality medical care; nonetheless, most patients die at the stage of advanced immunodeficiency.

Box 10.1 WHO AIDS case definition for AIDS surveillance

For the purposes of AIDS surveillance an adult or adolescent (>12 years of age) is considered to have AIDS if at least two of the following major signs are present in combination with at least one of the minor signs listed below, and if these signs are not known to be due to a condition unrelated to HIV infection.

Major signs

- Weight loss 10% of body weight
- Chronic diarrhoea for > 1 month
- Prolonged fever for > 1 month (intermittent or constant)

Minor signs

- Persistent cough for > 1 month*
- Generalised pruritic dermatitis
- History of herpes zoster
- Oropharyngeal candidiasis
- Chronic progressive or disseminated herpes simplex infection
- Generalised lymphadenopathy

The presence of either generalised Kaposi's sarcoma or cryptococcal meningitis is sufficient for the diagnosis of AIDS for surveillance purposes.

*For patients with tuberculosis, persistent cough for >1 month should not be considered as a minor sign.

Box 10.2 Expanded WHO case definition for AIDS surveillance

For the purposes of AIDS surveillance an adult or adolescent (>12 years of age) is considered to have AIDS if a test for HIV antibody gives a positive result, and one or more of the following conditions are present:

- 10% body weight loss or cachexia, with diarrhoea or fever, or both, intermittent or constant, for at least 1 month, not known to be due to a condition unrelated to HIV infection
- Cryptococcal meningitis
- Pulmonary or extrapulmonary tuberculosis
- Kaposi's sarcoma
- Neurological impairment that is sufficient to prevent independent daily activities, not known to be due to a condition unrelated to HIV infection (for example, trauma or cerebrovascular accident)
- Candidiasis of the oesophagus (which may be presumptively diagnosed based on the presence of oral candidiasis accompanied by dysphagia)
- Clinically diagnosed life-threatening or recurrent episodes of pneumonia, with or without aetiological confirmation
- Invasive cervical cancer

Figure 10.10 Squamous cell carcinoma of the conjunctiva: an unusual cancer, strongly associated with HIV infection. Its incidence has increased markedly in Uganda and Rwanda (courtesy of Dr Keith Waddell)

Box 10.3 Proposed WHO staging system for HIV infection and disease
Clinical staging

Patients with HIV infection who are aged ≥ 13 years are clinically staged on the basis of the presence of the clinical condition, or performance score, belonging to the highest level

- Clinical stage 1: asymptomatic or persistent generalised lymphadenopathy; performance scale 1 (asymptomatic, normal activity)
- Clinical stage 2: weight loss $<10\%$ body weight; minor mucocutaneous manifestations, varicella zoster within the last five years, recurrent upper respiratory tract infections (bacterial sinusitis); performance scale 2 (symptomatic but normal activity)
- Clinical stage 3: weight loss $>10\%$ body weight, unexplained chronic diarrhoea >1 month, unexplained chronic fever >1 month, oral candidiasis, oral hairy leukoplakia, pulmonary tuberculosis within the past year, severe bacterial infections; performance scale 3 (bedridden $<50\%$ of day during the last month)
- Clinical stage 4: most other CDC AIDS-defining diseases (but not pulmonary tuberculosis); performance scale 4 (bedridden $>50\%$ of day during the last month)

Clinical/laboratory classification

	Laboratory axis		Clinical axis			
			1 Asymptomatic	2 Early	3 Intermediate	4 Late
	Lymphocytes ($\times 10^6/l$)	or CD4 ($\times 10^6/l$)				
A	>2000	>500	1A	2A	3A	4A
B	1000–2000	200–500	1B	2B	3B	4B
C	<1000	<200	1C	2C	3C	4C

Treatment of HIV-infected people in developing countries

General approach

The general approach to treatment in developing countries should ideally be no different from that in the industrialised world, but is hampered by lack of infrastructure and resources for diagnosis and treatment. As for other diseases in resource-poor countries, treatment must often be decided on the basis of very limited information. Patients should be counselled about HIV infection and prevention of its transmission.

Treatment of opportunistic infections

Specific opportunistic infections should be treated as recommended (see chapter 9). Patients with some common diseases, such as tuberculosis and pneumococcal infection, usually respond well to standard treatment. Toxoplasmosis also responds well to treatment if diagnosed early, but as with many HIV-related diseases, is likely to relapse unless maintenance treatment is taken. In situations where precise diagnoses cannot be confirmed, a syndromic approach may be more practical. Individual symptoms such as diarrhoea or prurigo should be treated symptomatically if no treatable cause can be identified.

Prevention of opportunistic infections

Clinical trials have demonstrated the efficacy of preventive regimens against tuberculosis (for example, using isoniazid) among HIV-infected people in developing countries, and co-trimoxazole has been shown to reduce morbidity and mortality among HIV-infected individuals in Côte d'Ivoire. Both these interventions are now recommended by UNAIDS but have yet to be introduced on a large scale, particularly in the poorest countries, and will need to be evaluated under operational conditions. Pneumococcal polysaccharide vaccine was recently found to be ineffective in preventing invasive pneumococcal disease among HIV-infected people in Uganda; conjugate pneumococcal vaccines may be more effective, and are currently being investigated in children.

Antiretroviral therapy

Antiretroviral therapy is currently available to only a very small minority of HIV-infected people in developing countries. As

Figure 10.11 Kaposi's sarcoma: multiple skin nodules and plaques (courtesy of Dr AC Bayley)

Figure 10.12 Kaposi's sarcoma: bilateral leg oedema and inguinal lymph node enlargement, without any evident skin lesions (courtesy of Dr AC Bayley)

ABC of AIDS

antiretrovirals become less expensive, they will inevitably become more widely available and used. However, widespread implementation poses huge challenges in resource-poor countries, including identifying HIV-infected people before the stage of terminal disease; monitoring the response to therapy; continuity of drug supply; adherence, especially to complex regimens; and managing treatment failures. A priority will be to minimise the development of antiretroviral drug resistance by using rational and effective regimens, and maximising continuity of treatment and adherence. Resistance is probably inevitable unless triple drug regimens are used. Some populations will be easier to reach through existing infrastructures, such as occupational health schemes; tuberculosis programmes could also potentially be built upon if more resources were available.

Public health priorities

In response to the global epidemic of HIV/AIDS, WHO established the Joint United Nations Programme on HIV/AIDS (UNAIDS) in 1994. HIV/AIDS is the only disease for which a joint programme between several United Nations agencies has been established.

Essential components of public health programmes for HIV/AIDS

The key elements of public health programmes for HIV/AIDS are listed in Box 10.4. The global response to the HIV pandemic is based on fundamental principles, but HIV/AIDS prevention and control is implemented, successfully or unsuccessfully, at the local level. Involvement of heavily affected communities and non-governmental organizations has been crucial to a successful response. Key requirements of programmes are prevention of new infections, as listed in Box 10.4: youth (both in- and out-of-school), especially young women, are an important target group for HIV awareness and life-skills training. Preventing mother-to-child transmission is also important: antiretroviral drugs are most cost effective when used for this purpose, and effective and safe strategies for the reduction of transmission via breast feeding are also needed. Other important areas include prevention of discrimination and assurance of confidentiality for HIV-infected people, integration of sexually transmitted diseases control into HIV/AIDS prevention activities, and provision of services for HIV/AIDS care. Because of the close interrelationship between HIV/AIDS and tuberculosis, some countries have integrated tuberculosis and HIV/AIDS control activities.

Box 10.4 Essential components of HIV/AIDS programmes

Prevention of new infections

- Reduce sexual transmission
 - Awareness and life-skills education, especially youth
 - Condom promotion
 - STD control, including for commercial sex workers
 - Partner notification
- Blood safety
 - HIV testing of transfused blood
 - Avoid non-essential blood transfusion
 - Recruitment of safe donor pool
- Interventions to reduce transmission among injecting drug users (where necessary)
- Reduce mother–child transmission
 - antiretroviral therapy
 - avoidance of breast feeding (where safe): consider replacement feeding, or early weaning

Surveillance for HIV infections and AIDS

Voluntary counselling and testing

Mitigation of HIV-related disease

- Rational approach to care for HIV-related disease, especially tuberculosis
- Appropriate preventive therapies

Mitigating social impact

- Minimising stigma: respect for confidentiality, protection against discrimination
- Care for AIDS orphans

11 Injection drug use-related HIV infection

RP Brettle

Introduction

A variety of important medical problems, both infective and non-infective in nature, are associated with injection drug use (IDU) including the blood-borne viruses such as HIV, hepatitis B (HBV) and hepatitis C (HCV), all of which may be transmitted via the sharing of injection equipment. Consequently the medical care of patients using drugs requires a knowledge of both drug- and infection-associated conditions. The use of recreational drugs either occasionally or continually should not be a bar to or be used as a means of discriminating against access to health care in the UK as has been alleged recently. This right of access was explicitly addressed in the updated “*Guidelines on Clinical Management, Drug Misuse and Dependence*” published by HMSO in 1999. This report stated that:

- Drug misusers have *the same entitlement* as other patients to the services provided by the NHS.
- It is the responsibility of *all doctors* to provide care..., *whether or not the patient is ready to withdraw from drugs.*
- This should include *the provision of evidence-based interventions*, such as hepatitis B vaccinations, and providing harm minimisation advice.

Although combination therapy for HIV is not specifically mentioned in this document, because it is an evidenced based intervention the same principles apply.

Medical care systems

The difficulties of engaging drug users for medical care should not be underestimated. There are some particular characteristics of IDU that it may be helpful to be aware of, and the details will vary with geographical location (Box 11.1).

Drug users usually require a substantial supply of money to fund their addiction ‘habit’, which in itself results in other problems.

Not surprisingly the problems and illegality associated with the use of recreational drug use is associated with a number of difficulties for any health service in delivering medical care for drug users. For the health service these numerous crises, whether social, financial, legal, etc., lead to the impression of a chaotic lifestyle; in reality hospital appointments usually have a fairly low priority because of the enormity of their problems.

The social effects of HIV infection are similar for all risk groups – the infection effectively impoverishes the patient; however in the case of drug users these effects may be a little more dramatic.

More importantly the inability to fund a drug habit can have important consequences for a health service which are often not appreciated:

- A need to find additional sources of income – benefits fraud, drug dealing, hospitalisation (save money on food, etc.) – all of which increase the pressure on the NHS to prescribe addictive drugs (which may be greater than actual habit in order to provide additional funds).
- The physical weakness and mental slowing leads to peer victimisation.
- Practical problems such as problems with visitors, unexplained absences from ward, frequent self-discharge,

Box 11.1 General characteristics of IDU in UK

- Mainly an illegal activity
- Male dominated (10–30% females)
- Usually involves the young and initially healthy – 2 years before any contact with NHS
- Do not seem to be particularly health conscious
- Have often spent time in prison (up to 70%)
- Tend to have a crisis lifestyle
- Are often associated with violent or unpredictable behaviour, which in part is related to an excess of or withdrawal from recreational drugs and is more often than not related to problems with their peers

Box 11.2 Specific problems relating to drug addiction

- Expensive to maintain (£100–£200/day) and may be funded by a variety of means such as:
 - theft – car crime, burglary
 - fraud – credit and cheque cards, DSS benefits
 - drug dealing
 - prostitution – male or female
- Are often short of money
- May need to avoid police “warrants”
- Live for today (shortened “future time perspective”)
- May require 3–4 shots per day for opiates and every hour for cocaine

Box 11.3 Recreational drug use and health care

“Unreliable” individuals with chaotic type of lifestyle

- Irregular attendances – missed appointments, wrong day, frequent self-discharges from ward
 - Suspect motives for many of symptoms
 - Unexplained absences from wards
 - Disruptive visitors
 - Day/night reversal
 - Self-medication and drug dealing
 - Theft from other patients and staff
 - A threat for patients and staff
 - Attention seeking, demanding of time and often noisy
 - Aggressive behaviour both verbal and physical
 - Utilise a number of offensive weapons – knives, guns
- Come with a variety of staff “attitudes”
- “Others more deserving” of care
 - “Manipulative” of staff
 - “Dangerous”
 - “Frightening”
 - “Upset other patients”
 - “Not enough time”
 - “Never change”

ABC of AIDS

day/night reversal, theft of hospital property (related to a falling income), noise, manipulation of staff or other patients and attention-seeking behaviour.

- Increased frequency of verbal and physical abuse of both staff and other patients.

The net result may be an inability to cope in the community or the hospital, resulting in frequent precipitous admissions and discharges – “revolving door” type admissions with considerable frustration for patients, relatives and staff.

Without a *modified* healthcare system which understands and considers these problems, drug users have a tendency to record a high default rate in terms of attendance or frequent discharges from hospital units. The aim of an IDU service should be to initiate and maintain contact primarily in order to deliver health care and health education. The initiation and maintenance of that contact may require a variety of initiatives as described in box 11.5.

A system of providing both drug services as well as medical care from the same site by the same doctors seems to be an efficient model of care for drug users, whereas a system of delivering care via two distinct physical sites (one for drugs and one for physical care) is less efficient and seems to provide either a poor medical and/or a poor HIV service.

The dependency needs of IDU-related HIV are both physical and psychological. The physical care varies from mildly ill to high dependency, whilst on the psychological side it may vary from being entirely well to toxic confusional states, obsessive-compulsive states, anxiety and agitation as well as frank psychosis. The differential diagnosis is extensive and admission is commonly required to exclude the diagnosis of an organic psychosis. The time that patients may remain in a medical unit varies from a few days to over a month and this mixture of serious physical and mental ill health is rarely found in other areas of medicine. There is also the danger of fire from careless cigarettes, since the majority of patients smoke heavily and consume excessive amounts of sedative drugs. Because addiction to cigarettes seems to be greater or at least equal to opiates, it appears impossible to enforce a total no smoking policy for the inpatient areas if the policy of maintaining contact with patients is to be followed. In addition to the difficulties described above, there are also the problems of nursing individuals in some form of isolation. The requirement for cubicles is high as a consequence of an increased risk of infectious agents associated with HIV and IDU, such as tuberculosis. There is also an increased need for privacy because of mixed sexes (one third are female), mixed risk groups (homosexuals and drug users) and disturbed patients.

Management strategies for IDU-related HIV

There are a number of strategies which may be adopted in order to cope with IDU-related HIV admissions, including higher staffing levels, avoidance of high occupancy levels and continuity of care by both nursing and medical staff. Other issues are as listed overleaf:

Box 11.4 Social effects – physical and mental slowing

- More vulnerable to exploitation from peers
- More likely to get caught by the law
- Reduced income – “criminal unemployment”
- Increased demands on NHS to replace the missing funds
 - pressure for prescribed drugs
 - pressure for access to state benefits

Box 11.5 Initiatives for initiation and maintenance of contact with drug users

- Needle exchange
- Methadone prescribing
- Social provisions such as helping with housing
- Medical care

Box 11.6 Specific problems of IDU-related HIV for a health service

- Mixture of physical and psychological dependency
- Frequent security and fire incidents
- Increased need for cubicles
- Need for increased staffing levels

Box 11.7 Management strategies for IDU-related admissions

- Continuity of care from medical and nursing staff
- Increased numbers of nursing and medical staff
- Response to violence is to call police
- Tight control on drug prescribing
- A written smoking policy which is given to every patient on admission
- Coordination of drug prescribing between different agencies around admissions and discharges
- Increase contact with healthcare system gradually
- Clear guidelines and policies which all staff sign up to
- Such policies to be supportive and caring and based on health and safety principles
- Avoid situations leading to confrontation
- Avoid withdrawals in ward area but make it clear that no guarantee of increases on discharge
- Awareness of need for relief of pain and psychological distress

Box 11.8 Strategies for coping with IDU-related HIV admissions

- Violent activities, assaults, etc. are managed by calling the police. Patients need to be informed that recreational drug use is just as illegal in hospital as out, that other patients may complain to the police via a local drugs hot line if they observe illegal drug dealings or use on the wards and this could result in police raids.
- There is tight control of prescribed drugs early on in the disease process with accompanying harm reduction messages. The message concerning prescribing is that its function is to provide a safety net for the physical discomfort of addiction rather than to provide a free buzz or “stone”.
- There is a gradually increasing level of contact between hospital and patient over time which allows the service to get used to the behaviour of patients and for them to get used to the hospital’s routines. This is one form of re-socialisation for the individual with problem drug use.
- The aim is to provide a supportive and caring environment associated with firm discipline over misbehaviour and illegal activities. Wherever possible the rules are based on health and safety principles rather than moral or legal ones. Injecting in the hospital is forbidden because of the dangers to staff. Similarly being stoned is discouraged because of the increased risks of hypostatic pneumonia or fire hazards from concomitant smoking.
- A written smoking policy is provided to every patient on admission. It is based on health and safety principles and the need to reduce the danger of fires for everyone’s sake.
- The regime for outpatient appointments is reasonably flexible (anytime on a set day) in order to allow for missed appointments. However the patients are made aware of the need for some structure in the system by making the patient aware of the hospital’s limitations.
- The law relating to the prescribing of drugs such as methadone is explained in verbal and written instructions.
- Confrontation is generally avoided in situations that cannot be resolved. This means adapting the regime or removing the patient from the environment that they find difficult; this may require us either to allow the patient to self-discharge or if necessary to discharge the patient from the unit. The patients are always offered an outpatient appointment if they leave the hospital or are discharged.
- Treatment in the community is often arranged in order to avoid long spells in hospital. Increased drug taking in hospital or difficult behaviour is often a symptom of boredom and much can be done to avoid this, for instance by providing satellite TV or computer games.
- Coordination of substitute prescribing with other carers is very important to avoid double prescribing via hospital admissions. Careful prescribing on discharge is also required to avoid similar problems in the community.
- Illegal drug use in the ward requires careful discussion in order to arrive at a compromise over the amount of drugs prescribed and the amount of drugs used illegally. Generally this compromise is achieved by suggesting that the dose of prescribed drugs will be reduced until a satisfactory level of consciousness is achieved that reduces the fire risk and the necessity for increased nursing observation. Such reductions result in increased cost for the patient in terms of the need to purchase black market supplies of drugs.
- On occasions, in order to deliver inpatient care, illegal or extra drug use needs to be covered. In such situations the patients are warned that this does not imply any sort of contract or obligation for increased doses on discharge. If the admission is prolonged then an offer of detoxification to the doses prescribed would be made.
- Obvious withdrawal symptoms (alcohol or opiates) during a physical illness would be covered with extra doses of opiates or short courses of benzodiazepines (diazepam or chlordiazepoxide). Agitation from recent stimulant use would also be covered for inpatients. The prime aim would be to reduce the chance of agitation and disturbed behaviour in the wards.
- Fear of pain may be a major problem for drug-using patients. We have generally used either a subcutaneous infusion of opiate over and above maintenance drugs or the use of oral slow-release morphine preparations. Provided observation reveals that the patients are not excessively sedated from a health and safety point of view there is no upper limit on the doses employed to relieve pain.
- There may be concern amongst the staff over the level of prescribing of sedative drugs. The nursing staff need to have confidence in the medical management policy relating to sedative and pain control prescribing. A number of patients, particularly drug users, request high levels of sedation prior to death and this may cause concern amongst a number of staff, medical and nursing as well as relatives.

Management of IDU-related problems

Controlled Drug prescriptions

A working knowledge of the regulations surrounding Controlled Drug prescriptions is important when managing drug users. Attention to detail when a patient is admitted is imperative if centres are to avoid the problems of double prescribing. The front pages of the BNF give exact guidelines on how to prescribe Controlled Drugs legally and additional information is available via the updated *Guidelines on Clinical Management, Drug Misuse and Dependence* published by HMSO in 1999.

The medical effects of recreational drugs

Carers need to have a working knowledge of the effects of recreational drugs and equivalent doses of drugs (methadone or diazepam) if patients need to be temporarily covered for the effects of withdrawal. Tables of equivalence for opiates and benzodiazepines can be found in *Guidelines on Clinical Management, Drug Misuse and Dependence* (HMSO 1999). The differential diagnosis in a patient with IDU-related HIV is extensive and requires consideration of both infective and non-infective disorders. These are summarised in Table 11.1.

When patients are admitted with respiratory problems there is the dilemma of how to manage opiate prescribing.

- For those patients with mild respiratory depression a discussion over a temporary reduction in oral drugs by around 10–20% or splitting the daily dose into 3 or 4 doses may suffice.
- In those with more severe respiratory depression rapid improvement in pulmonary function is required. However if the opiate withdrawal is excessive as with intravenous bolus injections of naloxone, the patient may become disruptive with loss of venous access.
- The preferred solution is a naloxone infusion (2 mg in 500 ml perhaps starting at around 10 ml per hour) to achieve an acceptable improvement in respiratory rate (and therefore oxygenation) without too great an increase in physical arousal. The aim is to improve oxygenation rather than induce withdrawal from opiates. This improved oxygenation can be assessed by respiratory rate, oxygen desaturation or arterial blood gases. Such an infusion may be required for up to 48 hours in those on methadone because of its relatively long half-life compared to other opiates. In the event of a lack of venous access then regular small doses of intramuscular naloxone (0.2 mg i.m. every 1 hour initially) can also be employed to maintain oxygenation.

Excessive doses of benzodiazepines also produce drowsiness and/or coma which can usually be managed by simple supportive therapy with care over respiratory rate, etc. In extreme cases it is possible to utilise the antagonist flumazenil but there is a danger of inducing fits in those on chronic long-term doses. *It is therefore preferable to reverse the opiate element first (with an infusion of naloxone) before resorting to flumazenil.*

Opiate withdrawals should be considered in any agitated patient known to be on opiates, particularly those who have recently commenced drugs that induce liver enzymes such as rifampicin, rifabutin, phenytoin, etc.

Table 11.1 Medical (non-infection) problems of drug use

Problem	Medical complications
<i>Drug effects</i>	
Excess opiate	Narcosis, coma, small pupils, respiratory depression, aspiration pneumonia, and <i>rhabdomyolysis secondary to pressure</i>
Opiate withdrawal	Mild "URT" (sweating, coryza, lacrimation), pupillary dilatation, insomnia, nausea, vomiting, diarrhoea, lethargy, muscle weakness, myalgia, muscle twitching, tachycardia and hypertension
Excess cocaine	Apprehension, dizziness, syncope, blurred vision, dysphoric states, paranoia, confusion and aggressive behaviour, seizures, coma, hyperthermia, respiratory depression, apnoea, sudden death, spontaneous rhabdomyolysis
Excess amphetamine	Headaches, anorexia, nausea, tremors, dilated pupils, tachycardia and hypertension
Stimulant withdrawal	Sleepiness, lethargy, increased appetite, food binging, depression or even suicide
<i>Trauma</i>	
Frequent injecting	Track marks and skin scars, lack of veins and thrombophlebitis, deep venous thrombosis, persistent peripheral oedema, venous stasis and ulcers secondary to chronic venous obstruction
Misplaced injections	Arterial damage and insufficiency with secondary tissue damage, muscle compartment syndrome and traumatic rhabdomyolysis, false aneurysms and pulmonary emboli, traumatic neuropathy
<i>Immunology</i>	
IDU	Enlarged nodes, elevated IgM, false positive syphilis serology
<i>Endocrinology</i>	
Opiate use	Increase prolactin levels and gynaecomastia, amenorrhoea (may be secondary to weight loss)
Cannabis	Oligospermia, impotence and gynaecomastia
<i>Neurology</i>	
Stimulants	Psychosis, depression, cerebral infarcts and haemorrhages (CVAs)
Chronic use of benzodiazepines or barbiturates	Brain damage
<i>Cardiology</i>	
Cocaine	Cardiac arrhythmias such as sinus tachycardia, ventricular tachycardia and fibrillation as well as asystole, myocardial infarction, severe hypertension
Adulterants of illicit drugs, for example quinine	Cardiac arrhythmias and death
Tricyclic antidepressants	Sinus tachycardia and postural hypotension
Cannabis	Sinus tachycardia and postural hypotension
<i>Pulmonary</i>	
Inhaled cocaine	Excessive use of Valsalva – spontaneous pneumomediastinum and pneumopericardium
Excess sedatives or stimulants	Respiratory depression, coma and pneumonia
Opiate withdrawals	Mild "URT"
Stimulant use, for example cocaine	Tachypnoea
Opiates or cocaine	Pulmonary oedema
Hepatitis B	Polyarteritis nodosa
Foreign body emboli, (particles injected intravenously) for example talc granulomas	Pulmonary hypertension (and right heart failure) abnormal pulmonary function eg reduced DCO, restrictive defect due to interstitial lung disease

Medical problems of HIV-infected drug users

The extent of IDU-related conditions requires consideration of not only the clinical features of IDU but also the associated medical conditions such as HIV since confusion may arise as to the aetiology of specific symptoms. (See Box 11.9)

Pre-AIDS deaths

The phenomenon of pre-AIDS death amongst HIV-infected drug users was described soon after the onset of the AIDS epidemic in the USA. The IDU non-AIDS death rate was 2.5/100 person-years in Edinburgh (compared to 0.9/100 person-years in other risk groups), 3.8/100 person-years in Amsterdam and 2.6/100 person-years in New York. In Edinburgh 20% of pre-AIDS deaths were expected and related to conditions not ostensibly related to HIV. Liver disease was the single commonest cause of these deaths, accounting for 75% of expected pre-AIDS deaths or 25% of all pre-AIDS deaths, and is presumably related to the heavy co-infection with hepatitis B and C.

Respiratory infections

A review of pneumonia in all HIV positive patients suggested an increased annual incidence of bacterial pneumonia; 97–290 per 1000 compared to 21 per 1000 for HIV negative individuals. IDU-related HIV patients also have an overall higher incidence of bacterial infections; 12% (mortality of 2.2%) compared to 3% (mortality of 0%) in HIV negative drug users. The overall rate of bacterial sepsis in Edinburgh drug users was 7.0 per 100 person-years whilst in the Bronx cohort of drug users the rate was 8.0 per 100 person-years. In Spain 60% of the pneumonias in the HIV-infected patients occurred before a diagnosis of AIDS, in 55% of patients the problem was recurrent and the mortality was increased for HIV-infected patients (19% vs. 4%). *Streptococcus pneumoniae* and *Haemophilus influenzae* were the commonest organisms involved in the pneumonias. Additional susceptibility factors for drug users may be the use of opiates themselves because they are known to depress the cough reflex as well as the immune system. Latterly it has been suggested that the inhalation of drugs as well as the injection of drugs may increase the risks of bacterial pneumonias. The odds of developing pneumonia were twice as great for those reporting smoking cocaine, crack cocaine and marihuana and over 20-fold increased for those also having prior PCP and a low CD4. The effects of tobacco were not examined since all patients utilised this drug. The incidence of tuberculosis is much higher in HIV-infected drug users than in other risk groups outside the tropics, or in HIV negative drug users. In the USA, most patients with AIDS and tuberculosis have been drug users. One study showed a prevalence of 15% in drug users with AIDS but only 4% in other risk groups within a New York hospital. In New York the rate of tuberculosis was 4% among HIV positive drug users compared to 0% in HIV negative drug users. The 36% increase in reported cases of tuberculosis between 1984 and 1986 has been largely ascribed to infection amongst HIV positive drug users.

Hepatitis

Drug users with a history of IDU are highly likely to be co-infected with hepatitis B and C viruses (anywhere from 40% to 100% depending on location).

Anti-HIV drugs have long been associated with hepatitis and it is uncertain at present whether modern combination therapy for HIV will have a deleterious effect on those

Table 11.1 continued

Smoking of tobacco, heroin, marijuana	Abnormal pulmonary function for example reduced DCO, COAD
“Snorting” stimulants	Chronic rhinitis, rhinorrhoea, anosmia, atrophy of the mucosal membranes, ulceration and perforation of the nasal septum
“Snorting” opiates	Recurrent sinusitis

Box 11.9 Associated medical problems of IDU

- Lymphadenopathy is associated with both HIV and the injection of foreign materials.
- Fatigue, lethargy and excessive sweating are features of HIV as well as mild withdrawal from opiates.
- Diarrhoea, a common presentation of early symptomatic HIV (CDC stage IVA), is also a common symptom of opiate withdrawal.
- Weight loss and fever are both key symptoms of the constitutional symptoms associated with HIV (CDC stage IVA), infection with mycobacteria as well as heavy opiate or stimulant (amphetamines or cocaine) use.
- Epileptic seizures require consideration of cerebral toxoplasmosis in HIV, the intermittent use of benzodiazepines or even hepatic encephalopathy.
- The excessive use of cannabis and benzodiazepines interferes with memory and other cognitive functions in a similar manner to HIV as does frequent head injuries. Thus early dementia is difficult to detect in current drug users especially since reducing drugs will also help the dementing patient to improve function in relation to activities of daily living.
- Syncopal attacks in HIV may be associated with an autonomic neuropathy or a failing adrenal cortex but it is also associated with the use of antidepressant tricyclic drugs such as amitriptylene.
- Jaundice may be a result of acute or chronic hepatitis B or C infection, excessive alcohol ingestion or a side effect of the treatment of mycobacterial infections in HIV.
- Lastly shortness of breath and a persistent cough are common early symptoms of *Pneumocystis carinii* pneumonia (PCP) but can occur with endocarditis, bacterial pneumonia, excessive smoking, recurrent bronchitis and obstructive airways disease.

Greater detail can be obtained from the web site of the Regional Infectious Diseases Unit, Western Infirmary, Edinburgh (www.med.ed.ac.uk/ridu/History.htm).

Box 11.10 Co-infection of HIV and hepatitis viruses

Hepatitis B

- 10% of drug users will be carriers of hepatitis B
 - Re-emergence of carriers (HbsAg) with CD4 counts of < 200 cells/ μ l may occur
- Hepatitis C – data contradictory and may vary with risk groups because of length of HCV infection which is often unknown*
- HCV RNA levels rise with falling CD4 counts
 - Increased progression of both HIV and HCV disease reported in haemophiliacs
 - Studies on drug users have reported no change of HIV progression
 - Increased rate of HCV progression also reported in drug users

ABC of AIDS

co-infected with HCV or not. There are reports in the literature of therapy improving, worsening or having no effect on concomitant HCV. Thus despite a greater risk of hepatotoxicity in HIV/HCV co-infected patients on highly activated retroviral therapy (HAART), this is not a reason to withhold therapy from HCV HIV co-infected patients but rather such patients require more carefully monitoring. There is also the problem of additional hepatotoxicity associated with the use of antituberculous drugs in HIV/HCV co-infected individuals.

Although treatment for HCV is now available in the form of interferon and ribavirin, tolerance and interactions with HIV therapy are likely to be problematical since ribavirin has been reported to interfere with the phosphorylation of nucleosides such as zidovudine.

HIV dementia and encephalitis

HIV/AIDS is unusual in that it combines both immunological, neurological and psychiatric disorders and as a consequence patients may develop a variety of disabilities ranging from wasting disorders, severe pain, neurological dysfunction such as paralysis or cognitive impairment and psychological symptoms. These combinations of problems may result in considerable problems for both patients and carers. Autopsy studies in Edinburgh (prior to modern antiretroviral therapy (ART)) have shown that as many as 60% of IDU-related HIV patients have evidence of HIV encephalitis although only 6–7% have frank dementia.

AIDS

As for AIDS itself, little variation between the risk activities with regard to presentation has been reported. In the USA, figures available to the Centers for Disease Control show that conditions such as Kaposi's sarcoma are unusual in the absence of homo/bisexuality. In drug users, Kaposi's sarcoma, cytomegalovirus and chronic cryptosporidiosis are all significantly less common than for all other risk groups notified with AIDS, while PCP, tuberculosis, oesophageal candidiasis and extrapulmonary cryptococcosis are more common.

Progression from HIV to AIDS

No evidence has been found for a role of alcohol, opiates or other psychoactive drugs in accelerating the progression of immunodeficiency in HIV-seropositive homosexual and bisexual men. The major factors identified in the progression of HIV appear to be age and HLA type. A1 B8 Dr3 and Bw 35 are all associated with more rapid progression whilst B27 is associated with slower progression to AIDS and death.

Survival after the development of AIDS

Without treatment, in general, around half of patients with AIDS survive for one year but only a fifth for three years and the median survival time is around 18–20 months. In Edinburgh the one- and three-year post-AIDS survival rates were 66% and 25%. Older age at AIDS diagnosis and HLA type A1 B8 DR3 were associated with shorter survival. Whilst it had been generally assumed that the survival for injection drug users with AIDS would be shorter than for other risk groups, several studies including our own counter this presumption.

Figure 11.1 Opportunistic events/100 patient-years: Regional Infectious Diseases Unit, Edinburgh

Figure 11.2 Deaths/100 patient-years: Regional Infectious Diseases Unit, Edinburgh

Problems of pain management in IDU-related HIV

The investigation of pain in IDU-related HIV is a major problem for carers, particularly since it is a useful complaint to increase the size of opiate prescriptions. Considerable experience is required in both the investigation and management of pain in order to avoid ever larger prescriptions.

The commonest problem in the management of pain in drug users is that of insufficient doses as a consequence of existing high levels of opiate use and/or disagreement from carers over whether pain is real or being treated adequately. Self-medication is a common problem which increases the uncertainties around prescribing. The use of inappropriate drugs such as Diconal or Temgesic should be avoided because these drugs are highly sought after as recreational drugs in the community.

Our own practice has been to utilise increasing doses of existing drugs such as methadone, oral solutions of morphine, slow-release morphine preparations such as MST (although this also has some street value since it can be injected), morphine/diamorphine solutions via subcutaneous infusions or fentanyl patches.

There is the additional problem of providing adequate sedation during procedures. Patients may require unusually large doses of medazolam as a consequence of their regular intake of benzodiazepines. If adequate doses of medazolam are not used then there is no loss of memory for the procedure which can be quite distressing for the patients. Alternatively, particularly if the patient uses illicit benzodiazepines or opiates, excessive sedation occurs with even quite small doses. As with the elderly, some HIV/AIDS patients also exhibit an unusual sensitivity to neuroleptics such as carbamazepine or antidepressants, possibly because of the concomitant presence of HIV encephalopathy. Care is therefore required in the introduction of such drugs for pain control.

Antiretroviral therapy

It is perfectly possible to treat drug users with antiretroviral therapy although there are a number of simple difficulties such as venous access for monitoring of therapy.

When considering combination therapy for recreational drug users a number of important principles need to be understood by the drug users. Whilst these may seem obvious to ourselves this is not the case for the patients.

A number of groups have been exploring drug regimens thought to be particularly suitable for drug users, usually because they provide the possibility of a once-daily regimen, and therefore the option of employing directly observed combination therapy (DOCT) at a suitable location. Whilst DOCT may be offered to a patient as an option it should perhaps be seen as a means to an end rather than as a long-term solution.

Drug interactions

Drug interactions are an ever present problem with modern antiretroviral therapy for all patients, but even more so for those taking recreational drugs where there is the ever-present possibility of serious increases in the levels of pharmaceutical or recreational drugs. Of course from the patient's point of view reduced levels of recreational drugs is also an important problem.

Box 11.11 Common causes of pain in drug users

Dental caries

Traumatic neuropathies

Abdominal pain

- Constipation
- Cholecystitis
- Appendicitis
- Chronic hepatitis
- Lymph node enlargement
- MAI
- Lymphoma

Box 11.12 Problems of antiretroviral therapy in drug users

- Regular venous access required – consider external jugular rather than femoral artery
- Improved health may encourage a return to IDU – continue with harm reduction strategy

Box 11.13 Important principles in modern antiviral combination therapy

- Intermittent combination therapy is a major disadvantage because of the development of resistance which will impair future therapy choices
- Almost total (95%) adherence is required for the best chance of long-lasting success (undetectable viral load)
- Increasing the number of drugs used in combination therapy does not increase “wellness”, it simply increases the chance the regimen will be successful for a longer period
- However more antiviral drugs increase the chance of an adverse drug related event
- Intermittent recreational drug use is more dangerous and difficult to adjust for than regular recreational drug use (time and patience required by both patient and doctor) in terms of interactions with combination therapy

ABC of AIDS

The most extensively investigated interactions are with methadone since it is commonly used long-term for heroin substitution. Little other investigational work has been undertaken possibly because of the difficulties of working with illegal drugs such as cocaine or amphetamine and some lack of interest on the part of pharmaceutical companies. One proviso when discussing interactions is our relative lack of knowledge of methadone levels and symptoms of withdrawal. Very little work seems to have been carried out in this area recently and much more is required if we are to better understand the interactions that do occur.

Other drugs used in HIV

It is important also to remember that a number of other drugs commonly used in HIV medicine such as rifampicin or phenytoin also dramatically reduce methadone levels by enzyme induction and cause problems with acute withdrawal. Increased zidovudine levels have also been reported with sodium valproate, a drug that is commonly used to control seizures.

In summary the use of recreational drugs certainly affects the choice of anti-viral drugs and possibly also the time at which therapy starts. Individual regimes to suit particular problems are important. Because of the complexity of the interactions it is important to get over to the patient how vital it is to know what drugs are actually taken rather than what drugs are prescribed. Misinformation may be fatal and they need to understand why the information needs to be accurate. This will only work of course if the patient is truly persuaded of the need for therapy. The risks of not taking therapy have to be very real and to outweigh the risks of the therapy – which after all in the case of ecstasy and ritonavir could be sudden death – not a very good outcome measure for combination therapy. For drug users the risks of disease may not outweigh therapy until the CD4 count is below 200 cells/microgram when the immediate risk of ill health is 20% or one in five for the next 12 months and 80% or four in five for the next three years. By comparison, the risk of a drug-related adverse event lies somewhere between 3% and 30%. At levels of CD4 count of 350 or 500 the risks of an adverse event are likely to outweigh the risk of serious HIV disease.

Despite all these difficulties, in Edinburgh with around 50% of our patients being drug users, we have managed to achieve the same reductions in opportunistic infections and deaths noted in other areas.

Thus recreational drug use related HIV can be managed successfully via attention to drug dependence needs, social needs and the medical care needs.

Box 11.14 Substitute recreational drug therapy and interactions with HAART

NRTI (Nucleoside Reverse Transcriptase Inhibitors)

- Zidovudine
 - ZDV levels increased by opiates (AUC increased x 2)
- Stavudine and Didanosine
 - Absorption decreased by co-administration with methadone
- Abacavir
 - Rate but not extent of absorption of decreased by co-administration with methadone
 - Increased clearance of methadone – dose adjustment may be needed

NNRTI (Non Nucleoside Reverse Transcriptase Inhibitors)

- Nevirapine and efavirenz
 - AUC of methadone reduced by as much as 30% – dose adjustment may be needed
- Delavirdine
 - AUC of methadone increased – to date no reports of dosage adjustment required

PI (Protease Inhibitors)

- Ritonavir
 - No change in methadone dosage required
 - Heroin and morphine levels reduced
 - Dextropropoxyphene and pethidine levels increased
- Indinavir
 - Initially need to reduce methadone doses but after a few weeks return to previous levels
- Nelfinavir
 - Methadone levels reduced and dosage adjustment usually necessary

Figure 11.3 Survival of AIDS 1983–99: Regional Infectious Disease Unit, Edinburgh

12 HIV infection in children

Gareth Tudor-Williams, Diana Gibb

Epidemiological aspects

By the end of 2000, there were an estimated 1.4 million children under 15 years of age living with HIV infection worldwide and 4.3 million had died. Of these, UNAIDS estimates that 600 000 became infected during 2000 alone, over 90% via mother-to-child transmission (MTCT). Over 90% of people with HIV live in the developing world and, of these, over two-thirds live in countries in sub-Saharan Africa. Here HIV is reversing gains in child survival and significantly lowering life expectancy. Although the burden of HIV disease borne by African children is enormous, over half of the world's population live in the Asia/Pacific region. The HIV epidemic is at a much earlier stage here than in Africa and the explosive increase seen this decade is alarming.

Around half of women who acquire HIV become infected before 25 years of age and die before their 35th birthday, in the prime of their child-bearing years. As a result, by the end of 1999, the epidemic had left behind 13.2 million AIDS orphans under the age of 15 years. The difficulties that poor communities in Africa face in trying to care for this increase in children without parents is enormous and is largely dependent on existing family and social support structures already greatly affected by the AIDS epidemic.

For a vertically infected child in sub-Saharan Africa the probability of death by 12 months is estimated to be between 23% and 50%, and over 75% will not live to see their fifth birthday. HIV-infected children in Western Europe and North America contribute <1% to the total number of children worldwide living with the disease today. Over the last 5 years the epidemiology of paediatric HIV infection in affluent countries has changed as a result of a number of factors:

- First, there has been a dramatic decrease in MTCT as a result of widespread implementation of interventions for pregnant infected women and their newborns, resulting in few infected children.
- Second, new HIV infections increasingly occur either in children whose mothers acquired the disease in a country with a high prevalence of HIV, or come to light in older children who were themselves born elsewhere.
- Third, with the advent of potent antiretroviral therapy, children are living longer with HIV infection – for example, one-quarter of the 10 000 children living with HIV in the USA are now teenagers and the age of children in Europe is also increasing.

Unlinked anonymous monitoring of HIV through testing newborn dried blood spot (Guthrie) cards provides an unbiased estimate of the prevalence of HIV infection among women having live babies. This is being undertaken in the UK and covers 70% of births (see Figure 12.3). In 1999, the prevalence of maternal infection was 0.25% (1 in every 400 births) in London, compared with approximately 1 in 6000 births outside London. There has been an increase of around 30% in the number of pregnant HIV-infected women being reported in the last 2 years, which may in part reflect an increasing desire for infected women to have children in the new knowledge that the risk of MTCT is low. In London, three-quarters of seropositive

Table 12.1 End 2000 global HIV/AIDS estimates in millions

	Children	Total
People living with HIV/AIDS	1.4	36.1
New HIV infections in 2000	0.6	5.30
HIV/AIDS Deaths in 2000	0.5	3.0
Cumulative HIV/AIDS deaths	4.3	21.8

ABC of AIDS

newborns are delivered to mothers born in sub-Saharan Africa, and similar patterns are seen in European countries such as France and Belgium. In Scotland, Ireland and Southern Europe a high proportion of seropositive children are still born to women with IDU as a risk factor, but here too the proportion of women acquiring HIV from heterosexual transmission is increasing. Romania has the largest number of HIV-infected children in Europe, making up nearly half of the estimated 10 000 children living with HIV/AIDS in East and Western Europe. The majority belong to a cohort of children who were uniquely infected with HIV through contaminated blood products and needles in the late 1980s and early 1990s. Although many have died, there remain a considerable number of these children now entering their teenage years in Romania.

Antenatal testing and mother-to-child transmission

Most observational studies estimate the risk of MTCT without interventions to be around 15–20% in Europe and the USA and over 30% in African populations. Postnatal breastfeeding doubles the overall risk of transmission and accounts for most of the difference. In non-breastfeeding women, approximately 75% of perinatal transmission occurs around the time of delivery. Other factors independently affecting the rate of transmission include the HIV viral load and CD4 cell count of the mother at the time of delivery, duration of rupture of membranes, prematurity and mode of delivery. In the last five years, the MTCT rate has been reduced to less than 2% in the USA and most European countries by the introduction of antenatal testing, highly active antiretroviral therapy (HAART) for mother's requiring therapy, use of antiretroviral therapy perinatally even if not indicated on the grounds of the mother's disease status, delivery by elective caesarean section, and refraining from breastfeeding. A recommendation that HIV testing should be offered to all women in pregnancy has been successfully implemented in many European countries, notably France, Italy and Spain where the prevalence of HIV in pregnant women was highest.

In the UK, universal offer of HIV testing during the antenatal period has been recommended in London because of the high prevalence since 1992. However, until 1999, it was recommended that antenatal HIV testing should only be offered to women considered at high risk (selective testing) outside London. An economic analysis was published in 1999 showing that a universal offer policy was cost-effective throughout the UK provided that a high uptake of testing was achieved. Department of Health guidelines endorsing this approach were published in August 1999. In low prevalence areas, up to 50 pooled samples can be tested in batches to reduce costs. During most of the 1990s, detection of previously undiagnosed HIV in pregnancy has been low everywhere in the UK. However, during 1999, and more dramatically, during the first half of 2000, there has been a marked improvement in antenatal detection rates, with about 75% of all HIV infected women being aware of their diagnosis before their baby is born in inner London and Scotland, 66% in outer London and about 50% elsewhere in the UK. In most European countries and in the USA, a marked decrease in AIDS cases reported in infancy reflects the high proportion of pregnant women receiving appropriate care to reduce MTCT.

Among UK women who either knew their HIV status before pregnancy or are diagnosed during pregnancy, MTCT rates of 2% or less are being reported among those taking up

Box 12.1 Mother-to-child transmission of HIV infection

- HIV infection is transmitted to about 15–20% of babies born to HIV infected women (*between 1 in 5 and 1 in 6*).
- The transmission rate doubles if a woman breastfeeds to about 30% (*1 in 3*).
- In non-breast fed infants, approximately 70% of transmission occurs around the time of delivery
- Transmission is increased if a women has a high HIV viral load, low CD4 count and/or AIDS.
- Factors around delivery influence transmission.

Box 12.2 Interventions to reduce transmission from mother-to-child

- Not breastfeeding
- Antiretroviral therapy
- Elective caesarean section delivery (ie before the onset of labour or membrane rupture)
- **IMPLEMENTING ALL 3 CAN REDUCE TRANSMISSION RATES TO 2% OR LESS**

Figure 12.3 Proportion of HIV infections diagnosed prior to birth among pregnant women

Figure 12.4 Mother-to-child HIV transmission in European countries: AIDS cases in children aged less than 1 year at diagnosis. Source: European Non-aggregate AIDS data set, June 1999. European Centre for the Epidemiological Monitoring of AIDS, Saint Maurice, France

interventions. Women taking HAART for their own disease who have undetectable HIV viral load at delivery have a very low risk of transmitting HIV to their baby. For those women not needing therapy for themselves, most guidelines recommend zidovudine and elective caesarean section (CS) delivery, which limits exposure of mother and baby to antiretroviral drugs and is associated with a transmission rate of <2%. There have been recent concerns about the possible link between mitochondrial dysfunction and perinatal exposure to antiretroviral nucleoside analogues, particularly zidovudine (ZDV) and lamivudine (3TC). This was reported from the French cohort in 1998, but extensive retrospective analysis of US and other European data have not revealed additional cases. In Europe and the USA, it has been agreed that the benefits of antiretroviral therapy (ART) in reducing MTCT outweigh the possible adverse effects, but that it is important to prospectively follow all infants born to infected women as the long-term effects of exposure to ART *in utero* is unknown.

A European trial and a meta-analysis of cohort data from the USA and Europe showed that in women taking no ART or ZDV monotherapy, elective CS delivery decreased the risk of MTCT by approximately 50% compared with vaginal or emergency CS delivery. This approach has been widely adopted in Europe for women taking mono ART in pregnancy to prevent MTCT. However, it has been less widely adopted in some countries such as the USA, where women are more likely to be given triple HAART in pregnancy in order to reduce viral load to below the level of detection. In this situation the additional benefit of an elective CS delivery remains unclear. There is probably no place for dual ART with ZDV and 3TC in pregnancy, as this is rarely able to fully inhibit viral replication, adds little to reducing transmission with ZDV and elective CS, increases the potential for toxicity in the infant and has been associated with rapid selection of 3TC-associated mutants.

In the developing world, a number of major studies have evaluated the efficacy of cheaper and less complicated perinatal ART regimens. These include short-course ZDV and most notably the use of a single dose of the non-nucleoside reverse transcriptase inhibitor (NNRTI) drug nevirapine to the mother during labour and to the infant within the first three days of birth. This extremely cheap regimen has been shown to reduce transmission by nearly 40% compared with a regimen of intrapartum and neonatal ZDV for a week, even in breastfeeding women over a period of 12 months. It is now being implemented alongside antenatal HIV testing programmes in many parts of the developing world. A concern that resistance to nevirapine, which occurred in about 15% of women, might compromise its use in subsequent pregnancies is probably unfounded as virus returns to wild type in the months following delivery. However, there are concerns that giving a single dose of nevirapine during labour in addition to other ART to women in Europe and the USA who fail to achieve undetectable viral load, could compromise the woman's future ART options to any NNRTI drug because of the rapid selection of HIV strains resistant to nevirapine even after a single dose. Resistance testing to guide therapy choice is routinely recommended for all HIV-infected pregnant women in many developed countries because of *de novo* acquisition of drug-resistant strains of HIV-1.

Diagnosis

IgG antibodies to HIV are passively transferred to virtually all babies born to infected mothers, unless they are born extremely preterm or the mother has profound hypogammaglobulinaemia. Standard IgG antibody assays are so sensitive that traces of

Figure 12.7 Normal ranges for absolute CD4+ lymphocyte counts in HIV-uninfected children born to HIV-infected mothers. Source: European Collaborative Study

Table 12.2 Suggested follow-up of infants born to HIV-infected mothers

Age	Action	Comment
Birth to 4–6 weeks 24–48 hours	Give antiretroviral prophylaxis to baby Proviral DNA PCR*	Usually zidovudine monotherapy, but modified in light of maternal therapy If positive, suggests intrauterine transmission or high intrapartum inoculum: may be associated with more rapid disease progression. Not helpful if negative, as less than 50% of infected babies can be detected within 48 hours of birth
3–6 weeks	Proviral DNA PCR	Should detect 95% of infected infants. A positive result must be confirmed on two separate blood samples
4–6 weeks	Stop antiretroviral prophylaxis. Start PCP prophylaxis**	See text for PCP prophylaxis recommendations
3–4 months	Proviral DNA PCR	If all assays are negative and there are no clinical concerns, child is almost certainly uninfected. PCP prophylaxis can be stopped
18 months	HIV antibody test	Performed until seroreversion documented

*Initial infant sample should be tested in parallel with maternal sample obtained around the time of delivery, to ensure maternal strain of HIV can be detected.

**For very low risk infants paediatric specialists increasingly are not recommending PCP prophylaxis.

maternal antibody are frequently detectable in the baby up to 18 months of age. Waiting for antibodies to become undetectable (“seroreversion”) is therefore a slow way to establish the child’s infection status. Using techniques that detect proviral HIV DNA, by polymerase chain reaction (PCR) or other amplification techniques, 93% of infected infants can be diagnosed by one month of age, and virtually all by three months. Quantitative RNA assays are now widely available but are not licensed for diagnostic purposes because of problems with false positive results and variable performance with non-B clade viral isolates. Whichever test is used, it is essential to ensure that it efficiently detects the maternal strain of HIV.

Virus culture is a highly specialised assay that is available only in research laboratories and has been largely superseded by amplification assays. Immune complex dissociated p24 antigen assays (ICD p24 ag) detect the nuclear capsid antigen of the virus by a commercial ELISA kit. This is a cheap but less sensitive method of diagnosis. Similarly IgA assays are highly specific but lack sensitivity, particularly during the first three months of life.

If PCR assays which reliably detect the mother’s strain of HIV are negative on the infant’s blood at three different time points, with at least one set performed at or after three months of age, and there are no clinical concerns, the parents/guardians can be informed that their baby is almost certainly not infected (Table 12.2).

T-cell subsets and measurement of immunoglobulins (Ig) are non-specific tests. Reversal of the CD4:8 ratio and high Ig (>2 × upper limit of normal) are suggestive of infection but, for diagnostic purposes, should be supported by at least one other test that detects the virus directly. It is important to realise that absolute CD4 counts are physiologically much higher in infants and young children than in adults (Figures 12.7 and 12.8).

All children presumed to be uninfected should be followed until seroreversion is confirmed, and longer term follow-up to ensure normal development until four to five years is advised in children exposed to ART perinatally.

Natural history and clinical manifestations

As in adults, HIV-infected children present with a spectrum of signs and symptoms reflected in the revised Centre for Disease Control classification system (Box 12.3). The differences between adults and children with HIV disease are summarised (Box 12.4). In the absence of HAART, disease progression is generally faster than in adults, with 15–20% of children

Box 12.3 Centers for Disease Control 1994 revised classification system for HIV infection in children less than 13 years old

Category N: no symptoms

Category A: mildly symptomatic

- Lymphadenopathy
- Hepatomegaly
- Splenomegaly
- Dermatitis
- Parotitis
- Recurrent upper respiratory tract infections, sinusitis or otitis media

Category B: moderately symptomatic

Examples of conditions in clinical category B include:

- Anaemia, neutropenia or thrombocytopenia
- Bacterial infections: pneumonia, bacteraemia (single episode)
- Candidiasis, oropharyngeal
- Cardiomyopathy
- Diarrhoea, recurrent or chronic
- Hepatitis
- Herpes stomatitis, recurrent
- Lymphoid interstitial pneumonia
- Nephropathy
- Persistent fever > 1 month
- Varicella (persistent or complicated primary chickenpox or shingles)

Category C: severely symptomatic

Any condition listed in the 1987 surveillance case definition for AIDS, with the exception of LIP. For example:

- Serious bacterial infections, multiple or recurrent
- Candidiasis (oesophageal, pulmonary)
- Cytomegalovirus disease with onset of symptoms at age >1 month
- Cryptosporidiosis or Isosporiasis with diarrhoea persisting 1 month
- Encephalopathy
- Lymphoma
- *Mycobacterium tuberculosis* disseminated or extrapulmonary
- *Mycobacterium avium* complex or *M. kansasii*, disseminated
- *Pneumocystis carinii* pneumonia
- Progressive multifocal leucoencephalopathy
- Toxoplasmosis of the brain with onset at age > 1 month
- Wasting syndrome

developing AIDS-defining illnesses by 12 months. This subset of perinatally infected children typically present with PCP at around three to four months of age (Figure 12.8). Progression rates to AIDS in infancy have been shown to be reduced by the use of primary PCP prophylaxis with Septrin from 4 to 6 weeks of age onwards.

Approximately 70% of perinatally infected children will have some signs or symptoms by 12 months (Figure 12.14). In the absence of antiretroviral therapy, the median age at which children progress to AIDS is about six years, and 25–30% have died by this age. The median age of death is around nine years. In many cases, the child is the first family member to be diagnosed as HIV infected. Some children, however, do not present until the second decade of life. Disease progression in children in developing countries is more rapid (Figure 12.15). Survival following an AIDS diagnosis has greatly improved over the past 10 years, but even where antiretroviral therapy is available the mortality amongst children with PCP and CMV is appreciable (Figure 12.13). This is yet another reason for antenatal HIV testing which can render PCP in infancy wholly preventable.

Children with HIV infection frequently present with signs and symptoms that are common in general paediatrics and are non-specific. The most usual clinical features associated with HIV infection include persistent generalised lymphadenopathy, hepatosplenomegaly, chronic or recurrent diarrhoea, fever, and recurrent otitis or sinusitis.

Persistent oral candidiasis, bilateral parotitis or neurological signs are more specific of HIV infection. Herpes zoster (shingles) in childhood is uncommon and suggests a defect in cellular immunity justifying an HIV test in the absence of other explanations. Similarly, thrombocytopenia can be a presenting feature, and HIV should be considered in the differential diagnosis of idiopathic thrombocytopenic purpura.

Recurrent and often severe bacterial infections are frequent and include pneumonia, cellulitis, local abscesses, osteomyelitis, septic arthritis and occult bacteraemia. The common causative organisms are similar to those seen in children with hypogammaglobulinaemia and include pneumococci, salmonellae, staphylococci, streptococci and *Haemophilus influenzae*. This reflects the B-cell defect that accompanies the destruction of the CD4+ helper T cells. Children with HIV infection frequently have hypergammaglobulinaemia due to dysregulated polyclonal B-cell activation. The antibodies are generally non-functional.

Pulmonary disease is an important cause of morbidity and mortality and may be one of the first manifestations. Lymphoid interstitial pneumonitis (LIP), characterised by multiple foci of proliferating lymphocytes in the lung interstitium, occurs in 20–30% of vertically infected children, but is rare in adults. It presents with persistent bilateral reticulonodular shadowing on chest X-ray (Figure 12.9) and clinical features ranging from asymptomatic to chronic hypoxia. It may be an abnormal response to primary Epstein–Barr virus (EBV) infection. Co-infection with *Mycobacterium tuberculosis* is an increasing problem in children, and can be difficult to distinguish radiologically from LIP. Clinically a child with bilateral infiltrates due to TB would be highly symptomatic, as opposed to LIP which may be clinically silent.

Opportunistic infections, apart from PCP and primary disseminated CMV disease in the subset of children with very rapid disease progression, are usually a late complication of HIV infection and result from severe immunosuppression. The most common are oesophageal candidiasis, multidermatomal varicella zoster, disseminated mycobacterium avium complex (MAC) or CMV infections, cryptosporidiosis, and more rarely,

Box 12.4 Differences between children and adults with HIV disease

- More rapid disease progression:
 - 20% of children develop AIDS by 12 months
 - Child may be the first family member to present
- Higher viral loads at presentation
- Physiologically higher absolute CD4 counts
- Growth faltering common (affects height and weight)
- Encephalopathy presents with developmental delay and hypertonic diplegia
- Opportunistic pathogens encountered for the first time
 - primary illnesses often more severe than OIs in adults
- Poor primary responses to childhood infections/immunisations
- Lymphoid interstitial pneumonitis common
- Malignancy uncommon (accounts for less than 2% of AIDS-defining presentations in children)
- More rapid clearance of antiretroviral drugs, requiring higher than adult equivalent doses particularly in very young children

Figure 12.8 *Pneumocystis carinii* pneumonia (PCP) in a three month old. Diffuse bilateral ground-glass opacification, tending to confluence in right upper and both lower lobes. Air bronchograms are seen, which imply air space disease which is a late feature of disease. The earliest infiltrates are usually perihilar. The absence of pleural effusion or hilar adenopathy is typical. Less typical presentations include miliary, coin and nodular lesions, lobar consolidation and cavitations

Figure 12.9 Lymphoid interstitial pneumonitis (LIP) in a child aged 12 months. Diffuse, well-circumscribed nodules distributed uniformly throughout both lung fields. May be associated with hilar adenopathy. A radiological spectrum is seen in LIP, ranging from fine linear interstitial infiltrates to large nodules that tend to confluence in the right middle and lingular lobes

ABC of AIDS

toxoplasmosis. MAC should be considered in any child with advanced disease and unexplained fevers, weight loss and abdominal discomfort.

Encephalopathy due to effects of HIV infection on the central nervous system is seen most frequently in the subgroup of children with rapid disease progression. The most common neurological manifestations are hypertonic diplegia, developmental delay (particularly affecting motor skills and expressive language) or acquired microcephaly. Cranial imaging studies may show basal ganglia calcification and cerebral atrophy and MRI scans may show evidence of white matter damage. Seizures are not usually a feature of HIV encephalopathy which does not tend to affect the grey matter. The majority of school age children are attending normal school without requiring additional support in the classroom.

Malignancy, such as Kaposi's sarcoma or lymphoma, is a relatively uncommon feature of paediatric HIV disease, accounting for only 1–2% of AIDS-defining illness in children.

Prognostic markers

The most widely used surrogate markers for predicting disease progression in children, as in adults, are the CD4 values and viral load. Very high viral loads are frequently found in infected children, particularly following perinatal transmission (Figure 12.10). Absolute CD4 counts are physiologically higher in children compared with adults (Figure 12.7). CD4 percentages vary rather less, and according to the CDC classification system can be used across all age ranges; >25% is considered evidence of no immunosuppression, 15–25% moderate and <15% severe immunosuppression (Figure 12.6).

Tables 12.3–12.5 contain data from a pre-antiretroviral trial of intravenous immunoglobulin in the USA that illustrate the independent prognostic value of these markers, although positive predictive values of each are low. Age-adjusted rates of change for viral load and CD4 counts may be of higher positive predictive value for disease progression: an analysis of combined European and US data is presently underway to evaluate this concept.

Management

The aim of any intervention for HIV-infected children should be to maintain the best possible quality of life for the children as long as possible, with the hope that they will be able to take advantage of potential curative therapy in the future. This inevitably means balancing the potential benefits of new treatments against the need for increased monitoring, possible toxicities and limiting future therapeutic options.

As a result of advances in ART, there has been a shift in focus from diagnosing and managing opportunistic infections (OI) to preventing them by restoring and maintaining cellular immunity. For most established opportunistic infections, the best treatment is HAART.

Antiretroviral therapy

Virus replication in children, as in adults, is occurring at all stages of HIV infection and, as improved drugs and drug combinations become available, treatment is likely to be offered increasingly early. Highly encouraging results have been reported with three or more drug combinations in selected, infected infants, which demonstrate that complete viral suppression and maintenance of entirely normal immune development can be achieved and sustained for at least three years. These observations, and studies of adults treated during primary infection, provide a rationale for early aggressive therapy of infants.

Figure 12.10 Plasma viral load (HIV-1 RNA copies/ml) over time in a cohort of perinatally infected, non-breast-fed infants. Solid line represents median values at each time point. Note that median viral load on days 1–3 of life was below the limit of detection (<400.copies/ml). Most non-breast-fed infants are infected during labour or delivery, resulting in a lag before viral replication reaches detectable levels in the circulation

Table 12.3 Association of baseline CD4+ lymphocyte percentage with long-term risk of mortality in HIV-infected children

Baseline CD4+ percentage	Patients (no.)	Deaths (no.)	% mortality
≥25%	189	50	26
15–24%	93	31	33
5–14%	59	35	59
<5%	33	32	97

Table 12.4 Association of baseline HIV RNA copy number with long-term risk of mortality in HIV-infected children

Baseline HIV RNA (copies/ml)*	Patients (no.)	Deaths (no.)	% mortality
Undetectable	25	6	24
4001–50 000	69	19	28
50 001–500 000	105	34	32
500 001–1 000 000	20	8	40
>1 000 000	35	25	71

Table 12.5 Association of baseline HIV RNA copy number and CD4+ cell percentage with long-term risk of mortality in HIV-infected children

Baseline viral load/ CD4+ percentage	Patients (no.)	Deaths (no.)	% mortality
100 000 copies/ml			
15%	103	15	15
<15%	24	15	63
>100 000 copies/ml			
15%	89	32	36
<15%	36	29	81

Mean age = 3.4 years, mean follow-up = 5.1 years

* Data taken from the National Institute of Child Health and Human Development Intravenous Immunoglobulin Clinical Trial. Reproduced from Mofenson L *et al. Journal of Infectious Disease* 1997;**175**:1029–38.

Less impressive results have been documented outside clinical trials. Some children have failed due to inadequately defined pharmacokinetics for drugs like nelfinavir in infants, many of the infants have now been exposed to all three classes of ART and have few therapeutic options left, and adverse consequences of early prolonged therapy are unknown. Considerable support is required to enable families to sustain high levels of adherence long term. US guidelines recommend HAART for all infants, but European practice tends to be more conservative (Figure 12.11).

Older children presenting for the first time are a selected group who are not rapid disease progressors. For these children it is reasonable to monitor CD4 counts and only offer treatment if counts are declining steadily below 25%. There is no consensus level of viral load above which treatment must be started.

When starting HAART, most prescribers would initiate triple or even quadruple combination therapy, ideally sparing at least one class of drugs. The protease inhibitors (PI) are more difficult to formulate into palatable suspensions for children compared with the nucleoside analogues and non-nucleoside reverse transcriptase inhibitors. No data in children provide evidence to conclude that PI-containing or PI-sparing regimens have greater long-term clinical efficacy.

The management of heavily pretreated children who are failing therapy requires careful evaluation of past drug history, adherence, unused treatment options, possibly genotypic or phenotypic resistance testing, and pharmacodynamics. It has become clear that many drugs are more rapidly cleared in children. The problem of underdosing in infancy has already been mentioned. Adolescents may require higher than adult doses until reaching Tanner IV or V stages of puberty. Increasingly therapeutic drug monitoring will be used to understand population pharmacokinetics, and to tailor individual therapy.

Short- and long-term toxicities of specific drugs and drug classes are broadly similar in children as in adults, with 58% of children presenting with at least one side-effect in a recent national Italian survey of children on HAART. The most common toxicities are gastrointestinal symptoms and skin rashes. Lipodystrophy is increasingly described, particularly in adolescents who may wish to switch or discontinue therapy as a result. Lipid metabolism abnormalities with significantly raised fasting cholesterol and/or triglyceride levels are particularly associated with PI-containing regimens. Long-term consequences are not yet known and no consensus has emerged regarding the use of statins, but early onset cardiovascular complications are a potential risk.

It is likely that long-term control of viral replication in children will require adjunctive immune-based treatment, and several approaches are under investigation. The role of strategic treatment interruptions is also being evaluated. The long-term goal is to restore the child's HIV-specific immune responses to the point where HAART is no longer needed.

In view of the many uncertainties regarding optimal treatment, it is strongly recommended that children should be offered treatment as part of a clinical trial. Paediatricians in Europe and Brazil are collaborating in a series of studies coordinated by the Paediatric European Network for the Treatment of AIDS (PENTA). Information about the PENTA studies is available through the Medical Research Council Clinical Trials Centre in London (telephone +44 (0) 20 7670 4791/2, fax +44 (0) 20 7670 4814) or INSERM in Paris (telephone +33 1 4559 5201, fax +33 14559 5180).

Box 12.5 Issues to consider when starting therapy in Children

- Parental (and child) readiness
- Likelihood of good longterm adherence
- What formulations could this child take (taste testing: let child chose)?
- What pharmacokinetic data are available for infants/children/adolescents?
- What experience have other family members had on antiretroviral drugs?

Box 12.6 Drug combinations consider:

- Pill/liquid burden
- Ease of administration
- With/without food
- Number of times per day (avoid school hours, ?once daily for adolescents)
- Creative use of drug–drug interactions (boosting with ritonavir)
- Pill-swallowing techniques
- Adherence aids (sticker charts, dosette boxes etc.)
- Gastrostomy tubes to improve quality of life if this is severely eroded by difficulties taking medicines orally

Box 12.7 Recommendations for use of HAART in children (adapted from PENTA, 2001)

- Must start HAART if
Clinical stage C or immunological stage 3 disease (CD4<15%)
- Consider HAART if
Clinical stage B or
Steadily declining CD4% falling below 25%, or
High viral load (>10⁶ RNA copies/ml if age <1 year, >10⁵ if age over 1 year)
Infant <12 months, regardless of CD4 or viral load
- Defer HAART if
Stage N or A disease
CD4>25%
Low viral load:
<10⁵ in children between 1 and 30 months
<50 000 copies/ml in children >30 months

Figure 12.11 Antiretroviral therapy being received in 1999 by 1694 HIV infected children from paediatric centres in 9 countries, involved in the PENTA network of trials (unpublished data, Paediatric European Network for the Treatment of AIDS)

Prophylactic measures

Early-onset PCP is a preventable disease (Table 12.2). Infants at higher risk of acquiring HIV, whose mothers are identified during pregnancy, can be started on PCP prophylaxis from around 4 to 6 weeks of age onwards. Prophylaxis can be stopped once it has been established that the baby is uninfected. Infected children should continue on prophylaxis throughout the first year of life, as CD4 counts are unreliable indicators of risk (see Figure 12.7). Thereafter, it is not unreasonable to stop prophylaxis for children with CD4 counts consistently above 15%, provided the family are reliable clinic attendees and the child's clinical status and immune function can be regularly monitored. Any child with rapidly declining CD4 counts or counts consistently less than 15% should be on prophylaxis. Co-trimoxazole is the drug of choice. Regimens vary, but one convenient dosage regimen is suggested in Table 12.5. Rashes and bone marrow suppression due to co-trimoxazole may require switching to alternative prophylactic agents such as dapsone.

Routine active immunisation schedules should be followed for HIV-infected or -exposed infants, with the exception that BCG should not be given to symptomatic infected children because of the risk of dissemination. There is a theoretical risk of paralytic poliomyelitis in immunocompromised contacts of children excreting live polio vaccine virus. Inactivated polio vaccine (IPV) may be recommended by injection instead of the live oral polio vaccine. In practice it can be difficult to obtain supplies of IPV in the UK, and in view of the very low transmission rate of HIV, many units now condone giving oral polio vaccine (OPV), and advise carers about thorough hand-washing when changing nappies.

Pneumococcal polysaccharide vaccine has been recommended for HIV-infected children over two years of age, but is likely to be superseded soon by conjugate vaccines which can be given to younger children. Influenza vaccine is generally offered each winter, although data demonstrating its efficacy in this population are lacking.

Passive immunisation of symptomatic children is recommended if they are in contact with varicella zoster virus (VZV) and are either VZV naive or have no detectable specific antibodies to VZV. Varicella zoster immunoglobulin (VZIG) ideally should be given within 72 hours of contact. VZIG may prolong the incubation period to 28 days, so clinicians need to consider isolating these patients at clinic visits. Similarly normal human immunoglobulin should be given for susceptible symptomatic children in contact with measles. If children are stable on HAART with CD4 counts above 15%, passive immunisation is unnecessary.

Regular intravenous immunoglobulin infusions (400 mg/kg every 28 days) should be reserved for children with recurrent bacterial infections despite good compliance with co-trimoxazole prophylaxis, or those with proven hypogammaglobulinaemia. Higher doses may be useful in the management of thrombocytopenia (0.5–1.0 g/dose every day, for three to five days).

HIV-infected children who are household or day care contacts of individuals with open pulmonary tuberculosis should be carefully assessed, bearing in mind skin testing is frequently unhelpful because of anergy. If there is no evidence of infection, prophylactic isoniazid for six months, or isoniazid plus rifampicin for three months, is recommended. There is little enthusiasm for prophylaxis against *Mycobacterium avium intracellulare* in children because of adverse reactions and the potential for resistance and breakthrough on single agents such as rifabutin. The most appropriate prophylaxis for all OI is to optimise antiretroviral therapy to restore and preserve immune function.

Table 12.6 Suggested doses of co-trimoxazole for prophylaxis for *Pneumocystis carinii* pneumonia, to be given once daily on three days per week (usually Monday, Wednesday and Friday). Dose is based on 900 mg/m² dose

Surface area (m ²)	Dose of co-trimoxazole (mg)
0.25–0.39	240
0.40–0.49	360
0.50–0.75	480
0.76–1.0	720
> 1.0	960 (adult dose)

Figure 12.12 Survival of HIV infected children with an AIDS diagnosis by 1 year (UK and Ireland). Survival has improved significantly for those born after 1993 CMV, Cytomegalovirus infection; PCP, pneumocystis carinii pneumonia. Reproduced from Williams A *et al.* PCP and CMV infection in children with vertically acquired HIV infection. *AIDS* 2001;15: 1–5

Figure 12.14 Malawi study (infants enrolled at median age 8 months)

Supportive care

Unlike almost any other life-threatening disease of children, HIV simultaneously threatens the parents and other siblings. The parents' own health, their social isolation and feelings of guilt compound the difficulties of caring for a sick child. An effective well-coordinated multidisciplinary team is required to address the changing needs of infected and affected children and their caregivers. Continuity of care between inpatient and outpatient services, local referring hospitals and the community needs to be developed. Ideally adults and children should be treated in family-based units. All too often parents will ignore their own health needs because they put their children first.

Increasingly the work of the multidisciplinary team has shifted towards ways of helping families achieve long-term adherence to HAART. As children survive longer, meeting the needs of adolescents and planning transition to adult clinics is placing new demands on services.

The decision as to who should be informed should be tailored individually. Families may need help in explaining the diagnosis to older children. This needs to be undertaken at the child's pace, and is frequently most effectively achieved in gradual steps. It is not mandatory to tell staff at schools, as universal precautions should be employed for all children with cuts and abrasions. The risks of transmission from casual contacts in school or day care settings are virtually nil. Ensuring that adolescents are well informed and responsible before they become sexually active themselves is a priority.

The child's developmental needs require careful monitoring and support, with access to a clinical psychologist, a physiotherapist, occupational therapist and speech therapist.

The multidisciplinary team should include a dietician, as nutritional problems and growth faltering are very common

complications. Balanced supplements are sometimes required and enteral feeding through gastrostomy tubes and occasionally intravenous parenteral feeding may be necessary. Gastrostomy tubes have been used with success to allow unpalatable medicines to be given, even when they were not required for nutritional supplementation.

Because children below the age of eight years very rarely complain of symptoms of unilateral eye disease, regular monitoring of young children with CD4 counts less than 5% by a paediatric ophthalmologist is desirable. Chorioretinitis due to CMV is usually treated by intravenous induction therapy with ganciclovir followed by regular maintenance intravenous treatment five days per week. Paediatric formulations of oral ganciclovir are poorly bioavailable. Intravitreal injections and, in older children, implants have been used.

Pain management is of critical importance in late-stage disease. Complementary therapies such as therapeutic touch and aromatherapy may be useful and require evaluation. It is a testament to the success of HAART that very few children in industrialised countries are needing palliative or terminal care. However unless new treatment strategies become available, the next few years may see some children running out of therapeutic options.

Prevention remains the top priority in managing HIV infection in children. Reducing national perinatal transmission rates to below 2% is an achievable target that can only be realised if HIV-infected mothers can be identified prenatally and offered appropriate interventions. This will require continued effort by health professionals, public health planners and community organisations.

13 HIV counselling and the psychosocial management of patients with HIV or AIDS

Sarah Chippindale, Lesley French

What is HIV counselling?

Counselling in HIV and AIDS has become a core element in a holistic model of healthcare, in which psychological issues are recognised as integral to patient management. HIV and AIDS counselling has two general aims: (1) the prevention of HIV transmission and (2) the support of those affected directly and indirectly by HIV. It is vital that HIV counselling should have these dual aims because the spread of HIV can be prevented by changes in behaviour. One-to-one prevention counselling has a particular contribution in that it enables frank discussion of sensitive aspects of a patient's life – such discussion may be hampered in other settings by the patient's concern for confidentiality or anxiety about a judgemental response. Also, when patients know that they have HIV infection or disease, they may suffer great psychosocial and psychological stresses through a fear of rejection, social stigma, disease progression and the uncertainties associated with future management of HIV. Good clinical management requires that such issues be managed with consistency and professionalism, and counselling can both minimise morbidity and reduce its occurrence. All counsellors in this field should have formal counselling training and receive regular clinical supervision as part of adherence to good standards of clinical practice.

When is HIV counselling necessary?

Pre-test discussion

A discussion of the implications of HIV antibody testing should accompany any offer of the test itself. This is to ensure the principle of informed consent is understood and to assist patients to develop a realistic assessment of the risk of testing HIV antibody positive. This process should include accurate and up-to-date information about transmission and prevention of HIV and other sexually transmitted infections. Patients should be made aware of the “window period” for the HIV test – that a period of 12 weeks since the last possible exposure to HIV should have elapsed by the time of the test.

Patients may present for testing for any number of reasons, ranging from a generalised anxiety about health to the presence of HIV-related physical symptoms. For patients at minimal risk of HIV infection, pre-test discussion provides a valuable opportunity for health education and for safer sex messages to be made relevant to the individual. For patients who are at risk of HIV infection, pre-test discussion is an essential part of post-test management. These patients may be particularly appropriate to refer for specialist counselling expertise. In genitourinary medicine clinics where HIV antibody testing is routinely offered as a part of sexual health screening, health advisers provide counselling to patients who have been identified as high risk for testing HIV positive.

The importance of undertaking a sensitive and accurate sexual and/or injecting drug risk history of both the patient and their sexual partners cannot be overstated. If patients feel they cannot share this information with the physician or counsellor then the risk assessment becomes meaningless; patients may be inappropriately reassured, for example, and be unable to disclose the real reason for testing. Counselling skills are clearly an essential part of establishing an early picture of the patient

Box 13.1 Counselling

Prevention

- Determining whether the lifestyle of an individual places him or her at risk
- Working with an individual so that he or she understands the risks
- Helping to identify the meanings of high-risk behaviour
- Helping to define the true potential for behaviour change
- Working with the individual to achieve and sustain behaviour change

Support

- Individual, relationship and family counselling to prevent and reduce psychological morbidity associated with HIV infection and disease

Box 13.2 Different HIV counselling programmes and services

- Counselling before the test is done
- Counselling after the test for those who are HIV positive and HIV negative
- Risk-reduction assessment to help and prevent transmission
- Counselling after a diagnosis of HIV disease has been made
- Family and relationship counselling
- Bereavement counselling
- Telephone “hotline” counselling
- Outreach counselling
- Crisis intervention
- Structured psychological support for those affected by HIV
- Support groups

Box 13.3 Pretest discussion checklist

Indications for further counselling and referral to counsellor

- People who have been sexually active in areas of high HIV prevalence
- Men who have sex with men
- Current or previous sexual partners HIV positive
- Client presenting with clinical symptoms of HIV infection
- High-risk sexual behaviour
- High-risk injecting drug practices
- Learning or language difficulties

Points for counsellor and/or physician to cover

- What is the HIV antibody test (including seroconversion)?
- The difference between HIV and AIDS
- The window period for HIV testing
- Medical advantages of knowing HIV status and treatment options
- Transmission of HIV
- Safer sex and risk reduction
- Safer injecting drug use
- If the client were positive how would the client cope: personal resources, support network of friends/partner/family?
- Who to tell about the test and the result
- Partner notification issues
- HIV status of regular partner: is partner aware of patient testing?
- Confidentiality
- Does client need more time to consider?
- Is further counselling indicated?
- How the results of the test are obtained (in person from the physician or counsellor)

HIV counselling and the psychosocial management of patients with HIV or AIDS

and his/her history and of how much intervention is needed to prepare him or her for a positive result, and to further reinforce prevention messages. It is at this stage that potential partners at risk are identified which will become an important part of the patient's management if HIV positive.

Post-test counselling

Results

HIV results should be given simply, and in person. For HIV negative patients this may be a time where the information about risk reduction can be "heard" and further reinforced. With some patients it may be appropriate to consider referral for further work on personal strategies to reduce risks, for example one-to-one or group interventions. The window period of 12 weeks should be checked again and the decision taken about whether further tests for other sexually transmitted infections are appropriate.

HIV positive patients should be allowed time to adjust to their diagnosis. Coping procedures rehearsed at the pre-test discussion stage will need to be reviewed in the context of the here and now; what plans does the patient have for today, who can they be with this evening? Direct questions should be answered but the focus is on plans for the immediate few days, when further review by the counsellor should then take place. Practical arrangements including medical follow-up should be written down. Overloading the patient with information about HIV should be avoided at the result giving stage – sometimes this may happen because of the health professional's own anxiety rather than the patient's needs.

Newly diagnosed patients

Counselling support should be available to the patient in the weeks and months following the positive test results. Immediate issues often include disclosure to others which may present a complex challenge to the patient. Current and previous sexual partners at risk will have been identified at the pre-test discussion stage and possible ways of informing these people will be explored with the counsellor. It is also important to discuss safer sex with those diagnosed with HIV. Pregnant women who test HIV positive need information and advice on the management of their pregnancy, including: options on reducing the risk of materno-fetal transmission, options for their own treatment and referral to specialist medical and counselling support. Although testing HIV positive is not a reason *per se* for seeking a termination of pregnancy, all women should be given the opportunity to discuss this if appropriate. Families may be a source of support but in many instances patients need time to come to terms with their diagnosis and to fully understand its implications before they have the capacity or resources to raise it with parents, siblings and/or loved ones who will inevitably be distressed. Being identified HIV positive may facilitate constructive planning for the future, such as deciding on the future welfare and care of children, although this tends to happen later in the counselling process when the early shock has resolved.

Counselling involves understanding a person in their social and familial contexts and many patients will derive crucial support and strengthening of coping mechanisms from this intervention during this vulnerable period. Counselling support can also help a patient engage in wider medical care and monitoring. If a person is inadequately prepared for the test, or a positive result is given inappropriately, he or she may reject further intervention including accessing medical care and therefore the likelihood of psychological morbidity and disease progression may be increased. It seems the "getting it right" for patients at early stages of diagnosis has a profound effect upon

Box 13.4 Counselling skills

- Empathy
- Non-judgemental approach
- Active listening
- Clear discussion and information giving
- Ability to establish working relationship with client
- Facilitating appropriate planning by the client
- Motivating appropriate self-care and reflective abilities

Box 13.5 Post Test Counselling – HIV Positive Result IMMEDIATE FOLLOW-UP

- Time for "ventilation"
- Awareness of shock factor – keep information to a minimum
- Focus on coping today, tonight, next few days
- Who knows the patient is receiving the result today?
- Safer sex/Partners
- Arrangements for confirmatory HIV test
- Follow-up medical and counselling appointment
- Written information – support numbers

Box 13.6 Psychological issues in HIV/AIDS counselling

Shock

- of diagnosis
- recognition of mortality
- of loss of hope for the future

Fear and anxiety

- uncertain prognosis
- effects of medication and treatment/treatment failure
- of isolation and abandonment and social/sexual rejection
- of infecting others and being infected by them
- of partner's reaction

Depression

- in adjustment to living with a chronic viral condition
- over absence of a cure
- over limits imposed by possible ill health
- possible social, occupational and sexual rejection
- if treatment fails

Anger and frustration

- over becoming infected
- over new and involuntary health/lifestyle restrictions
- over incorporating demanding drug regimens, and possible side-effects, into daily life

Guilt

- interpreting HIV as a punishment; for example, for being gay or using drugs
- over anxiety caused to partner/family

ABC of AIDS

their capacity to cope in the subsequent months and years, and to access help appropriately in later stages of disease.

The importance of encouraging and working towards coping strategies involving active participation (to the extent the patient can manage) in planning of care and in seeking appropriate social support has been demonstrated clinically and empirically. Such an approach includes encouraging problem solving, participation in decisions about their treatment and care, and emphasising self-worth and the potential for personal control over manageable issues in life.

Psychological responses to an HIV positive result

Many reactions to an HIV positive diagnosis are part of the normal and expected range of responses to news of a chronic, potentially life-threatening, medical condition. Many patients adjust extremely well with minimal intervention. Some will exhibit prolonged periods of distress, hostility or other behaviours which are difficult to manage in a clinical setting. It should be noted that serious psychological maladjustment may indicate pre-existing morbidity and will require psychological/psychiatric assessment and treatment. Depressed patients should always be assessed for suicidal ideation.

Effective management requires allowing time for the shock of the news to sink in; there may be a period of emotional “ventilation”, including overt distress. The counsellor should provide an assurance of strict confidentiality and rehearse, over time, the solutions to practical problems such as who to tell, what needs to be said, discussion around safer sex practices and adherence to drug therapies. Clear information about medical and counselling follow-up should be given. Counselling may be of help for the patient’s partner and other family members.

Counselling can also be offered to the patient and their partner together. This should only take place with the patient’s explicit consent, but it may be important for the following reasons listed in Box 13.7.

Partners and family members sometimes have greater difficulty in coming to terms with the knowledge of HIV infection than the patients do themselves. Individual counselling support is often required to manage this, particularly role changes within the relationship, and other adjustment issues that may lead to difficulties. This is part of a holistic approach to the patient’s overall health care.

In many cases the need for follow-up counselling may be episodic and this seems appropriate given the long-term nature of HIV infection and the different challenges a patient may be faced with. The number of counselling sessions required during any of these periods largely depends on the individual presentation of the patient and the clinical judgement of the counsellor.

The worried well

Patients known as the “worried well” present with multiple physical complaints which they interpret as sure evidence of their HIV infection. Typically, fears of infection reach obsessive proportions and frank obsessive and hypochondriacal states are often seen. This group shows a variety of characteristic features, and they are rarely reassured for more than a brief period after clinical or laboratory confirmation of the absence of HIV infection. A further referral for behavioural psychotherapy or psychiatric intervention may be indicated, rather than frequent repetition of HIV testing.

Box 13.7 Advantages of counselling patient with their partner

- Adjustments to sexual behaviour and other lifestyle issues can be discussed and explained clearly to both.
- If the patient’s partner is HIV negative (i.e. a serodiscordant couple) particular care and attention must be paid to emotional and sexual consequences in the relationship.
- Misconceptions about HIV transmission can be addressed and information on safer sex given.
- The partner’s and the patient’s psychological responses to the diagnoses or result, such as anxiety or depression, can be explained and placed in a manageable perspective.
- There may be particular issues for couples who have children or who are hoping to have children or where the woman is pregnant.

Box 13.8 Causes of uncertainty

- The cause of illness:
 - Progression of disease
 - Management of dying
 - Prognosis
 - Reactions of others (loved ones, employers, social networks)
- Effects of treatment
- Long-term impact of antiretroviral therapy
- Impact of disclosure and how this will be managed

Box 13.9 Characteristics of the worried well

- Repeated negative HIV tests
- Low-risk sexual history, including covert and guilt-inducing sexual activity
- Poor post-adolescence sexual adjustment
- Social isolation
- Dependence in close relationships (if any)
- Multiple misinterpreted somatic features usually associated with undiagnosed viral or postviral states (not HIV) or anxiety or depression
- Psychiatric history and repeated consultation with general practitioners or physicians
- High levels of anxiety, depression and obsessional disturbance
- Increased potential for suicidal gestures

Linking with community and statutory agencies

Counselling and testing should never be provided without clear, working links with services for back-up and complementary management. Links with these services should be planned as an integral part of any HIV/AIDS counselling initiative from the outset. This is particularly important for patients from ethnic minority communities. Such links must be kept open and flexible to ensure that medical information and advice are consistent across all levels of intervention. Finally, the value of groups in HIV psychosocial and stress management is amply demonstrated. Groups are valuable in reducing an individual's sense of isolation, in providing a safe place to express feelings, to share experiences, and to learn successful coping styles from others, for example support groups for those who are newly diagnosed.

HIV counselling and combination antiretroviral therapy

Significant developments in combination antiretroviral therapy have led to a surge of optimism about long-term medical management of HIV infection and people are now living much longer with HIV. Patient adherence is an important factor in the efficacy of drug regimens. However, taking a complicated drug regimen – often taking large numbers of tablets several times a day – is a constant reminder of HIV infection. The presence of side-effects can often make patients feel more unwell than did the HIV and some may be unable to cope with the side-effects. Counselling may be an important tool in determining a realistic assessment of individual adherence and in supporting the complex adjustment to a daily routine of medication.

Discussions on safer sex are important, as drug-resistant HIV strains are emerging which limit treatment options for those acquiring such strains. Many patients diagnosed with HIV some years ago are now feeling well enough to return to work, to study and are, paradoxically, learning to readjust to living as they had formerly adjusted to the possibility of dying. Patients also have to deal with the uncertainty which remains about long-term efficacy of current medical treatment, and there are some who will fail on combination therapy. Even with the significant medical advances in patient management, counselling remains an integral part of the management of patients with HIV, their partners and family.

Box 13.10 Coping strategies

- Using counselling
- Problem solving
- Participation in discussions about treatment
- Using social and family networks
- Use of alternative therapies, for example relaxation techniques, massage
- Exploring individual potential for control over manageable issues
- Disclosure of HIV status and using support options

Box 13.11 Who is HIV and AIDS Counselling for?

- People worried that they might have HIV
- People considering being tested for HIV
- People who have been tested for HIV (both negative and positive)
- People unaware of the risks involved in behaviours that they are, or have been, engaged in
- People with HIV infection and disease, including AIDS
- People needing support with antiretroviral therapies
- People experiencing practical and emotional difficulties as a result of HIV infection
- Family/Partners/Friends of people with HIV/AIDS

14 Palliative care and pain control in HIV and AIDS

Rob George, Chris Farnham, Louise Schofield

This chapter looks at changes in the palliative care of HIV disease before offering practical guidelines in pain and symptom control and managing the days prior to death.

Managing uncertainty vs. managing death

HIV disease constantly challenged the acute/palliative interface with clinical constellations in which “curable” and palliative elements coexist. HAART (highly activated antiretroviral therapy) is the most recent example since which progression beyond “treatability” is less easy to discern. Similarly in cancer, palliative care’s role now includes support early in the disease journey to help manage the uncertainties associated with toxic treatments as well as the worries about disability and mortality. Such psycho-emotional, spiritual and social fallout is beyond the capabilities of linear, curative medicine to manage. Palliative (symptom-based) and therapeutic (pathology-based) approaches are not mutually exclusive. The unifying concept of palliative care these days is the management of uncertainty and suffering, only part of which is care of the dying.

A challenging disease

Many patients with HIV/AIDS come from marginalised groups. Characteristically, these minorities take up services late or sit uneasily with conventional care because of different health beliefs or mistrust. Consequently, we cannot approach them all in the same way; neither can we assume what makes a good death nor what comprises a family or close social group. These are the practical realities of patient-centred care.

Flexibility, collaboration and support

Effective care for patients in whom deterioration or death is a real but fluctuating possibility also confronts us with the need to integrate care flexibly. Patients facing chronic ill health or those with acute, highly symptomatic disease may benefit from specialist advice or shared care as much as those may in the terminal phase of their illness. It is only by close collaboration between teams that good outcomes will be achieved. This brings us to our shared problem: that of uncertainty and the ways in which curative and palliative strategies coexist.

The therapeutic dilemma

When palliation is simply supporting aggressive curative therapy, there is no problem. However, when disease is progressive or debilitating, or where prophylactic and maintenance regimens maintain residual health, but compromise the quality of the patient’s life, therapeutic decisions must take account of the burdens and benefits in personal as well as pathological terms. This is the idea that treatments may be futile not just by being ineffective, but also by being so destructive to quality of life that they may be worse than useless. Ethicists call this qualitative futility. In order for us to be of genuine benefit clinically, we must find effective ways of living in this tension between cost and benefit.

The quantity/quality equation

Balancing the costs and benefits of treatment formally and explicitly clarifies a patient’s best interest, particularly as health

Figure 14.1 Inter- and multidisciplinary care: essential professional groupings necessary for effective supportive and palliative care

Figure 14.2 Treatment – applying a cost–benefit ratio

begins to fail. Certainties, such as time and energy expended on a course of treatment or immediate and short-term benefits etc. then become increasingly important.

Try not to make assumptions about a patient's views or wishes. The subtle ways in which illness and the individual interact mean that social, psychological and existential/spiritual elements may be every bit as relevant to symptomatology as the underlying pathology. Be sure to discuss these issues with the patient trusting that those not wanting to be involved in decision-making will let you know. Refer on for psychological or pastoral help if you need to.

Working with uncertainty

One of the greatest fears for the chronically sick or dying is helplessness. The more a patient and family feel their agendas, wishes and hopes are being taken seriously, the better able they are to cope.

Never make rash promises or be blindly optimistic about all treatments. Patients respond very negatively to hopes that are raised and dashed. Professional denial is the single most common cause of anger expressed by patients against doctors. Avoid presenting options as unchallengeable. There are ways to communicate boundaries or margins of our uncertainty to ensure that patients are informed. Don't forget, consent is a dynamic process.

Discussing prognosis

Open sharing of information inevitably leads to questions about prognosis. Always speak to individuals where they are able to express emotions openly. Never do it on an open ward. Include significant others if possible and invite another professional (for example, the key nurse), who can reinforce the discussion and offer support after you have gone. Patients and families need to "re-run" many times and characteristically will hear only the first and last thing that you say.

To gauge a patient's level of knowledge, anxiety or fear, explore their understanding of the situation by starting conversations in an open way, simply by asking what they think is going on or how they feel their disease is fairing.

When you talk about time, according to the stage of illness, break the future into tangible and appropriately small blocks of time such as one to three months. The intervals chosen will depend on each case. Confine your prognostication to this period and use general terms such as better, the same or worse.

Never give a finite prognosis. Always say that the unexpected may happen. If possible arrange to review the discussion to answer outstanding questions. This will also provide the opportunity to revise an opinion.

Summary

Palliative and curative care are inescapably entwined but changeable and good practice recognises the fluid involvement of different colleagues in care. Palliative care brings: ways of talking about and engaging uncertainty, looking at care planning and dealing with the ethical difficulties around consent and refusals and is valuable at any stage of illness. Palliative care workers should be called on when necessary, not just when you have run out of options and certainly not left until a patient is actually dying.

Symptom Control

General points

The significance of symptoms

Noxious and debilitating symptoms, and pain in particular, can destroy one's quality of life sufficiently to be significant risk

Box 14.1 The essentials of partnership with patients

- The patient's priorities may be very different from yours
- Try not to make assumptions about a patient's views or wishes
- Quality of life generally, but not necessarily, becomes more important than the quantity as health wanes
- Be sure to discuss costs and benefits openly and in detail

Box 14.2 The patient is at the centre of decision-making

- Work in partnership with the patient and family
- Share responsibility for making decisions
- Maximise the patient's control over decision-making
- Work in a positive framework
- Agree specific tasks
- Set realistic goals
- Review regularly
- Remain open to creative options

Box 14.3 Consent is a dynamic process

- Set goals and objectives with the patient.
- Revised them as regularly as necessary – clearly it would be stupid to review weekly when a patient's prognosis is years and equally unhelpful to give a patient a 2-month appointment when you expect them to die in a few weeks.
- Particularly, review aggressive treatment to reach a specific goal immediately that objective is met: a patient's wishes may alter radically as a result of success or failure.
- Be realistic, yet at the same time be prepared to allow a patient to risk things such as travel, provided they are well informed.
- Above all plan positively: people wish to live not to exist.

Box 14.4 Answering questions about prognosis

- Choose a "safe" place
- Include significant others and/or other professionals
- Explore the patient's understanding
- Be honest; don't collude with unrealistic hopes and don't be afraid to say "I don't know"
- Be kind; allow the patient to set the limits on the discussion when exploring painful truths
- Arrange a future contact

ABC of AIDS

factors for depression and suicide irrespective of whether they are from a disease or its treatment. Symptom control is an essential part of curative treatments.

Interventions may not be conventional, for example using a drug for its side-effect rather than its accustomed indication (for example, opiates for breathlessness), or working psychologically with a patient's perceptions to alter a symptom's impact or its threshold. This idea of a symptom threshold or altering perception may be unfamiliar, but it holds the key to effective symptom control.

Thresholds

Symptoms only become problematic when a threshold is passed and one *perceives* there to be a problem. Anything that changes perception generally (fear, anxiety, etc.) can also alter symptomatology – information (bad news, unexpected deterioration, a new complication etc.) or feelings that are unwanted (fear of failing health, death, guilt, anger, bitterness, etc.) are all examples.

Non-medical symptom control

Equally, symptom thresholds can be raised by psychological interventions and measures that calm, allow patients to unwind or promote a coping mechanism. For example aromatherapy and other complementary therapies, meditation and prayer are effective for some. Massage and acupuncture have solid evidence to support their effects on musculoskeletal and myofascial pain, as do breathing exercises and respiratory pacing in breathlessness. Diet is obviously important in nausea, vomiting and bowel control.

Pain management

Pain is what the patient says it is. Leaving emotion and “soul” for the moment, pain can be classified in several different ways (Table 14.1). This is simplistic, but practical. Nociceptive pain is usually opiate sensitive and neuropathic pain is opioid resistant.

Evaluating pain

Over 90% of pains are controllable. All pain can be improved. Take a proper history and examine the patient to establish exactly what is going on.

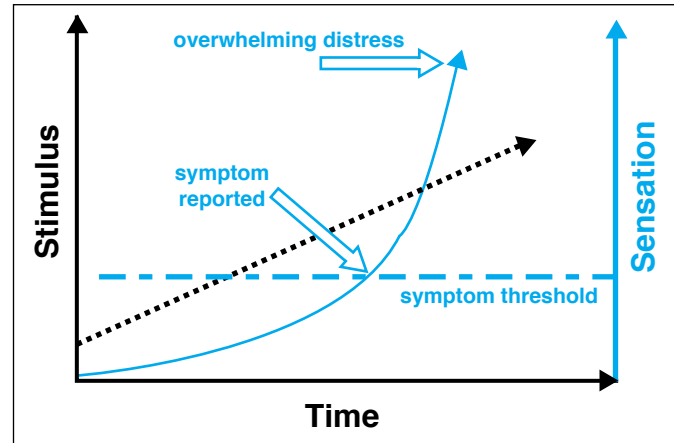

Figure 14.3 Symptom thresholds: the relationship between a noxious stimulus (for example, pain) and the reported symptom is exponential. Once past its threshold, without adequate treatment or a reduction in the process, the symptom will soon become intolerable. If the patient's threshold falls, the symptom will escalate in the same way, even when the underlying disease is stable

Figure 14.4 Symptom thresholds and what can change them

Table 14.1 Classification of pain

Location	“Source”		Opioid (morphine) Responsiveness			Anti-inflammatory
	Nociceptive	Neuropathic	Full	Partial	Resistant	
Visceral eg liver, bowel, myocardium, pleura	✓	✓	✓	✓		X (unless from lymph nodes)
Somatic for example, soft tissues damage, inflammatory diseases		✓	✓	✓	✓	✓
Bone pain for example, metastases, infarction	✓	✓	✓	✓		✓
Root irritation for example, compression, inflammation		✓	✓		✓	✓
Peripheral neuropathy, cord pathology		✓			✓	✓

Table 14.2 Drugs used in pain management

Weaker opioids	Strong opioids	Co-analgesics	Non-opioids
DHC	Oramorph	Anaesthetic agents	Muscle relaxants
Codeine	Diamorphine	Anti-convulsants	NSAIDs
Tramadol (?)	Hydromorphone	Anxiolytics	Paracetamol
Co-proxamol	Fentanyl	Corticosteroids	COX ₂ inhibitors
Oxycodone (also used as strong opioid)	Dextromoramide	Tricyclic antidepressants	
	Dipiponone		

To be able to monitor the pain it must be recorded accurately. Use body charts to localise the pain and get an estimate of each element of the pain by asking to score or grade the pain as a score out of 10 for intensity (0 = no pain, 10 = the worst pain you could imagine). This will help in monitoring treatment, but it will also give the patient a sense that pain is not fixed and can improve.

Opiates and nociceptive pain

Nociceptive pain is managed by using the World Health Organization (WHO) analgesic ladder. Over 90% of such pains are controllable in this way.

When prescribing *any* opiate, nearly all patients need a laxative and nearly 50% need an antiemetic.

Bottom rung: Paracetamol influences other drug's metabolism. However, in general, palliative physicians use doses up to 6 g a day. Similarly gastrointestinal complications (with appropriate prophylaxis) or renal impairment with NSAIDs are not absolute contraindications in patients with a short prognosis and severe pain.

Middle rung: The weak opiates, or compound analgesics (co-codamol, co-dydramol, etc.), may be helpful for mild to moderate pain. Formulations differ slightly in efficacy and prescribing is empirical. Low-dose strong opioid can be used. Dependency is less than 0.1%.

Upper rung: Many strong opiates are available. Morphine is the drug of choice by mouth. Use other opioids *only* where there is a specific problem with morphine. Alternatively using co-analgesics may reduce side-effects.

Box 14.6 Morphine facts

- Dose range is 1000-fold, (2.5 mg 4-hourly to 2.5 g 4-hourly or more)
- Most patients require less than 200 mg morphine equivalent per day
- It is not addictive when used therapeutically

Opiate toxicity

Toxicity is idiosyncratic and dose dependent. For some the therapeutic window may be very small. In poorly controlled pain (usually non-opioid responsive), escalating doses may lead to toxicity: confusion, hallucinations, agitation and myoclonic jerks. Paradoxical pain (loss of analgesia and increasing pain) may occur.

Confusion in the dying is complex and increasing opiates is not the only solution to increasing pain. You may need to stop all opiates until symptoms have subsided. *Seek the advice of an expert*

Good prescribing

Opioid responsive pain can normally be controlled within 24–48 hours. Morphine should be titrated using immediate-release formulations (Oramorph elixir, Sevredol tablets). Their effect peaks within the hour and last four hours. Titrate with a four-hourly regimen with “top-ups” for breakthrough pain of 25–50% dose and a 25–50% increase in the next scheduled dose as necessary. In individuals with hepatic or renal impairment the increases should proceed more slowly. Slow-release preparations (for example, MST b.d. or MXL o.d.) are best for maintenance. Immediate release formulations should continue to be available for breakthrough pain at a dose at least one-sixth the final 24-hour dose.

Box 14.5 Fundamentals of pain management

- Any pain, however generated, is a genuine symptom
- Always assume that there is a physical trigger, until proven otherwise
- The vast majority of patients have a combination of pain types
- The correct dose of an analgesic is that which relieves the pain

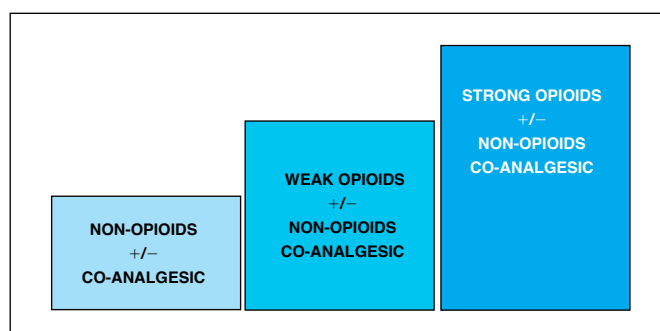

Figure 14.5 The WHO analgesic ladder

Box 14.7 Opioid side effects

- *Nausea and vomiting* – dose related
- *Constipation* – may be desirable, dose related
Peripheral effect
Always prescribe laxatives
- *Clouding of consciousness* – hallucinations rare
Central effect, fades with time
Warn the patient of initial drowsiness
- *Respiratory depression* – good for dyspnoea
Central + peripheral cough suppression
Pain has a partially protective effect
Increase dose carefully where chronic lung disease present
- *Itch* – histamine release

Box 14.8 Dealing with opiate toxicity

- The half-life of morphine and diamorphine is four hours
- Respiratory rates down to 5 or 10 are acceptable for a few hours
- Central effects can be antagonised, but will lead to rebound agitation and hyperresponsiveness
- It is best simply to stop the opiate and wait
- *In extremis*: naloxone is the specific antidote and reverses all the actions of opiates. Use very small doses
- Physostigmine can be used to selectively antagonise respiratory depression

Box 14.9 Prescribing for nociceptive pain

- By the ladder:
Don't forget that co-analgesics and non-opioids should be added to what you already use
- By the clock:
NEVER use prn pain control for example, 4-hourly for morphine liquid, 12-hourly for MST
- By the right route:
Use the mouth where possible, parenteral drug is no more effective

ABC of AIDS

Opioid non-responsive pain

Neuropathic pain: Drugs affecting nerve conduction or central processing usually work. Regimens are empirical as the numbers needed to treat (NTTs) between groups are similar; benefit may take several days to gain; neuropathic analgesics have significant side-effects and dose increases should be made slowly. Patient, family and staff may need support in keeping a steady hand whilst the best combinations are found.

Intractable cases or root or cord problems (for example, CMV) may need a nerve block or long-term epidural. Many different techniques are available. They carry potential morbidity, so use cost-benefit analysis with the patient to decide a plan. Do not make choices on behalf of the patient; immobility and incontinence free of pain may be a valid choice.

Compound pains: Many patients have pain from tissue damage and the nervous system simultaneously. Their treatment requires accurate diagnosis and specific co-analgesics. Morphine may play a part in their management. To read more on this see Further reading on page 95. Make a habit of enlisting specialist support with neuropathic and compound pains.

Total body pain and suffering

This is the difficult area of suffering and the subtle interactions of our psyche, beliefs and body. Some people use the terms “soul”, spiritual, or “emotional” pain. It is complex, distressing and very real (Fig 14.6). It stems out of a lowered threshold of distress and may occur with other symptoms as well. For understandable reasons, there is always an element of this in any dying person as they process and face their death and what it means. Fear and guilt are the common roots for many. Don't forget, *paene* (punishment) is the Latin root of pain.

Box 14.10 Neuropathic pain

- Generated in nervous system
- Source can be local nerve to thalamus
- Caused by:
 - Toxins for example, chemotherapy
 - Invasion/compression, for example, by tumour
 - Damage by viruses for example, HSV, CMV, HIV
 - Demyelination of any kind
 - Often coexists with nociceptive pain
 - May not present with classical dysaesthesia
- Seldom opioid responsive

Box 14.11 Neuropathic analgesics

- *Tricyclic antidepressants:*
 - Lofepamine (70 mg 1–3 times/day) or Amitriptylline (10–150 mg nocte +/- day time doses)
- *Anticonvulsants:*
 - Gabapentin (start dose of 300 mg up to 2700 mg)
 - Carbamazepine (100 mg b.d. up to 1600 mg per day),
 - Valproate (ranging from 200 mg to 1200 mg per day)
 - Phenytoin (up to 300 mg per day).
- *Benzodiazepines:*
 - Clonazepam (0.5–4 mg nocte),
 - Diazepam, midazolam (parentally)
- *Membrane stabilisers:*
 - Flecainide (100–200 mg b.d.),
 - Lidocaine (lignocaine) (subcutaneous or i.v. infusion in doses of 0.5–2 mg/kg/h)
- *Others:*
 - Clonidine, octreotide, etc. seek advice

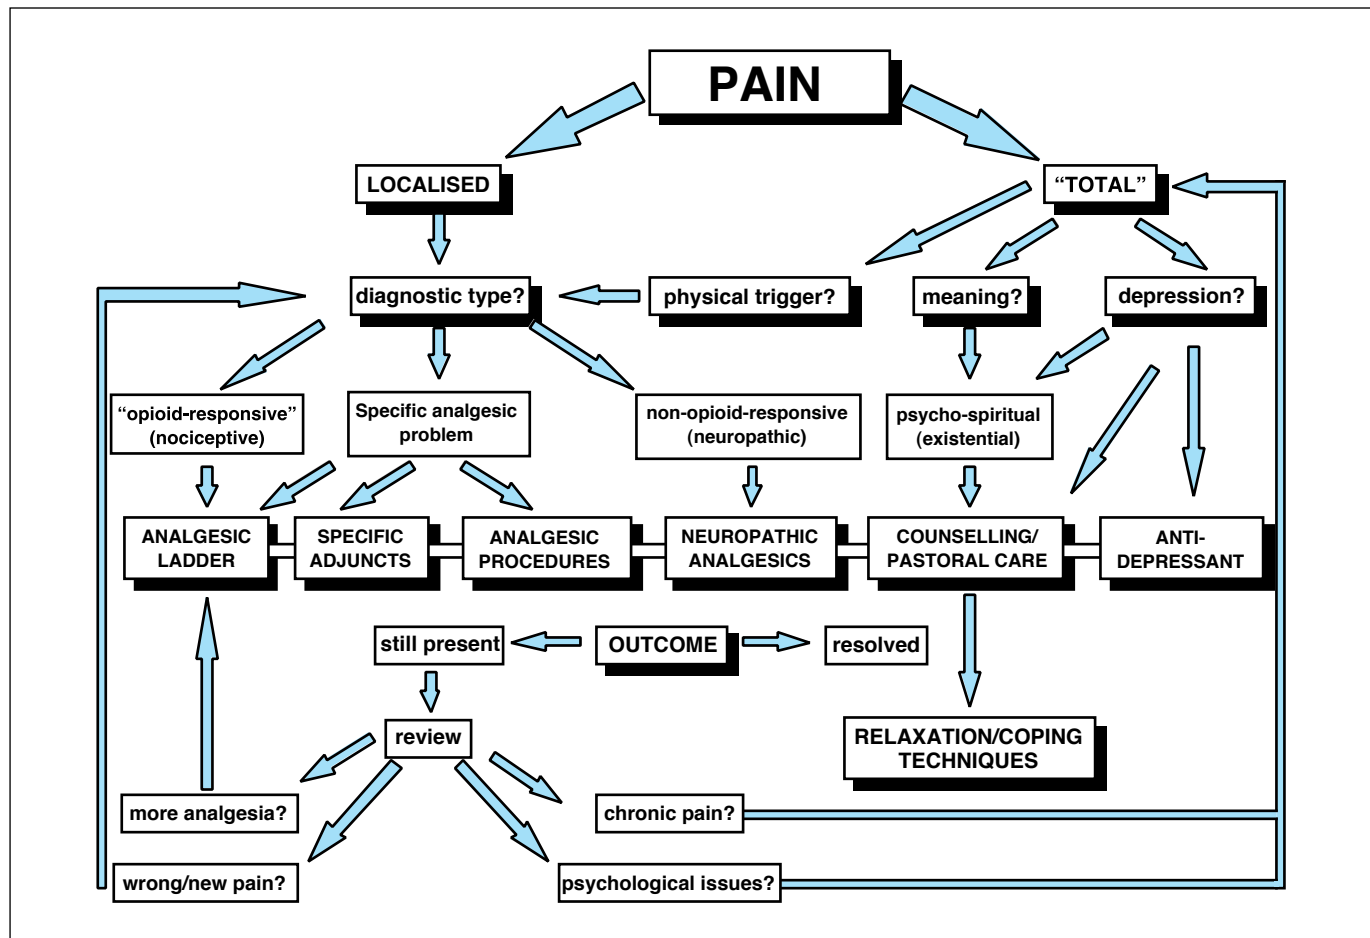

Figure 14.6 A therapeutic approach to pain

Effective management requires one to deal not only with any physical component, but also with the meaning of the symptomatology and the exacerbating effects of fear, anxiety, sleeplessness, loss of future, and of death and its connotations for the individual. In this difficult area do not be afraid to refer for help from a counsellor, psychologist or spiritual adviser.

Nausea and vomiting

These are the second most common symptoms, not least because of the burgeoning numbers of drugs that have gastrointestinal side-effects. Careful assessment should ensure a logical and methodical use of antiemetics.

General guidelines

Nausea and vomiting is usually “uncontrolled” because of erratic and illogical prescribing in inadequate doses given orally. These guidelines are therefore common sense, but necessary.

Assess nausea and vomiting separately. Nausea tends not to respond to prokinetics. Treat any potentially reversible causes and stop emetogenic drugs if possible. Anxiety exacerbates nausea and vomiting and may need specific treatment.

Box 14.12 Logical and methodical use of antiemetics

- One-third of patients require more than one antiemetic for satisfactory control
- Select the most appropriate drug for the putative cause
- Use regularly, at optimum dose
- Have a low threshold for parenteral routes
- Careful re-evaluation on a regular basis
- Use adjuvant drugs such as corticosteroids and antisecretory drugs

Figure 14.7 Guidelines for pain evaluation

ABC of AIDS

Prescribe the most appropriate first-line antiemetic for the likely cause according to the figure. Prescribe both regularly and as required. If the patient is vomiting, or has been nauseous for some time administer parenterally, preferably by continuous subcutaneous or intravenous infusion preceded by a stat dose. Optimise the dose daily taking into account breakthrough doses and reported level of nausea and vomiting.

If there is no improvement, rather than changing the drug, optimise the dose, and re-evaluate the cause. It may influence your drug choice. After 48 hours, substitute or add an appropriate second-line, broader spectrum antiemetic. A significant minority of patients need more than one antiemetic. Consider non-drug treatments, including acupuncture bands, control malodour, and ensure patient avoids foods that may precipitate nausea. If control remains poor, then refer. Only consider converting to equivalent oral regimen after 72 hours of good control and continue antiemetics indefinitely unless the cause is self limiting.

Other common symptoms

Other common symptoms are cognitive impairment, weight loss, malaise, weakness, pruritis, cough, diarrhoea, etc. Their differential diagnosis and appropriate investigations and management are covered more widely in the *ABC of Palliative Care*.

Death and dying

When treatment is futile, persevering with treatment and investigation can be obstructive in allowing a patient a dignified and meaningful death. The patient should be at the centre of the decision-making process as much as is possible. It is at this time that the multiprofessional team is so important.

Facilitating choice

If you have been managing your patients properly and involving them in decision-making, the groundwork for managing the last weeks or months should have been done, you will have a good enough relationship to be honest and open and to finish these last preparations. If you have not faced these with your patient in some form, even by flagging that “a time will come...” whilst not failing them as a technician, you will have failed as a doctor. This is the time to check regularly about a patient’s wishes. Proper links and services from primary care and social services are essential and friends, family and professionals should be as much “in the know” as possible.

Two additional symptoms

Movement-related pain

This is a common problem in dying patients with HIV and is best managed with NSAIDs. If the patient cannot swallow, then rectal indometacin is very effective.

Pulmonary secretions

Retained secretions in patients too weak to clear them can be controlled with hyoscine 0.6–1.2 mg s.c. over 24 h or glycopyrronium 0.6–1.2 mg s.c. over 24 hours. If they fail to clear, use furosemide (frusemide). Reassure family that noisy breathing of itself is not distressing to the patient.

Figure 14.8 Aspects of palliative care: some elements necessary to holistic practice in chronic or progressive disease

Box 14.13 Preparing for death

- Do they want active treatment if they deteriorate? If so, what level of resuscitation do they want? Is there a time or circumstances in which they wish treatment to be withdrawn or withheld?
- Will they feel more in control if these are written formally? A ‘Living Will’ or Advance Directive can be of great help to some patients by ensuring that their wishes are known if they become incapable. (See the BMA guidelines “Advance Statements: a guidance to practitioners”.)
- Have they said their goodbyes, sorrys and thank yous?
- Are there remaining personal matters to address: a will, funeral preparations, etc?
- Do they want to be at home? If so, is it suitable?

As death approaches

In the last days of life, pragmatism and sensitivity are essential. Patients have no appetite, are weak and somnolent or unconscious. Altered breathing patterns can last for days. Be calm and reassuring; relieve anxiety for both patient and carers by explanation that these changes are normal and don't cause physical suffering, which is true.

Most importantly continue to visit. The clinical situation can change very quickly. Assess symptoms regularly and change palliative therapeutics as necessary (even several times a day). As swallowing becomes difficult swap to parenteral routes. Most drugs for symptom control can be given continuously via a syringe driver subcutaneously. (Drugs can be mixed, see the charts in Twycross *et al.* 1998.) Figure 14.5 summarises management in the last few days of life.

With the limited communication, problems may manifest themselves as pre-terminal restlessness or distress. Possible physical and psychological/spiritual triggers need to be checked and acted on.

In general encourage the family to talk normally to the patient and to say whatever they need to say. Reassure them that the patient can hear and continue to explain all that you do to the patient and chat normally through procedures. This period of life, when the dying process is actively underway, may be short lived or take many days. In most cases we do not know what is taking place. Where beliefs are unknown or unfamiliar it is best presented neutrally as a time of transition; when our place is to care.

Box 14.14 Pre-terminal restlessness

- Exclude urinary retention
- Treat any suspected pain
- Check that there is not an important visitor that the patient must see or hear
- Check for an important date or anniversary
- Exclude any important religious rite
- Sedate as necessary; midazolam (starting at 10 mg/24 h), levomepromazine (12.5–300 mg/24 h).

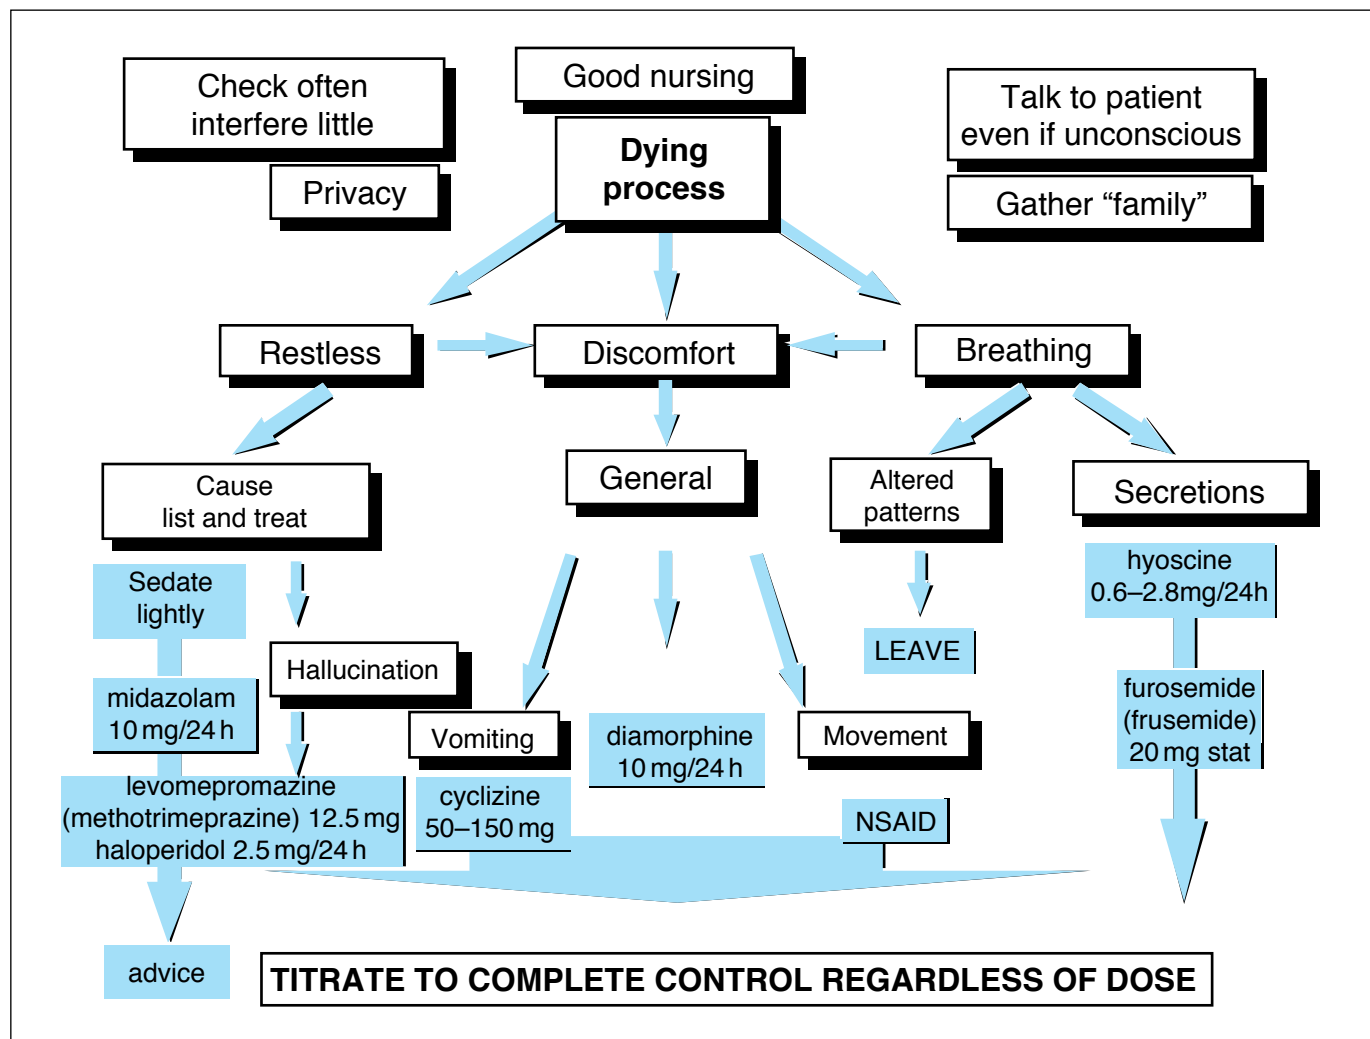

Figure 14.9 Pain management in the last few days of life

ABC of AIDS

It is important to allow those with religious beliefs the opportunity to see their advisors and perform necessary rituals as they wish. This can often lead to conflict if partners and family are of differing opinions. Give time to friends and family to spend talking over what has happened. Obviously you must be aware of the dynamics of the group and you must respect the patient's confidentiality.

Finally, a death affects us and the team involved. De-briefings and supervision work either individually or as a team can be most beneficial.

15 Control of infection policies

IJ Hart, Celia Aitken

Intensive epidemiological studies of HIV infection have shown that it is not transmitted in the community by casual or intimate non-sexual contact.

As of December 1999 there have been 96 documented instances of confirmed occupational transmission of HIV. There have been, in addition, 171 cases of HIV infection, possibly resulting from occupational transmission in exposed individuals with no other known risk of infection. The rate of transmission after a single percutaneous exposure to HIV positive material is 0.32% (21 confirmed infections after 6498 exposures in 25 studies). The risk of infection after exposure of mucous membranes and/or conjunctivae to infected material is 0.03% (one confirmed infection after 2885 exposures in 21 studies).

It is important to design infection control policies which, while protecting staff against the risk of infection, do not compromise medical and dental care. HIV is one of several blood-borne viruses; carriers of these viruses may be perfectly well and individuals may be unaware that they are infected. Some, including the hepatitis viruses B and C, are potentially more infectious than HIV. Thus, healthcare workers and society in general need to adjust to the concept that direct contact with the blood of others may present a potential, albeit low, risk of infection.

In the UK the Department of Health and many other bodies have issued guidelines to educate and protect healthcare and community workers. Routine HIV screening of antenatal patients is now recommended, and testing of all those at risk is encouraged. Awareness of the risks, education, careful attention to work practices, provision of protective equipment and immunisation against hepatitis B, where appropriate, are measures which will reduce to a minimum the risk of infection with all blood-borne viruses.

Hospital care

HIV positivity *per se* is not an indication for isolating a patient in hospital. It may be necessary to consider source isolation, however, if there is evidence of active infection with other agents, such as *Mycobacterium tuberculosis*, varicella-zoster virus, or if there is a likelihood of extensive exposure to body fluids from, for example, haemorrhage or severe diarrhoea.

Medical practices should be of a sufficiently high standard to eliminate any risk of patient-to-patient spread of HIV in hospital. This is achieved, as part of general infection control procedures, by using disposables, and by paying careful attention to decontamination and sterilisation. Attempts to recycle disposables or to bypass accepted disinfection procedures may lead to nosocomial infection.

Staff should adopt sensible precautions if contamination with blood or other body fluids is likely. This applies particularly for the management of known virus carriers but should also be the routine for any patient. The concept of "universal precautions" for all patients is being introduced increasingly into healthcare. In most cases precautions entail no more than wearing disposable gloves and an apron, but in certain circumstances, such as bronchoscopy, protective spectacles and a mask may be necessary to protect the eyes and mouth. Most aspects of patient care and examination do not

ABC of AIDS

expose the staff to body fluids, and protective clothing is not required.

Many staff sustain inoculation injuries while manipulating needles and sharp instruments. Education and careful attention to technique will reduce the risks to a minimum. No attempt should be made to resheath needles unless a safe resheathing device is available, and needles should be placed immediately into safe sharps disposal containers, which should not be overfilled.

Although there is little epidemiological evidence of increased risk, many hospitals assume that special care should be taken during surgery on known or suspected HIV carriers. This usually means adopting pre-existing policies for hepatitis B carriers and may include the introduction of double-gloving and additional unnecessary protective clothing. Preventing unnecessary exposure to body fluids and trying to reduce the incidence of penetrating injuries to a minimum are the best defence against infections, which may be present, but unsuspected, in any patient.

Reports of transmission of HIV from a dentist to his patients have raised public concerns about the risks of acquiring HIV and other blood-borne viruses from healthcare workers. Guidelines produced by the UK Health Departments identify work practices known as “exposure-prone invasive procedures” as aspects of medical care that present a potential risk of transfer of a blood-borne virus from healthcare workers to patients.

Exposure-prone procedures are those where there is a risk that injury to the worker may result in the exposure of the patient’s open tissue to the blood of the worker. These procedures include those where the worker’s gloved hands may be in contact with sharp instruments, needle tips or sharp tissues (spicules of bone or teeth) inside a patient’s open body cavity, wound or confined anatomical space where the hands or fingertips may not be completely visible at all times.

Healthcare workers who are HIV positive or HbeAg positive carriers of hepatitis B are excluded from exposure prone procedures. HbeAb positive carriers are excluded if there is $>10^3$ copies/ml of HBV DNA in their blood. There are many reports of hepatitis B transmission from staff to patients but only one report of HIV transmission from a surgeon to one of his patients during orthopaedic surgery. The risk of HCV transmission from staff to patient is still not known but may be higher than previously thought. Clearly, the risks to the patient from HIV in health care workers are extremely low but the frequency of inoculation injury to the surgeon during the course of major surgery highlights the need for continued surveillance.

Sharps disposal

Clinical laboratory staff are at risk from certain pathogens which may be present in specimens. The Advisory Committee on Dangerous Pathogens originally produced specific guidelines for work on samples from HIV positive patients. These have now been reissued to encompass potential risks from all blood-borne viruses. The most important aspects of safety in the laboratory are education, training, and prevention of inoculation and skin contact with body fluids. It is important to review all laboratory procedures to reduce the use of needles and the danger of exposure to glass fragments. This may necessitate increased investment in automatic pipetting systems to replace the need for glass pipettes. The absence of evidence of airborne transmission means that HIV positive samples may be handled on the open bench providing the work is conducted in optimal facilities and the operator is free from distraction and

Figure 15.2 A vacuum collection system of the type shown reduces the risk of spillage when large volumes of blood are required

Figure 15.3 Safe sharps disposal

disturbance. The current practice of alerting laboratory staff to samples from known or suspected HIV positive patients by the use of biohazard stickers may be defended on the basis that it reduces risks. It must, however, be emphasised constantly that in the present epidemic no unfixated specimens can be considered free from infection.

Community aspects

HIV carriers in the community present no risk to others from normal day-to-day contact. The combined effects of dilution, temperature and detergent action ensure that standard washing procedures will satisfactorily decontaminate cutlery, crockery and clothing. All blood spillages should be decontaminated with hypochlorite (bleach) and carefully cleaned up. The absence of evidence that saliva can transmit HIV means that nobody should withhold mouth-to-mouth resuscitation from someone who has suffered a respiratory arrest. Members of the rescue services who frequently carry out resuscitation, often in cases in which facial injury exposes them to blood as well as saliva, are provided with masks and other devices. Anyone attempting to use a resuscitation device must be adequately trained as, in the wrong hands, it may prejudice the life of the casualty and in some cases increase the potential risks to the operator by causing bleeding.

Disinfection

An important method of reducing the potential infectivity of viruses is dilution. Thus procedures such as thorough cleaning and handwashing are central to any infection control policy and must never be neglected. HIV has been described as a fragile virus, and this is true to an extent. Although it is effectively inactivated by many different agents, survival of virus may be prolonged at ambient temperatures, and infectious virus may still be present in dried blood after a week. This means that any surfaces and fomites that have been in contact with clinical material must be decontaminated.

The trend towards the use of disposables reduces the need for decontamination in many areas. Thorough cleaning followed by heat sterilisation should be adopted, if at all possible, for any reusable equipment. Although HIV is inactivated by boiling, autoclaving has become the norm in clinical practice. With increasing numbers of HIV carriers in the community it is important for their protection to ensure that instruments are rendered free of all organisms, including bacterial and fungal spores. Organisms that may present no risk to people with normal immunity may lead to opportunistic infections if they are immunocompromised by HIV infection or other agents such as chemotherapeutic drugs.

Liquid disinfectants must always be considered a poor alternative to heat sterilisation. Difficulties exist controlling their potency, most are caustic, and most are rapidly inactivated by organic matter. For hospital or community use, if it is necessary to use a liquid disinfectant, it is sensible to choose one which is known to inactivate hepatitis B and other pathogens such as *Mycobacterium tuberculosis*, as well as HIV.

All waste that is contaminated with blood must be considered potentially infective and treated as "clinical waste" in accordance with the Health Services Advisory Committee's document "The safe disposal of clinical waste". Sharps containers must meet Department of Health specifications and must be incinerated before disposal.

Box 15.2 Community aspects of decontamination

- Cutlery, crockery, clothing decontaminated by normal washing
- Decontaminate blood spillages with bleach (hypochlorite)

Figure 15.4 Secure bagging for specimen and request sent to laboratory

Box 15.3 Disinfection

- Autoclave or use disposables if possible
- Hypochlorite (1000 ppm available chlorine) for general decontamination
- Hypochlorite (10 000 ppm available chlorine) if organic matter, including blood, present
- 2% Glutaraldehyde (freshly activated) NB: Beware of dangerous fumes

First aid and inoculation injuries

In the event of exposure to blood, simple first-aid measures should be applied immediately. Any blood or other body fluids on the skin should be washed away with soap and water. Splashes into the mouth or eye should be diluted by washing, and sterile eyewash bottles should be provided in any areas where this is likely to occur. A skin puncture should be encouraged to bleed in an attempt to express any material deposited in the wound. The wound should then be washed thoroughly. Any injury to a member of staff should be reported immediately to the person in charge and then to the occupational health physician or other medical adviser. In hospital this allows for the opportunity to investigate the state of health of the person inoculated and, if necessary, to take protective measures such as hepatitis B prophylaxis or antibiotic cover, or testing the source patient or the use of antiretroviral drugs. At present the recommended drugs for postexposure prophylaxis are zidovudine, lamivudine and indinavir. They should be taken for four weeks. An acceptable recommended alternative regimen is the use of nelfinavir instead of idinavir. However, allowances for pregnancy, drug interactions and potential antiviral resistance in the source may result in some modification to the final regimen. In these circumstances expert advice should be sought. The medical adviser should discuss whether blood samples should be taken for future reference of HIV testing and whether a programme of follow-up consultations should be started.

The medical adviser will need to obtain information about the source patient concerning possible indicators of HIV infection, including risk factors and results of previous HIV tests, medical history suggestive of HIV infection, and details of past and current antiretroviral therapy in patients known to be HIV infected. The source patient should be asked to consent to testing for HIV infection. This will entail pre-test discussion and obtaining fully informed consent. If the patient is unconscious when the injury occurs consent should be sought once the

Box 15.4 First aid

- Body fluids on skin, in eyes, or in mouth
wash away immediately
- Penetrating wounds
encourage bleeding
wash with soap and water
report to the supervisor and medical officer

patient has regained full consciousness. If the patient refuses testing, is unable to give consent because of mental illness or disability, or does not regain full consciousness within 48 hours, testing should be considered in exceptional circumstances only, such as where there is good reason to think that the patient may be HIV infected. In this case testing an existing blood sample for HIV infection may be done but only after consultation with an experienced colleague. The decision to test may be challenged in courts so be prepared to justify the decision. Only the source patient and those exposed to the infection may be told the result of the test and the result can only be entered into the patient's personal medical record with the patient's consent. If the patient dies HIV testing can be done if there is good reason to think the source patient may be infected. It is usual to seek the agreement of a relative before testing.

Those concerned with counselling people who have sustained inoculation injuries should have enough knowledge to provide current information about the risks of occupational exposure and should be able to advise on changes in lifestyle such as the adoption of safer sex practices.

In summary, the risk of transmission of HIV within hospitals and to carers in the community is low. Education of staff, good infection control procedures and safe working practices can help to minimise this risk. Due attention to these measures at all times will ensure the protection of patients and staff.

16 Strategies for prevention

John Imrie, Anne M Johnson

Introduction

Limiting the spread of HIV relies on health promotion activities to encourage and help sustain behavioural changes that reduce the risk of acquiring or transmitting the virus. Despite advances, the prospect of a widely available effective vaccine remains some distance off and behavioural interventions are likely to remain the backbone of HIV prevention for the foreseeable future. Appropriate prevention strategies are required in both developed and developing country settings and must be specific to the cultural, epidemiological and socio-economic environment of each country. This chapter focuses on HIV prevention strategies in the UK although some of the principles outlined are generalisable to other countries (chapter 10). This chapter deals with sexual and parenteral transmission of HIV. The prevention of perinatal transmission is addressed in chapter 12.

General health education

Government information campaigns and media attention in the 1980s raised the general public awareness of HIV/AIDS. Knowledge of transmission routes and risk reduction strategies (for example, condom use and reducing partner numbers) remains high, although public campaigns for HIV risk-reduction no longer have the same profile in the UK. Recent increases in sexually transmitted infections (STI) (for example, chlamydia and gonorrhoea) and high teenage pregnancy rates indicate that safer sexual practises are not consistent among young people. Age at first intercourse continues to decline and while there is some evidence of increased condom use in many countries, there has been little change in the numbers of people reporting multiple sexual partners. Those at greatest risk of poor sexual health outcomes are men who have sex with men, the under 25s, injecting drug users and their partners, inner city populations and some ethnic minority populations

Epidemiological data show an increasing trend in the number of heterosexually acquired HIV infections diagnosed in many developed countries. In the UK in 1999, for the first time the number of newly diagnosed HIV infections acquired heterosexually exceeded those acquired through sex between men. However the majority of heterosexually acquired infections in the UK remains among those with sexual partners in Africa (chapter 1).

These trends indicate the continued importance of general health education strategies for HIV prevention and sexual health promotion. Prevention messages can be delivered in many different settings, ranging from mass media, school sex education, community and youth organisations, through individual interventions in primary care, contraception services and specialist STD services. All health professionals can provide practical information and personally tailored messages to individuals.

Given the particular risk among young people, education for HIV prevention needs to take place in the broader context of sexual health education in schools, before young people become sexually active, as part of Personal Health and Social Education (PHSE). To remain effective over time, however, school-based sexual health and general HIV education strategies need to be

Figure 16.1 Dutch scratch card shows prevention messages can be delivered in different settings using a range of age appropriate techniques reproduced with permission from the Dutch Foundation for STD Control

Figures 16.2a and b Sex education content and delivery should be gender sensitive and take account of the different needs of boys and girls reproduced with permission from the Family Planning Association

ABC of AIDS

sustained, politically supported by central and local government, financially secure, and routinely assessed and revised to meet the changing needs of new generations of sexually active young people.

Current approaches to sex education in schools include both teacher-led and peer-led approaches. Generally outcomes of sex education have been poorly evaluated and the most effective methods of delivering sex education for achieving improvements in sexual health outcomes are uncertain. However, observational studies have indicated some key components of effective sex education programmes. Several randomised trials are currently under way examining a range of approaches, and they will hopefully provide some more definitive answers.

Preventing sexual transmission

The epidemiology of HIV within the UK indicates that the greatest risk of infection is still associated with particular behaviours or demographic characteristics. Identified behaviours with the highest risk of HIV infection are: sex between men, injecting drug use; sex with injecting drug users, and sexual contact in parts of Africa and other parts of the world, where heterosexual transmission predominates. In other parts of the world commercial sex workers are at greatly increased risk of HIV. In the UK, other than among sex workers who are also injecting drug users (IDUs), high rates of condom use with commercial partners have maintained low HIV prevalence among prostitutes.

While there has been massive expenditure on HIV prevention over the last decade, until recently there has been a dearth of high-quality evaluation and little evidence from randomised trials to demonstrate effectiveness of different interventions. However, there is now a growing evidence base to support targeted HIV prevention interventions, tailored to the cultural context and needs of particular groups. A small number of randomised trials have shown the interventions to be effective in reducing the frequency of specific risk practices (for example, unprotected penetrative vaginal or anal intercourse) and, in a few cases, the incidence of new STI. In general, these interventions have aimed to provide basic HIV/AIDS education (including instruction on correct and appropriate condom use), enhance motivation for behavioural change, and teach risk reduction and safer sex negotiation skills (including the ability to resist pressure for sex) and have been delivered in community, small group and individual settings.

However, effective interventions in a research setting may not yield the same results in “real life”. Careful consideration of local HIV epidemiology with a critical view of the generalisability of the intervention, will help to determine whether a specific intervention is appropriate and prevent spending limited resources on a programme that shows little benefit, or worse still, a negative effect. The literature contains examples of both.

No single intervention strategy is likely to be sufficient to address all of a group’s prevention needs. There is no evidence that “single-shot” prevention interventions have enduring effectiveness at a population level. Interventions need to be sustained, with careful monitoring to indicate when changes are necessary, and must adapt, particularly, to the evolving epidemiological, social and cultural changes in successive new generations.

Little has changed with respect to the core content of prevention messages: it requires sexual contact involving the exchange of body fluids or blood-to-blood contact for transmission to occur. Those who know they are HIV negative and in a mutually monogamous relationship, are not at risk of

Box 16.1 Approaches to sex education most likely to improve sexual health outcomes in young people:

1. Begin early (i.e. sex education should start with pre-teens)
2. Cover issues in an incremental and age-appropriate fashion
3. Address knowledge and attitudes, and provide practical skills (for example, using condoms)
4. Provide information, improve knowledge and build confidence to access sexual health and contraceptive services
5. Employ participative approaches (for example, role play)
6. Ensure content and delivery are gender sensitive, taking into account the different needs of boys and girls
7. Ensure understanding of different sexual choices (for example, delaying first intercourse, resisting pressure for sex) and different sexualities
8. Deliver interventions in a range of settings across the community (for example, involve parents and youth services)

Box 16.2 Practises that reduce the risk for acquisition or transmission of HIV

- Using condoms for all penetrative sexual intercourse
- Using adequate quantities of water-based lubricant for both vaginal and anal intercourse. (Oil-based products will cause latex condoms to perish. Lubricants containing spermicides (for example, Nonoxyl 9) may cause irritation and have not been demonstrated to be effective in reducing HIV transmission *in vivo*)
- Reducing numbers of sexual partners
- Adopting sexual practises that carry a lower risk for HIV transmission (for example, oral sex, mutual masturbation)
- Avoiding recreational drug use during sexual activity, or when sex is likely to happen
- Ensure timely screening and treatment for suspected STI
- For young people, delaying the age at which first sexual intercourse takes place

infection through sex. To limit sexual risk of infection, the most effective strategies are to reduce numbers of sexual partners, know about partners' previous sexual and drug-use history and adopt safer sex practices (for example, oral sex, mutual masturbation and use condoms). Although condoms do not provide total protection, correct and consistent use will substantially reduce the sexual risk of HIV, STI and pregnancy.

The challenge that remains is how to deliver innovative HIV prevention messages through a range of different community, and individual focused interventions to reduce HIV transmission.

The following sections examine some effective strategies in relation to specific populations at high risk.

Gay, bisexual and other men who have sex with men

In most industrialised countries, homosexual and bisexual men have been disproportionately affected by HIV/AIDS. Unprotected anal sex is the primary mode of transmission and receptive intercourse carries the greatest risk. The success of early safer sex promotion campaigns primarily led by gay organisations has been highlighted as one of the greatest early successes in HIV prevention with evidence of falling STI rates, stabilisation in HIV prevalence and rapid uptake of safer sex practices. Over time these changes have proved difficult to sustain. Although condom use has become a social norm within the gay community, in recent years increasing proportions of homosexual men are engaging in unprotected anal sex. This particularly involves sex between men who are known to be HIV positive, partners whose HIV status is unknown to each other and younger men (< 25 years) who are likely to have become sexually active in the era of HIV/AIDS, and were not exposed to the intensive campaigns of the mid 1980s.

Factors which may contribute to increasing risk behaviour include: "boredom" with prevention messages; failures to target appropriate messages to a new generation of gay men; and perceived decreased threat of HIV in the era of highly active antiretroviral therapy (HAART).

The content of the successful interventions targeting gay men varies, but have often included motivational training, audiovisual presentations (for example, eroticising safer sex), brief safer sex negotiation skills training, stress reduction training and intensive group counselling. Interventions such as these are likely to attract individuals with particular concerns about their sexual risk behaviours and greater motivation to address them, so such interventions alone are not likely to meet all of the prevention needs of men who have sex with men. These interventions are particularly relevant to men using genitourinary medicine (GUM) clinics and HIV testing services.

Knowing that face-to-face interventions will never be able to reach all of the people at risk, community level strategies offer the potential of reaching those who do not attend services. Broader strategies focused at the community level have been shown to be effective in reaching higher risk and vulnerable men who often do not participate in small group interventions. Prevention programmes involving outreach workers and peer-educators can be used to target men using community venues (for example, bars, clubs, saunas), public sex environments (for example, cruising grounds, public toilets) and other places where homosexual men meet to have sex. These strategies often follow the principals of empowerment or community-building models of health promotion, with the intervention being developed either by gay communities themselves, or in collaboration with public health or sexual health providers. The

ABC of AIDS

content of successful community-focused interventions varies, but among the most important components are peer and opinion-leader delivery of risk reduction messages, community-building activities and peer-outreach providing safer sex materials (i.e. condoms and lubricant). One of the very few rigorously evaluated and effective interventions that specifically targeted young gay men (for example, aged 18–29) was developed using these approaches.

Injecting drug users

HIV transmission between injecting drug users (IDUs) occurs primarily through sharing of HIV-contaminated syringes, needles and injecting equipment. IDUs and their partners are also at risk through sexual transmission. Since many, particularly female, IDUs support their drug habit through commercial sex they may be at risk of sexual transmission both to and from their commercial and non-paying partners.

The epidemiology of HIV infection in IDUs and the social and cultural context of drug use vary substantially between geographical areas. Identifying promising interventions most likely to succeed within a particular setting is reliant upon understanding the local epidemiology and drug-use culture.

Preventing HIV transmission in injecting drug users relies primarily on reducing the frequency of sharing needles, syringes and other paraphernalia used for injecting (“works”), and on ensuring that the risk of sexual transmission for paying and non-paying partners is minimised through safer sex practices. Effective strategies that reduce the risk of HIV transmission through injecting will have other benefits in reducing the incidence of other viral infections (for example, hepatitis B and hepatitis C).

Social, political and legal controversies have hampered prevention strategies to minimise the potential harm of injecting drug use to both the individual and the community, because of particular concerns that increasing the supply of clean injecting equipment would encourage injecting drug use. Research evidence from largely observational evaluations has shown these concerns to be largely unfounded.

Observational studies have demonstrated that needle exchange programmes (i.e. providing sterile needles and syringes in exchange for used ones) are the most effective base for prevention strategies with drug users. Needle exchange has been successfully delivered within health and social services, through outreach workers, and dispensing machines, and has been demonstrated to be associated with reduced HIV prevalence without increasing levels of drug use. Improved access to bleach cleaning kits (for shared needles and syringes) and training in effective cleaning procedures may reduce HIV transmission through needle sharing. However, the quality of available products and the complex skills required make this a poor substitute to access to clean needles, but better than no intervention at all.

Evidence supports outreach and peer-educators as the most effective way to reach drug users in the community. Former injectors and current injectors have been employed successfully in both roles. Other interventions, specifically low-threshold easy-access drug treatment programmes and oral methadone maintenance, have been shown to reduce overall levels of drug injecting. These interventions bring drug users into regular contact with service providers (whether outreach or service based), where opportunities to deliver other information, education and counselling interventions exist. In particular, treatment and methadone maintenance programmes can offer adjunct social, educational and rehabilitation interventions to break the cycle of drug use and increase the possibility of an individual’s integration into routine employment and

Box 16.3 Effective HIV prevention strategies targeting injecting drug users

- Making easily available sterile needles and syringes
- User-friendly, low-threshold drug treatment programmes, including oral methadone maintenance
- Sustained education through outreach programmes and peer education providing information, skills (for example, safer injecting), health services and social support
- Providing access to counselling and HIV testing
- Facilitating access to health care, support and STD services for IDUs with HIV infection
- Special programmes for high-risk subgroups (for example, sex workers, prison inmates, youths in detention)

Figures 16.5a and b An example of good practice in provision of effective accurate information for injecting drug users, reproduced from “A Guide to Safer Injecting”, with permission from HIT

mainstream culture. A supportive environment including political, financial and legal support for the programmes at both central government and the local level is essential for the long-term success of comprehensive programmes.

In parts of the world such as the USA where IDUs have suffered a particularly severe HIV epidemic, sexual transmission to the partners of IDUs is a major source of increasing heterosexual transmission. Programmes to prevent sexual transmission among IDUs have received much less attention than those for harm minimisation from injecting and there has been little demonstrable success in changing the sexual behaviour of IDUs. Approaches to changing behaviour in this population clearly need to incorporate those shown to be appropriate to all heterosexual populations. In addition, approaches that have shown some promise specifically among drug users include skills training in correct condom use, voluntary HIV testing and counselling, and sexual negotiation skills. Such programmes need to target in-treatment drug users, sex workers and female sexual partners of male drug users.

African and other ethnic minority communities

African and ethnic minority communities have become an important focus for targeting HIV prevention interventions, however evidence for effective interventions with this group is limited. The few interventions that have been rigorously evaluated have been developed in careful collaboration with the affected communities. They have considered carefully the cultural and social factors influencing sexual attitudes of the communities and treated HIV prevention within the context of wider sexual health, contraception and pregnancy. Within the UK context recent research into the sexual attitudes and lifestyles of diverse ethnic communities has provided guidance for the development of linguistically and culturally appropriate strategies. African communities in the UK are particularly severely affected by HIV. Many within these communities also face the additional challenges of relatively recent migration including problems of language, culture and isolation often along with possible economic and/or legal difficulties associated with refugee status. All these difficulties may in turn limit access to local service for treatment and HIV prevention.

Strategies for people with HIV infection

Until recently targeting prevention interventions to HIV positive individuals has been largely neglected. Affected communities have been understandably concerned about stigmatisation and discrimination, while those responsible for prevention have felt poorly equipped to tackle many of the key issues. As stigma and exceptionalism associated with HIV diminishes, opportunities emerge to build HIV prevention strategies where people living with HIV are partners in development and delivery of the interventions. The advent of highly active antiretroviral therapy (HAART) has led to improved survival and thus to an increasing number of people living with HIV in the population. This brings with it particular public health challenges for individuals and society. Clinicians and policy makers need to be aware that with widespread use of HAART comes responsibility for ensuring that the risk of transmission, and particularly the transmission of resistant or virulent strains, is minimised and that public health is protected. For those living with HIV, HAART may lead to improved quality of life and sexual relationships and increased longevity, but also raises the challenge of maintaining life-long safer sex

Box 16.4 Guidance for enhancing sexual health promotion and HIV prevention in minority ethnic communities

- Facilitating access to appropriate confidential adolescent and adult sexual health and HIV prevention services, including specialist services outside routine clinical settings in line with the expressed needs of the community
- Developing materials using appropriate language and images including materials appropriate for non-native English-speakers
- Early and continued sex education in schools to supplement and support provision in the home
- Assisting parents from cultures where sex in general is rarely discussed to discuss sex education
- Providing focused interventions for young boys in either school or community settings
- Prohibitive messages may be supported by some particularly older generations
- Exploiting and explaining the wider benefits of safer sex in relation to contraception and avoidance of other infections may increase the overall acceptability of messages with all audiences
- Focused work exploring assumptions made about “safe” partners and concurrent relationships in cultures where they are common
- Use of appropriate and community-specific delivery points, for example, settings appropriate to the specific culture
- Awareness of different migration, refugee and acculturation experiences between communities and between generations
- Promoting HIV testing within high-risk ethnic communities is likely to be extremely sensitive and should be treated with careful consideration and caution based on a clear understanding of the individual and community issues

Figure 16.6 Key materials should be available using appropriate language and images for minority groups and for non-native English speakers

ABC of AIDS

practices to avoid infecting others. Collectively, increased survival leads to a larger pool of infected people in the community who may pass on infection and there is already evidence that new HIV infections may once again be increasing in parts of the USA. While there are theoretical reasons to believe that HAART may decrease infectivity by decreasing viral load, at the population level, such gains may be counterbalanced by increased unsafe sexual behaviour, increased incidence of STIs, and the emergence of drug-resistant strains amongst those failing therapy, which in turn may lead to new infections resistant to currently available therapies.

Prevention trials specifically with those living with HIV are scarce. However, recent research and community consultation has provided indications of acceptable primary prevention approaches. Acceptable primary prevention strategies with HIV positive people include providing counselling and support in both one-to-one and small group contexts, providing specialist sexual health and STI screening services for HIV positive people, and offering social, emotional and sexual counselling support within HIV outpatient treatment services. As with other groups, interventions are more likely to achieve success if they occur in genuinely productive partnerships with leadership from the affected communities to overcome wider social prejudice and stigmatisation.

Voluntary counselling and HIV testing

Diagnosis of infected individuals has an important role in secondary prevention, because it allows infected individuals to benefit from treatment to reduce the chance of progression to severe immunodeficiency. Identifying those who are HIV positive in order to work with them to prevent onward virus transmission is also fundamental to primary HIV prevention.

Routine HIV antibody testing of pregnant women is now recommended throughout the UK. Positive women can then benefit from antiretroviral therapy to prevent perinatal transmission of HIV and advice to avoid transmission through breast feeding. Detailed recommendations on the management of HIV positive pregnant women is dealt with in chapter 12.

HIV counselling and testing is widely available in many clinical settings in the UK, particularly in genitourinary medicine (GUM) clinics. Counselling for HIV testing was originally developed in the pre-antiretroviral therapy era and much of the content focused on the nature and interpretation of the test, and the advantages and disadvantages of knowing ones' status in the context of an untreatable infection. All clients were also advised on risk-reduction strategies to prevent the acquisition or transmission of HIV through sex or injecting drug use. In the era of HAART, GUM clinics are increasingly offering routine testing and counselling as part of their clinical services in order to identify HIV positives.

The effectiveness of testing and counselling services in achieving behavioural change for primary prevention is limited and somewhat confusing. Brief client-centred counselling has been shown to be an effective strategy in reducing future STI acquisition in only one large-scale trial, while another study demonstrated its effectiveness in different developing countries using behavioural change endpoints. However, two major reviews of the effectiveness literature have concluded that testing and counselling are only effective as primary prevention strategies for achieving sexual behaviour change within carefully defined groups, including in-treatment drug users, commercial sex workers and post-test counselling and support for those who receive a positive result. Nevertheless, for its secondary prevention benefits and primary prevention value with specific groups, voluntary

counselling and HIV testing is still an important component of any comprehensive HIV prevention strategy.

The testing scenario has much to offer with respect to individually focused prevention. The process of HIV testing offers an opportunity to use a client-centred counselling approach to undertake an individual risk assessment, discuss and develop individually tailored personal prevention strategies and consider the implications of a positive result.

Control of sexually transmitted infections (STIs) and STI screening

There is now substantial evidence from observational, biological and intervention studies to show that STIs (both ulcerative and non-ulcerative) may increase the susceptibility of uninfected individuals to HIV and increase the infectiousness of HIV positive individuals. Control of STIs therefore has an important role in the primary prevention of HIV. In the UK, the network of GUM clinics provides open-access services for screening, treatment and partner notification for STIs. STI control is particularly important among populations at high risk of HIV infection. Screening and treatment offer an opportunity to focus behavioural interventions on those who have STIs. Increasingly, GUM clinics are recognising the importance of offering regular STI screening as part of routine HIV treatment services alongside appropriate counselling on risk-reduction strategies.

In developing countries, where the burden of untreated STIs is much greater and diagnostic and treatment services more limited, syndromic management approaches have been used. These combine clinical history with knowledge of local pathogens to devise treatment algorithms. Such strategies however appear to be most effective in terms of their specificity and sensitivity in identifying STI cases, where the prevalence of STIs is high.

Blood transfusion and blood products

In the UK and other developed countries, the risk of HIV transmission through blood transfusion has been minimised by testing all blood samples for HIV antibody and excluding those at increased risk from HIV from donating blood. The current categories for exclusion from blood donation in the UK are shown in Figure 16.8.

Travel to countries with high HIV prevalence

In some countries in Africa, HIV prevalence in the general population exceeds 20% and STI rates are much higher than in the UK. Unprotected sex is therefore associated with a high risk of both HIV and STI infections. All travellers to these countries need clear advice on sexual risk reduction through limiting sexual partnerships and always using condoms. There is no risk of transmission from casual contact. However, in some countries, HIV screening programmes for blood transfusions are not always in place, and there may be shortages of sterile medical equipment for injections and intravenous infusions. Sterile needle packs, first-aid kits (including needles, syringes and suture packs) and minor surgery kits are available for purchase or mail order from the Hospital for Tropical Diseases (London) Travel Clinic (2nd Floor Mortimer Market Centre, off Capper Street, London WC1E 6AU, tel. 020 7388 9600). Basic needle packs and larger made-to-order first aid and surgical packs can be ordered from Nomad Travellers Store and Medical Centre (3–5 Wellington Terrace, Turnpike Lane, London N8 0PX, tel. 020 8889 7014).

17 Being HIV antibody positive

Jonathan Grimshaw

Late in, 1984, when I was tested, HIV had only just been identified as the cause of AIDS. There was no formal counselling before or after testing, no organised emotional or social support in the community and certainly no prospect of treatment. The doctor who gave me the positive test result told me, kindly, that I seemed the sort of person who would be able to cope. I agreed. Never having been confronted by anything like this before I was ignorant of what “coping” would involve.

Initial reactions

I was very frightened. I was convinced I was going to die painfully and soon. I felt very alone. I knew no one else in the same situation. Public fear of AIDS and stigmatisation of “AIDS carriers” were at their height. Confiding in people, even friends, risked hostility and rejection, but I knew equally that friendships would not survive the level of deceit needed to conceal something so devastating. I thought I would never know sexual intimacy or love again. At that time, safer sex was not common behaviour; asking for it could raise the suspicion in a potential partner’s mind that you “had AIDS” and no one, I thought, could possibly want to be intimate with or have a relationship with someone who had the “AIDS virus”.

I expected, through illness, to lose my income, my security, my independence, my dignity and my self-esteem. I came to realise how much the things that give a life meaning and purpose – aspirations, dreams, motivation, hope, endurance, fulfilment – depend on the unconscious assumption of a future. Coping with HIV meant firstly coming to terms with the loss of that assumed future and secondly trying to give life some meaning and purpose in its absence. This comes with hindsight. At the time I couldn’t cope at all and spent much of the first few weeks after diagnosis drunk or tranquillised.

Peer support, counselling and referral

At the end of 1984 the Terrence Higgins Trust established its first support group for people diagnosed with HIV. It gave me and the others there a safe environment in which, for the first time, we could talk openly and honestly about what had happened to us. Most importantly, hearing other people describe feelings and experiences almost identical to one’s own made each of us realise that we were not alone. Learning that the frightening and unfamiliar extremes of fear, anger and grief that each of us had felt were a common and natural reaction to the situation we were in was the first step in our being able to see ourselves again as normal people rather than the “AIDS carrier” pariahs of popular perception.

The potential psychological and social impact of a positive HIV antibody test result are now well understood, as is the importance of counselling and referral to agencies that can support people emotionally and practically as they come to terms with the diagnosis and its implications for their lives. For many people, peer support continues to be a key part of that process.

Coping with uncertainty

It took some time for it to sink in that the positive result wasn’t necessarily a sentence of imminent death, but no one could tell me how long I had to live. In many ways an AIDS diagnosis would have been easier; it would have given me something

concrete to deal with. Being HIV antibody positive was a kind of limbo where you knew the axe would fall, but never when.

How people cope with this kind of uncertainty probably reflects how they cope with uncertainty in other areas of their lives; some avoid thinking about the future if it threatens contentment in the present, some throw themselves aggressively into trying to shorten the odds in their favour, some fatalistically assume the worst and prepare themselves for it.

My way of coping was to throw myself into community work developing services for people with HIV and prevention campaigns and establishing Body Positive. This was the first self-help group in the UK, and perhaps the world, for people with HIV. If I couldn’t fight the HIV inside me, I could at least fight the HIV outside me. I became very driven because, like many people confronted at a relatively young age by their mortality, and not knowing how long I had left, I didn’t want to die insignificantly. I had a lot to achieve with perhaps very little time.

One would very occasionally hear someone with HIV say that the diagnosis was the best thing that had ever happened to them. More than any other event or crisis, it forced them to think about what was important and re-arrange their lives accordingly. Certainly, the years after my own diagnosis were lived with an intensity and with a sense of fulfilment in my work that would probably not have been achievable without HIV to concentrate the mind.

Retirement

In the early 1990s my CD4 count, which had been declining very slowly over time, suddenly seemed to plummet and I developed some minor illnesses. In fact, the CD4 count never fell below the lower limit of what would be considered a normal range, but I convinced myself that the suddenly rapid decline meant that the deterioration to AIDS had begun. I retired from work, cashed in my pension and bought a nice place by the sea in which to pass my remaining few years. I had achieved what I needed – to feel that I had done something useful with my life – and I was completely ready for death.

After leaving work, my CD4 count stopped declining and I remained well. In retrospect, the retirement was probably necessary as I was almost certainly approaching “burn-out”, but it felt at the time as though HIV had fooled me into a premature withdrawal from life.

During 1997 my viral load started to double every three months and I began combination therapy. Since then my CD4 count has dropped below 500 only once, when I became resistant to one of the drugs. Since changing the combination, my viral load has been undetectable.

Living with HIV in the era of combination therapy

It is sometimes assumed that combination therapy has transformed the lives of people with HIV. Well, yes and no. In people who are HIV antibody positive it can postpone illness or an AIDS diagnosis. But in doing so it prolongs the uncertainty. The long-term efficacy of antiretroviral therapy is unknown.

This brings dilemmas of its own. For example, many healthy people in mid-life seeing an advertisement for a pension plan might wish they could put more money aside for their old age. But an HIV antibody positive person has to ask him/herself

“do I spend money and enjoy life now because there may not be an old age to save for, and risk impoverishment if there is; or do I save for old age and risk lying on a hospital bed in a year or two’s time regretting not spending my money and living life to the full while I was well?”.

I can only imagine how much more acute and agonising dilemmas of this kind – involving trade-offs between present and future – must be in families where a parent and possibly also a child has HIV.

There are other trade-offs, some more difficult than others. Never, for example, during all the years before combination therapy did I have to adapt my life to a medication regimen. It took some time to learn full adherence to the regimen, initially, I would simply forget very occasionally to take a dose when due. But, more fundamentally, adherence involves restricting freedoms that most of us take for granted – to eat what you want when you want, for example. It was difficult to adjust to my freedom being compromised by the treatment rather than the disease itself, although viewed in the light of the benefits of the treatment, these compromises were insignificant.

Although public education has removed much of the fear and prejudice surrounding HIV and AIDS, there are communities where HIV remains highly stigmatised and where people with HIV are discriminated against. Discrimination, real or perceived, restricts the choices one is able to make in life; it limits life’s potential – a cruel irony when medicine has found ways to prolong life with HIV.

Nor does combination therapy remove anxieties about falling in love and sexual intimacy. There is still the fear of revealing one’s status to a potential partner in case of rejection. Although my viral load is currently undetectable, I can’t assume that I’m not infectious. I must still insist on safer sex. The social acceptance of safer sex as normal, or at least sensible,

behaviour means that asking for it is less likely to be met with rejection, but having sex with someone entails a risk, however small, that unsafe sex could occur. I know from experience that it isn’t always possible to be totally in control of an activity in which someone else is playing an equal part. However much I rationalise that preventing transmission is a shared responsibility, because everyone has a responsibility to protect themselves, and that anyone wanting unsafe sex is probably HIV antibody positive themselves, I know I would feel a tremendous sense of guilt and failure of moral responsibility if unsafe sex did occur.

The HIV “veteran”

I was aware before combination therapy arrived that I had remained well for an unusually long time since diagnosis. Now it seems that combination therapy may keep me alive and possibly well for many years more. During the millennium celebrations it occurred to me that, if adulthood begins at 18 years, I have lived with HIV for over half my adult life.

I read recently that there is sometimes a striking similarity in how long-term survivors of HIV and war veterans describe their feelings about life. Both have had to confront their own mortality in a way that has led them to question, and sometimes reject, many of the assumptions which most people rely on to get through life. Large numbers of their peers and people they loved have died. As time goes on there are fewer and fewer people with whom they have a shared life experience. War might have made life more intense for a while, but with the perspective of long hindsight there is some bitterness about the damage it has done to their lives. They have a strange sense of not knowing quite where they belong. This describes me pretty well.

18 Having AIDS

Caroline Guinness

I was diagnosed in 1986 when there was very little knowledge of HIV. I had just been diagnosed as having precancer of the cervix, but I felt there was something else wrong – just an instinctive feeling – there was nothing in particular. So I went to my GP, and in fact saw a locum who was very young and enthusiastic. He felt my neck and said my glands were up, which I suppose alerted him to HIV, although he didn't say anything, suggesting it might be glandular fever. He took some blood, and said I should return three days later.

When I went back for the results he said they were negative for glandular fever, but that he had also requested an "AIDS test". I remember feeling really cold when he said that. I knew that maybe that was what it was, because two years beforehand, shortly after my husband left me and I was very vulnerable, I had slept with a bisexual man. I told the doctor that I thought he should have talked to me about it first, and that I wanted the test stopped. He said it was too late as it had already gone to the laboratories. I said in that case I didn't want to know what the result was.

About two weeks later, my own doctor who was back, just turned up at my house. He knew that I didn't want to know the result of the test, but he thought that, as an intelligent woman, I should know that it was positive. Even though I had some suspicions, I found that being told for definite was a different thing altogether. I went into shock. My first reaction was to ask how long I had to live, and he said probably about five years. My next thought was for my daughter, who was three years old at the time, and whether she would be infected too. The doctor didn't think there would be any risk to her as I had obviously contracted it after she was born, but I knew nothing about transmission or anything like that. He suggested another doctor at the practice who had more experience than him, and had been treating a couple of gay men, and that I should go and see her, which I did. She was really sweet, but she didn't know anything about other genitourinary medicine (GUM) clinics, voluntary agencies etc. On the other hand, she was good because she was a very firm believer in complementary therapies, so recommended vitamins and minerals and things which, looking back on it, was actually the best thing she could have done. But not having any counselling and not being in a specialist situation were not good. For the next six months or so I was just in denial – it hadn't sunk in at all. I didn't want to tell anybody because the atmosphere was really bad those days, lots of scaremongering in the Press, calling it the "gay plague" etc.

I did tell a couple of close friends whom I lived with at the time. One, as a gay man, found it very ironic as he thought that if anyone should have tested positive it should have been him, and the other was a girlfriend of mine who sort of panicked. She was OK, but having lost her partner a couple of years before, she couldn't bear the thought of losing somebody else, which of course didn't help me. I didn't want anyone like Social Services to know, as Lee had just started nursery school, and I didn't want it getting out. So I just kept quiet and I continued in my state of denial.

I couldn't cope with work at all – it seemed irrelevant. I told my colleagues that I needed treatment for my cervix which I thought might help explain my lack of concentration. Their reaction was that it wasn't such a big deal, and as I felt I couldn't tell them what was really happening, I resigned. That

left me with financial problems, but I didn't want to go to Social Services because of Lee.

I had a partner at the time whom I had been with for six months before being diagnosed, and having to tell him, and him having to get tested was the other thing that was really frightening. Because I didn't know how to tell him, I asked my best friend, whom he got on very well with, if he would tell him. My partner thought that he was going to be told I wanted to split up, so when he realised what it actually was, his initial reaction was one of relief, but the following two weeks, while he got tested and waited for the results, were pretty fraught. We had no information about transmission, but luckily the test came back negative, which was a relief.

My fears about Lee being infected went on for quite some time because I felt I was not getting any real reassurance. I worried about things like her using my toothbrush, and I remembered I had cut my finger and she had helped me put the plaster on, and stuff like that. All those things kept going through my mind. The doctor I was seeing didn't recommend that I had her tested, as she firmly believed Lee would be alright. Looking back on it, I think that if I had just had her tested then I would have felt a lot more reassured, because the whole issue bugged me subconsciously for a long time.

Another very stressful event which happened that year was that a close friend of mine told me he had AIDS. He didn't want anybody to know, and he asked if myself and a couple of other friends could look after him. His health went downhill so quickly and he started getting dementia and incontinence etc, and for me it was like looking in a mirror – very frightening. He did actually go public in the end, but he died shortly before Christmas, so all in all it was quite a bad year.

In 1987, about a year after my diagnosis, through the Terrence Higgins Trust (THT) I finally found out about GUM clinics and I attended James Pringle House, Middlesex Hospital, which made a huge difference to me. I really wanted to meet other HIV positive women – I'd never met any, and still felt as if I was the only woman who had the virus. Someone at THT told me about a support group called Positively Women, who met once a week, so I went along to the group and met a couple of other positive women which helped a lot. I eventually became the Director of Positively Women, and the next three years were really hard work. There was nothing for women at all, so we tried to produce leaflets and information. Despite doing interviews and media work, I never went public about my HIV status. Although our slogan said "For positive women, run by positive women", people never seemed to twig with me; I think they had some vision of what someone with HIV should look like, which I didn't really fit into. Positive women were very much seen as drug users or prostitutes, and most of the women were keeping quiet, usually to protect their families. Through Positively Women, I did many hospital visits to AIDS wards and I used to find that stressful, worrying that I might catch something if I was going to see someone with meningitis or TB.

However, after three years my energy was beginning to dwindle, and I also felt I wasn't spending enough time with Lee, so in 1991, I resigned as the Director, and went part-time. It gave me a bit more time to myself, and because I felt so run down I started using complementary therapies such as acupuncture reflexology, which I'm still having, and which made a difference.

I continued to attend the clinic every three months for a regular follow-up, and the relationship I had with my doctor was very good. She trusted my own judgement on my health, and I found we could work together. She also understood my need for complementary therapies. Seeing the same people on each visit helped maintain continuity and build up a relationship, which was important.

I decided to tell my daughter when she was about 10 years old. She's very bright and reads the newspapers, and it seemed the right time for her. Although I had never gone public about it, I knew it was going to get out at some point, and I didn't want Lee to find out from anyone else. I thought Lee might suspect, but in fact she hadn't. Her first reaction when I told her was to burst into tears, and then she felt embarrassed about crying which made me feel awful as it was quite a natural reaction. For a week or so she kept asking me how I was, and if there was anything in particular that she could do to help. I said she could give me a hand with the housework, but that didn't last very long – I don't think that was what she was expecting! It became immediately apparent that there were no services for children, and she was desperate to meet other kids in the same situation. I suggested to Lee that she didn't tell any friends for a while until she got used to the fact. Anyway she did actually tell a schoolfriend who immediately told everyone else which was exactly what I didn't want to happen.

Her school had been helpful – I had spoken to the Head, her teacher, and the school counsellor before telling her, but she still needed to talk to a trained counsellor, and again she needed to meet other kids in the same situation. None of the organisations offered services for children, but I got a letter from a woman in a similar situation and we met up so that Lee could meet her daughter, which was good for both of them, and at least she knew she wasn't on her own. Lee also started seeing a child psychologist which she really benefited from and she still goes along there when she wants to, but nothing regular.

I think that over the last year or so my energy really hasn't been so good, and as Lee has now reached 13 and is going through everything that 13 year olds do, I could really do with some help now. Her father was in Australia when I was diagnosed, and I didn't want to tell him by 'phone or letter, so I was hoping that he would be coming over to the UK at some point. Because I'd been told that I had about five years to live, I wanted to sort things out as quickly as possible. Anyway, he did come over and I told him, and he had a really odd reaction: he seemed to think I was trying to emotionally blackmail him, which really upset me. It was only later that I found out through a mutual friend that he felt that if he hadn't left me for someone else, I would never have slept with this bisexual man, and so he felt responsible, a thought which had never entered my head. His whole reaction was one of pure guilt, but then over the years that all changed, and for the last few years he's been really supportive.

At the beginning of 1992 I found I was pregnant, and I decided I wanted a termination, and that at the same time I wanted to be sterilised as I didn't want to go through this worry again. I knew enough about transmission at that point to know there was a 10–15% chance that I could pass the virus on, and although that's quite a low risk, I had seen enough other women take the chance and go through the whole nine months and following 18 months not knowing whether the child was infected or not, and I felt I didn't have that in me. I was referred to a hospital and I went there and saw a doctor in outpatients. She knew nothing about HIV – absolutely nothing. She automatically assumed I would want a termination, and before she examined me she removed all the blankets and coverings from the table, so again obviously had no idea about

transmission or anything. She also asked the nurse what precautions she should be taking in front of me. It made me feel awful at what was a traumatic time anyway.

About a month ago I was involved in a conference called Living Proof, the first conference for long-term survivors ever, which was really illuminating and quite empowering. There were a lot of other women there which was great to see. I went to three workshops during the two-day event and it was amazing how the experiences of both women and men were so similar. We had all been told first that we probably had five years, then seven years, then 10 years etc. Although my Consultant never said this, it had been the general consensus, and the type of the thing you read in the press, so that when you go past those dates you feel more and more isolated. When you have also suffered so much loss and lost so many people on the way, there is a tinge of guilt that you are still here. Friends whom I told originally have sort of forgotten about it now because it's been going on for so long and they don't seem to realise that I'm still going through it all, and that it takes a large chunk out of my life, that I had to resign my job and go onto benefits.

You feel that people are waiting for you to die. It's still the uncertainty of just not knowing, constantly trying not to be in denial, because there've been enough people I know who have had the virus longer than I have and have died, and I do have definite symptoms. If I was in America I would have been diagnosed as having AIDS a while ago because my CD4 count has been hopping between 150 and 200 over the last two years. Luckily they don't do that here, because psychologically that's a hard one.

When I was admitted into hospital last year, the doctor was trying to be reassuring, saying that it wasn't necessarily HIV-related, but I didn't believe it. I found that most of the nurses had had no specialist training which made me feel a bit vulnerable. One morning I woke to find a young agency training nurse looking at my file; she said, "Oh, you were diagnosed in 1986 and you're still alive – that's amazing", and I thought "I just don't need this, I really don't". I was feeling so ill and didn't really have the strength to deal with it.

When you live in a little closed society like I do medically, where you go into a clinic, where everybody is wonderful and the service is fantastic, you forget about the lack of knowledge and the attitudes outside that world.

Update since 4th edition

It is now the year 2000 and I am still here. I am amazed at just how much my life has changed over the last four years, not to mention the changes in medical advances, from which I have benefitted greatly.

In 1996 I became steadily more and more ill. I was suffering from constant night sweats, my face was covered in molescums, warts appearing everywhere, my hair falling out in huge clumps, my weight plummeting and the most appalling constant fatigue, it was as much as I could do to get a meal together for Lee on her return from school. This was very frightening for her. Finally I came down with pneumonia and having just recovered from that, I immediately got *E. coli* septicaemia and very nearly died. While I was in hospital it was suggested that I start on combination therapy – I felt I had nothing to lose and agreed. The viral load test had just come in and my count was nearly one million, and my T cells were hovering around 50. To my mind I had no choice but to begin treatment.

I started with "Dual Combination" (which is not advisable today). I was taking 3TC and D4T. Almost immediately I started to feel better. My viral load became undetectable, my T cells rose to over 200, my hair stopped falling out, the

ABC of AIDS

molescums disappeared, as did the warts, the night sweats stopped, but the most remarkable thing for me was to suddenly be flooded with masses of energy. I experienced complete euphoria.

The psychological effects were strange. Having prepared myself for death I found myself strangely afraid of life. I had been forced to opt out of the “rat race”, which in a way was rather comforting. Now I needed to join it again. I realised that I had missed years of planning for a future. No pension plans, no savings etc... I also felt a strong sense of “survivor’s guilt”. I had lost so many close friends and colleagues, and asked myself the question “why me”? Out of the 600 or so women who used Positively Women there were only four of us left from the original group. I decided to start from the beginning again and threw myself into working in the music and film business.

After 18 months I developed a strange side-effect – lipodystrophy. My fat just disappeared off my arms and legs, I had no buttocks to speak of and my face aged about 20 years. My breasts grew enormous and I had a bulging stomach. My viral load was at this point about 5000 and my T cells were dropping again. I decided to see if my body would return to its normal shape and to discontinue any form of treatment. I was still on 3TC and D4T.

After about four months, all my old HIV symptoms were reappearing. My viral load reached 650 000 and my T cells were around 50. The lipodystrophy had not changed at all – if anything it was worse – but this could have been “AIDS wasting”. Time for a new combination. At this point (September 1998), dual combination was not recommended and I started on triple combination – DMP, AZT and DDI. It took longer for this to work than the last combination, but after about three months my viral load was below 50 and my T cells ranged between 200 and 250. I am still on this combination and still undetectable and, much to my doctor’s surprise, my body fat has gone back to normal. My triglycerides are still high, but I have the weight back on my buttocks, arms, legs and face – and it seems to get better by the day.

I have recently married a wonderful man, Lee is now 17 and life goes on. I am more confident of a future, but by no means complacent. I see too many of my peers suffering appalling side effects or complete treatment failure for me to take my life for granted. If I am still around for the next edition of the *ABC of AIDS*, I am sure it will all have changed just as radically again – watch this space.

Preface

The chapters in this book appeared originally as articles in the *British Medical Journal* and were welcomed by practitioners. The articles were retuned for publication as a book, the first edition appearing in 1992. Demand asked for more and so the book was updated for a second, a third and now a fourth edition in 2002.

Antenatal care has evolved from a philanthropic service for mothers and their unborn babies to a multiphasic screening programme. Much has been added in the past few years but a lack of scientific scrutiny has meant that little has been taken away. Healthy mothers and fetuses need little high technological care but some screening is desirable to allocate them with confidence to the healthy group of pregnant women. Women and fetuses at high risk need all the scientific help available to ensure the safest environment for delivery and aftercare. The detection and successful management of women and fetuses at high risk is the science of antenatal care; the care of other mothers at lower risk is the art of the subject and probably can proceed without much technology. Midwives are practitioners of normal obstetrics and are taking over much of the care of normal or low-risk pregnancies, backed up by general practitioner obstetricians in the community and by consultant led obstetric teams in hospitals.

This book has evolved from over 40 years of practice, reading, and research. We have tried to unwind the tangled skeins of aetiology and cause and the rational from traditional management, but naturally what remains is an opinion. To broaden this, the authorship has been widened; Dr Margery Morgan, a consultant obstetrician and gynaecologist at Singleton Hospital, has joined Professor Chamberlain as a co-author, bringing with her the new skills used in antenatal care.

We thank our staff at Singleton Hospital for willingly giving good advice and contributing to this book, especially Howard Whitehead, medical photographer, and Judith Biss, ultrasonographer. Our secretaries Caron McColl and Sally Rowland diligently decoded our writings and made the script legible while the staff of BMJ Books, headed by Christina Karaviotis, turned the whole into a fine book.

Swansea

1 Organisation of antenatal care

Looking after pregnant women presents one of the paradoxes of modern medicine. Normal women proceeding through an uneventful pregnancy require little formal medicine. Conversely, those at high risk of damage to their own health or that of their fetus require the use of appropriate scientific technology. Accordingly, there are two classes of women, the larger group requiring support but not much intervention and the other needing the full range of diagnostic and therapeutic measures as in any other branch of medicine. To distinguish between the two is the aim of a well run antenatal service.

Antenatal clinics provide a multiphasic screening service; the earlier women are screened to identify those at high risk of specified problems the sooner appropriate diagnostic tests can be used to assess such women and their fetuses and treatment can be started. As always in medicine, diagnosis must precede treatment, for unless the women who require treatment can be identified specifically, management cannot be correctly applied.

Background

Some women attend for antenatal care because it is expected of them. They have been brought up to believe that antenatal care is the best way of looking after themselves and their unborn children. This is reinforced in all educational sources from medical textbooks to women's magazines.

Prenatal care started in Edinburgh at the turn of the 20th century, but clinics for the checking of apparently well pregnant women were rare before the first world war. During the 1920s a few midwifery departments of hospitals and interested general practitioners saw women at intervals to check their urine for protein. Some palpated the abdomen, but most pregnant women had only a medical or midwifery consultation once before labour, when they booked. Otherwise, doctors were concerned with antenatal care only "if any of the complications of pregnancy should be noticed". Obstetrics and midwifery were first aid services concerned with labour and its complications: virtually all vigilance, thought, and attention centred on delivery and its mechanical enhancement. Little attention was paid to the antenatal months.

During the 1920s a wider recognition emerged of the maternal problems of pregnancy as well as those of labour; the medical profession and the then Ministry of Health woke up to realise that events of labour had their precursors in pregnancy. Janet Campbell, one of the most farsighted and clear thinking women in medicine, started a national system of antenatal clinics with a uniform pattern of visits and procedures; her pattern of management can still be recognised today in all the clinics of the Western world.

Campbell's ideas became the clinical obstetric screening service of the 1930s. To it has been added a series of tests, often with more enthusiasm than scientific justification; over the years few investigations have been taken away, merely more added. Catalysed by the National Perinatal Epidemiological Unit in Oxford, various groups of more thoughtful obstetricians have tried to sort out which of the tests are in fact useful in predicting fetal and maternal hazards and which have a low return for effort. When this has been done a rational antenatal service may be developed, but until then we must work with a confused service that "grewed like Topsy". It is a mixture of the traditional clinical laying on of hands and a

Figure 1.1 New mother and her baby

ABC of Antenatal Care

Figure 1.3 Uptake of antenatal care by women in England and Wales

Figure 1.4 Antenatal clinics evolved from child welfare clinics, producing a prenatal version of the infant clinics

patchily applied provision of complex tests, whose availability often depends as much on the whims of a health authority's ideas of financial priority as on the needs of the women and their fetuses.

As well as these economic considerations, doctors planning the care of women in pregnancy should consider the women's own wishes. Too often antenatal clinics in the past have been designated cattle markets; the wishes of women coming for care should be sought and paid attention to. A recurrent problem is the apparent rush of the hospital clinic. The waiting time is a source of harassment and so is the time taken to travel to the clinic. Most women want time and a rapport with the antenatal doctor or midwife to ask questions and have them answered in a fashion they can understand. It is here that the midwives come into their own for they are excellent at the care of women undergoing normal pregnancies.

In many parts of the country midwives run their own clinics in places where women would go as part of daily life. Here, midwives see a group of healthy normal women through pregnancy with one visit only to the hospital antenatal clinic.

To get the best results, women at higher risk need to be screened out at or soon after booking. They will receive intensive care at the hospital consultant's clinic and those at intermediate risk have shared care between the general practitioner and the hospital. The women at lower risk are seen by the midwives at the community clinics. Programmes of this nature now run but depend on laying down protocols for care agreed by all the obstetricians, general practitioners and midwives. Co-operation and agreement between the three groups of carers, with mutual respect and acceptance of each other's roles, are essential.

Janet Campbell started something in 1920. We should not necessarily think that the pattern she derived is fixed forever, and in the new century we may start to get it right for the current generation of women.

Styles of antenatal care

The type of antenatal care that a woman and her general practitioner plan will vary with local arrangements. The important first decision on which antenatal care depends is

Figure 1.5 An antenatal clinic in 2001

Figure 1.6 Place of birth in England and Wales, 1998

where the baby will be delivered. Ninety seven per cent of babies in the UK are now delivered in institutions, a third of the 2.2% of domiciliary deliveries are unplanned, so about 1.5% are booked as home deliveries. If the delivery is to be in an institution there is still the choice in some areas of general practitioner deliveries either at a separate unit run by general practitioners isolated from the hospital or in a combined unit with a consultant. Most deliveries take place in an NHS hospital under the care of a consultant team. A small but possibly increasing number in the next few years may be delivered in private care, by a general practitioner obstetrician, a consultant obstetrician, or an independent midwife. Recently a series of midwife led delivery units have been established with no residential medical cover.

Once the plans for delivery are decided, the pattern of antenatal visits can be worked out. If general practitioners or midwives are going to look after delivery, antenatal care might be entirely in their hands, with the use of the local obstetric unit for investigations and consultation. At the other end of the spectrum, antenatal care is in the hands of the hospital unit under a consultant obstetrician and a team of doctors and midwives, the general practitioner seeing little of the woman until she has been discharged from hospital after delivery.

Most women, however, elect for antenatal care between these two extremes. They often wish to take a bigger part in their own care. In some antenatal clinics the dipstick test for proteinuria is done by the woman herself. As well as providing some satisfaction, this reduces the load and waiting time at the formal antenatal visit.

During pregnancy there may be visits, at certain agreed stages of gestation, to the hospital antenatal clinic for crucial checks, and for the rest of the time antenatal care is performed in the general practitioner's surgery or midwives' clinic. These patterns of care keep the practitioner involved in the obstetric care of the woman and allow the woman to be seen in slightly more familiar surroundings and more swiftly. In some areas clinics outside the hospital are run by community midwives; these are becoming increasingly popular. Home antenatal care visits also take place, including the initial booking visit.

Delivery may be in the hospital by the consultant led team, by a general practitioner obstetrician, or by a midwife. It is wise, with the introduction of Crown indemnity, that all general practitioner obstetricians have honorary contracts with the hospital obstetric department that they attend to supervise or perform deliveries. About 2% of women now have a home delivery. More than half of these are planned and for this group, antenatal care may well be midwifery led (see *ABC of Labour Care*).

Early diagnosis of pregnancy

When a woman attends a practitioner thinking that she is pregnant, the most common symptoms are not always amenorrhoea followed by nausea. Many women, particularly the multiparous, have a subtle sensation that they are pregnant a lot earlier than the arrival of the more formal symptoms and signs laid down in textbooks. Traditionally, the doctor may elicit clinical features, but most now turn to a pregnancy test at the first hint of pregnancy.

Symptoms

The symptoms of early pregnancy are nausea, increased sensitivity of the breasts and nipples, increased frequency of micturition, and amenorrhoea.

Figure 1.8 Time at which a group of primiparous women first thought that they were pregnant in relation to the more conventional symptoms. The mean (▲) and range are given in weeks of gestation. ---- = extremes.

ABC of Antenatal Care

Signs

The doctor may notice on examination a fullness of the breasts with early changes in pigmentation and Montgomery's tubercles in the areola. The uterus will not be felt through the abdominal wall until about 12 weeks of pregnancy. On bimanual assessment uterine enlargement is detectable before this time while cervical softening and a cystic, generally soft feeling of the uterus can be detected by eight weeks. This more subtle sign is not often sought as vaginal examination is not usually performed on a normal woman at this time.

Tests

Mostly the diagnosis of pregnancy is confirmed by tests checking for the higher concentrations of human chorionic gonadotrophin that occur in every pregnancy. The old biological tests using rabbits and frogs are now gone and have been replaced by immunological tests. These depend on the presence of human chorionic gonadotrophin in the body fluids, which is reflected in the urine. The more sensitive the test, the more likely it is to pick up the hormone at lower concentrations—that is, earlier in pregnancy.

Enzyme linked immunosorbent assay (ELISA) is the basis of many of the commercial kits currently available in chemist shops. The assay depends on the double reaction of standard phase antibody with enzyme labelled antibody, which is sensitive enough to detect very low concentrations of human chorionic gonadotrophin. Positive results may be therefore detectable as early as 10 days after fertilisation—that is, four days before the first missed period.

Vaginal ultrasound can detect a sac from five weeks and a fetal cardiac echo a week or so later (Chapter 4), but this would not be used as a screening pregnancy test.

Conclusion

At the end of the preliminary consultation women may ask questions about the pregnancy and the practitioner will deal with these. Most of these queries will be considered in the chapter on normal antenatal management. For most women the onset of pregnancy is a desired and happy event, but for a few it may not be so and practitioners, having established a diagnosis, may find that they are then asked to advise on termination of pregnancy. This they should do if their views on the subject allow; if not, they should arrange for one of their partners to discuss it with the patient. Most women, however, will be happy to be pregnant and looking forward to a successful outcome.

Figure 1.9 Human chorionic gonadotrophin values rise sharply in early gestation but are reduced in the second half of pregnancy. The normal range ± 2 SD is shown

Figure 1.10 Clearview pregnancy test results. The horizontal bar in the top chamber shows that a urine sample has progressed satisfactorily from the lower chamber. A horizontal bar in the middle chamber shows a positive result (right) and its absence a negative result (left)

Antenatal care has evolved from a hospital based service to a community based service for normal women. Those with a higher risk of problems are best seen in hospital clinics.

The picture of the infant welfare clinic is reproduced by permission of William Heinemann from *University College Hospital and its Medical School: a History* by W R Merrington. The Clearview pregnancy test result is reproduced by permission of Unipath, Bedford.

2 The changing body in pregnancy

Pregnancy is a load causing alterations not just in the mother's pelvic organs but all over the body. Fetal physiology is different from that of an adult, but it interacts with the mother's systems, causing adaptation and change of function in her body. These adaptations generally move to minimise the stresses imposed and to provide the best environment for the growing fetus; they are usually interlinked smoothly so that the effects on the function of the whole organism are minimised.

Cardiovascular system

The increased load on the heart in pregnancy is due to greater needs for oxygen in the tissues.

- The fetal body and organs grow rapidly and its tissues have an even higher oxygen consumption per unit volume than the mother's.
- The hypertrophy of many maternal tissues, not just the breasts and uterus, increases oxygen requirements.
- The mother's muscular work is increased to move her increased size and that of the fetus.

Cardiac output is the product of stroke volume and heart rate. It is increased in pregnancy by a rise in pulse rate with a small increase in stroke volume. Cardiac muscle hypertrophy occurs so that the heart chambers enlarge and output increases by 40%; this occurs rapidly in the first half of pregnancy and steadies off in the second. In the second stage of labour, cardiac output is further increased, with uterine contractions increasing output by a further 30% at the height of the mother's pushing.

During pregnancy the heart is enlarged and pushed up by the growing mass under the diaphragm. The aorta is unfolded and so the heart is rotated upwards and outwards. This produces electrocardiographic and radiographic changes which, although normal for pregnancy, may be interpreted as abnormal if a cardiologist or radiologist is not told of the pregnancy.

Blood pressure may be reduced in mid-pregnancy, but pulse pressure is increased and peripheral resistance generally decreases during late pregnancy.

Figure 2.3 Systolic and diastolic blood pressures during pregnancy. The mid-trimester dip found in some women is seen more in the diastolic than in the systolic pressure

Pregnancy causes physiological and psychological changes, which affect all aspects of the woman's life.

Figure 2.1 Increase in oxygen consumption during pregnancy. A major part of the increase goes to the products of conception (fetus and placenta)

Figure 2.2 Cardiac output in pregnancy. The increase occurs very early and flattens from 20 weeks

Box 2.1 Changes in the ECG in normal pregnancy

- Deep Q waves in I and II
- T wave flattened or inverted in III
- ST segment depressed
- Extra-systoles frequent

ABC of Antenatal Care

Maternal blood volume increases, the changes in plasma volume being proportionally greater than the increase in red cell bulk. Hence haemodilution occurs; this used to be called a physiological anaemia, a bad phrase as it is paradoxical to have a physiological pathological process.

The heart sounds are changed.

- A systolic ejection murmur is common.
- A third cardiac sound is commonly heard accompanying ventricular filling.

The electrical activity of the heart on an electrocardiogram changes.

- The ventricles become hypertrophied, the left to a greater extent than the right and therefore left ventricular preponderance is seen in the QRS deviation.

Heart valves and chamber volumes may change during pregnancy. The heart becomes more horizontal so cardiothoracic ratio is increased and it has a straighter upper left border. These changes can be visualised by cross-sectional echocardiography, which depends on the reflection of high frequency sound from inside the heart.

Respiratory system

Box 2.2 Changes in chest radiographs in normal pregnancy

Lungs

- Show increased vascular soft tissue
- Often have a small pleural effusion especially straight after delivery

The most common changes seen on chest x ray films are shown in the box. Always ensure that the radiology department is told on the request form that a woman is pregnant and give an approximate stage of gestation. Only when there are strong indications should chest radiography be performed in pregnancy at all and then full radiological shielding of the abdomen must be used.

In early pregnancy women breathe more deeply but not more frequently under the influence of progesterone. Hence alveolar ventilation is increased by as much as a half above prepregnant values so that pO_2 levels rise and carbon dioxide is relatively washed out of the body.

Later the growing uterus increases intra-abdominal pressure so that the diaphragm is pushed up and the lower ribs flare out. Expiratory reserve volume is decreased but the vital capacity is maintained by a slight increase in inspiratory capacity because of an enlarged tidal volume. This may lead to a temporary sensation of breathlessness. Explanation usually reassures the woman.

Urinary system

Changes in clearance

Renal blood flow is increased during early pregnancy by 40%. The increase in glomerular filtration rate is accompanied by enhanced tubular reabsorption; plasma concentrations of urea and creatinine decrease.

The muscle of the bladder is relaxed because of increased circulating progesterone. Increased frequency of micturition due to increased urine production is a feature of early pregnancy. Later the bladder is mechanically pressed on by the

Figure 2.4 Increase in blood volume and its components in pregnancy

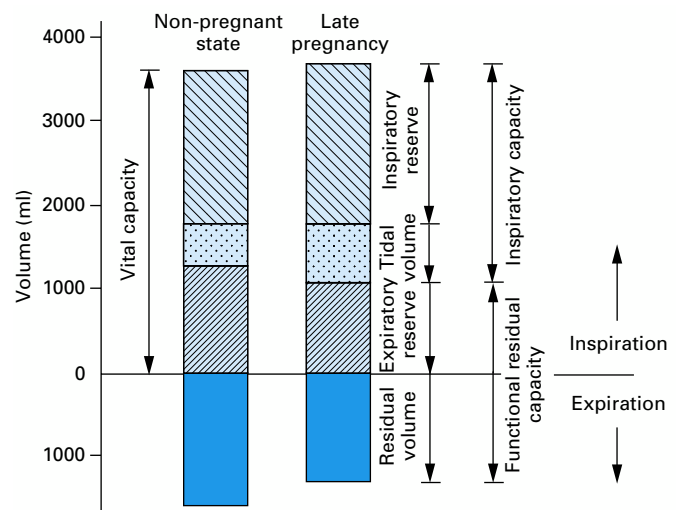

Figure 2.5 Changes in inspiratory and expiratory volumes in pregnancy

Figure 2.6 Changes in the glomerular filtration rate and in renal blood flow in pregnancy

growing uterus and the same symptoms occur but for a different reason.

The muscle walls of the ureters are relaxed by progesterone so that the ureters become larger, wider, and of lower tone. Sometimes stasis occurs in the ureters; therefore proliferation of bacteria and the development of urinary infection is more likely to occur.

Endocrine system

All the maternal endocrine organs are altered in pregnancy, largely because of the increased secretion of trophic hormones from the pituitary gland and the placenta.

Pituitary gland

The pituitary gland is increased in size during pregnancy, mostly because of changes in the anterior lobe.

Anterior lobe

- **Prolactin.** Within a few days of conception the rate of prolactin production increases. Concentrations rise until term following the direct stimulation of the lactotrophs by oestrogens. Human placental lactogen, which shows shared biological activity, exerts an inhibitory feedback effect. Prolactin affects water transfer across the placenta and therefore fetal electrolyte and water balance. It is later concerned with the production of milk, both initiating and maintaining milk secretion.
- **Gonadotrophins.** The secretions of both follicular stimulating hormone and luteinising hormone are inhibited during pregnancy.
- **Growth hormone.** The secretion of growth hormone is inhibited during pregnancy, probably by human placental lactogen. Metabolism in the acidophil cells returns to normal within a few weeks after delivery and is unaffected by lactation.
- **Adrenocorticotrophic hormone** concentration increases slightly in pregnancy despite the rise in cortisol concentrations. The normal feedback mechanism seems to be inhibited secondary to a rise in binding globulin concentrations.
- **Thyrotrophin** secretion seems to be the same as that in non-pregnant women. The main changes in thyroid activity in pregnancy come from non-pituitary influences.

Posterior lobe

There are increases in the release of hormones from the posterior pituitary gland at various times during pregnancy and lactation. These, however, are produced in the hypothalamus, carried to the pituitary gland in the portal venous system, and stored there. The most important is oxytocin, which is released in pulses from the pituitary gland during labour to stimulate uterine contractions. Its secretion may also be stimulated by stretching of the lower genital tract. Oxytocin is also released during suckling and is an important part of the let down reflex.

Thyroid gland

Pregnancy is a hyperdynamic state and so the clinical features of hyperthyroidism may sometimes be seen. The basal metabolic rate is raised and the concentrations of thyroid hormone in the blood are increased, but thyroid function is essentially normal in pregnancy.

Figure 2.7 Changes in the ureters in pregnancy, during which they lengthen and become more tortuous and dilated

Figure 2.8 Pituitary gland showing secreting areas

Figure 2.9 Changes in prolactin concentrations in pregnancy (means and SEMs)

ABC of Antenatal Care

In pregnancy the renal clearance of iodine is greatly increased but thyroid clearance also rises so absolute iodine levels remain in the normal range. The raised hCG levels are associated with a reduced (inside the normal range) TSH; hCG probably stimulates the gland in early pregnancy and is capable of stimulating TSH receptors.

Adrenal gland

The adrenal cortex synthesises cortisol from cholesterol. In pregnancy there is an increase in adrenocorticotropic hormone concentration along with an increase in total plasma cortisol concentration because of raised binding globulin concentrations. The cortex also secretes an increased amount of renin, possibly because of the increased oestrogen concentrations. This enzyme produces angiotensin I, which is associated with maintaining blood pressure. Some renin also comes from the uterus and the chorion, which together produce a large increase in renin concentrations in the first 12 weeks of gestation. There is little change in deoxycorticosterone concentrations despite the swings in electrolyte balance in pregnancy.

The adrenal medulla secretes adrenaline and noradrenaline. The metabolism seems to be the same during pregnancy as before; the concentrations of both hormones rise in labour.

Placenta

The oestrogen, progesterone, and cortisol endocrine functions of the placenta are well known. In addition, many other hormones are produced with functions related to maternal adaptation to the changes of fetal growth.

In some susceptible women, progesterones may soften critical ligaments so that joints are less well protected and may separate (e.g. separation of the pubic bones at the symphysis).

Genital tract

The uterus changes in pregnancy; the increase in bulk is due mainly to hypertrophy of the myometrial cells, which do not increase much in number but grow much larger. Oestrogens stimulate growth, and the stretching caused by the growing fetus and the volume of liquor provides an added stimulus to hypertrophy.

The blood supply through the uterine and ovarian arteries is greatly increased so that at term 1.0–1.5l of blood are perfused every minute. The placental site has a preferential blood supply, about 85% of the total uterine blood flow going to the placental bed.

The cervix, which is made mostly of connective tissue, becomes softer after the effect of oestrogen on the ground substance of connective tissue encourages an accumulation of water. The ligaments supporting the uterus are similarly stretched and thickened.

3 Normal antenatal management

Antenatal care has six functions (see Box 3.1). The first two are the same as any performed in an outpatient clinic (treatment of symptoms); the second two relate to multiphasic screening, of which antenatal care was an early example; the third pair are part of health education.

Box 3.1 Aims of antenatal care

- Management of maternal symptomatic problems
- Management of fetal symptomatic problems
- Screening for and prevention of fetal problems
- Screening for and prevention of maternal problems
- Preparation of the couple for childbirth
- Preparation of the couple for childrearing

Antenatal care in the UK is performed by a range of professionals: midwives, general practitioners, and hospital doctors. In many areas up to 90% of antenatal care is in the hands of general practitioners and community midwives. In many parts of the country midwives hold their own clinics outside the hospital or visit women at home. Probably those initially at lower risk do not need routine specialist visits for they offer little or no benefit. Many women now carry their own notes, which leads to greater understanding of what is going on.

In the UK many women book for antenatal care by 14 weeks and are seen at intervals. There is no association between the number of visits and outcome; in Switzerland there are an average of five and in The Netherlands as many as 14, but outcomes are the same. The number of visits depends on a traditional pattern laid down by Dame Janet Campbell in the 1920s (Chapter 1) rather than on being planned with thoughts relating to the contemporary scene. In an ideal world, the follow-up antenatal visits would be planned individually according to the needs of the woman and assessment of her risk.

A more rational plan of care of normal primigravidas and multigravidas is laid down in Table 3.1. With these criteria, antenatal care would be more cost effective and no less clinically useful. When pioneers have tried to reduce the number of visits from the traditional number, however, there has been resistance from older obstetricians, conventional midwives, women having babies, and their mothers, all of whom think that Campbell's by now traditional pattern must be right. A randomised controlled trial in south-east London actually found women in the fewer visits group were more likely to be dissatisfied although outcomes of the groups were the same.

As well as the clinical regimen, antenatal care now entails a whole series of special tests, but these are not generally used for the normal pregnant population.

Prepregnancy care

Some aspects of a couple's way of life may be checked before pregnancy. The man and the woman's medical and social history, and, if relevant, her obstetric career can be assessed. Immunity from infections such as rubella can be tested; alternative treatments to some longstanding conditions such as ulcerative colitis can be discussed. The possibility of a recurrence of pre-existing problems such as deep vein thrombosis can be assessed. Dietary habits and problems at work can be assessed and changes in consumption of cigarettes or alcohol may be considered. Once pregnancy has started the

ABC of Antenatal Care

couple have only two options—that is, to continue or stop the pregnancy. Prepregnancy care allows more time for the correction of detectable problems and the prevention of their repetition—for example, giving supplementary folate to women whose children have abnormalities of the central nervous system. It is now recommended that extra folate is started by all women before pregnancy to avoid deficiency in very early pregnancy when the fetal neural tube is closing (21–28 days of fetal life) so as to reduce the risk of spina bifida.

Booking visit

Once pregnancy has been diagnosed, the woman usually books a visit at the antenatal clinic, the GP surgery or at home with the midwife who will lead in antenatal care. This is the longest but most important visit. It used to take place at 8–12 weeks' gestation, but in many clinics it has moved to 12–14 weeks. The woman's medical state is assessed so that the current pregnancy can be placed into the appropriate part of a risk spectrum. Baseline data are essential at this point and are obtained from the history, an examination, and relevant investigations.

History

Symptoms that have arisen in the current pregnancy before the booking visit are ascertained—for example, vaginal bleeding and low abdominal pain.

- **Menstrual history.** To assess the expected date of delivery details are needed about the last normal menstrual period including its date, the degree of certainty of that date, and whether cycles are reasonably regular around 28 days. The use of oral contraception or ovulation induction agents that might inhibit or stimulate ovulation should be discussed. A firm date for delivery from the last menstrual period can be obtained from about 80% of women.

From this calculate the expected date of delivery with a calculator. Do not do sums in the head; this can cause trouble when a pregnancy runs over the end of a year. A woman can be told that she has an 85% chance of delivering within a week of the expected date of delivery, but we must emphasise at this point that this date is only a mathematical probability and, as with other odds, the favourite does not always win the race. Most units now rely on ultrasound to confirm gestation and alter the EDD if the scan date varies considerably, i.e. more than 10 days difference.

- **Medical history.** Specific illnesses and operations of the past should be inquired about, particularly those that entail treatment that needs to be continued in pregnancy—for example, epilepsy and diabetes.
- **Family history.** There may be conditions among first degree relatives (parents or siblings) that may be reflected in the current pregnancy, such as diabetes or twinning.
- **Sociobiological background.** Age, parity, social class, and race of the woman all affect the outcome of the pregnancy. Smoking and alcohol consumption also affect the outcome. Socioeconomic class is usually derived from the occupation of the woman or her partner. It reflects the influence of a mixed group of factors such as nutrition in early life, diseases in childhood, education, and past medical care. It also correlates with potential birth weight, congenital abnormality rates, and eventually perinatal mortality. Less strongly associated are preterm labour and problems in care of the newborn.
- **Obstetric history.** The woman's obstetric history should be discussed carefully as it contains some of the best markers for

Box 3.2 Aims of prepregnancy care

- To bring the woman to pregnancy in the best possible health
- To attend to preventable factors before pregnancy starts—for example, rubella inoculation
- To discuss diabetes and aim for excellent glycaemic control
- To assess epileptic medication in terms of fit control and teratogenicity
- To discuss antenatal diagnoses and management of abnormality
- To give advice about the effects of:
 - pre-existing disease on the pregnancy and unborn child
 - the pregnancy on pre-existing disease and its management
- To consider the effects of recurrence of events from previous pregnancies
- To discuss the use of prophylactic folate before conception

Figure 3.2 An adjustable obstetric calculator should always be used to calculate the current stage of gestation and the expected date of delivery

Figure 3.3 Distribution of length of gestation for spontaneous and induced single births when the last menstrual period is known (n=16 000)

performance in the current pregnancy. If the woman has had a previous miscarriage or termination of pregnancy, the doctor should ask about the stage of gestation, and any illness afterwards. Of babies born, the progress of the pregnancy, labour, and puerperium are needed and the stage of gestation and birth weight of the infant. Intrauterine growth restriction and preterm labour may be recurrent and should be inquired about in previous pregnancies. The terms gravidity and parity are often applied to women in pregnancy. Gravidity refers to pregnancy, so anyone who is gravid is or has been pregnant. A woman who is pregnant for the first time is a primigravida. Parity refers to having given birth to a viable liveborn or a stillborn child.

Examination

A brief but relevant physical examination should be performed. The woman’s height is important as it correlates loosely with pelvic size, but shoe size is a poorer predictor. Weight is less often monitored in pregnancy these days, but a booking weight will enable a Body Mass Index (BMI) to be measured. This is the weight in kilograms divided by the height squared (weight (kg)/height (cm²)). BMI is useful in determining those at increased risk during pregnancy (over 30) who require consultant obstetric care. A value of over 39 (morbidly obese) may indicate that an anaesthetic assessment is necessary to assess potential problems in labour at delivery. The clinical presence of anaemia should be checked and a brief examination of the teeth included, if only to warn the woman to visit a dentist. Tooth and gum deterioration may be rapid in pregnancy and dental care is free at this time and for a year after delivery.

Check whether the thyroid gland is enlarged. The blood pressure is taken, preferably with the woman resting for a few minutes before. The spine should be checked for any tender areas as well as for longer term kyphosis and scoliosis, which might have affected pelvic development; the legs should be examined for oedema and varicose veins.

The abdomen is inspected for scars of previous operations—look carefully for laparoscopy scars below the umbilicus and for a Pfannenstiel incision above the pubis. Palpation is performed for masses other than the uterus—for example, fibroids and ovarian cysts. If the booking visit is before 12 weeks the uterus probably will not be felt on abdominal examination, but in a multiparous woman it may be; this should not cause the examiner to make any unnecessary comments about an enlarged uterus at this stage.

A vaginal assessment was traditionally performed at the booking visit. Its function was to confirm the soft enlargement of the uterus in pregnancy, to try to assess the stage of gestation, to exclude other pelvic masses, and to assess the bony pelvis. Many obstetricians now do not do a pelvic assessment at this stage; no woman likes having a vaginal examination and, if done in early pregnancy, it is associated in the woman’s mind with any spontaneous miscarriage which may occur subsequently, even though this is irrelevant to the examination. Fetal size will soon be checked by ultrasound. Even assessment of the bony pelvis in late pregnancy may not be required as the fetal presenting part is available for check against the inlet while the effect of progesterone on the pelvic ligaments is at its maximum. By this time the woman has more confidence in the antenatal staff and is more willing to have a vaginal examination. If the head is engaged, this is a good measure of pelvis size. If it is not, a vaginal assessment may still be needed.

Table 3.2 Proportions of live births in each socioeconomic class in England and Wales adjusted by job description of husband or partner (1998)

Social class	Job description	Population having babies (%)
I + II	Professional & supervisory	25.6

Not married		37.8

* In many surveys unemployed people are classified by their last occupation if they had one.

Figure 3.4 Gravidity (G) and parity (P)

ABC of Antenatal Care

Investigations

A venous blood sample is checked for:

- Haemoglobin concentration or mean cell volume (see Chapter 8).
- ABO and rhesus groups and, if relevant, rhesus antibodies. The former is to allow swifter cross-matching of blood if needed in pregnancy or labour; the latter is to warn of problems and be a baseline if a rhesus-positive fetus is in the uterus of a rhesus-negative woman.
- Antibodies to other blood groups—for example, Kell, to give warning of potential incompatibility with the fetus in the presence of less common blood groups.
- Haemoglobinopathies in women originating from Mediterranean, African, and West Indian countries.
- Syphilis. A Wassermann reaction (WR) is non-specific; most clinics now use the *Treponema pallidum* haemagglutination test to investigate more specifically, but no test can be expected to differentiate syphilis from yaws or other treponematoses.
- Rubella antibodies.
- HIV antibodies. If the woman is at risk of infection through intravenous drug misuse, having received contaminated blood transfusions, coming from parts of the world with a high HIV rate (e.g. sub-Saharan Africa), or having a partner who is HIV positive, she may request or be advised to have an HIV test. Full counselling should include her understanding the implications of both having the test and any positive result. In some parts of the UK, antenatal testing is offered to all with a modified advice service beforehand. The mother can opt out.
- Hepatitis B antibodies.
- Toxoplasmosis antibodies (if clinically appropriate).
- Cytomegalic virus antibodies (if clinically appropriate).

Later blood checks are for:

- α Fetoprotein level analysis for abnormality of the central nervous system.
- Down's syndrome serum screening by double or triple test.

The urine is checked for:

- Protein, glucose and bacteria.

Chest radiographs are rarely taken except in women from parts of the world where pulmonary tuberculosis is still endemic.

An ultrasound assessment is now performed on most pregnant women in the UK. It is best done at about

Figure 3.8 Ultrasound of fetal head showing the midline echo, the biparietal diameter of the head circumference outline

Figure 3.5 Laparoscopy and Pfannenstiel scars

Non-pregnant	8 weeks	10 weeks

Figure 3.6 Relative growth of uterus in early pregnancy. Growth is usually in width rather than length, so the uterus seems fuller at first. It is also softer and has a cystic quality

Figure 3.7 Size of uterus at various stages of gestation in pregnancy

18–20 weeks to measure the biparietal diameter and so get a baseline value of fetal size and confirmation of the stage of gestation to firm up the expected date of delivery. Gross congenital abnormalities may be found (Chapter 4).

Ultrasound between 10 and 13 weeks can measure nuchal translucency, which is being evaluated as a screening test for Down's syndrome (Chapter 4). At 18 weeks congenital abnormalities such as spina bifida, omphalocele, and abnormal kidneys may be excluded. A four chamber view of the heart is also possible at this stage to exclude gross abnormalities, but details of cardiac connections may not be obvious until 22–24 weeks. Other conditions which are characterised by decreased growth such as microcephaly or some forms of dwarfism may also not be apparent until late in the second trimester.

Hence, though 16–18 weeks would be a useful time to assess gestational age by ultrasound, much later assessments are needed to assess fetal normality. In addition, more highly skilled ultrasonographers and equipment of high resolution are needed to produce scans to enable assessment of normality. Many of these ultrasound studies of fetal anatomy have been developed in specialist units with highly skilled obstetric ultrasonographers. The ordinary ultrasound service at a district general hospital cannot be expected always to provide such skill or equipment, although with increased training and better machines, some centres are now providing a fuller exclusion service at 20–24 weeks' gestation. Also at 24 weeks Doppler flow

studies may identify those mothers at risk of later hypertension or fetuses for growth restriction (Chapter 4).

Subsequent antenatal visits

At each antenatal visit an informal history is sought of events that have happened since the last attendance. The woman's blood pressure is assessed and compared with the previous readings; proteinuria and glycosuria are excluded each time. Palpation of the abdomen and measurements of the fundus above the symphysis give a clinical guide to the rate of growth of the fetus, especially if they are performed at each visit by the same observer. In later weeks the lie and presentation of the fetus is assessed. In the last weeks of pregnancy the presenting part, usually the head, is checked against the pelvic inlet to ensure that it engages. If the fetal head is not engaged by 37 weeks it is helpful to see if it will engage. To do this, the top of the couch should be propped up to 60° from the horizontal and the lower abdomen re-examined. If this small change in entry angle allows engagement of the fetal head, it will usually go down when labour contractions start. This is a simple test giving useful information about the potential of the fetal head to negotiate the mother's pelvis; it deserves wider usage in antenatal clinics.

The amount of amniotic fluid is assessed clinically and if fetal movements are seen by the observer or reported by the mother, the fetal heart need not be auscultated at the antenatal clinic. If, however, the mother reports reduced movements, the heart should be checked with a hand held Doppler fetal heart monitor and by cardiotocography so that the woman, too, can observe the heart beats and be reassured.

In a visit in the last few weeks of pregnancy a pelvic examination may be performed to check the bony pelvis, the points of importance being shown in Box 3.3. A well engaged fetal head after 36 weeks indicates, however, that the pelvis is adequate in this pregnancy and that digital assessment need not be performed. With a persistently non-engaged head or a breech presentation it should be done. Assessment of the cervix is wise at 32 weeks if the woman is at high risk of a preterm labour or is having a twin pregnancy, although it can be done in many units by vaginal ultrasound. It is also useful to assess cervical ripeness if the pregnancy is postmature after 42 weeks.

Malpositions

By 37 weeks, most fetuses will have settled into a cephalic presentation, but about 3% will still be a breech or transverse lie. Many obstetricians would offer an external cephalic version (ECV). The earlier ECV is done, the easier it is to turn the fetus but the more likely it is to turn back. Most versions are offered from 36 weeks onwards.

Before the version takes place the fetal heart is recorded for about 20 minutes and the lie checked with ultrasound. The fetal breech is then carefully disimpacted from the mother's pelvis. When above the brim, it is grasped in one hand and the head is swung round with the other hand in a series of moves so that the head is pointing downwards.

The fetal heart is checked on a cardiotocograph immediately after the version for about 20 minutes. Success rates vary between 10% and 50%.

End of pregnancy

Traditionally in Britain many obstetricians have been concerned when a singleton pregnancy goes past 42 weeks. In the 1960s the actuarial risk of perinatal mortality did sharply increase after 41 weeks, but this is no longer so and the passage

Figure 3.12 Lie of the fetus. (A) Longitudinal lie, which is deliverable vaginally. (B) Transverse lie, which if it persists has to be delivered abdominally

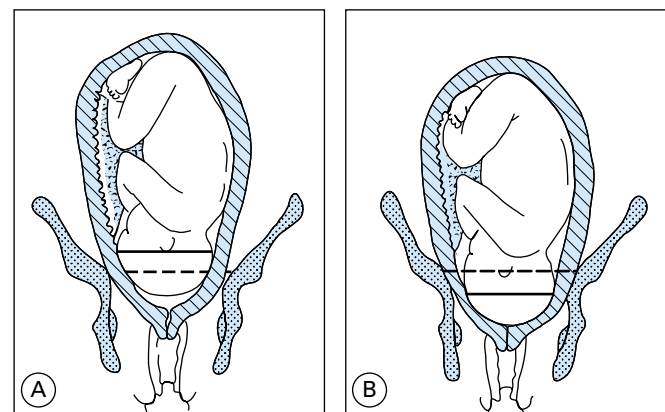

Figure 3.13 (A) The fetal head is not engaged as its maximum diameter (—) is above the inlet of the mother's pelvis (-----). (B) The fetal head has descended so that its maximum diameter is below the inlet

Figure 3.14 (A) The fetal head is not engaged, but when the mother sits up (B) gravity allows the head to sink below the inlet of the mother's pelvis so that the head will engage

Box 3.3 Clinical assessment of bony pelvis should include checking the:

- anteroposterior diameter from symphysis pubis to promontory of the sacrum (S1)
- curve of the sacrum
- prominence of the ischial spines
- angle of the greater sciatic notch
- width of the inferior border of the symphysis pubis
- subpubic angle

of 42 proved weeks is not used by all obstetricians as an indication for induction of labour. For example, if the cervix is not ripe some would consider it unwise to induce merely on calendar dates. Instead, the unusually long length of gestation might be used as an indication for better and more frequent fetal surveillance with Doppler and CTEG rather than to take action, but this should be done at the consultant clinic in the hospital rather than in the community. The results of fetal monitoring after 42 weeks should be assessed carefully for the normal reduction of amniotic fluid volume can lead to false conclusions.

Antenatal education

Pregnancy counselling

The visits to an antenatal clinic can be a helpful time for the woman and her partner to learn about pregnancy. Formal antenatal education classes are held in most district hospitals, and couples are encouraged to attend a convenient course of counselling. Furthermore, informal discussions with midwives and doctors at the antenatal clinic are educational and much can be learnt from other mothers in the waiting time at the clinics. This is complemented by many excellent videos, which are often displayed in the antenatal waiting area.

Many good books exist about pregnancy and childbirth, offering a spectrum of styles and detail according to a woman's needs. A woman should be steered towards a well written account of what she needs in a form that best suits her lifestyle and religious observances in a language that she can understand. Plenty of such books are now available, but all hospital and obstetricians should read the material that is offered to the women who visit their clinics to make sure that they agree with and actually offer the services that the books advocate, e.g. it is no good the literature being about epidural pain relief in labour if the hospital at which the woman is booked cannot provide it.

Pregnancy social support

In the welfare state of the UK pregnant women are entitled to several social security benefits, although in many ways this country lags behind many countries in the European Union. The doctors at the clinic would do well to keep up their knowledge from time to time as benefits change rapidly according to the whims of the Department of Social Security and of their political masters. The Maternity Alliance frequently produces excellent pamphlets on these matters to help

Box 3.4 Problems with antenatal ECV

- The fetus may be too big.
- Extended legs may splint the fetus.
- The cord may be wound around the neck or limbs and so anchor the fetus.
- The abdominal muscles may be too tense to allow a grip of the fetal pole.
- Obesity may limit the grip of the fetal pole.
- The uterine muscle may contract and so resist manipulation. Try a uterine relaxant.
- Excess of amniotic fluid will allow reversion to breech presentation.
- A uterine abnormality (e.g. septum or fibroids) may not allow ECV.
- The membranes may rupture.

Figure 3.15 External cephalic version is usually performed by disimpacting the breech from the pelvis and then swinging the fetus through 180°

Figure 3.16 Antenatal instruction includes relaxation classes with a physiotherapist

Figure 3.17 A wide variety of antenatal information books is available

ABC of Antenatal Care

both women and professionals keep up to date (Maternity Alliance, 45 Beech St, London EC2P 2LX).

Conclusion

The antenatal visit in the community, general practice surgery, or hospital should be friendly and held at a time when women can mix with others who are also pregnant and so informally discuss their problems. It also provides a nidus for antenatal counselling both formally at the antenatal classes and informally from staff and other women. The medical component is the core of the clinic and consists of the regular screening and assessment of symptomatic problems to bring the woman and her fetus to labour in the best state at the best time.

Antenatal care is now the cornerstone of obstetrics. Though the problems of labour are more dramatic, some of them could be avoided by effective detection and management of antenatal variations from the normal.

4 Checking for fetal wellbeing

The great reduction in maternal mortality and morbidity in the past 30 years has allowed more attention to be concentrated on the fetus during antenatal care. Perinatal mortality has been reduced, but still in England and Wales out of 100 babies born, one will die around the time of birth, two have an abnormality, and six have a birth weight under 2500 g. With smaller family sizes in the Western world, parents expect a perfect result. General practitioners and obstetricians are performing more thorough checks to try to detect the fetuses that are likely to be at increased risk. These investigations do not replace clinical examination but provide the fine tuning of assessment. The mother still needs, however, to see someone who can talk to her and discuss the implications and results of these new tests with her.

Some groups of women are at high risk because of their medicosocial background. The extremes of maternal age (under 16 and over 35), high parity (over four pregnancies), low socioeconomic class (Office for National Statistics, social class V), and some racial groups (Pakistan-born women) seem to confer a higher actuarial risk on the babies born to such women. Consequently these women deserve extra antenatal surveillance to detect a fetus with variations from normal. Others show poor growth of the fetus in the latter days of pregnancy or develop raised blood pressure during pregnancy, two manifestations of a poor blood flow to the placental bed. Such fetuses have poor nutritional reserve—a decreased blood flow to the placental bed reduces the amounts of nutrients and oxygen. A series of tests have been developed; some of these are screening tests best applied to the total antenatal population or to a subset considered to be at higher risk. Other tests are diagnostic and specifically used for women with babies thought to be compromised clinically. All these investigations can be done in a day care unit and do not necessitate admission.

Tests in early pregnancy (up to 13 weeks)

Ultrasound

The earliest in pregnancy that the embryo may be visualised by abdominal ultrasonography is six to seven weeks; it will be shown a week earlier with a vaginal probe. At six weeks the embryonic sac can be seen but embryonic tissue cannot be confidently visualised, even with machines of high resolution and skilled ultrasonographers. By seven to eight weeks most ultrasound machines should be able to show the embryo and a fetal heart pulse can often be seen. Most obstetric departments are moving to the use of vaginal probes in early pregnancy because of the better resolution of the image. Nuchal translucency measurements are dealt with in Chapter 5.

Hormone tests

Tests are currently being developed that may be helpful in very early pregnancy to detect women who are likely to miscarry. They mostly measure proteins derived from the placenta, for example, human chorionic gonadotrophin and Schwangerschaftsprotein 1. Oestrogen and progesterone tests are too non-specific to be of prognostic value so early in gestation.

Table 4.1 Perinatal mortality in England and Wales in 1995–96 according to various maternal factors

Maternal factor	Rate per 1000 total births
Age (years)	
<20	8.5
20–24	7.1
25–29	6.6
30–34	6.7
35+	8.6
Parity	
0	6.6
1	6.4
2	8.6
≥3	15.0
Socioeconomic class

UK	8.2
Republic of Ireland	9.8
India	9.5
East Africa	12.4
West Indies	11.5
Pakistan	15.8

Figure 4.1 (A) The embryonic sac can be seen at six weeks gestation in decidua. As yet no fetal parts can be identified. (B) The same sac two weeks later. Fetal parts can easily be seen between the arrows. The pulsation of the fetal heart may also be seen at this time

Chorionic villus sampling

This is at present mainly used to detect chromosomal abnormalities and is considered in the next chapter.

Isoimmunisation

Maternal immune reactions may be stimulated by ante- or intrapartum fetomaternal bleeding whenever any fetal blood group factor inherited from the father is not possessed by the mother. The emphasis used to be on the Rhesus factor risk but this is rapidly being overcome by preventative anti-D gamma globulin injections given after any potential fetomaternal bleed (delivery, external cephalic version, termination of pregnancy). ABO and other blood groups become relatively more important now and antibodies for these should be screened. Management depends upon an early diagnosis of the blood groups of the mother and the presence of any antibodies. If these are detected at booking, repeat tests of antibodies should be made at intervals until the middle of pregnancy. If the antibody titre is rising the mother should be referred to a special centre capable of dealing fully with isoimmunisation.

If the rise is gradual so that the effect of the maternal antibodies passing back across the placenta is minimal to the fetus, then one might await events or stimulate an early delivery. If the position is worse, then intrauterine exchange transfusions are required. Now these are nearly always done (through a fetoscope) directly into the fetal umbilical vessels. The intraperitoneal transfusions have mostly been abandoned in the Western world. Perinatal survival rates are now reported at over 80% in even severely isoimmunised fetuses but one must remember there are complications of the invasive processes themselves. The procedure related mortality of intravascular transfusion is between 4 and 9%. The value of percutaneous transuterine umbilical artery transfusion should be compared with early delivery and performing extrauterine intravascular exchange transfusions in each centre.

Tests in mid-pregnancy (14–28 weeks)

Ultrasound

Ultrasound has become a more sophisticated tool in the past 40 years, so that by 20 weeks of pregnancy the fetus can be visualised precisely. Two separate sets of measurements are taken of the fetus to assess growth and detect malformations. The detection of malformations is the subject of the next chapter.

Growth may be determined by assessment of a series of measurements of the individual fetus at different times in pregnancy. These may then be compared with a background population to see whether the fetus is growing at the same rate as a statistically comparable group of its peers. Obviously the growth chart should relate to a population from which the fetus comes and not be taken from another population mix, although growth charts generated by ultrasonography are similar for many races except South Eastern Asians.

Crown-rump length

From 7 to 12 weeks the length of the embryo's body can be measured precisely from the crown of the head to the tip of the rump. This measurement is helpful in dating the maturity of an embryo or early fetus, but after 12 weeks it becomes less reliable because the fetus flexes and extends to a greater degree.

Figure 4.2 Maternal serum concentrations of Schwangerschaftsprotein 1 in pregnancies with no ultrasonic evidence of fetal heart action. This protein is made by the fetus and placenta; concentrations increase steadily through pregnancy. Many fetuses who abort spontaneously have concentrations below the 10th centile in the first weeks of gestation

Figure 4.3 Crown-rump length by days of gestation and biparietal diameter by weeks of gestation show a narrow range inside ± 2 SD of the mean, indicating a good test

Figure 4.4 Abdominal circumference by weeks of gestation showing the mean ± 2 SD. The variability is slightly wider than that in biparietal diameter but growth rates are almost linear until 38 weeks

Biparietal diameter

The distance between the two parietal eminences of the skull gives a precise measurement of fetal head size. From about 16 weeks the range of variation in a normal population widens so that in the last trimester this measurement is less useful. Early biparietal measurements are extremely helpful in dating the pregnancy with more precision even than using the date of the last menstrual period when the woman is certain of her dates. Currently, this is probably the most commonly used technique of ultrasound fetal monitoring in the Western world. If the date by ultrasound differs significantly from that expected by the last menstrual period (usually > 10 days) a revised EDD is usually calculated.

Figure 4.5 Late in pregnancy fetal growth can be detected by examining the fetal abdomen and the circumference can be marked out (by a series of dots)

Abdominal circumference

Measurement of the fetal waist at the level of the umbilical vein provides a good assessment of the size of the fetal liver. Poor fetal nutrition prevents adequate growth of the liver following the failure to lay down glycogen. Serial measurements of abdominal circumference (or area) give good warning of placental insufficiency. A fetus who is growing well is unlikely to die except from an acute event.

Femur length

This can be readily measured from about 12 until 40 weeks. It allows a check on the somatic growth of the fetus. Impaired femur growth with skeletal dysplasia and some chromosomal anomalies invalidates this as a measure.

Figure 4.6 Femur length (between two arrowheads) can be measured easily by ultrasonography

Amniotic fluid volume

The estimation of amniotic fluid volume is a measure of fetal metabolism. Volume is estimated by measuring the height of the largest vertical column of fluid detected by ultrasonography. A column < 2 cm indicates poor production of amniotic fluid (oligohydramnios).

All these five measurements have different uses at different times of pregnancy.

Early measurements of the biparietal diameter should be used for assessing gestational age. Growth is best assessed by serial circumference measurements of the fetal head and abdomen. In late pregnancy fetal weight can be estimated by using abdominal circumference and biparietal diameter. Assessment of amniotic fluid is an attempt to study dynamic changes as it reflects fetal urine production; this is decreased in placental underperfusion.

Tests in late pregnancy (29–40 weeks)

One of the main signs of fetal wellbeing in late pregnancy is continued growth, measured by serial ultrasound examination of abdominal circumference. Readings from early pregnancy are needed to give a baseline to the growth measurements in the third trimester. This method of monitoring fetal growth has a high predictive power of detecting poor growth with high sensitivity and specificity.

Movements

Movements of the fetus are felt by the mother from about 20 weeks. In the last 10 weeks of pregnancy they may be used as

Figure 4.7 Growth in fetal femur length by weeks of pregnancy showing mean ± 2 SD

Figure 4.8 Biparietal diameter during pregnancy. Left: Growth follows the normal range of variation and stays within 2 SD of the mean. Middle: Growth tails off from about 32 weeks, the head growing hardly at all in the last weeks. Right: The first reading at 20 weeks is well outside the normal range. If the readings are put back four weeks, growth falls inside the normal range. The woman in this case was probably incorrect in her dates

a coarse measure of fetal wellbeing. Many women feel individual movements distinctly; they record these on a Cardiff Count to Ten kick chart, which estimates how long it takes for the fetus to make 10 movements. In most cases this happens within the first hour or two of the observation period, but fewer than 10 movements in 12 hours may be an early warning sign of problems. The woman should report to her obstetric department for more intensive testing, usually cardiotocography.

Cardiotocography

The fetal heart rate bears some relation to the body’s response to lack of oxygen—hypoxaemia. This may be measured from 24 weeks by an external ultrasound transmitter and receiver attached to a recording system. The changes in the fetal heart rate in relation to events external to the heart rate such as uterine contractions or fetal movements can be assessed.

The baseline is important, a bradycardia being a warning sign. Episodic changes are more commonly seen, the most healthy being an acceleration; decelerations are of serious import.

Fetal heart rate varies with the balance of the sympathetic and parasympathetic nervous systems, the activity of chemoreceptors in the aorta, and concentrations of adrenaline and acetylcholine. In consequence, when the fetus is awake, baseline variability is normal. Reduced variability so that the trace becomes flat is a sign that the heart is not responding to the interaction of stimuli. This may mean accumulation of metabolic catabolites—that is, fetal acidosis. Sleep patterns need to be excluded from this diagnosis, particularly in less mature babies, as a flat trace can occur for 40 minutes or so when the fetus is asleep. The easiest way to distinguish the two is to wake the baby up by asking the mother to move around and repeat the test.

Other sinister changes include episodic decelerations with or without uterine contractions and a solitary long deceleration lasting for over five minutes.

Cardiotocography records are widely used in the UK to monitor women at high risk in the later weeks of pregnancy to determine the best time for delivering the baby. Because of the

Figure 4.9 Cardiff Count to Ten kick chart. The timing of fetal movements can be graphically displayed on this chart by the mother, who is asked to contact the hospital if there are <10 movements in 12 hours

Figure 4.10 Antenatal cardiotocography showing fetal heart rate above and uterine pressure below in each trace. Top left: Fetal movements (shown by the vertical bars) are accompanied by accelerations in the heart rate. Top right: The fetus is asleep but wakes at the end of the trace. Bottom: The heart rate shows episodic decelerations, which have a bad prognosis

poor prognostic value of the individual variables that make up an antenatal cardiotocograph trace, their precise value in prediction is hard to define. A severely abnormal trace probably indicates action but an apparently normal one should not blinker decisions. The trace should be considered with other data from the pregnancy and rarely be regarded as a solitary indicant for action.

Doppler studies

The flow of blood in the arcuate branches of the uterine artery on the maternal side of the placental bed and in the umbilical artery on the fetal side can be measured by the Doppler principle.

- The afferent supply of oxygenated blood to the placental bed through the spiral arteries indicates background nutrition of the fetus in pregnancy giving longer term warning.
- The flow along the umbilical vessels indicates fetal cardiac output, a more acute measure of what is happening at the moment as reduction of flow follows poor fetal cardiac function giving more immediate warning.

Flow in other fetal vessels may help to assess the fetal state. The middle cerebral vessel, the carotid artery, the hepatic or renal vessels may be used. Ultrasound waves are beamed in and their reflected echo patterns vary with the ratio of different flows. This method of monitoring is not yet fully validated, but the interpretation of patterns is beginning to show that it is useful clinically. Abnormal waveforms from the arcuate artery are useful in predicting which women will develop severe hypertension in pregnancy. In a fetus shown to be small by ultrasound measurements, the umbilical artery waveforms help to identify the truly pathological from the constitutionally small baby. Absence or reversal of flow in the umbilical artery during diastole carries a 25–40% mortality, and up to a quarter of survivors have substantial morbidity. Conversely, small fetuses with normal umbilical waveforms have a good outcome. The middle cerebral arteries are the vessels most commonly used to assess cerebral circulation. These show a change from high to low resistance after about 30 weeks, possibly indicating dilatation as normal pregnancy progresses. During hypoxia, blood is redistributed away from the body to vital organs, achieving a brain sparing response. Measuring the ratio of flow in the middle cerebral artery to that in the aorta can give an indication of fetal hypoxia.

Invasive studies

In the second half of pregnancy fetal blood may be sampled by cordocentesis, when the oxygen saturation, carbon dioxide concentration, and concentrations of non-volatile bases such as lactate and pyruvate are measured in small blood samples. Blood is removed from the umbilical vein in the cord; the procedure carries a 1–2% risk of fetal death but the results can be invaluable about the state of fetal acid–base and blood gas concentrations. Furthermore, in some cases chromosome studies yield results that would change management.

Hormone concentrations

The estimation of oestriol concentration (or total oestrogens) in the mother’s urine or blood in late pregnancy was used to give some idea of the state of the fetoplacental unit. Unfortunately, the wide variance of results within the normal range did not allow precise enough prediction and the tests have mostly been replaced by biophysical ones.

Testing for progesterone and human placental lactogen has suffered the same fate as that for oestrogen, for the same reasons.

Conclusion

The clinical assessment of the fetus can be further refined by a series of tests. Some are simple and easy to do and are used as screening tests on the whole antenatal population—for example, ultrasound for checking fetal growth. Most fetal

Figure 4.11 Doppler studies showing the waveforms of normal (left) and narrowed (right) arcuate arteries of the placental bed

Figure 4.12 Left: Normal waveforms of the umbilical artery. Right: Severely abnormal waveforms of the umbilical artery showing reduced and even reversed flow in the diastolic phase, which suggests that the fetus is compromised

Figure 4.13 Obtaining fetal blood by cordocentesis

Figure 4.14 Urinary oestriol concentrations (mean \pm 2 SD) during gestation. The range is much greater than that of biophysical tests. Left: Variation during a normal pregnancy. Right: Acute placental malfunction in a woman with hypertension. Currently, signs of fetal compromise measured biophysically would have indicated that she be delivered before the last oestriol readings were available

Fetal investigations should be considered to be either screening, for use in large populations, or specifically diagnostic, for use in a selected number of fetuses in which there is clinical suspicion of significant pathological lesions.

investigations, however, should be kept for women who are at high risk of specific conditions—for example, doppler studies in a fetus thought to be small.

The development of more complex biophysical tests has led to a concentration of antenatal care for women at high risk in specialist hospital units. Many district general hospitals do not have all the facilities required so the proper use of regional centres for specialist tests must be encouraged. It may be unpleasant for a woman to have to move from her home area to a centre 40 or 60 km away, but this is usually acceptable if benefits of fetal diagnosis and treatment can be explained by the doctor or midwife so that the woman realises she is helping her baby. Unfortunately, resources and skills cannot be spread

uniformly throughout the country. A natural resistance to the new does happen in medicine, but it is Luddite to ignore new investigations merely because they were developed after the practitioner qualified.

5 Detection and management of congenital abnormalities

A congenital abnormality in their expected baby is greatly feared by couples; we are not many generations away from the superstitious who looked on malformation as a retribution for moral misbehaviour. Congenital abnormalities are still one of the major causes of perinatal mortality and morbidity.

The known causes of abnormality are genetic or environmental. Genetic abnormality depends on the chromosomes we inherit from our parents together with the breaks and realignments occurring at fertilisation. As well as the single gene diseases and those following chromosomal rearrangement at meiosis, a large number of conditions appearing in later life, such as hypertension and some cancers, are genetically associated. A whole new philosophy of preventive care is opening. Maternal ageing also increases the risk of abnormalities in genes. A good account of genetic abnormalities is found in the *ABC of Clinical Genetics*.

If parents ask about the risks of recurrence of congenital abnormality, having already had one child with a problem, there are two sets of variables the practitioner has to consider: those who may have a similar defect and those who may have a different defect. Whilst the former are fairly high there is also a small increased risk of new defects.¹

Table 5.1 Risks of similar and dissimilar congenital abnormalities in the second infants of mothers with an affected first infant*

Defect in first infant	Defect in second infant	
	Similar defect relative risk†	Dissimilar relative risk†
Talipes	7.3 (5.9–9.1)	1.4 (1.0–1.7)
Limb defect	11.3 (7.2–17.0)	2.4 (1.7–3.3)
Cardiac defect	6.0 (2.2–13.0)	1.1 (0.5–1.9)
Cleft lip	31.4 (19.0–52.0)	2.2 (0.6–2.2)
Cleft palate	44.5 (9.0–13.4)	0.7 (0.1–2.5)

* Based on 1.5 million births in Norwegian Medical Birth Registry.¹
 † 95% confidence intervals for the odds ratios in parentheses.

Environmental factors interfere with embryonic development at a precise stage of organogenesis. They are difficult to pinpoint and often are misassociated. Obvious insults such as exposure to thalidomide, x rays, and rubella can be identified; more difficult is the precise place of factors such as organic solvents in the cleaning industry and infections such as toxoplasmosis, cytomegalovirus, and parvovirus.

An antenatal service should aim at diagnosing congenital abnormalities as early as possible. Though the ideal treatment is prevention, this is too late by the time the woman joins the antenatal clinic. If an abnormality can be detected early the couple may be offered the choice of a termination of pregnancy. This is allowed in the UK under statutory grounds of the modified Abortion Act 1967 with no gestational age limit (Fig. 5.3).

Not all couples want to abort their unborn child even if it has an abnormality. Antenatal diagnostic facilities should be made available not only to those who wish a termination pregnancy if an abnormality is found but to affected couples for the reasons given in Box 5.1.

Figure 5.1 Proportions of congenital abnormalities by outcomes of pregnancy

Figure 5.2 When women joined antenatal care. By the time they arrived in the hospital clinic it was far too late for advice to have any influence on the embryo in the first trimester. Maybe the GP visit is the time to provide help

Box 5.1 Reasons for providing an antenatal diagnosis of congenital defect to all relevant couples

- It gives the couple more time to accustom themselves and other children in the family to the idea that an abnormal child is to be born.
- If the abnormality is not lethal, early diagnosis allows plans to be made for delivery in a centre where full treatment may be given early.
- If the abnormality is serious and possibly lethal, counselling for termination of pregnancy can be considered.
- If one of a pair of twins shows a serious anomaly, the option of fetocide can be discussed.

Currently antenatal screening for congenital abnormalities is still mostly concerned with detection of malformations of the central nervous system, the skeleton, and abnormalities of chromosomal origin. The diagnosis of abnormalities of the cardiovascular, alimentary, and urinary tracts is improving; many of these abnormalities are now treatable by neonatologists and paediatric surgeons. Hence, if diagnosed in pregnancy, a woman can be transferred to a hospital where such skills are found. She can have antenatal counselling and the baby can be treated at the best time after the delivery, promptly if necessary.

Testing in early pregnancy

Chromosomal problems

To examine fetal chromosomes, fetal cells are required. In chorionic villus sampling (CVS) a minute piece of trophoblast tissue is removed for examination of the chromosomes in the cell nucleus and, with increasing confidence, DNA assessment. Such sampling is commonly performed at 10–12 weeks of gestation, and a preliminary result is available a couple of days after the test compared with the delay of at least 14 days for amniocentesis. Sampling is under ultrasound control by the transcervical or the transabdominal route (Fig. 5.4). Reports of fetal damage being associated with the transabdominal approach before 10 weeks gestation have led to reservations about its use.² There has been a concomitant trend to use amniocentesis at an earlier stage. It is now possible to get a good sample of cells from amniotic fluid safely at 12–13 weeks, so this too is swaying some against CVS.

The attraction of CVS and its quicker results are offset by the higher risks of stimulating a miscarriage. Abortion rates associated with CVS are 2–4% compared with 0.3–1.0% with 16 week amniocentesis. At 10–12 weeks of gestation, however, the rate of spontaneous miscarriage is biologically much higher than at 16 weeks, so the comparison is not only of techniques. Many obstetric units are now using CVS for women at high risk, and with experience the miscarriage rates would be expected to fall.

A nationally organised randomised controlled trial found that CVS had more problems than amniocentesis in diagnostic accuracy, safety, and the need for further testing. However, the obvious advantages of earlier testing and receiving a quicker answer must be weighed against this. Doctors would do well to refer women asking for either procedure to a department of obstetrics that performs both and will give impartial and balanced advice in each individual case. In many centres both tests show similar risk rates.

Trisomy 21 (Down's syndrome) is much commoner in women over 35, but still half of the babies with this condition are born to women under that age. Although the risks to mothers under 35 are less, the overall number of babies born is much greater. To negate this, simple screening is required since both CVS and amniocentesis are unsuitable, invasive procedures

We hereby certify that we are of the opinion, formed in good faith, that in the case

of
(Full name of pregnant woman in block capitals)

of

.....
(Usual place of residence of pregnant woman in block capitals)

(Ring appropriate letter(s))

A the continuance of the pregnancy would involve risk to the life of the pregnant woman greater than if the pregnancy were terminated;

B the termination is necessary to prevent grave permanent injury to the physical or mental health of the pregnant woman;

C the pregnancy has NOT exceeded its 24th week and that the continuance of the pregnancy would involve risk, greater than if the pregnancy were terminated, of injury to the physical or mental health of the pregnant woman;

D the pregnancy has NOT exceeded its 24th week and that the continuance of the pregnancy would involve risk, greater than if the pregnancy were terminated, of injury to the physical or mental health of any existing child(ren) of the family of the pregnant woman;

E there is a substantial risk that if the child were born it would suffer from such physical or mental abnormalities as to be seriously handicapped.

Figure 5.3 Part of the modified certificate A of the Abortion Act 1967 (revised 1991)

Figure 5.4 Chorionic villus biopsy. Under ultrasound guidance there can be (A) a transcervical approach of the cannula to the edge of the developing placenta or (B) a transabdominal aspiration by needle from the middle of the trophoblast mass

Table 5.2 Refining the risk of Down's syndrome by comparing age alone with results of age and the Triple Test using levels (multiples of mean, MoM) of α fetoprotein (α FP), oestriol, and human gonadotrophin (hCG)

Age alone	Age (years)						
	≤20	21–25	26–30	31–39	≥40		
	1:1530	1:1350	1:900	1:385	1:110		
Age and triple test (MOM)							
α FP	Oestriol	hCG					
>0.5	>0.5	<2.0	1:1200	1:100	1:70	1:30	1:10
>2.0	>2.0	<0.5	1:140 000	1:120 000	1:84 000	1:35 000	1:1000

that are very labour intensive. Hence the combination of biochemical tests of maternal blood in early pregnancy to screen for Down's syndrome is widely used. Maternal α fetoprotein, human chorionic gonadotrophin, and oestriol concentrations are measured and the relative risks of each are computed along with the risk advanced by the mother's age at any given gestation. A double test leaves out the oestriol estimation. A combination of risk values for these four markers plus age gives a detection rate (see Table 5.2) and provides the odds of the fetus being affected with Down's syndrome given a procedure screening result. Thus women can be identified who are at high enough risk to justify the hazards and costs of amniocentesis or CVS, the only currently practical ways of getting fetal cells and performing a diagnostic procedure. If the gestational dates used are derived from ultrasound rather than clinical measures, a 10% increase in detection rate is found. Current research is assessing additional markers in both urine and blood at 12 and 15–16 weeks gestation, including pregnancy associated protein A, inhibin A, and urinary β hCG.

Such screening should be offered in all women irrespective of age. It is illogical to restrict it to the over 35-year-olds. As a screening method, maternal age and biochemical estimates would replace the poorer age-only based screen, giving the woman a more precise prognosis of risk and so allowing a more informed decision before going into the diagnostic test of checking fetal chromosomes.

Fetal cells can be detected in the mother's serum as early as 6 week gestation. Though few, they can be identified and isolated. With DNA reduplication, the chromosomal material can be increased and examined. So far male cells have been identified; only female adult cells are present in the mother, any with male chromosomes must have crossed the placenta from the male fetus. Soon DNA manipulation could allow chromosomal abnormalities to be detected and may remove the need for amniocentesis but this is not yet clinical practice.

Ultrasound tests

The association of ultrasound measured fetal nuchal translucency with Down's syndrome (Table 5.3) and other chromosomal abnormalities has a sensitivity exceeding that of serum screening and a high predictive value. Equally importantly, nuchal translucency measurements correlate with serum screening levels, so that the combination of both tests might increase sensitivity and specificity.

The big advantage is that this is a non-invasive test done at about 10 weeks of gestation so might be used as a screening test to indicate which women should go forward for fuller chromosome analysis by CVS or amniocentesis.^{3,4} However, sensitivity varies widely according to the skill of the ultrasonographers and the equipment they use.

Those experienced in using the test claim that sensitivity will improve and are now adding a series of other ultrasound markers of Down's syndrome (Box 5.2) in later pregnancy.

Table 5.3 Rising risk of Down's syndrome with increase in nuchal skin fold oedema (from Nicholaides *et al. Br J Obs & Gyn* 1995;101:782–786)

Nuchal oedema (mm)	Relative risk of Trisomy 21
<3	0.2
3	3.2
4	19.8
5	28.6
>5	45.2

Figure 5.5 Risks of Down's syndrome. The risk increases after 35 and sharply after 40. The percentage of women in the UK who deliver by each age group is also shown. Although the risk is high after 40, the numbers of women delivering are small

Figure 5.6 Oedema of the back of the neck shows on ultrasound; increased oedema is associated with increased rates of chromosomal abnormalities

Testing in mid-pregnancy

Structural abnormalities

Open neural tube defects such as anencephaly and open spina bifida allow α fetoprotein to escape from cerebro-spinal fluid into the amniotic fluid, whence it is absorbed into the maternal blood, producing higher than normal concentrations. This is the basis of serum α fetoprotein screening performed between 14 and 16 weeks. It is virtually non-invasive, entailing only a blood sample, and has a high predictive value. Fetal gestational age must be estimated by ultrasonography. False positive results can be caused by multiple pregnancy, a dead fetus, bleeding behind the placenta (which may manifest as a threatened miscarriage), and a few rather rarer abnormalities of the fetus such as gastroschisis.

If the serum α fetoprotein concentration is high a special ultrasound scan may be performed to examine the spine and head carefully at 16–17 weeks of gestation. In some units ultrasound alone is used for the detection of neural tube defects.

By 20 weeks the fetus can be seen clearly on ultrasonography and many neural tube defects will have been detected. At this gestation the heart can be examined and the four chambers identified. The appearance and orientation of

Figure 5.7 Maternal serum α fetoprotein concentration by weeks of gestation. The lower line is taken as the upper boundary of the normal group so it is important to date the pregnancy precisely – that is, by ultrasound measurement of the biparietal diameter. This is magnified by $\times 2.5$ the mean to exaggerate differences

Figure 5.8 Ultrasound scan of a fetus with a sacral meningocele taken at 19 weeks

Figure 5.11 Ultrasound scan showing male genitalia resting on the section of the thigh in a fetus of 30 weeks

Figure 5.9 Scan of a fetus with anencephaly taken at 17 weeks

Figure 5.12 Double bubble effect of duodenal atresia, with the lower bubble in the stomach and the upper bubble in the duodenum. Normally continuity can be traced between these two bubbles

Figure 5.10 Ultrasound scan of the heart of a fetus with mitral atresia taken at 23 weeks gestation

Figure 5.13 Hydrocephalus showing enlarged posterior horn of the ventricle (between single arrows) and anterior horn (between double arrows)

the great vessels can also be checked so that major cardiac abnormalities can be excluded. Limbs can be seen to exclude any shortening and, if relevant, the sex of the child may be determined by sighting the external genitalia.

Later still the kidneys may be assessed for cysts or damming back of urine, producing hydronephrosis. Blockage in the intestinal tract can be checked by the presence of bubbles of fluid in the stomach, duodenal, or large bowel area. The cerebral cortex and ventricles can also be easily visualised and measured; any persistent choroid plexus cysts can be detected. Structural abnormalities of the limbs and digits will be apparent later and some degrees of cleft lip or palate can be found.

The volume of amniotic fluid can be calculated from measurements inside the uterine cavity or more pragmatically by measuring the longest column at the maximum diameter of the largest fluid pool.

These investigations permit a thorough knowledge of the unborn child. Many of the skills are available in the ultrasound departments of district general hospitals, but there is more expert back up at the special obstetric ultrasound clinics of tertiary referral hospitals.

Chromosomal abnormalities

In mid-pregnancy the chromosomal state of the fetus may be checked from cells removed at amniocentesis. Early amniocentesis (before 14 weeks) appears to be associated with significant problems including increased fetal loss, fetal talipes, and difficulty with culturing the chromosomes. New polymer chain reaction techniques have enabled preliminary results to be available within 24 hours but the full results for chromosome cultures still take some weeks.

The commonest use of amniocentesis is for the diagnosis of Down's syndrome (trisomy 21), and in most parts of England and Wales women over the age of 35 are offered this screening test. Serum screening of hCG, α fetoprotein and oestriol is used to determine those at higher risk of Down's syndrome. Amniocentesis is an invasive procedure with a small risk of spontaneous miscarriage (0.3–1.0% above background rate of miscarriage). This risk is less if the procedure is done under ultrasound guidance by an experienced obstetrician (0.3–0.8%).

Occasionally from about 20 weeks of pregnancy it is necessary to be certain that the fetus has normal chromosomes if a high risk pregnancy is to be continued under adverse circumstances. It is wise to know that the baby is normal before putting the mother through many weeks of anxiety and possibly a caesarean section. The white cells of fetal blood can be obtained at cordocentesis by penetrating the umbilical cord where the vessels are held firmest, close to the placenta or to the fetal belly wall. Chromosome examination of the white blood cells gives a result fairly speedily (two or four days).

Figure 5.14 Amniotic fluid estimation. (A) The largest pool has the longest column of 5.3 cm (between the arrows); this is normal. (B) In polyhydramnios the longest pool between the arrows has a column of 9.1 cm. Generally 8.0 cm is taken as the upper limit of normal

Figure 5.17 Metaphase spread of chromosome material from a nucleus after culture. The chromosomes are photographed and the print cut out and arranged in pairs to show the normal arrangement for a female, two X chromosomes at the end of the bottom grouping

Abnormalities of the central nervous system

The total number of abnormalities of the central nervous system in England and Wales has fallen since the early 1970s. Data are based on three sources:

- notification of termination of pregnancy for abnormalities of the central nervous system;
- death certification of stillbirths and neonatal deaths because of abnormalities;
- notification of abnormalities of babies who live.

Whilst rates are at 1.75 per 1000 in Wales, there is a differential in the south of Britain, where the proportional decrease is even greater. In many parts of southern England, the rate of abnormalities of the central nervous system is less than 1 per 1000. At this level a screening programme that used α fetoprotein might do more harm than good because action might be taken on false positive results. Many authorities have abandoned biochemical screening for these reasons.

Ultrasound as a screening test for anencephaly has good results, and when modern, high resolution equipment is available spina bifida can be detected. Although the special skills and equipment are currently not always available in DGH ultrasound clinics, regional centres do provide them.

Availability of tests

Biochemical screening for abnormalities of the central nervous system and for Down's syndrome is patchy and varies from one district health authority to another. The reasons lie not just in the whims of economic diktat but with variations in the interpretation of epidemiological data.

Congenital abnormalities

Down's syndrome

As explained previously, the risks of Down's syndrome are greater in women over 35, but because most babies are born to women under this age about half of the babies with the syndrome will be missed if age is used as an indicator for fetal chromosome tests. The use of serum screening with ultrasound has offered younger women the option of testing for Down's syndrome, although costs will have to be considered. To detect one affected fetus it now costs about £15 000 to screen for Down's syndrome. Some health authorities would set this against the cost of maintaining a child born with Down's syndrome for the rest of his or her life in an institution, probably between £17 000 and £30 000. The cost of diagnosis, however, comes from one year's budget, whereas the cost of maintenance is spread over many years' budgets in the future; local health authorities are forced into this philosophical financial juggling.

Many units in the UK have introduced serum screening enabling those women considered to be at high risk by age alone to be reallocated to a lower risk group if the results are favourable. With recent advances in early ultrasound, it is likely that a combination of serum screening and measurement of the nuchal fold will produce the best pick-up rate for the lowest level of false positives.

Figure 5.18 Chromosomes of a woman with trisomy 21. The last but one grouping (position 21) has three chromosomes instead of two

Figure 5.19 Cordocentesis

Figure 5.20 Birth prevalence of spina bifida in England and Wales. A slight reduction has occurred from the mid-1960s, becoming sharper from 1973. Testing for α fetoprotein, although described in the early 1970s, was not widespread until the 1980s and so there may be a coincident factor in this reduction as well as the effect on screening. Many think this is due to an improved diet for the women of this country

Conclusion

At first the antenatal detection of congenital abnormalities may seem to lead only to a nihilistic outcome, but the diagnosis can lead to other lines of management such as the preparation for early paediatric surgery or, in future, to genetic engineering. This is unlikely to be of any help once the embryo has started its development, but work done now on forming embryos can be extrapolated back to research on the oocyte. Here recombinant DNA technology may be used to change the affected part of a chromosome before cell development starts, thus producing a normal fetus. Such technology obviously needs to be controlled by society to help couples who previously had no chance of producing a normal baby.

Detection of fetal abnormalities in early pregnancy need not just lead to termination of pregnancy. Many results confirm normality and so reassure the mother. Even when positive, the results lead to the provision of better neonatal services when the affected baby is born.

6 Work in pregnancy

Both the proportions and numbers of women in the paid workforce have been increasing in England and Wales since before the second world war. In 2000 46% of the workforce were women, many in part-time posts, and this statistic has important implications for childbearing and reproduction.

Other important changes are women working longer in pregnancy and the postponement of starting a family to an older age. Three-quarters of couples need two incomes to pay the mortgage and other loans. When the woman becomes pregnant she receives maternity benefits, but these are poor compared with those in other European countries and income will be reduced. Every woman is entitled to 18 weeks of maternity leave. During the first six weeks of this she gets 90% of her average pay and for the next 12 weeks she gets standard maternity pay which is currently £62.20, going up to £75 per week in 2002 and £100 in 2003, hence the total standard maternity pay is for 18 weeks for those who have worked before pregnancy. Maternity allowance is separate and may be claimed. Currently this is £62.20 a week for women who are employed in pregnancy. There are no deductions for tax or National Insurance contributions. This is paid for 18 weeks when the woman is not working.

These and other allowances change often and practitioners would be wise to update themselves from time to time. Details can be obtained from the local Social Security Office or Factsheets from the Maternity Alliance (45 Beech Street, London EC2P 2LX) who provide up-to-date information on this and many other matters. They are most helpful to the cause of women who work in pregnancy.

In the UK the number of women over the age of 35 having babies has increased in the past 30 years because the years of reproduction are those of career advancement and each pregnancy becomes a gap in climbing the ladder of promotion.

Two-thirds of the women in the paid workforce currently continue to work longer into pregnancy than women did in the 1960s. Whereas some stop around the 28th week of pregnancy, most of them continue into the 34th or 35th week. Women are entitled to maternity leave for six weeks on 90% and 12 weeks on £62.20. This can start from 11 weeks before the expected time of delivery, as certified by a doctor or midwife on the MATB1 form. Most women, however, prefer to have as much time as possible with their newborn child after delivery and so do not leave work early.

In certain circumstances a woman leaving her job during pregnancy is entitled to return after maternity leave up to one year after delivery. The employer must, however, employ more than five people and the woman must have worked with the employer for two years in a full-time job or longer in a part-time post. If she wishes to protect her job she must give her employer 21 days' notice of her intent to stop working and she cannot leave until the 28th week of pregnancy. In return for this the employer must keep the job open for a year and, though the exact job may not be there, a job of an equivalent nature must be offered.

Types of work

It is an implicit and undiscussed assumption (by men) that any woman who works outside the home will continue to keep house as well. Hence housework must always be considered when examining work in pregnancy. All women work in the

house, where there is washing, cooking, cleaning, and the loads imposed by other children, a husband, and maybe parents. When a woman works at home she has no rest or meal breaks; if she works outside the home as well, housework is often done in the evenings and at weekends.

About 45% of jobs done by women are part time so, although the activity may be great, the number of hours spent away from the home are fewer.

Specific hazards at work

Outside the home three million women work in offices, two million in hotels and shops, and one million in the health service or education; another four million work in a wide range of jobs, though few women in this country do the very heavy jobs that are done by women in the United States and the former Soviet Union, for example. Indeed, in this country under the Mines Act 1889 women are not allowed to work down mines.

Most women are aware of specific hazards in their workplace. These are most important in very early pregnancy, when teratogenic influences may occur at a specific time in embryogenesis. The same stimulus acting later in pregnancy can affect growth, causing intrauterine growth restriction.

Chemical hazards

Over 30 000 individual chemicals are used in industry, with a further 3000 compounds being added each year. It is impossible to test all of them on pregnant animals, and much of the evidence about safety depends on retrospective reports of damage to humans. The number of chemicals that are proved to be teratogenic are few.

If a woman is worried about chemicals in her workplace and consults her family doctor, the doctor would do well to discuss the problem with a health and safety officer or trade union official at the woman's work. If there is no help there, the best reference source is the local or central office of the Health and Safety Executive. Any woman who thinks that she is working with a toxic hazard should discuss this well before pregnancy for it is often too late to start making enquiries in early pregnancy. There are special codes of practice for certain toxic chemicals which safeguard pregnant women and their unborn children. The employer should offer alternative work with no loss of pay or benefits. Toxic chemicals can still enter the mother's body after childbirth and be excreted in milk, so a lactating mother also should take precautions against such chemicals.

Many chemicals have been blamed at some time for affecting an early embryo. This makes big news but when, a few years later, the reports are refuted, it is not newsworthy and often not reported in newspapers.

Box 6.2 Chemical hazards in pregnancy

- Metals—for example, lead, mercury, copper
- Gases—for example, carbon monoxide
- Passive smoking
- Insecticides
- Herbicides
- Solvents—for example, carbon tetrachloride
- Drugs during their manufacture
- Disinfecting agents—for example, ethylene oxide

Physical hazards

At specific times in embryogenesis physical hazards can cause abnormalities. X rays are a risk in early pregnancy, particularly if a series of films of abdominal structures are exposed during

Figure 6.5 Female economic workforce by age

early pregnancy, e.g. for intravenous urography or barium studies of the intestine. It is wise always to ask about the last menstrual period, contraceptive practices, and the possibility of pregnancy specifically before any x ray in women of childbearing age. The 10-day rule (whereby no woman is exposed to x rays within 10 days of the next menstrual period) has now lapsed in most hospitals but inquiry should be made.

The risks of x rays to the female staff in a well managed therapeutic radiation department are probably low, but some women work with radioisotopes in laboratories. The Health and Safety Executive has laid down standards that women should follow. Less well regulated are the x ray machines used for security checks in many large firms. There is probably little risk to a visitor passing once through the system, but the people who work the equipment might be exposed to repeated radiation, which should be checked.

Ultrasound is used widely in industry and at the dosage used is probably safe. Certainly, diagnostic ultrasound used in medicine has low energy and is pulsatile; the risk of cell damage or vacuolation that occurs with high energy ultrasound does not exist with this common use. There is no epidemiological evidence of medical ultrasound associated abnormalities: some 60 million women have been exposed to ultrasound in early pregnancy, yet no pattern of problems has yet been shown. Nearly all pregnant women in the UK have one or two ultrasound scans but 46% report having more than two during the pregnancy.

Another physical hazard which caused a scare was the use of visual display units (VDUs) in personal computers (PCs). There are millions of PCs in the homes and offices of the UK. Some 20 years ago small groups of women working with VDUs were reported to have a high rate of pregnancy wastage. These were small clusters, and the measured outcomes were often a mixture of miscarriage, congenital abnormality, and stillbirth. More recent studies show no increased risk due to the use of such units and a wide ranging review concluded, "At present it seems reasonable to conclude that pregnancy will not be harmed by using the VDU. Statements on the contrary are not soundly based."¹

Biological hazards

Nurses, female doctors, and others who handle body fluids, as well as women who work in microbiological laboratories may be handling toxic materials, but usage is usually well regulated for all workers in or out of pregnancy. Rules must be followed.

Animal workers may be at increased risk, and there have been reports of miscarriage after handling ewes at lambing because of the passage of ovine chlamydia, and toxoplasmosis infection may be more prevalent among those who handle domestic pets in their jobs. The position with bovine spongiform encephalopathy (BSE) for pregnant workers is unclear for too few cases have been documented. There is probably no extra risk over background for the pregnant.

Probably the most commonly transmitted infection which may affect the fetus is German measles. Epidemics occur among young children, and so teachers who are constantly in contact with them are at risk. All young women entering teaching should have their serum rubella antibody titre checked; if they are found to be seronegative they should be offered vaccination.

Non-specific hazards

As well as specified toxins, various physiological changes of pregnancy in the mother might affect the embryo deleteriously. During strenuous exercise the blood supply to the non-skeletal parts of the body are reduced, including the kidneys, intestines,

Box 6.3 Physical hazards in pregnancy

- Ionising radiation—for example, x rays
- Noise
- Vibration
- Heat
- Humidity
- Repetitive muscular work—for example, at visual display units
- Lifting heavy loads
- Uninterrupted standing

Normal pregnant women in jobs with no toxic risk need not be deterred from working for as long as they wish into pregnancy.

Box 6.4 Biological hazards in pregnancy

- Contact in crowded places—for example, in travelling to work
- Contact with higher risk group—for example, schoolchildren
- Food preparation
- Waterborne infections
- New arrivals from abroad

ABC of Antenatal Care

and uterus; the blood supply to the leg muscles can be increased 20-fold and that to the uterus halved. Hence in hard physical work, as occurs in agriculture, there may be some diminution of uterine blood flow, but this is unlikely with ordinary work. Similarly, stress can reduce blood flow to the uterus if the degree of agitation is high enough; if a woman is working inside her own limits there probably will be no problem.

Environmental factors at work that induce boredom and fatigue were found to have effects on pregnant women in a French study.² Women in industrial and agricultural jobs were compared with those working in offices. Multivariate analyses of the repetitive nature of the work, the physical effort required, the boredom of the work, standing, and the effect of background noise showed an increased proportion of preterm deliveries when these factors were high, and this might be important in women who have previously had preterm labours.

Recent British and U.S. studies found no effect of work on birth weight.³ Infants born to women in full-time employment had no significant differences from those born to women who were not in paid work. Data on hours of work, energy expenditure, and posture were collected at 17, 28, and 36 weeks, and these too had no discernible association with birth weight.

It is probable that a higher proportion of those who work are well women and those with chronic ill health do not work. (Further, those of better educational attainments report more out of home work than those with less.) Nevertheless, once the sociobiological variables are removed, work in pregnancy is still associated with a better outcome.

Travel to work

If a woman has paid work outside the home, she has to get there. If travelling entails a short walk in the morning and evening it can be enjoyable, but most women live in large towns with an unpleasant 30–90 minutes of travel at the beginning and end of the day. There is noise, heat, fatigue, and, in some cases, other people's tobacco smoke. Travel is stressful in crowded, unpleasant conditions. Studies in Spain showed that the likelihood of preterm labour increases with the duration of stressful public travel the woman has to suffer.⁴ It may be wise for a woman contemplating pregnancy to arrange to work flexible hours if her work is in a big city. The employer could then perhaps allow her to arrive a little before or after the rush hour, with time being made up in other ways.

Conclusion

More women work during pregnancy and want to continue for longer. Pregnancy is a normal event and, generally speaking, most jobs cause no increased hazard to the mother or baby. A woman should, however, be warned that if any complications arise she must be able to leave work easily. If there is flexibility and the job is not one entailing a high risk from toxic agents most women can continue working for as long as they wish in pregnancy.

When the effects of work on maternal and fetal outcomes are assessed, after adjusting for environmental and background social factors, work seems to have very little detrimental or beneficial influence.

7 Vaginal bleeding in early pregnancy

Bleeding drives patients to their general practitioner swiftly. Vaginal bleeding early in pregnancy makes the woman think that she may be miscarrying, so this brings her even more promptly; the practitioner thence has the opportunity to diagnose the cause and start management.

Bleeding has four known causes in early pregnancy (Box 7.1). In addition, bleeding may occur for no apparent reason in a large number of cases. In early pregnancy such cases are commonly categorised as threatened miscarriage, but this is fudging the issue for in many cases the conceptus and its future placental system are not involved; doctors should be honest and say that they do not know the cause rather than mislabel it.

Box 7.1 Causes of bleeding in early pregnancy

- Miscarriage
- Ectopic pregnancy
- Trophoblast disease
- Lesions of the cervix or vagina

Box 7.2 Types of miscarriage and abortion

- Threatened miscarriage
- Inevitable miscarriage
 - complete
 - incomplete
- Silent miscarriage
- Recurrent miscarriage
- Criminal abortion
- Septic abortion
- Therapeutic abortion

Miscarriage and abortion

Figure 7.1 In a *threatened* miscarriage the cervix is still closed and there is not much bleeding. In an *inevitable* miscarriage the cervix has started to open and the membranes often have ruptured. There is usually more bleeding. A *complete* miscarriage means that the uterus is empty of clot and decidua. In an *incomplete* miscarriage the embryo has been passed vaginally but some part of the membrane or decidua is retained. There may also be clots

The terms miscarriage and abortion have been used synonymously but miscarriage is the word which should be associated with the spontaneous event.

- *Threatened miscarriage.* Women bleed a little from the vagina during a threatened miscarriage but there is not much abdominal pain. The uterus is enlarged and the cervix closed. Pregnancy may continue.
- *Inevitable miscarriage.* Miscarriage is inevitable if the cervical os is open. Blood loss can be great and lower abdominal cramping pains accompany the uterine contractions. Some products of conception and clots may be passed but often decidua is retained and then the miscarriage is called incomplete.
- *Complete miscarriage.* The cervical os is open and the uterus completely expels its contents. Such miscarriages are more likely after 14 weeks of pregnancy than earlier, when they are often incomplete.
- *Septic miscarriage.* This follows the ascent of organisms from the vagina into the uterus, often after an incomplete miscarriage or an induced abortion under non-sterile conditions. As well as heavy bleeding and pain, the woman commonly has a fever and may develop signs of endotoxic shock. The commonest organisms are *Escherichia coli* and *Streptococcus faecalis*.
- *Silent miscarriage.* The embryo dies and is eventually absorbed but the uterus does not expel the decidua and sac of membranes. The woman sometimes feels a dull weight in

Figure 7.2 Terminations of pregnancy by age group in England and Wales, 1968–99. Many operations are performed outside the NHS, some being done through charity clinics

the pelvis, the symptoms of pregnancy regress and the uterus stops enlarging. Old blood is passed as a brown, watery discharge. This condition is diagnosed more frequently now that ultrasonography is used in very early pregnancy.

- *Recurrent miscarriage* is diagnosed when a woman has three or more consecutive spontaneous miscarriages. Such women deserve gynaecological and immunological investigation; many gynaecologists start investigations after two consecutive miscarriages in women over 35. A specific cause for the recurrence can be found in up to 40% of cases.
- *Therapeutic abortion*. This is now common in Britain, with over 180 000 women in England and Wales having such abortions each year. Usually the general practitioner knows but occasionally the woman has bypassed him, presenting only after the event with vaginal bleeding, an open cervix, and some abdominal pain. This means that decidua or blood clot is left in the uterus and needs the same attention as does an incomplete miscarriage.

Causes of miscarriage

Embryonic abnormalities

Chromosomal abnormalities are common, arising from a change in the nucleus of either gamete or a spontaneous mutation inside the fertilised oocyte. At the time of fertilisation splitting and rejoining of genetic material may be imperfect. Such changes are not usually recurrent, and parents should be told this.

Immunological rejection

The fetus is genetically foreign to the mother and yet most fetuses are not rejected. In many cases blocking antibodies that inhibit the cell-mediated rejection of the embryo are stimulated by antigens from the trophoblast. Antiphospholipid antibodies have been linked with recurrent early pregnancy loss as well as later placental bed insufficiency. This may act through placental thrombosis or decidual vasculopathy. Treatment with aspirin, heparin or a combination offers hope of a successful pregnancy.

Uterine abnormalities

The uterus is formed during embryonic development from two tubes fusing together to make a common cavity. Occasionally various degrees of non-absorption in the midline septum occur, leaving either two cavities or a cavity partly divided by a septum down the middle. The blood supply to this median structure is usually poor and implantation of an embryo here may be followed by miscarriage.

Cervical incompetence

The cervix may have some weakness which could be associated with a spontaneous miscarriage in the mid-trimester (13–27 weeks). This can be either congenital or acquired after overstretching at a previous dilatation and curettage or birth. The unsupported membranes bulge into the cervical canal through the internal os and rupture early, which causes the abortive process. The incompetence may be diagnosed before pregnancy by a hysteroqram (a radiological examination of the uterine cavity) or in pregnancy by ultrasonography. Cervical cerclage is usually performed in pregnancy following a history of mid-trimester miscarriage, particularly if the membranes ruptured before any uterine contractions occurred (see Chapter 12).

Maternal disease

This is unlikely to be a major cause of miscarriage in the UK, but hypertension and renal disease are still associated with

Figure 7.3 Congenital abnormalities of the uterus caused by non-absorption of the septum during fusion of the Müllerian ducts. (A) Complete double uterus, double cervix, and vaginal septum. (B) Double uterine cavity within a single body; the cervix and the vagina have a septum. (C) A subseptate uterus in which the septum does not reach down to the cervix. ABC of Antenatal Care

higher rates of miscarriage in later pregnancy. Maternal infections can affect the fetus, particularly rubella, toxoplasmosis, cytomegalic inclusion disease, and listeriosis. Severe maternal malnutrition is most unusual in this country, though it can still occur in developing countries. Deficiency of individual vitamins (such as vitamin E) is extraordinarily rare in the mixed diet of this country, and there is no evidence of it being a substantial cause of miscarriage in women. Shortage of folic acid is associated with fetuses with major central nervous system abnormalities, some of which may miscarry.

Endocrine imbalance

Diabetes and thyroid hyperfunction are associated with increased risks of spontaneous miscarriage. If diagnosed, both are now usually well controlled and the risk is reduced. Abnormalities in the ratio of luteinising hormone to follicle-stimulating hormone in a particular cycle may lead to miscarriage. An insufficiency of progesterone from the corpus luteum used to be regarded as a cause of miscarriage. This is hard to prove, and most randomised trials using progestogens in early pregnancy have failed to show an improvement. Some consider that hCG injections may help. If, however, the woman has faith in this treatment and had a previous successful pregnancy taking it, the practitioner would do well to treat the psyche as well as the soma and prescribe a progestogen or hCG.

Criminal abortion

This is now much less common in Britain but still occurs in other countries and in populations derived from those countries. Although infection has been introduced, only rarely do criminal abortionists leave signs that can be spotted in the genital tract and so the woman is often treated for an incomplete or septic miscarriage. With the reduction in illegal abortion, maternal mortality from this cause has disappeared in the UK.

Presentation

A woman who is miscarrying usually presents with vaginal bleeding and may have some low abdominal pain. The bleeding is slight in a threatened miscarriage, greater amounts being present with an inevitable miscarriage. Pain with uterine contractions may be compared with dysmenorrhoea. The degree of shock usually relates to the amount of blood loss from the body and the degree of cervical dilatation.

The differential diagnosis includes ectopic pregnancy and salpingitis.

Management

Threatened miscarriage

A woman with a threatened miscarriage is best removed from an active environment. If the practitioner tells her to go to bed to rest for 48 hours she may feel happier but there is no real evidence that bedrest makes any difference to the incidence of miscarriage. Some 5% of women who deliver safely report vaginal bleeding in the same pregnancy; the effectiveness of specific treatments is difficult to assess. The avoidance of sexual intercourse is probably sensible as it might act as a local stimulus.

Inevitable miscarriage

If events progress to an inevitable miscarriage the woman often needs to be assessed in hospital;¹ an ecobolic agent might be

Figure 7.5 The number of deaths reported after illegal abortion is reducing rapidly in England and Wales, with none reported for the 14 years 1982-96. Death used to be mostly from sepsis or renal or hepatic failure

Box 7.3 Treatment of miscarriage

Threatened	Bedrest Avoid intercourse Reassure with ultrasound
Inevitable	Hospitalisation If heavy bleeding, use ecobolic Evacuate uterus

Figure 7.6 (A) Ultrasound scan of an empty sac in the uterus at seven weeks gestation. This woman had a silent miscarriage, the embryo having been resorbed. (B) Ultrasound scan of a continuing pregnancy at just over seven weeks; fetal tissue is easily seen between the crosses

given if the bleeding is excessive and a paramedic may be needed to cover transfer. Ultrasound is useful in determining if the miscarriage is complete. Retained products can be removed surgically under a general anaesthetic or medically using vaginal prostaglandins.

Complete miscarriage

This is more common than was once thought; practitioners may see the sac containing the embryo and feel that this is complete. They would do well to remember, however, that a large amount of decidua can be left behind and an evacuation may prevent the woman having a haemorrhage or infection a week or so later. Ultrasound in an early pregnancy unit can help to make the diagnosis.

Silent miscarriage

This is sometimes diagnosed from the woman's symptoms of a brown discharge and a heavy, dull feeling in the pelvis; the finding of no embryonic tissue inside the gestation sac on ultrasonography confirms the diagnosis. It can also appear as a complete surprise at a routine ultrasound. Management options include a conservative line with a repeat ultrasound, surgical evacuation or medical management with prostaglandins.

Septic abortion

This may require the full management of severe sepsis. Endocervical swabs should be sent to the laboratory and treatment with a broad spectrum antibiotic started immediately. Central venous pressure measurement and intravenous rehydration will be required; the urinary output should be watched carefully. Evidence of disseminated intravascular coagulopathy should be sought and the uterus evacuated once a reasonable tissue concentration of antibiotics has been achieved. Watch for renal failure.

Recurrent miscarriage

The management of recurrent abortion is outside the scope of this series but some aetiological features are given in Box 7.1. It requires sympathetic handling by both general practitioners and specialists.

Ectopic pregnancy

An ectopic pregnancy is one that implants and develops outside the uterine cavity. The sites are shown in the figure, but most (96%) are in the fallopian tube.

Causes

Anything that slows the passage of the fertilised oocyte down the fallopian tube can cause a tubal ectopic pregnancy. Previous tubal infection, an intrauterine device in place, and late fertilisation are quoted causes, but in most ectopic pregnancies no cause is found.

Presentation

A tubal ectopic pregnancy may either rupture through the wall (more common with isthmal and cornual implantations) or leak a little blood from the lateral end of the fallopian tube (with ampullary or fimbrial implantations). Vaginal bleeding can occur.

With rupture there is a brisk peritoneal reaction and the woman may fall to the ground as though kicked in the stomach.

ABC of Antenatal Care

She quickly becomes very shocked because of the large volume of blood released into the peritoneal cavity and the stimulation of the peritoneum. The abdomen is tender with guarding and rebound tenderness, and vaginal examination causes intense pain on touching the cervix.

A more gradual leak from the tubal end causes irritation of the pouch of Douglas. The woman goes to her doctor complaining of vague, low abdominal pain, sometimes with vaginal bleeding occurring after the pain. The abdomen may be uncomfortable in the suprapubic area, and a very gentle vaginal assessment may show a tenderness in the pouch of Douglas or in the adnexa on one side.

The differential diagnosis includes an abortion or any other cause for a sudden release of blood into the peritoneal cavity, such as a bleeding vessel over an ovarian cyst. Inflammatory conditions such as appendicitis may mimic a leaking ectopic pregnancy. Ectopic pregnancy should always be considered in any cases of lower abdominal pain because an unruptured ectopic pregnancy, leaking a little blood over the course of some days, is hard to diagnose. A negative routine pregnancy test is not exclusive; it is usually positive.

Management

The management of a woman with a ruptured ectopic pregnancy is straightforward. She should go to hospital immediately, if necessary accompanied by her general practitioner. Intravenous support may be required in the home, and in severe cases a flying squad (if available) may be required. Once in the hospital, surgery should be immediate. Most tubal ectopic pregnancies need a laparoscopy to confirm the diagnosis and maybe provide access for treatment. Those in severe shock due to a ruptured ectopic will also need a laparotomy and surgical removal. Unruptured ectopics can be managed laparoscopically by opening the tube and aspirating the gestational material. If some part of the tube can be left behind it is psychologically helpful to the woman. There is a small risk of a second ectopic pregnancy developing in the remaining tube but there is also the possibility of reparative surgery later. This is particularly important when a woman has had a previous ectopic pregnancy and one fallopian tube has already been removed.

A leaking tubal pregnancy is harder to diagnose, such cases being usually referred to outpatient departments in a more leisurely fashion. If the diagnosis is suspected, laparoscopy is the best test; ultrasonography is not exclusive, although fluid in the pouch of Douglas with no intrauterine pregnancy in a woman with 6–8 weeks' amenorrhoea and a raised hCG level is highly suggestive.² At laparoscopy the swollen area of the tube can usually be seen and little blood may come from the lateral end. Under ultrasound guidance, injections of fetotoxic agents such as methotrexate or potassium chloride are given. Alternatively, some, having made a firm diagnosis of ectopic pregnancy by a raised hCG, an empty uterus, and ultrasound evidence of fluid in the pouch of Douglas, will treat the woman conservatively if the ectopic is unruptured. Systemic methotrexate given as a single dose works in 90%. If hCG levels persist, a second dose a few days later usually suffices. The results of such minimally invasive management are as good as those of more conservative surgery, with the time spent in hospital and the emotional effects on the woman's life being much reduced.

Any woman treated for an ectopic pregnancy should be warned of the increased chances of a recurrence. The increased risk is said to be seven times above background.

Figure 7.8 The most common ectopic pregnancies are in the fallopian tube. (A) Those at the medial end rupture. (B) Those at the lateral end leak more gradually

	Unruptured	Ruptured
Symptoms	Gradual onset Dull ache over days	Sudden onset Severe pain over minutes
Signs	No shock Vague suprapubic tenderness No great cervical tenderness Vague mass often felt	Commonly shocked Rigid abdomen with rebound tenderness Extreme tenderness on cervical movement Too tender to palpate

Figure 7.9 Tubal ectopic pregnancy. (A) Laparoscopic injection of methotrexate, a fetocidal substance. (B) Clamping and cutting out of the affected part of the tube at open surgery

Gestational trophoblastic disease

Causes

Chromosomal changes in the fertilised oocyte lead to degeneration of the stem blood vessels in the villi in very early pregnancy, so producing a vast overgrowth of swollen villae (vesicles) inside the uterus. This is a hydatidiform mole, and commonly no embryo is found. It is usually benign but in less than 10% of cases it develops into an invasive mole or even a gestational choriocarcinoma.

Although rare in the UK (0.6 per 1000 pregnancies), hydatidiform moles and their malignant sequelae seem to be reported more commonly in other parts of the world such as in the Pacific region (2.0 per 1000 pregnancies).

Presentation

A woman with a mole will bleed, sometimes heavily, after 6–8 weeks of gestation. She is often unwell with signs of anaemia and excessive vomiting. Proteinuric hypertension can occur as early as eight weeks. After 12 weeks of gestation the uterus often feels much bigger than expected for dates but no fetal parts can be felt or fetal heart heard. Occasionally the woman may pass vesicles through the vagina; this is diagnostic but rarely occurs.

Moles are diagnosed from this clinical presentation backed up by either an excessively high estimation of human chorionic gonadotrophin in the urine or by ultrasonography, when a characteristic picture is seen.

The differential diagnosis must include twins with a threatened miscarriage, but ultrasonography, which should be readily available to most general practitioners, gives the answer immediately.

Figure 7.10 Above: Hydatidiform mole. The bunch of vesicles rapidly expands the uterine cavity. Below: A hydatidiform mole may be diagnosed readily on ultrasonography, the sound waves being reflected off the vesicles to give a picture of soap bubble foam. With early ultrasound equipment, however, hydatidiform moles looked like a snowstorm and so this term came into use. Do not expect snow if you use a B scan machine, the now commonly used apparatus

Figure 7.11 Human chorionic gonadotrophin values are much higher in women with a hydatidiform mole than in women with a normal pregnancy (note the log scale on the y-axis)

Management

Once diagnosed a mole should be evacuated quickly. The woman should be admitted to hospital and a suction curettage performed under anaesthesia with the protection of an oxytocin drip. All tissue is sent to the laboratory for examination of its neoplastic potential.

After an evacuation all women should be registered for follow up at one of the supraregional trophoblast disease centres, where human chorionic gonadotrophin concentrations in urine or blood can be measured. If these are high at six weeks chemotherapy is recommended to prevent subsequent malignancy.

Figure 7.12 After evacuation of a hydatidiform mole the human chorionic gonadotrophin concentration remains high. Methotrexate and folinic acid were given on nine occasions, the treatment being associated with a reduction in hormone concentration

Other causes of vaginal bleeding

Bleeding may come from local problems in the vagina or cervix.

- Cervical ectropion is common in pregnancy; bleeding is not profuse.
- Vaginal or cervical infections can cause mild bleeding.
- Adenomas and polyps of the cervix become more pronounced during pregnancy. They may bleed on stimulation.
- Carcinoma of the cervix is rare but important in women of childbearing age. It may cause bleeding on stimulation and examination with a speculum reveals the cause. If there is any doubt a biopsy must be performed under anaesthesia even when a woman is pregnant.
- A general maternal disease such as blood dysplasia, von Willebrand's disease, or leukaemia may cause symptoms in rare cases.

Lesions of the cervix or vagina may cause bleeding in early pregnancy.

8 Antenatal medical and surgical problems

Pregnant women are usually young and fit. They rarely have chronic medical conditions but when they do, those in charge of antenatal care need to consider how the disease might affect pregnancy and how pregnancy might affect the disease.

Heart disease

Most heart disease in women of childbearing age is rheumatic in origin despite the recent great reduction in the prevalence of rheumatic fever. Better living conditions in the UK and the more prompt treatment of streptococcal sore throats with antibiotics in childhood have reduced rheumatic damage to the heart valves and myocardium. An increasing proportion of pregnant women have congenital heart lesions that have been treated previously.

Pregnancy puts an increased load on the cardiovascular system. More blood has to be circulated so that cardiac output increases by up to 40% by mid-pregnancy, staying steady until labour, when it increases further. This increased cardiac work cannot be done as effectively by a damaged heart; if the heart is compromised a woman would be wise to avoid other increased loads that might precipitate cardiac failure. The most frequently encountered are:

- Household work
- Paid work outside the home
- Care of other family members
- Pre-eclampsia
- Anaemia
- Recrudescence of rheumatic fever
- Respiratory infection
- Urinary infection
- Bacterial endocarditis

Care should be taken just after delivery; with the uterine retraction up to a litre of blood can be swiftly shunted from the uterine veins into the general venous system.

Rheumatic heart disease

The commonest single cardiac lesion found in women of this age group is rheumatic mitral stenosis, sometimes accompanied by the after effects of rheumatic myocarditis. The commonest complication of overload is pulmonary oedema in late pregnancy or immediately after delivery. Right-sided cardiac failure may occur but is less common.

Cardiomyopathy of pregnancy occurs mostly post partum but occasionally in late pregnancy. There is no obvious predisposing cause; the heart is greatly distorted, leading to right-sided cardiac failure.

Congenital lesions

The most serious of the congenital lesions in pregnancy are those accompanied by shunts.

- Women with Eisenmenger's syndrome do particularly badly in pregnancy, especially those with severe pulmonary hypertension, which leads to a right to left shunt.
- Tetralogy of Fallot has a lower risk of cardiac failure because there is less resistance at the pulmonary valve regulating right ventricular outflow.
- Artificial heart valves are now present in an increasing number of women who become pregnant. Commonly they are man-made replacements of the mitral or aortic valve; affected women continue anticoagulant treatment with warfarin despite the theoretical risk of teratogenesis in early

ABC of Antenatal Care

pregnancy and fetal bleeding later. It is still widely used and may be replaced two or three weeks before the expected date of delivery by heparin.

Management

Most women with heart disease who are of childbearing age are known to their family practitioner. He or she should ensure that they go for antenatal care at a centre where a cardiologist works alongside an obstetrician, ideally at a combined cardiac antenatal clinic if there are enough cases.

Early assessment should be made of the severity of the disease, paying attention to the features that may worsen the prognosis: the woman's age, the severity of the lesion, the type of lesion, and the degree of decompensation (exercise tolerance). Rest should be encouraged during pregnancy and extra physical loads avoided. Labour should be booked at a consultant unit with an interested cardiologist involved. The ward may need the extra drugs and equipment to be available if a woman with a heart condition is admitted. Delivery should be planned at a unit with ready access to a cardiac centre and availability of cardiologists and cardiac anaesthetists.

Care should be taken to avoid the development of acute bacterial endocarditis by ensuring that the woman is given antibiotics when she has any infection or is at potential risk of developing an infection—for example, at a tooth extraction or labour. This precaution is more important for congenital lesions of the heart than for rheumatic lesions.

The prognosis for a woman with heart disease in pregnancy is now greatly improved. It used inevitably to be associated with deterioration of the heart condition, but now, with proper care, this is not so.

Diabetes

Diabetes is a metabolic disease found in about 1% of women of childbearing age. In addition, another 1–2% of women will develop gestational diabetes during the course of their pregnancy; the incidence is higher in older than younger women. Glycosuria (checked by dipstick testing) is even more common than this, occurring at some time in pregnancy in up to 15% of women and is no longer a screening test for diabetes in pregnancy. Instead finger-prick or venous blood samples should be checked for blood sugar levels.

Established insulin dependent diabetes

Four fifths of women with diabetes are known to the practitioner before they become pregnant. All diabetic women of reproductive age should be using effective contraception and be encouraged to attend a prepregnancy clinic so that pregnancy is planned. Good control of diabetes before and in early pregnancy reduces the incidence of congenital anomalies and miscarriage.

Antenatal care is best performed by an obstetrician and a diabetic physician at a combined diabetic antenatal clinic. The general practitioner must be kept well informed of changes in management of the diabetes during pregnancy, because between antenatal clinic visits the woman may depend on her family practitioner for continuity of care. Detailed ultrasonography to exclude congenital abnormalities and to monitor growth is vital.

Pregnancy makes the control of diabetes more difficult; close monitoring is the key to a successful outcome. Women are encouraged to eat enough carbohydrate to satisfy them without

restriction and should take regular snacks between meals. Most women who have attended a prepregnancy clinic will have already been converted to a basal bolus insulin regime. This consists of three short-acting doses during the day and one long-acting insulin dose at night. This regime enables good glucose control to be achieved and is started in early pregnancy, if not before.

Glucose concentrations in blood are measured by the woman as frequently as four times a day with her own glucose meter at home. Virtually all diabetic women require an increase in their insulin dosage during pregnancy. Frequent clinic visits are necessary to facilitate this and the careful monitoring of the fetus.

Diabetes controlled by oral hypoglycaemia agents

Oral hypoglycaemic agents are not advised in pregnancy and conversion to the basal insulin regime is best done before conception, if possible. Such women are then monitored in the same way as women with established insulin dependent diabetes.

Gestational diabetes

Gestational diabetes is diagnosed when a woman develops abnormal glucose tolerance for the first time in pregnancy; a small number of such women will remain diabetic after the pregnancy. Currently, many hospitals will perform a random blood glucose test during the antenatal course, interpreting the result in relation to the timing of the last meal. Women with high values will then have a glucose tolerance test or have blood glucose concentrations measured serially (preprandial and postprandial tests three times a day) to determine whether they are glucose intolerant.

Women with gestational diabetes do not have an increased rate of babies with congenital abnormalities but the babies are at risk of being large. There is no consensus on treatment, which ranges from controlling dietary intake to insulin treatment and dietary control. Such women usually have labour induced at term and are at risk of having long labours and babies with shoulder dystocia.

After delivery insulin should be stopped; all affected women should have a glucose tolerance test at six weeks. About 40–60% of such women will develop non-insulin dependent diabetes (type II) in later life but this proportion rises to 70% among those who are obese.

Thyroid disease

Hyperthyroidism

Women who are already hyperthyroid are usually receiving treatment, which may have to be continued throughout pregnancy. The most commonly used drugs are carbimazole and propyl-thiouracil; the former is in more common use but the latter is often chosen in pregnancy as it is less often associated with congenital abnormalities of the scalp. The minimum dose should be prescribed to alleviate any symptoms and to suppress free thyroxine concentration to the normal range. However, some of these women find that their hyperthyroidism ameliorates in the last weeks of pregnancy. In such cases withdrawal of antithyroid drugs may reduce the severity of any fetal goitre.

These women should be tested for the presence of IgG thyroid antibodies (long-acting thyroid stimulator and thyroid receptor antibodies) as these cross the placenta and cause neonatal thyrotoxicosis when present in high titres. Thyroid

free	Increased	No change
protein bound	Increased	Increased
Thyroxine binding globulin	No change	Increased

ABC of Antenatal Care

crises (storm crises) are now rare in pregnancy and the immediate puerperium. They are best treated with iodine, which works quicker than β blockade and carbimazole. Operation on the thyroid is rarely indicated in pregnancy but is safest in the middle trimester.

Hypothyroidism

Hypothyroid women are commonly anovular. If they are receiving adequate replacement treatment, however, they ovulate as normal. Such treatment should be continued and may need to be increased during pregnancy.

Epilepsy

An epileptic woman will often consult before becoming pregnant as she may have heard of the potential hazards of antiepileptic drugs. Most antiepileptic drugs have teratogenic properties to a varying extent, but it must be emphasised that epileptic women have an inbuilt increased risk of having babies with malformations even without treatment. This risk should be carefully balanced against the risks to the embryo if the woman has a series of convulsions when anticonvulsant treatment is withdrawn in early pregnancy.

Generally, the woman may stop or modify treatment after full consultation when she has not had a recent fit. However, if the epilepsy is well controlled, there is little point in changing antiepileptics in pregnancy. If she needs treatment the same dose must be continued; phenytoin treatment may be associated with a slightly lower risk of fetal neural tube defects and might be substituted instead of valproate or carbamazepine.

Seizure frequency seems to be the same in pregnancy as outside pregnancy for most epileptic women; if the rate of fitting worsens, blood concentrations of all anticonvulsants should be checked as overdose as well as underdose may be responsible for loss of seizure control.

Prophylactic folic acid (5 mg/day) should be given before and during pregnancy as folate absorption is changed by the antiepileptic drugs. Vitamin K should be given to all the newborn infants of such mothers for similar reasons.

Status epilepticus is unusual in a pregnant woman unless she is known to be a severe epileptic. Diazepam is the best drug to use.

HIV infection

The human immune suppression retrovirus (HIV) attacks CD 4 lymphocytes leading to their suppression and hence increasing susceptibility to infection. The acquired immune deficiency syndrome (AIDS) is the end stage of such a process and develops some years after the initial HIV infection. Transplacental transmission of the virus antenatally from mother to fetus or breast feeding after delivery can lead to an infected baby.

HIV infection is found more commonly in the big towns such as London where 1 in 600 antenatal attenders is HIV positive. In the country generally it is nearer 1 in 10 000. It is probable that pregnancy does not increase the progression of the disease in the mother.

The baby will be infected in 15–20% of cases.¹ There is a possibility that elective caesarean section would reduce this risk by eliminating fetal exposure to the secretions of the genital tract. The European Study, considering 1000 mother/baby pairs, considered that caesarean section halved the risk of infection¹ although subsequent analyses have shown only a

Table 8.3 Therapeutic concentrations of anticonvulsants in blood

	mg/l
Phenytoin	10–12
Phenobarbitone	15–40
Carbamazepine	4–12
Primidone	5–12
Ethosuximide	5–12
Valproate	4–100

Box 8.4 Potential effects of epilepsy on the fetus

- Increased risk of epilepsy in the baby:
 - if mother alone affected 4%
 - if both parents affected 15%
 - if another child affected 10%
- Increased risk of congenital abnormalities:
 - if either parent affected
 - if mother takes more than one anti-epileptic drug
- Isolated maternal fits do not usually affect fetus. Status epilepticus does

For most epileptic women the frequency of seizures is not affected by pregnancy.

Box 8.5 Transmission of HIV

Transmission of HIV from mother to fetus may be:

- across the placenta in pregnancy
- due to exposure to blood during vaginal delivery
- by breast feeding

The most frequent cause is vaginal transmission which can be reduced by bypassing the vagina (i.e. CS)

20% reduction due to caesarean section.² At present the best prospect of management is to prevent women becoming HIV infected. In pregnancy, the established infected women should be detected by antenatal screening for HIV with proper counselling and offered treatment with anti-retroviral agents, the current product being zidovudine.

It is worth diagnosing HIV in pregnancy for now there is a reasonable treatment which reduces the rate of transmission of HIV to the fetus from 25% in a control group compared with 7% in a zidovudine group.

All infants of HIV positive mothers should be commenced on zidovudine for six weeks and tested at one month and four months for antibodies. Breast feeding is contraindicated in the UK but may be the only method of contraception available in developing countries; the extra risks of HIV transmission should be weighed against further unwanted pregnancies. Folate supplements are especially recommended for the prepregnancy period and the first trimester for all women with HIV infection, to prevent neural tube defects. Infected women who have a high viral load or who have not had any antenatal treatment may be better delivered by caesarean section to reduce the transmission to infants.

Jaundice

The commonest causes of jaundice in pregnancy are the various forms of hepatitis and drugs that affect the liver. Gall stones and severe pre-eclampsia may be responsible, but in the UK gall stones are rare in the age group concerned. Cholestasis in the last trimester may occur spontaneously or follow the use of steroids; fatty degeneration of the liver in the last weeks of pregnancy is very rare but can lead to liver failure as can severe autoimmune disease.

The results of the conventional liver function tests are not as helpful during pregnancy, and the early participation of liver experts in the care of a woman with jaundice during pregnancy is essential.

Anaemia

In pregnancy, anaemia might be due to:

- lack of haemoglobin from a low intake of iron (microcytic anaemia) or of folate (megaloblastic anaemia)
- haemorrhagic anaemia following chronic blood loss
- haemolytic anaemia in those with abnormalities of the genes of the haemoglobin molecule or of the envelope of the red cell.

Iron deficiency anaemia

This is the most common form of anaemia in the UK. The daily need for iron rises from 2 mg per day to 4 mg in pregnancy. This can be provided by improved diet or more practically by taking regular prophylactic tablets containing 60 mg per day of elemental iron. This supplement is given to most pregnant women in the UK. If they cannot take iron tablets, a liquid preparation or intramuscular iron should be provided.

Folate deficiency anaemia

This is less common than iron deficiency anaemia in the UK. Folate needs are increased because of increased maternal demands from growth of the uterus and breasts as well as the increased tissues laid down in the growing fetus.

The woman may produce symptoms of anaemia with breathlessness and pallor; the blood film may show a low

haemoglobin concentration, maybe with macrocytes. The latter may be missing and a bone marrow sample from the iliac crest may be required to show megaloblastic changes.

The condition is treated by oral folate; the diet can be improved and should contain dark green leaf vegetables and yeast extracts. However, in Britain, usually folate is given prophylactically, often combined with iron, to prevent folate deficiency. Those with twins and women taking antibiotics require extra folate. These needs are in addition to the folate used before pregnancy and in early gestation to prevent the formation of central nervous system abnormalities.

Haemorrhagic anaemia

Haemorrhagic anaemia is rare in the UK among women of childbearing age, but chronic bleeding from peptic ulceration, aspirin ingestion, or piles may occur. In other countries tapeworms or hookworms may cause a constant chronic blood loss. Treatment is that of the causative condition.

Haemolytic anaemia

Hereditary haemolytic anaemia is also a rare disease in the white population of the United Kingdom, but other races may show a variety of haemolytic anaemias.

Haemoglobinopathies

Women liable to haemoglobinopathies and their antecedents usually come from Mediterranean countries or Asia and are often known to the family doctor beforehand. All such women should have a blood film examined and their blood checked by electrophoresis at the booking clinic. If they are found to be carriers, their partner's blood should be checked. If they too are carriers, fetal diagnosis is available from early chorionic villus sampling and from fetal blood sampling in later pregnancy. Such women are best managed at special combined antenatal-haematological units and should be sent to such hospitals early in pregnancy so that plans can be made to cover all eventualities. If not, as luck would have it, the crisis will always come on Saturday night at 11.30 pm.

Sickle cell disease

Most women in the UK have haemoglobin A. Defective genes can alter the amino acid sequence of haemoglobin, which may produce symptoms. Haemoglobin S originated in the Middle East but is now found in Africa and the West Indies. Those with haemoglobin C come from West Africa. The partner's blood should be tested and antenatal diagnosis of the fetus is available by direct gene probe from a chorionic villus sample if both partners carry the trait.

In pregnancy a woman with sickle cell disease is at high risk of complications; she deserves special antenatal supervision. Even in experienced hands the perinatal mortality rate can be four times that in a normal population and maternal mortality is also greatly increased. In extreme cases sickling produces crises, leading to sudden pain in the bones, chest, or abdomen after small vessel infarction. Rates of severe pre-eclampsia are higher, as are the incidences of chest and urinary infections. Intrauterine growth retardation and fetal death occur because of placental infarction.

If a crisis occurs then both haemoglobin concentration and red cell volume should be checked every few hours. Hospital treatment with intravenous hydration, partial exchange transfusion or packed red cell transfusions, and antibiotics may be required. Women with haemoglobin concentrations below 6.0 g/dl should have exchange transfusions before elective

delivery. Babies of high risk couples should be tested and followed up if they have sickle cell disease.

Thalassaemia

In thalassaemia, the life of a red cell is shorter than the usual 120 days and so anaemia follows because there is a more rapid breakdown than production of cells. Haemoglobin concentration is low but the serum iron concentration is high.

Again, iron may not be needed if stores are adequate but many such women need extra iron as iron deficiency anaemia may accompany thalassaemia. The stress of hypoxia or acidaemia should be avoided as both increase the breakdown rate of red cells.

Urinary tract infection

Acute urinary infection occurs in about 2% of women during pregnancy. Infection of the urethra and trigone of the bladder is signalled by dysuria and increased frequency of micturition, whereas infection of the upper tract affecting the ureters or kidney produces loin pain and spikes of fever.

A midstream urine specimen should be checked for the presence of cells and bacteria (with bacterial sensitivity to antibiotics) before any treatment is started. The woman should drink much more and take a wide spectrum antibiotic such as amoxycillin until the results of the test are known. Antibiotic treatment may have to be changed according to the sensitivity results but usually amoxycillin suffices. (Alkalinisation of the urine may be performed, though this is unpleasant and entails taking potassium citrate mixture.)

After 7–10 days, a second midstream specimen of urine should be sent to the laboratory. If bacteria are still detected, continuous low dose antibiotic prophylaxis using trimethoprim (second and third trimesters only) or amoxycillin should be considered. Cranberry juice may be useful in preventing recurrent infection.

Asymptomatic bacteriuria

Infection may be low grade and asymptomatic. About 4% of pregnant women have evidence of bacterial infection of the urine; its significance level is arbitrarily set at more than 100 000 bacteria per ml of urine.

If all women are screened early in pregnancy and asymptomatic bacteriuria is detected it is probably wise to treat, as the risk of developing acute pyelonephritis in pregnancy is about 30%. Treatment is for five days with an antibiotic to which the bacteria are sensitive. A urine sample should be recultured 14 days later. If bacteria are still present continuous antibiotic prophylaxis should be considered.

Any woman with persistent asymptomatic bacteriuria through pregnancy should have her urinary tract checked after delivery. About 20% of this subgroup will be found to have a structural abnormality of the kidneys, ureters, or bladder.

Chronic renal disease

Most women with chronic renal disease are well known to their general practitioner and have usually been counselled by a renal physician about the risks of pregnancy and the precautions required. In brief, renal function usually improves in pregnancy, and there is no evidence that pregnancy adversely affects the long-term prognosis from the renal disease. The outlook in pregnancy is favourable if the patient is not hypertensive and does not have proteinuria before pregnancy. Pregnancy should be carefully supervised by the obstetric and renal team.

ABC of Antenatal Care

Transplant recipients have normal fertility. There is little evidence that the commonly used immunosuppressive agents cause an excess of fetal abnormalities. Episodes of rejection are not more common in childbirth, but if they occur they usually do so in the puerperium. If the transplanted kidney is in the pelvis a caesarean section may be necessary for mechanical reasons.

Abdominal pain in early pregnancy

From the uterus

Miscarriage

One of the commonest causes of pain in early pregnancy is spontaneous miscarriage. This subject is dealt with in Chapter 7.

Retroverted uterus

Retroversion is a common position for a normal uterus. In pregnancy the uterus expands into the abdomen. If adhesions are present, however, this cannot occur; by 10–12 weeks the enlarging uterus fills the pelvis and pain is associated with retention of urine. The urethra is stretched by the uterine bulk and the bladder pushed to the abdomen so that urine cannot pass. These findings can be confirmed by ultrasonography.

Management includes draining the urine with an indwelling catheter. The cure eventually comes when the uterus grows into the general abdominal cavity by anterior sacculation, so relieving the urethral stretch.

Fibroids

Fibroids are found in older pregnant women (those aged 30–40), particularly among Afro-Caribbean women. In pregnancy fibroids can undergo torsion if they are subserous; this is more common in the puerperium. Red degeneration is commonest at 12–18 weeks of pregnancy but can occur throughout, with resulting necrobiosis in the fibroid. The woman presents with tenderness over the mass accompanied by vomiting and mild fever.

Red degeneration is self limiting; if the diagnosis is firm, management is bedrest with analgesia and intravenous correction of any dehydration. Ultrasound may help to confirm the presence of fibroids, although necrobiosis may not show clearly. In truly doubtful cases, as in a low-right sided fibroid that mimics appendicitis, a laparotomy should be performed to exclude surgically correctable conditions. If red degeneration is diagnosed the surgeon would do well not to remove the fibroid at this stage but to close the abdomen and continue conservative management.

From the fallopian tube

Ectopic pregnancy

Unruptured ectopic pregnancy causes chronic symptoms and needs to be managed in hospital whereas ruptured ectopic pregnancy produces acute symptoms and collapse and needs urgent hospital management. The condition is dealt with in Chapter 7.

Torsion

Torsion is uncommon and occurs mainly in younger women during early pregnancy when a long tube may twist on its pedicle accompanied by torsion of the ovary, especially if the latter has a cyst in it.

The woman has non-specific hypogastric pain and a constant area of tenderness suprapubically on the lateral edge

Box 8.13 Considerations for pregnancy in chronic renal disease

Figure 8.8 Fibroids are benign quiescent tumours consisting of whorls of fibres and few cells

If you do not think of an ectopic pregnancy you will not diagnose one. Always consider unruptured ectopic pregnancy in any young woman having sexual intercourse who has lower abdominal pain.

Box 8.14 Fibroids in pregnancy

- Usually increase in size but become hypovascular
- Necrobiosis (red degeneration) is painful but treat conservatively
- Torsion of subserous fibroid is acutely painful and needs surgical removal

of the rectus abdominis muscle. Ultrasound does not help but diagnostic laparoscopy in early pregnancy is useful. A laparotomy is required; if the lateral end of the fallopian tube is non-viable it must be resected; in rare cases the ovary is also ischaemic and requires removal.

From the pelvic ligaments

Round ligament

These stretch as the uterus rises in the abdomen and pulls on the uterine round ligaments like an inflating hot air balloon tugging its guyropes. Usually the ligaments stretch easily, but if the pull is too strong small haematomas occur. This commonly starts at 16–20 weeks' gestation.

On examination tenderness is localized over the round ligament and often radiates down to the pubic tubercle alongside the symphysis pubis.

Treatment is bedrest, analgesia, and local warmth.

Figure 8.9 Haematoma of round ligament

From the ovary

Ovarian tumours

In early pregnancy an ovarian cystic tumour may rupture to release the contents of the cyst, irritating the parietal peritoneum. Bleeding may occur into a corpus luteal cyst. An ultrasound scan may confirm the diagnosis, and a laparotomy is indicated if the clinical situation does not settle. At laparotomy, only that part of the ovary containing the cyst should be removed. If it is a luteal cyst, conservation is necessary as the corpus luteum is probably the major source of progesterone in the first trimester and some of this metabolism continues into later gestation.

Box 8.15 Ovarian pain in pregnancy

- Torsion of pedicle of ovary with lateral end of tube
- Stretch of capsule of a cyst
- Bleeding into cavity of cyst (corpus luteum)
- Rupture of cyst with release of contents

Extrapelvic causes

Vomiting

Though many women who vomit in pregnancy have little upset, vomiting or retching may be sufficiently severe to cause muscle ache from stretch. The upper abdominal wall is tender and no specific masses can be felt. If a woman is vomiting this much it is probably wise to admit her to hospital for intravenous fluids, antiemetic treatment, and sedation to allow her intestinal tract some peace. The pain usually settles down as the vomiting decreases.

Figure 8.10 During pregnancy the ureters lengthen and become more tortuous and dilated

Pyelonephritis

Stasis in the urinary tract associated with ascending urinary infection often follows dilatation of the ureters (due to raised progesterone concentrations) and the pressure of the increasing uterus on the bladder. It is most likely in mid-pregnancy, when the woman presents with vomiting, symptoms of fever, and low hypogastric or loin pain.

Appendicitis

Appendicitis and pregnancy both occur in young women and therefore may occur concurrently by chance. The incidence of appendicitis in pregnancy is not increased but its diagnosis may be more difficult. For this reason and because of a reluctance to operate, appendicitis used to have a high mortality and morbidity in pregnancy.

As it grows, the uterus displaces the caecum from the right iliac fossa upwards and sideways, so the inflamed appendix may present with symptoms and signs in unexpected places. No longer tucked into the right iliac fossa, the appendix is now in the general abdomen and is less easy to wall off by omentum and gut when it becomes inflamed; generalized peritonitis is commoner in pregnant than non-pregnant women.

Figure 8.11 The site of the appendix changes as pregnancy advances

ABC of Antenatal Care

A history may elicit the characteristic pain shift, although it is not always localised to the right iliac fossa. Nausea and anorexia occur, sometimes confused by the symptoms of pregnancy. The tenderness over the appendix will shift higher as pregnancy continues. The treatment is operation, the incision being placed over the point of maximum tenderness marked by the surgeon before anaesthesia. Occasionally the results of a rectal examination can be falsely reassuring if the appendix has migrated from the area reached by an examining finger.

The previous reluctance to operate must be overcome; anyone suspected of having appendicitis in pregnancy should have a laparotomy by an experienced surgeon. Even in late pregnancy, caesarean section is not necessary at the same time unless the woman is in labour; women can have a normal vaginal delivery within a few days of an appendicectomy.

Other causes

Cholecystitis is commoner among women who live in or originate from countries whose residents characteristically have high cholesterol diets such as Australia and New Zealand. The pain is usually upper right abdominal with tenderness centred on the eighth or ninth rib tip. Treatment in the absence of jaundice is conservative with antibiotics or removal, depending on the surgical need.

Volvulus of large bowel can occur in pregnancy, though it presents more characteristically in the puerperium.

Small bowel colic may follow an attack of gastroenteritis.

Urinary lithiasis occurs in the same frequency in pregnancy as in non-pregnant women.

Figure 8.12 Pain in cholecystitis

Abdominal pain in late pregnancy

From the uterus

Uterine contractions

All pregnancies end in labour, which may occur well before term. Premature labour can present with abdominal pain, taking the woman and sometimes her general practitioner by surprise. Usually the pain is intermittent and recurrent and the uterus can be felt contracting coincidentally with the pain. There may be a loss of mucus or a little blood from the vagina, on vaginal examination the cervix is soft, thin, taken up, and sometimes dilated. When labour is very preterm (26–32 weeks) the woman should be transferred to a hospital with an expert neonatal unit rather than necessarily to the one where she has booked (see Chapter 12).

Placental abruption

Separation of the placenta from its bed before the third stage of labour is painful and results in shock (see Chapter 10).

Extraperitoneal causes

Pregnancy-induced hypertension

In severe fulminating pregnancy-induced hypertension a woman may complain of epigastric pain associated with vomiting. She will probably have raised blood pressure and proteinuria with oedema and be known to be hypertensive. There may also be visual symptoms (outlined in Chapter 9).

Rectus haematoma

Very rarely the rectus muscle may dehiscence and the inferior epigastric veins behind the muscle rupture. As the anterior

Figure 8.13 A cardiotocograph in early labour showing the fetal heart rate (above) and the regular uterine contractions every three minutes (below)

abdominal wall is greatly overstretched by the uterus, a fit of sneezing could cause this. Pain is severe and usually localised to one segment of the muscle. Blood loss is slight with the haematoma but increases if the veins rupture. Rectus haematoma is diagnosed from the fact that pain and tenderness worsen when the woman contracts the rectus muscles by raising her head. Ultrasound is helpful.

If the diagnosis is firm, management is conservative, but in doubtful cases a laparotomy should be performed, and haematoma behind the rectus muscle confirms the diagnosis.

Pelvic arthropathy

Relaxation of the ligaments guarding the pelvic joints follows the secretion of the hormone relaxin. This allows appreciable separation of the symphysis pubis, giving abdominal pain that is much aggravated by walking. In extreme cases weight bearing is impossible and the woman has to retire to bed completely. Treatment is rest; binders are of little help. Vaginal delivery should be anticipated. This condition may take up to two months to resolve after delivery, but it usually does slowly get better. Severe cases may last for up to a year, and long-term follow-up is wise.

Conclusion

Most women who present with abdominal pain in pregnancy may have nothing serious the matter. Pain can, however, lead the doctor to diagnose a serious condition, when action needs to be taken. As investigations play a small part in many of these diagnoses, experienced general practitioners can often diagnose its cause and continue the management of many women at home, but if there is any doubt the local obstetric department ought to be consulted.

All general medical conditions are modified by pregnancy; diagnosis may be clouded and treatment may have to be changed. Early abdominal examination will usually help differentiate serious from lesser conditions. If the condition is thought to be serious consult an obstetrician early rather than send to a general surgeon.

9 Raised blood pressure in pregnancy

One of the original aims of promaternity (antenatal) care in 1901 was the prevention of fits and convulsions due to eclampsia, which was often associated with pre-eclampsia. The term pre-eclampsia has been refined in later years as eclampsia now occurs rarely.

Raised blood pressure affects the fetus as well as the mother. In the later weeks of pregnancy it may fall into one of several categories.

- Chronic hypertension is present before the 20th week and has causes outside pregnancy.
- Pregnancy-induced hypertension develops after the 20th week of pregnancy and usually resolves within 10 days of delivery.
- Pregnancy-induced hypertension with proteinuria now is called pre-eclampsia and occurs mostly in primigravidas.
- Pregnancy-induced hypertension with or without proteinuria may be superimposed on chronic hypertension and this is a most dangerous combination, the effects of pregnancy being added to those of chronic hypertension.
- Eclampsia is a convulsive condition usually associated with proteinuric hypertension.

Causes

The mechanism of pregnancy-induced hypertension is now almost completely understood, with reasonable educated guesses being possible in unknown cases. The primary defect is failure of the second wave of trophoblastic invasion into the decidua. Usually the trophoblast invades the entire length of the spiral arteries by 22 weeks of gestation. This leads to an appreciable fall in peripheral resistance and therefore a fall in blood pressure. In addition, as the trophoblast usually removes all the muscle coat of the spiral arteries, blood flows unimpeded into the intervillous space, gushing like a fountain over the villous tree that contains the fetal vessels. This ensures adequate time for exchange of oxygen, nutrients, and the waste products of metabolism.

If the second wave of trophoblastic invasion fails, the peripheral resistance does not fall and the haemodynamic mechanisms are not reset for the increased vascular space of pregnancy. Furthermore, the muscle coats retained by the spiral arterioles are sensitive to circulating pressor agents, particularly angiotension II. Most of the hypertensive changes are due to hormonal rather than sympathetic nervous system influence. At the spiral arterioles, the reduced volume of trophoblast leads to an imbalance in the prostacyclin–thromboxane system. The comparative overproduction of thromboxane encourages vasospasm of the spiral arteries and also local platelet aggregation. The lower concentrations of prostacyclin remove the protection that pregnancy offers against angiotension II.

The damaged muscle coating and intima of the spiral arteries undergoes acute atherosclerosis, an accelerated form of arteriosclerosis that further narrows and then occludes the arterioles. A further increase in blood pressure follows, and the decrease in perfusion of the intervillous space leads commonly to intrauterine growth retardation.

Low dose aspirin may reduce the severity of pregnancy-induced hypertension in patients at risk, moderating the disease once established. The mode of action is irreversible

Box 9.1 Some accepted definitions of raised blood pressure

- Hypertension
 - Mild—diastolic blood pressure >90 mm Hg
 - Severe—diastolic blood pressure >110 mm Hg
- Pregnancy-induced hypertension
 - Mild—diastolic blood pressure >90 mm Hg after the 20th week of pregnancy with no raised blood pressure beforehand and no proteinuria
 - Moderate—diastolic blood pressure >100 mm Hg after the 20th week of pregnancy with no raised blood pressure beforehand and no proteinuria
 - Severe—diastolic blood pressure >90 mm Hg after the 20th week of pregnancy with no raised blood pressure beforehand but with any degree of proteinuria

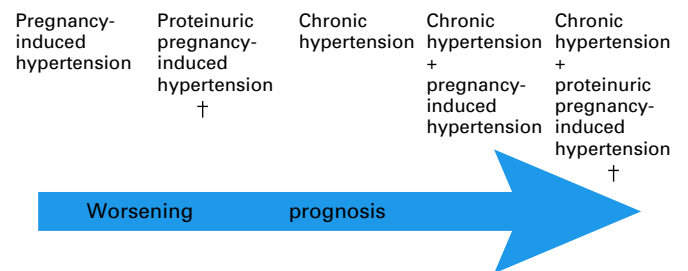

Figure 9.1 Permutations of hypertensive disease in pregnant and non-pregnant women. †These are designated as pre-eclampsia

Figure 9.2 The invasion of spiral arteries by the trophoblast converts them into deltas and so improves blood flow

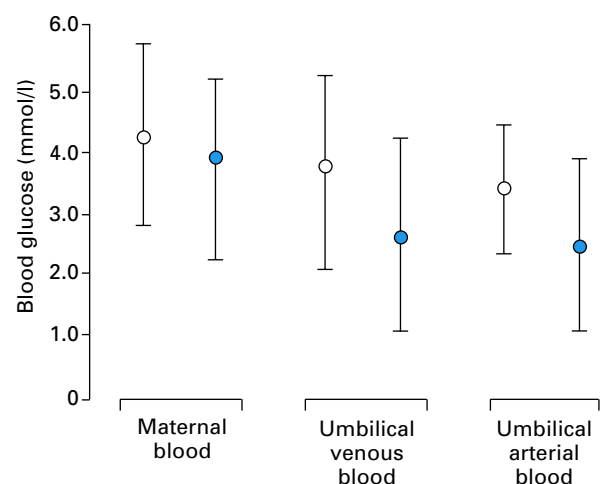

Figure 9.3 Transfer of glucose from mother to fetus in babies who show normal growth (O) and in those who are small for gestational age

poisoning of platelet cyclo-oxygenase. This probably prevents or delays clotting in the spiral arterioles.

The effects of pregnancy-induced hypertension on organs other than the placenta are mediated by the effects of hypertension or by activation of the complement system. This causes immune complexes to be deposited on the basement membrane of the kidney and allows protein to leak into the urine. In severe disease platelets are both consumed and activated so that coagulopathy may follow.

Management

Though pregnancy-induced hypertension develops out of the blue, particularly in first pregnancies, many women who already have hypertension will wonder about becoming pregnant and the effects that the pregnancy may have on their underlying hypertension. This matter should be considered carefully before a woman becomes pregnant, and if necessary the woman should be referred to a local pre-pregnancy advisory service. Since tobacco is associated with increased risks of cardiovascular disease in general, one would expect smoking mothers to have a higher rate of pre-eclampsia. This is not so and many studies have shown that smoking is associated with lower rates of pre-eclampsia. However, if it does occur it is often more severe in the smoker.

Generally speaking, if the blood pressure is not very high, or it can be kept low with antihypertensive drugs, and if there is no concomitant proteinuria before pregnancy, most women will have a successful pregnancy. They should continue their antihypertensive treatment in pregnancy.

Women with renal damage already leading to proteinuria and those who have diastolic pressures above 100 mm Hg despite adequate antihypertensive treatment should be investigated more thoroughly. Such women have a three to seven times increased risk above background of developing pregnancy-induced hypertension on top of their disease and the prognosis is worse for both mother and baby.

The ideal start to the management of pregnancy-induced hypertension, with or without proteinuria, is to detect it early. Each visit to the antenatal clinic includes a blood pressure recording. Recently, women likely to develop pregnancy-induced hypertension have been detected before this happens at 24 weeks by the use of Doppler measurements of blood flow velocity of uterine arteries, from which a measure of placental vascular resistance is derived. Doppler investigation may become available as a screening test in the next few years, providing, for example, an indicator of which women would benefit from low dose aspirin. Once prostaglandin was shown to be involved, an obvious antidote seemed to be aspirin and for a while this was in favour. Unfortunately the randomised CLASP study showed that in 9264 women there was only a 12% reduction in the incidence of proteinuria pre-eclampsia which was not significant.¹ Another possible organic cause of proteinuric hypertension has been the reduction of nitric oxide. This has led to the use of glyceryl trinitrate patches but this is still in the realms of research.

Once raised blood pressure is established, rest is usually central to primary management. Without accompanying proteinuria, the woman may be treated at home, where rest must take priority over everything else, including work at home or outside and care of other members of the family. Those with other children find it difficult to follow this regime and probably a third of women do not rest when so advised. If the hypertension increases despite proper bedrest, or proteinuria follows, admission to hospital is required.

Figure 9.4 The suggested pathways (—O—) of pregnancy-induced hypertension changes related to their outcomes (■)

Table 9.1 Risk factors for the development of pregnancy-induced hypertension

Risk factors	Ratio
Nulliparity	3:1
Age above 40 years	3:1
Chronic hypertension	10:1
Chronic renal disease	20:1
Twins	2:1

Figure 9.5 Blood pressure measurement is a simple and useful screening test when performed repeatedly by standardised techniques. All doctors and midwives in a unit should use the same criterion for diastolic pressure—probably the loss of phase V Korotkoff sound

In hospital rest will be reinforced and the condition will be monitored by using ultrasound measurements of the growth of the fetus, Doppler measurements of blood velocity in the umbilical arteries and some would measure flow in the uterine arteries. Cardiocotographic measurements of variations in the fetal heart rate may also be used. Plasma urate concentrations and an increase in the liver enzyme aspartate transferase are useful biochemical indicators of deterioration, and a fall in the platelet count reflects severe disease. (The HELLP Syndrome – Haemolgia Elevated Liver Enzymes, Low Platelets). The management of severe hypertension now no longer includes treatment with sedatives or diuretics; sedatives tend merely to reduce the mother’s level of consciousness and cross the placenta, causing depression of the fetal central and peripheral nervous systems. Similarly, diuretics are of little use, except for the relief of acutely painful oedema. They may even be harmful by reducing plasma volume and therefore perfusion of the placental bed.

Antihypertensive drugs are useful in protecting the mother’s circulation, mostly against the risk of a stroke. They have no effect on the progression of the pregnancy-induced hypertension or on fetal growth but they help to maintain the pregnancy longer, so allowing the fetus to become more mature. These drugs tend to be kept for women whose hypertension increases despite bedrest. Methyldopa is still the commonest oral drug used in the short term. Hydralazine is given intravenously as first aid in acutely deteriorating hypertension. Combined α and β blockers, such as labetalol, are gaining in popularity because they give better control.

Calcium channel blockers such as nifedipine are being used more widely for they are effective in the control of acute hypertension. No serious fetal side effects occur although maternal side effects of flushing and headache may demand discontinuation.

The final and ultimate treatment of pregnancy-induced hypertension is delivery. Induction of labour or caesarean section should be reserved until the fetus is mature enough for the neonatal facilities available, but it must be used when the condition deteriorates. Two changes in managing pregnancy-induced hypertension have considerably altered the outlook for mother and fetus.

- Firstly, use of antihypertensive drugs to allow the fetus to spend longer in the uterus has spread rapidly and widely. Formerly, such drugs were thought to reduce placental bed perfusion and so affect the fetus deleteriously; their use in pregnancy was restricted. Now most obstetricians use them, and by reducing maternal risk, pregnancy is prolonged by a few more weeks so that the child is more mature.
- Secondly, the obstetrician’s reluctance to perform a caesarean section earlier in pregnancy has diminished. With improved intensive neonatal care, caesarean section as early as 28 weeks gives a reasonable chance of fetal survival. The worst effects of prolonged renal and cerebral damage are reduced for the mother and the fetus is delivered before being affected by serious chronic hypoxia *in utero*.

The treatment of women with severe pregnancy-induced hypertension is best performed in special regional hypertension units, where neonatal and obstetric care is planned together. The Confidential Enquiries into Maternal Deaths have urged for years that each Health Authority should have one or more such designated units. A woman with or at risk of severe pregnancy-induced hypertension should be admitted to such a unit to obtain the best concentrated and coordinated obstetric and neonatal care.

The future management of pregnancy-induced hypertension may lie in the reduction of platelet agglutination during early

Figure 9.6 Changes in plasma urate concentration from 16 weeks of gestation showing 10th, 50th, and 90th centiles and the accepted upper limit of normal values. □—□ shows the levels in a woman with severe pre-eclampsia

Table 9.2 Drugs and dosages used in treatment of pregnancy-induced hypertension

Drug	Route	Dosage	Comment
<i>Centrally acting drugs</i>			
Clonidine	Oral	500–100 µg three times a day	
Methyldopa	Oral	250–1000 mg daily	Safe to use
<i>Vasodilators</i>			
Sodium nitroprusside	Intravenous	0.3–1.0 µg/kg/min	Only for short-term use
Hydralazine	Intravenous	5–20 mg over 20 minutes	Drug of choice in emergency
<i>β Adrenoceptor blockers</i>			
Propranolol	Oral	80–160 mg daily	Used to be thought to reduce placental perfusion
<i>α and β Adrenoceptor blockers</i>			
Labetalol	Intravenous	50 mg over a minute	Water soluble and so crosses placenta; may not be effective in acute problem
	Oral	100–200 mg daily	

The ultimate treatment of pregnancy-induced hypertension is delivery.

Figure 9.7 Survival by gestational age, Wales 1993–9

pregnancy, so preventing damage to the placental bed. This might halt the whole cascade of problems. Aspirin in early pregnancy might block the cyclo-oxygenase enzymes of the platelets so that they would not be able to produce thromboxane. It was thought that low dose aspirin (75 mg a day) may be helpful in mitigating the worst effects of pregnancy-induced hypertension with proteinuria but the published results of the CLASP study do not substantiate this.¹

Eclampsia

Imminent eclampsia

The old term fulminating pre-eclampsia is less often used, but semantics are not as important as the recognition of this severe, acute change in a woman's condition. Having had moderate or even severe but symptom-free pregnancy-induced hypertension with proteinuria, the woman suddenly starts to produce symptoms. She may have frontal headaches and visual symptoms with jagged, angular flashes at the periphery of her visual fields and loss of vision in areas, both symptoms being due to cerebral oedema. She often has epigastric pain due to stretch of the peritoneum over the oedematous liver. In addition, some women have a curious itch confined to the mask region of the face. On examination her blood pressure may be much raised above previous readings or proteinuria may increase sharply; she may have increased and brisk reflex responses at knee and clonus. This woman needs urgent hypotensive and anticonvulsant treatment. If she is at home she should be admitted, with intravenous diazepam and, if necessary, hydralazine running continuously. Diazepam prevents fits and hydralazine reduces blood pressure but magnesium sulphate does both.²

Eclampsia

Convulsions associated with pregnancy-induced hypertension are termed eclampsia; they are very similar in form to those of epilepsy. Occasionally women in the beginning of the third trimester have eclamptic fits, having had perfectly normal blood pressure readings and urine test results within the previous few weeks at the routine visits to the antenatal clinic. Most women with eclampsia, however, give prodromal signs of pregnancy-induced hypertension with proteinuria in pregnancy; most are preterm (<37 weeks) while a fifth are before 32 weeks. The fits may develop in labour or the puerperium, the first day after birth having the highest risk.

The general practitioner's first move is to control the fits and prevent them causing damage to the woman. She should be laid on her side and an airway established. Intravenous diazepam is given to stop the fits, usually about 20–40 mg. This is followed in hospital by intravenous infusion of magnesium sulphate. This drug has been used for more than 60 years in the USA to prevent and treat eclamptic convulsions but has only recently found favour in the UK. It is thought to have central anticonvulsant activity. Clinical experience and research support its use in the prevention of subsequent eclamptic fits. It is usually given for at least 24 hours following the fit. Care must be taken as respiratory depression and loss of patellar reflexes may indicate toxicity.

Should the blood pressure be steeply raised, intravenous hydralazine is also given, either in a 5 mg bolus over 20 minute intervals or given intravenously as 25 mg in 500 ml of Hartmann's solution, with the drip rate titrated against the woman's blood pressure. This is best administered through a separate drip set so that magnesium sulphate and antihypertension treatments can be given at different rates

Box 9.2 Symptoms and signs of imminent eclampsia

- Upper abdominal pain
- Itching on the face
- Flashes of light
- Headache
- Rapidly increasing blood pressure
- Increasing proteinuria
- Increased knee jerks—hyper-reflexia

Box 9.3 Treatment of eclampsia

- Lie the woman on her side in the recovery position
- Keep airway clear
- Prevent trauma during fits
- Give diazepam immediately
- Give IV hydralazine if blood pressure is raised
- Give IV magnesium sulphate
- Use epidural anaesthesia if the woman is in labour or a caesarean section is planned

Box 9.4 Mode of delivery after control of eclampsia

- Factors favouring vaginal delivery
 - Multiparous mother
 - Stable blood pressure and diminished cerebral irritability
 - Ripe cervix
 - Mature fetus (>1500 g estimated weight)
 - Cephalic presentation
 - Normally grown fetus
 - Fetus in good state to stand uterine contractions
- Factors favouring caesarean section
 - Primiparous mother
 - Unstable blood pressure control or cerebral irritability
 - Unripe cervix
 - Immature fetus (<1500 g estimated weight)
 - Breech presentation
 - Intrauterine growth restriction
 - Poor prognosis of fetal state from Doppler blood flow rates or cardiotocography

according to clinical needs. If the woman is in labour or induction is considered, an epidural anaesthetic may be helpful, both to lower the blood pressure and to reduce the tendency to fit by removing the pain of intrauterine contractions. Any tendency of the woman to have disordered blood clotting should be excluded before insertion of a regional anaesthetic.

The ultimate treatment of eclampsia is delivery. Should eclampsia occur at home the woman must be transported to hospital immediately. Although rare, eclampsia still occurs in this country and the triennium 1994–96 was associated with 8 maternal deaths in the UK.

Timing of delivery

It must be emphasised that the ultimate cure of pregnancy-induced hypertension and eclampsia is delivery. The obstetrician must weigh the answers to two often conflicting questions:

- When would it be safer for the mother to be delivered?
- When would it be safer for the baby to be outside the uterus rather than on the wrong side of a failing placental exchange system?

Maternal considerations may be judged by the speed of deterioration of the condition (blood pressure and proteinuria) and the expected proximity of severe complications such as eclampsia. Fetal state is best evaluated by assessing the circulation supplying the fetus both in the spiral arteries with Doppler ultrasound measurements coming to the placental bed and in the umbilical vessels (discussed in Chapter 4). If there is time, serial ultrasound measurements of fetal growth are useful. If these data are available a rational decision can be made about the timing of the removal of the fetus from the hostile environment in a hospital with a neonatal intensive care unit. Women should be transferred early to regional centres for hypertension in pregnancy when it is obvious that the pregnancy-induced hypertension is not going to settle with bedrest and mild or moderate drug treatments. There is little place for heroic management in peripheral hospitals of a greatly compromised baby and mother.

Once it has been decided that it would be safer for the mother and the baby that delivery should occur the method and route of that delivery should be considered. If it is thought unsafe for the baby to undergo the contractions of labour, or if the baby is immature or has an inappropriate presentation, a caesarean section is indicated. If the mother's condition is deteriorating rapidly, again, the abdominal route would be swifter. An unripe cervix or an unsatisfactory presentation would also be grounds for a caesarean section. If, however, the woman has a ripe cervix, the hypertensive state is not worsening rapidly, and the fetus is in an acceptable position and of reasonable maturity, induction of labour should be performed with prostaglandin pessaries or membrane rupture, depending on the usage in the individual labour ward.

Intrauterine growth restriction is associated with pregnancy-induced hypertension. The two go together and share common causes. Narrowing of the placental bed vessels reduces nutrition to the fetus in pregnancy just as it reduces available oxygen during labour. Many fetuses born to women with unmanaged pregnancy-induced hypertension are small for their gestational age. Unfortunately so are many fetuses born to women who are very well managed; the fetal growth restriction therefore probably starts long before conventional management of the mother.

The ultimate treatment of eclampsia is delivery.

Maternal and fetal factors must be considered to find the best time for delivery of the fetus.

Figure 9.8 Partogram of a woman with severe pregnancy-induced hypertension before and after delivery

Box 9.5 Method of delivery (%) after various onsets of labour in women with pregnancies complicated by hypertension

- Spontaneous onset
 - Normal delivery – 3%
 - Vaginal operative delivery – 5%
 - Caesarean section – 10%
- Induced labour
 - Normal delivery – 17%
 - Vaginal operative delivery – 23%
 - Caesarean section – 22%
- Elective caesarean section – 11%

Conclusion

Pregnancy-induced hypertension is still a major problem in antenatal medicine but many of its worst effects can be mitigated by early diagnosis from blood pressure readings at clinic visits. The future includes predictive Doppler measurements of blood flow and preventive treatment, which may include aspirin, although the results of the CLASP trial in the United Kingdom are disappointing. If the condition is severe the mother's and baby's prognoses will be greatly improved if a regional hypertension in pregnancy unit is used.

10 Antepartum haemorrhage

Antepartum haemorrhage is bleeding from the genital tract between 24 completed weeks of pregnancy and the onset of labour. Some of the causes exist before this time and can produce bleeding. Although strictly speaking such bleeding is not an antepartum haemorrhage, the old fashioned definition is not appropriate for modern neonatal management.

The placental bed is the commonest site of antepartum haemorrhage; but in a few cases bleeding is from local causes in the genital tract. In a substantial remainder the bleeding may have no obvious cause but is probably still from the placental bed.

Placental abruption

If the placenta separates before delivery, the denuded placental bed bleeds. If the placenta is implanted in the upper segment of the uterus the bleeding is termed an abruption; if a part of the placenta is in the lower uterine segment it is designated a placenta praevia.

Placental abruption may entail only a small area of placental separation. The clot remains between placenta and placental bed but little or no blood escapes through the cervix (concealed abruption). Further separation causes further loss of blood, which oozes between the membranes and decidua, passing down through the cervix to appear at the vulva (revealed abruption).

In addition, the vessels around the side of the placenta may tear (marginal vein bleeding), which is clinically indistinguishable from placental abruption. The differentiation between revealed and concealed abruption is not very useful. The important factor is the amount of placenta separated from its bed and the coincident spasm in the surrounding placental bed vessels. If the area of separation and the proportion of placental bed vessels driven into spasm is sufficient, it will lead to fetal death.

Figure 10.1 Causes of antepartum haemorrhage

Figure 10.2 Placenta sited in (A) upper and (B) lower segment

Figure 10.3 (A) Concealed and (B) revealed abruption from a normally sited placental bed

Pathology

Bleeding between the placenta and its bed causes separation; as more blood is forced between the layers, detachment becomes wider. Blood also tracks between the myometrial fibres, sometimes reaching the peritoneal surface. The mother's pain and shock depend on the amount of tissue damage rather than on the volume of bleeding. The fetal state depends on both the

Figure 10.4 The degree of fetal effect depends on the amount of separation and spasm of placental bed vessels (A), while the maternal effect depends on the amount of tissue damage to the myometrium (B)

ABC of Antenatal Care

amount of separation and the spasm of the more peripheral blood vessels in the placental bed.

Sometimes amniotic fluid or trophoblast tissue is forced into the maternal circulation after a placental abruption. Thromboplastins start disseminated intravascular coagulation, which in a mild case is coped with by the maternal fibrinolytic system, but if an amniotic fluid embolus is large, maternal plasma fibrinogen concentration is depleted. Uterine bleeding continues with activation of the maternal fibrinolytic system; widespread deprivation of fibrin and fibrinogen follows, producing a vicious circle of more bleeding.

The cause of placental abruption is unknown. It happens more commonly in association with a uterine abnormality and there is a 10% risk of recurrence if it has occurred previously. Conditions of uterine overstretch such as twin pregnancy are associated with higher rates of abruption if amniotic fluid is released suddenly at the rupture of the membranes. Abdominal trauma is a less common association.

Diagnosis

The woman presents with poorly localised abdominal pain over the uterus; there may be some dark red vaginal bleeding or clots. Depending on the degree of placental separation, uterine spasm, and the loss of circulating blood into the tissue space, clinical shock may also be present. If the abruption is severe the uterus contracts tonically so that fetal parts cannot be felt; the fetus may be dead with no fetal heart detectable. Ultrasonography may show the retroplacental clot but gives no measure of the extent of functional disorder.

The differential diagnosis is from:

- Placenta praevia, which is not usually accompanied by pain, often results in brighter red bleeding as the blood is fresher and rarely results in so much shock.
- Rupture of the uterus, which may present with a similar picture to that of placental abruption.
- Red degeneration of a uterine fibroid at 24–30 weeks' gestation.
- Bleeding from a ruptured vessel on the surface of the pregnant uterus, which is rare.

The diagnosis of abruption is finally confirmed after delivery by finding organized clot firmly adherent to the placenta.

Management

A woman with an abruption is in a potentially dangerous condition and requires all the facilities the emergency services can provide. She must be admitted to hospital quickly. Group O rhesus negative blood may rarely be required urgently in the home but even if not, supportive intravenous treatment should be established. Hartmann's solution or saline may be used at first followed by a commercial plasma expander such as Haemaccel. Pain may be relieved by morphine, and the woman must be transferred to hospital, escorted by her GP, trained paramedic staff or the Flying Squad, when her condition is stable.

In hospital the antishock measures will be continued and blood given. At least six units of blood must be crossmatched, irrespective of the scant external blood loss; fresh frozen plasma and platelets should be available. Central venous pressures are a guide to the amount of blood required to prevent undertransfusion before delivery or overtransfusion afterwards. Once the condition is stabilised delivery should take place immediately. If the fetus is still alive, this could mean a caesarean section. This can be a difficult operation needing a

Figure 10.5 Points in the clotting cascade at which the sequelae of a placental abruption can intervene and so lead to disseminated intravascular coagulopathy

Figure 10.6 Ultrasound scan of placental abruption

Box 10.1 Management of placental abruption

- Get the woman to hospital urgently
- Replace volume of blood estimated lost from circulation rather than that seen at external loss
- Monitor central venous pressure
- Check for disseminated intravascular coagulopathy
- Check renal function and urinary output
- If fetus alive and mature, Caesarean section
- If fetus dead, induce (artificial rupture of the membranes)

senior obstetrician. If the fetus is dead, induction by rupture of the membranes usually leads to a rapid labour.

After a mild abruption and if the fetus is immature and lives the woman may continue the pregnancy under controlled conditions. She should stay in hospital with antenatal monitoring until the fetus is mature enough for delivery. In cases occurring very early in gestation the woman may have to be transferred for delivery to a regional unit with intensive neonatal facilities available.

Severe abruption may lead to severely disordered blood clotting which must be managed with the help of a haematologist. After delivery fluid balance should be carefully managed and urine output must be recorded hourly. Oliguria following reduced plasma volume is usually the result of acute tubular necrosis, though in rare cases acute cortical necrosis may occur. The help of anaesthetists trained in intensive care and of a renal physician will be needed.

Placenta praevia

Figure 10.7 The older grades of placenta praevia were 1–4. They are now described in three grades: marginal, lateral, and central

The blastocyst usually implants in the thicker, receptive endometrium of the upper uterus, but occasionally it glissades to the endometrium of the isthmus or over a previous lower segment uterine scar. Then invasion by the trophoblast secures the embryo and when the uterus grows to form a lower segment later in pregnancy some part of the placenta is implanted there.

About a quarter of all antepartum haemorrhages are due to placenta praevia, the proportion increasing with more thorough investigative ultrasonography. In the last weeks of pregnancy the lower segment stretches whereas the placenta is comparatively inelastic. In consequence, the placenta which has implanted in the lower segment is peeled off the uterine wall with bleeding from the placental bed. A placenta praevia may be detected by ultrasonography in the mid-trimester but usually little bleeding occurs until the lower segment is formed after the 30th week.

Diagnosis

A woman with placenta praevia may have bright red, painless vaginal bleeding. It comes unexpectedly, blood often being found on waking in the morning. The woman is in no way shocked and may wish to ignore the symptom as she feels normal.

A few women present with a persistent transverse lie or breech presentation in late pregnancy. The possibility of

Figure 10.8 Ultrasound scan of placenta praevia

placenta praevia should always be considered in such a case and an ultrasound scan requested urgently. The result may lead little the woman's admission to hospital, even if she has had little bleeding.

In a third group of women a placenta praevia is diagnosed incidentally on ultrasound examination. This finding is common in the middle weeks of pregnancy. A low lying placenta diagnosed at 22 weeks' gestation is often normally sited by 32 weeks. About 5% of women present with a low lying placenta at 24 weeks but only 1% of them have a placenta praevia at term. The upper segment of the uterus grows and the placental site moves with it as the lower segment is formed. If not, such women should be treated in the same way as others diagnosed clinically because the risk of bleeding in late pregnancy is as great.

The uterine spasm of placental abruption does not occur in placenta praevia and the fetus can be felt easily. The fetus is usually alive with a good heart beat. The woman's degree of shock will vary directly with the amount of blood lost. If shock is moderate the woman needs admission to hospital. If blood loss is slight she can go to the hospital conventionally but she needs to be warned of the probable diagnosis.

No vaginal examinations should be performed on any woman who bleeds in late pregnancy until a placenta praevia has been excluded by ultrasonography. If this principle is broached, further separation of the placenta may occur with very heavy, and sometimes fatal, haemorrhage. Any woman who presents to a general practitioner with vaginal bleeding in late pregnancy should be considered to have a placenta praevia until the diagnosis is disproved. She must be referred to a hospital for an urgent appointment that day. If necessary, she should be admitted if ultrasound investigations cannot be performed straight away.

In hospital blood is crossmatched and the placental site demonstrated by ultrasonography. The older diagnostic radioisotope studies and soft tissue x ray examinations now have no place in the UK.

Once placenta praevia is diagnosed, the aim of treatment is to maintain the pregnancy until the fetus is mature enough to be delivered; at 38 weeks an elective caesarean section will probably be performed unless the placenta praevia is a minor one with the fetal presenting part below it. Should the placenta be anterior, the descending fetal head may compress it against the back of the symphysis pubis, so allowing a vaginal delivery, but this is uncommon. The Caesarian operation may be difficult with much blood loss and should be performed by a senior obstetrician.

Other specific causes of bleeding

General

Few haemorrhagic diseases occur in young women but vaginal bleeding may occur in von Willebrand's disease, Hodgkin's disease, and leukaemia. All are probably known about beforehand, and the diagnosis is confirmed from the results of haematological studies.

Local

Lesions of the cervix and vagina cause slight bleeding, often only a smear of blood and mucus. Moderate bleeding may occur with a carcinoma of the cervix—unusual in women of childbearing age—or varicose veins of the vulva and lower vagina. Lesser bleeding is more likely from a polyp or an erosion of the cervix. Monilia infection may be accompanied by spotting as plaques of fungoid tissue are separated from the vaginal walls.

Figure 10.9 These old steel engravings show what a vaginal examination could do to a placenta praevia (central (above) and lateral (below)). NEVER DO A VAGINAL EXAMINATION UNLESS PLACENTA PRAEVIA HAS BEEN EXCLUDED

Table 10.1 Causes of antepartum bleeding from the lower genital tract

Cause	Characteristic bleeding
Cervical ectropion	Smear of blood loss often with mucous loss
Cervical polyp	Spotting of blood
Cervical cancer	Smear of blood on touch (rare, but diagnosis is important)
Vaginal infection	May bleed heavily Spotting of blood with white or pink discharge
Vaginal varicose veins	Occasionally heavy bleeding

All these causes can be diagnosed by using a speculum, but this procedure must be done in hospital after the woman has been assessed and ultrasound examination has excluded placenta praevia. If the haemorrhage is due to a benign local lesion it will be managed appropriately.

Fetal

A most unusual cause of bleeding is from fetal blood vessels. There may be a succenturiate lobe or the umbilical cord may be inserted into the membranes over the internals so that the arteries and veins pass unsupported to reach the edge of the placenta. If by chance the placenta is also low lying, the umbilical blood vessels pass over the internal os of the cervix (vasa praevia); when the membranes rupture the fetal vessels may tear and bleed. The blood is fetal and a small loss can lead to severe hypovolaemia of the fetus.

The presence of vasa praevia is difficult to diagnose but sometimes they can be suspected with colour Doppler ultrasonography. More usually the fetal heart rate may alter abruptly after membrane rupture accompanied by a very slight blood loss. Bedside tests exist to differentiate fetal from maternal haemoglobin but are rarely used. The treatment must be a rapid caesarean section as the fetus cannot stand such blood loss for long.

Bleeding of unknown origin

The real cause of antepartum haemorrhage is unknown in a large number of women. They may have bled from separation of the lower part of a normally sited placental bed or the membranes may have sheared with tearing of very small blood vessels. Some placentas bleed early from their edge.

If the cause of antepartum haemorrhage cannot be diagnosed precisely, the woman should not be dismissed lightly. The risk to her baby at subsequent labour is higher than background, although the risk to the mother does not seem to be great. It is good practice to keep such women in hospital for some days, allowing them to return home if no further vaginal bleeding occurs. This rule of thumb seems to cover most eventualities and so many women do not stay in hospital for long. Fetal growth should be monitored by ultrasonography. In labour, however, the fetus should be monitored for hypoxia: for there is a higher risk than in fetuses whose mothers have not bled.

Figure 10.11 The relative risks of increased perinatal mortality from antepartum haemorrhage compared with those in pregnancies with no such haemorrhage

11 Small for gestational age

The problems of small babies and preterm labour often go together and are now the major causes of perinatal mortality and morbidity in the UK. Furthermore, they use up large amounts of facilities, manpower, and finance. Preterm labour and premature rupture of the membranes are considered in the next chapter and the antenatal care of fetuses that are small for gestational age and of their mothers in this one.

Figure 11.1 Distribution of length of gestation and birth weight (singletons, last menstrual period certain)

The diagnosis of a small fetus is made more specific by examining the ratio of birth weight (or estimated birth weight) to gestational age. Both these measures have inherent problems.

Obstetricians estimate fetal weight either clinically or from measuring ultrasound determined diameters of the fetus *in utero*. Gestational age is derived from the mother's menstrual dates, which are usually confirmed by an ultrasound scan measuring the biparietal diameter performed before 20 weeks. In most parts of the UK, about 80% of women are sure of their dates. The figure shows the distribution of length of gestation for women according to whether they were sure of their dates. The frequency of heavier babies was increased among those uncertain of the date of their last menstrual period. All women in the UK with unsure dates should have gestational age established by ultrasound, as should those in whom there is a discrepancy between the dates derived from the last menstrual period and fetal size in early pregnancy. Obstetricians consider a baby to be small for gestational age when abdominal circumference readings fall below the second standard deviation below the mean; this is approximately the second centile on serial ultrasonography.

After birth paediatricians can weigh the baby and so have a precise measure, although even this varies slightly with the conditions of weighing and when it is done. Gestational age is obtained from the obstetrician by one of the previously mentioned measures or from Dubowitz scoring. The data are plotted on a specific centile chart; various groups of paediatricians take small for gestational age as being below the 10th, the fifth, or the third centile. It is very important when examining data to know which of these measures was used. The 10th centile is rather crude and will include many normal babies at the lower end of the normal birthweight distribution curves whose growth has not actually been affected by placental bed disease.

Much simpler was the old measure of prematurity, taking a cut off point of a birth weight of less than 2500 g. Unfortunately, this includes small babies whose birth weight is appropriate for their gestational age and those who are small for their gestational age, two very different groups in clinical medicine. For example, babies born with a birth weight below

The phrase "intrauterine retardation" is no longer used in current obstetrics. It has been replaced by "intrauterine growth restriction" because the former phrase implied that there was some retardation of the child, particularly cerebral, and some parents found this difficult to accept.

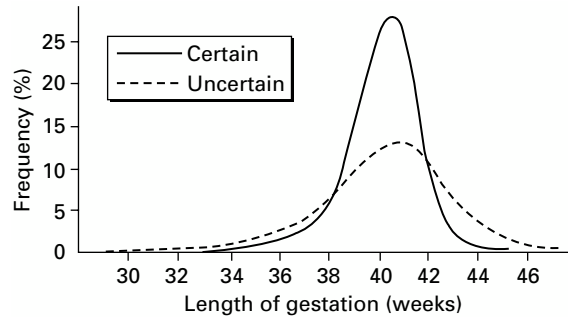

Figure 11.2 Distribution of length of gestation by knowledge of last menstrual period (singletons)

Figure 11.3 Weighing a newborn

Figure 11.4 The relation between preterm and low birth weight babies. Babies who are small for gestational age fall under the 10th centile

2500 g make up about 7% of the newborn population in the UK, about 3% in Sweden, almost 11% in Hungary and a much higher proportion in many parts of the Eastern hemisphere. Such mixed data would make a nonsense of studying the influences on fetal growth and so the definition of small for gestational age relating birth weight to length of intrauterine life stands at the moment.

Causes

Genetic abnormalities

Genetic abnormalities are an identifiable but not very common factor causing growth restriction. Trisomy 21 is the commonest example, though osteogenesis imperfecta, Potter's syndrome, and anencephaly may all be associated with intrauterine growth restriction. Other congenital malformations not yet proved to have a genetic component are commonly found in fetuses that are small for gestational age; among them are gastrointestinal abnormalities such as atresia of the duodenum, gastroschisis, and omphalocele.

Maternal nutrition

In the UK the effect of maternal nutrition on low birth weight is probably small. Extremes of starvation associated with small babies are rare in Britain. During a pregnancy about 80 000 kilocalories (335 MJ) of extra energy is required, of which 36 000 kilocalories (150 MJ) is for maintenance metabolism.¹ Much of this can come from an everyday diet, and among well nourished women requirements change little for the first 10 weeks of pregnancy. Thence requirements gradually increase, but ordinary variations in food intake are unlikely to affect events. It is unwise to recommend that a mother eat for two in order to produce a larger baby. As well as the nutritional value of the food consumed, there are other factors of appetite, maternal obesity, and heartburn which must be remembered when making recommendations.

Intrauterine infection

Most intrauterine infections are viral or bacterial. Some 60% of babies with congenital rubella are born below the 10th centile of weight for gestation. Cytomegalovirus and toxoplasmosis (much less common in this country than in mainland Europe) are associated with growth restriction in about 40% of infected infants. Malaria, ubiquitous in many tropical countries, causes a massive accumulation of monocytes in the intravillous space, which is associated with a fetus being small for gestational age.

Drugs

Drugs may be a cause of babies being small for gestational age. The commonest cases in the UK are the results of tobacco fumes being absorbed during cigarette smoking. The association between smoking and small for gestational age babies is well documented. The number of affected babies whose growth drops below the 10th centile increases during the last weeks of gestation.

The effect of alcohol is difficult to sort out. At the extreme end of the range, i.e. women drinking more than 45 units of alcohol a week, some babies are born with the fetal alcohol syndrome and a distinctly reduced birth weight. At lower intakes of alcohol covariables come into play; a deficient maternal diet and increased cigarette smoking are often associated with the alcohol habit. In some studies multivariate analyses show that the main causal factor associated with low birth weight is not alcohol intake but cigarette smoking. The whole lifestyle is probably the important factor. Some doctors

In the UK most of the energy required by a pregnant woman can come from an ordinary diet, with little need for supplementation.

Figure 11.5 Centiles of birth weight by length of gestation and mother's smoking habit (singletons, last menstrual period certain)

Figure 11.6 Distribution of birth weight in a normal population of women and in one consisting of women who drank more than 45 units of alcohol a week (heavy drinking)

ABC of Antenatal Care

consider that smoking in pregnancy is the most important single cause of low birth weight, the greatest single factor associated with death and illness in the first weeks of life.

The use of narcotic drugs is commonly associated with low birth weight but, again, the total lifestyle of the woman may be the real factor. For this reason, perhaps, an increased incidence of small for gestational age babies persists with methadone users.

Therapeutic drugs such as carbamazepine and the valproates have been associated with an increased incidence of small for gestational age babies, as have the more powerful antiviral drugs such as azathioprine. Such powerful drugs are not given in pregnancy unless they are needed to treat a serious maternal medical condition, which in itself may affect nutrition or metabolism of the mother and therefore growth of the fetus.

Hypertension

One of the major current causes of babies being small for gestational age in the UK is hypertension in the mother, either pregnancy induced or pre-existing. After other features have been taken into account such types of hypertension are associated with about a third of all cases of intrauterine growth restriction. The effects of hypertension are made worse when raised blood pressure is associated with proteinuria, implying a greater reduction of the maternal perfusion of the placental bed. The duration of the condition also has an effect; for example, 80% of mothers who have proteinuric pregnancy-induced hypertension before the 34th week of pregnancy have infants with a birth weight below the 10th centile.

Other factors

The maternal body habitus is not a major factor in babies being small for gestational age, but big women do produce larger children. The father's influence is less important, classically shown in the 1938 study of Walton and Hammond on Shire horses and Shetland ponies.²

The altitude at which a woman lives in pregnancy has a negative effect on fetal growth, particularly if she is not used to high altitudes.

Diagnosis

Extreme examples of fetuses that are severely small for gestational age can sometimes be diagnosed by palpation. This is most likely if the same midwife or doctor sees the woman at each antenatal visit and uses the written records of previous visits longitudinally. In several control studies false positive rates as high as 50% and low predictive values have been found in the clinical estimation of intrauterine growth restriction.

The use of symphysio-fundal height measurements is probably of more use in detecting the large baby or polyhydramnios than the small baby or oligohydramnios. A randomised trial of symphysio-fundal height measurements was able to detect fewer small for gestational age fetuses by this method, 28% compared with 48% in the palpation group without measuring fundal height.³

Sometimes the lack of amniotic fluid is diagnosed more readily; oligohydramnios accompanies fetuses that are small for gestational age and therefore may lead to ultrasound investigation more swiftly than when fetal size has been estimated clinically.

Figure 11.7 Relationship between amount of cigarette smoking in black American women and various non-weight related indices at birth and seven months later

Figure 11.8 The effects of sire and mare on the size of offspring are shown in this 1938 experiment in which Shire horses and Shetland ponies were mated. The maternal influence predominates

Figure 11.9 Mean (\pm SD) of symphysio-fundal height by weeks of gestation. Note the wide range of readings for any given week of gestation and the even wider range of expected gestation weeks for any given reading

Most fetuses that are small for gestational age are diagnosed in this country by ultrasound. When a good estimate of gestational age in early pregnancy has been obtained and fetal abnormalities have been excluded, ultrasound scans can give valuable measures of fetal growth. Scans of the abdominal circumference at the level of the umbilical vessels give a measure of liver growth. Another measure of somatic growth is femur length.

Fetuses with small abdominal circumferences can have their head circumference measured and the ratio of head to abdominal circumference derived. A small for gestational age fetus with a normal ratio of head to abdominal circumference tends to be a perfect miniature (bonsai baby) and is usually normal, representing the lower end of biological variation. Such fetuses, however, may also be associated with chromosomal anomalies, drugs, infection, and malnutrition.

Fetuses suffering from placental bed malperfusion tend to preserve growth of the head at the expense of the body because a protective mechanism shunts blood to the brain. Measuring the ratio of head circumference to abdominal circumferences can sometimes differentiate those that are just normally small (normal ratio) and those that are growth restricted (increased ratio).

Occasionally there may be a chromosomal reason for the poor growth picture and an ultrasound assessment may help determine if a karyotype is indicated. Structural anomalies such as cardiac defects, dilated renal pelves, or abnormal head shapes may be suggestive. Alternatively a history of maternal infection or increased viral antibodies may point to an infective cause.

All small babies require close assessment. Estimating fetal weight should include serial ultrasound including measurements, liquor volume, and Doppler studies of the umbilical artery. Cardiography is used to give reassurance especially if there is doubt about fetal movements.

Small for gestational age fetuses may be screened by using early ultrasound to confirm gestational age and later to confirm growth. Finer tuning is possible by Doppler measurement of the afferent blood supply to the placental bed, with later changes in blood velocity along the umbilical vessels giving a more precise warning of fetal state. Should the umbilical artery end diastolic frequencies be lost, delivery should be considered very soon, provided pregnancy is far enough advanced that the neonatal unit of the hospital concerned is happy to deal with a child of that gestation.

In the past, most babies had ultrasound reading of the biparietal diameter at 16–20 weeks to confirm gestation and a second scan of abdominal circumference at 32–36 weeks to check growth. The later scan is now more commonly done only on suspicion of poor fetal growth and has been dispensed with in most UK obstetric departments.

Mothers whose fetuses are at greater risk of intrauterine growth restriction often have several ultrasound readings performed in later pregnancy. Such women include those with a history of perinatal death and of intrauterine growth restriction previously as well as those in whom the fetus is exposed to some of the aetiological factors already considered and where oligohydramnios may give a clue.

Treatment

The ultimate treatment of a fetus with impaired growth associated with an abnormal placental bed is delivery. Diagnosis encapsulates the fact that a baby getting insufficient nutrition

Figure 11.10 Ultrasound measures of the head and abdominal circumference. Although growth rates are diminished, they fall at the same rate—symmetrical growth restriction

Figure 11.11 Ultrasound measures of head and abdominal circumference. Abdominal growth slows more than head growth—asymmetrical growth restriction

ABC of Antenatal Care

for normal growth will be in greater danger of oxygen deprivation in labour. Removal from the hostile environment would be the ultimate answer, but this might not be wise in earlier gestation (24–28 weeks); efforts are made to improve the blood supply to the placental bed.

Rest, particularly with the woman lying on her left side for some hours a day, should theoretically improve placental perfusion, but Doppler studies show little evidence for its effectiveness. Measures to restore the plasma volume and to give adequate hydration may be useful theoretically as they should decrease viscosity and lead to an improvement of intrauterine blood flow. Again, theory is not matched by practice.

In fetuses that are small for gestational age, correction and reversal of some of the causal factors might have helped, but it is too late to do this when the fetus is detectably small for gestational age. For example, curtailment of cigarette smoking should happen in early pregnancy. Such reduction in the first 16 weeks allows fetuses to follow a normal growth pattern rather than that of growth restricted babies of smoking mothers.

The mother of a fetus that is small for gestational age should attend a hospital with the capacity for more precise diagnosis and where special ultrasound and Doppler measurements are available. Many tertiary referral centres have a fetal assessment unit run on a day care basis. Women who live near large hospitals with such facilities can still be outpatients while having full surveillance. If they live away from the centre, however, they may have to be transferred and become inpatients; this is the keystone of the *in utero* transfer system widespread in the UK. Probably a third of the women admitted as *in utero* transfers have fetuses that are small for gestational age as their indication for admission.

The ultrasound surveillance of fetal growth, liquor volume, and umbilical vessel blood flow allows more precise fetal prognosis. Prospective frequent and regular consultations with the neonatal paediatrician who will be involved are essential. This will help to prepare for a premature delivery. The mother is also given steroids to reduce the risk of respiratory distress syndrome in her baby.

The fetus must be delivered at the most appropriate time by the most appropriate method. The time depends on weighing up the risks of keeping the fetus inside the uterus, that is, those of diminished placental bed perfusion, against the risks of being outside, that is, the risks of immaturity and survival in a good intensive care neonatal unit. The critical gestational age for these decisions is being pushed back all the time; now the worrying time for most obstetricians and neonatal paediatricians is 24–28 weeks. Once a pregnancy passes 28 weeks the concern is much less, although the respiratory distress syndrome can still cause morbidity and even death after delivery, especially in those small for gestational age.

The next time

Studies of pregnancies subsequent to one producing a small for gestational age baby showed that growth restriction only recurs in 20% and when it did it was less severe. In consequence, although this gives a better prognosis, it makes any management plans hard to assess for four-fifths of women will not get the problem anyway in the next pregnancy, prevention measures used prospectively thus may not have been needed. Even harder is research; use of paired studies with controls or randomised controlled trials is essential.

Figure 11.13 Corner of a fetal assessment unit

Figure 11.14 The relative risks to a fetus of staying in the uterus on the wrong side of a poor placental bed perfusion system (▨) compared with the risks of being delivered too soon (▩)

Conclusion

It must be remembered that the definitions of small for gestational age are used imprecisely and much that was thought to be known about its causation depended on data that were not mutually comparable. Until Doppler measurement, the measures of fetal wellbeing were also inexact; even Doppler ultrasound is not the last word on the subject. The ultimate management depends on avoiding trouble. Maybe we are overprotective of fetuses that are small for gestational age, but it is the best that we can do in 2001.

12 Preterm labour

Preterm labour may result in the birth of an immature infant. Together with intrauterine growth restriction it is the main problem of obstetric care in the UK. The conventional definition of preterm labour includes women delivering before 37 completed weeks of gestation, but in practice in the UK problems arise mostly with births before 34 weeks. Babies more mature than this can be cared for successfully in many district general hospitals without intensive care facilities; most problems arise in babies weighing less than 1500 g (3.5 lb).

Perinatal mortality rates relate sharply to maturity and birth weight; similarly, neonatal mortality rates relate to weight at birth. Probably some 6% of babies in the United Kingdom are born before 37 weeks and 2% before the 32nd week of pregnancy.

Figure 12.2 Neonatal deaths per 1000 live births by sex and birth weight, England and Wales 1995

Causes

Sociobiological background

The capacity for preterm labour is often predictable by a clustering of high risk factors. The mother's age, parity, and socioeconomic class bear strong associations with preterm labour. Socioeconomic class is an indicator of the woman's behaviour, nutrition, smoking, and previous preterm delivery. Also important is a woman's work in early pregnancy, particularly if it involves continuous standing. These may not be individual factors in their own right but are useful to identify women whose risk of preterm labour is increased.

Reproductive history

A multiparous woman's obstetric history may give prognostic clues; the chances of a preterm delivery are tripled after one previous preterm birth and increased sixfold after two. These are two simple sets of risks; other outcomes bring in differential variables. Past studies have been diminished by not including the woman's total obstetric history, which needs careful consideration in the case of each woman.

Medical history

Recurrent lower urinary tract infections are not usually associated with recurrent preterm labour, although pyelonephritis may be. The renal tract should be investigated

Figure 12.1 Relation between length of gestation and birth weight. Babies born in the crosshatched area are preterm irrespective of weight

Figure 12.3 Birth weight specific survival to 28 days 1993-9 (Welsh Perinatal Survey)

Figure 12.4 Singleton births before 37 weeks by socioeconomic class (Scotland 1990-95)

between pregnancies and reinfection prevented by prophylactic antibiotics in future pregnancies.

Uterine structural abnormalities can be a recurrent factor, the best documented being cervical incompetence. This follows damage or overstretch of the cervical internal os—an ill-formed muscular sphincter—and is a mechanical diagnosis first observed by obstetricians in the 1940s and made familiar by the work of Shirodkar and McDonald in the 1950s. The truer picture of the place of cervical incompetence and its management in preterm labour had to await a randomised controlled trial in the 1980s run jointly by the Medical Research Council and the Royal College of Obstetricians and Gynaecologists; the results put into proportion the importance of cervical incompetence as an individual factor in preterm delivery.¹ A much smaller report had more optimistic results (Table. 12.1).

Complications of pregnancy

Multiple pregnancy is a marker for preterm labour. The mean gestation of twins is 37 weeks and therefore many will be born before this time.

Several studies have shown the association of preterm labour with antepartum haemorrhage, irrespective of the cause of the bleeding.

Hard physical work in pregnancy is associated with preterm labour, particularly if it is repetitive and boring or in an unpleasant, noisy environment. This factor is discussed in Chapter 6.

Abnormalities of the fetus are often associated with preterm labour when there may also be polyhydramnios, which in itself can lead to premature membrane rupture and preterm labour.

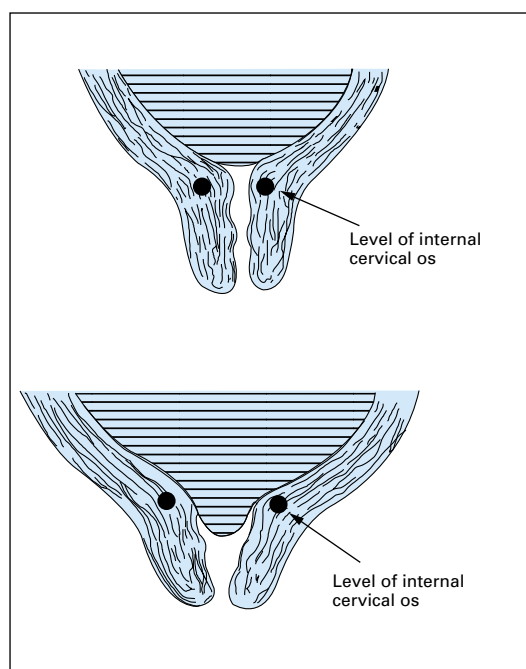

Figure 12.5 Cervical incompetence leads to a cone of unsupported membranes

Infection and premature membrane rupture

Infection of the lower uterus and the membranes is an important feature that is poorly investigated epidemiologically. The presence of micro-organisms in the membranes is associated with an increased production of prostaglandins, one of the main factors associated with the onset of labour. Proteases, coagulases, and elastases are also produced by invading micro-organisms, whose endotoxins may stimulate labour directly as well as through prostaglandin metabolism. Low grade chorioamnionitis (infection of the membranes) is much commoner after premature rupture of the membranes, when an ascending infection from the vagina may produce such biochemical changes. One of the commonest organisms is the β haemolytic streptococcus, which is found as a commensal in the vagina in about 5% of women but may be a factor in preterm labour in up to 20%. Other anaerobic vaginoses are more common in women with premature rupture of

Figure 12.6 Cumulative gestational age at delivery for multiple pregnancies. By 37 weeks delivery has occurred in 97% of quadruplet, 96% of triplet, 55% of twin, and 25% of singleton pregnancies

membranes and preterm labour than in those who go to term. Changes in vaginal flora have been shown by culturing vaginal flora in mid-trimester and before labour. The persistence of *Bacteroides* in the last months of pregnancy was associated with preterm birth. Coliforms when associated with preterm labour were acquired later in pregnancy.³ Premature membrane rupture itself is a commonly quoted cause of preterm labour; this may be due to the infection that weakened the forewaters or to the removal of the forewaters' mechanical support from the cervix.

Induction

Preterm labour is caused iatrogenically in about 15% of women in this country, though in some units the rate rises to 40%. Many of the inductions will obviously be in women after 37 weeks' gestation but some will be performed before this. The problem of rhesus incompatibility, previously a major indication, has reduced markedly; in its place is pregnancy-induced proteinuric hypertension and intrauterine growth restriction. Women with either of these problems should be delivered at hospitals that can cope with the neonatal sequelae of such induction; these groups produce a large proportion of babies who are born well before the 37th week of pregnancy.

Prevention

The recognition of some of the triggers of preterm labour has led some obstetricians to take action to prevent labour. There is little objective evidence that bedrest and the use of prophylactic tocolytic agents are helpful, although a doctor might use either of these managements to satisfy a mother who has previously undergone preterm labour and has faith in them. Repeated, carefully taken, high vaginal swabs to give the pattern of micro-organisms in the upper vagina may be useful. Active antibiotic treatment will eradicate colonisation and thus reduce the risks of preterm labour. Clindamycin is being used in this field and the whole approach is under evaluation.

Several centres have used programmes during early and mid-pregnancy to educate women with a history of preterm delivery to try to prevent a recurrence of the problem. There is no easy method of doing this in a group; the success of such programmes depends on the individual woman and her individual midwives and doctors. All the factors discussed so far must be considered, and the woman should obviously try to avoid those which seem to be the more relevant in her case. Even with the most intensive antenatal education programmes, preterm deliveries are not cut to less than about 3.5%, a background rate in many populations. Success in this subject may come eventually after a conscious effort to modify the lifestyle, socioeconomic conditions, and medical problems of each individual patient.

Diagnosis

As with labour at term, diagnosing the onset of preterm labour is more easily performed retrospectively than at the time. You can look back and say a labour probably started at a certain time, but to do so prospectively is much harder. The general practitioner is left with the difficult task of deciding whether any group of uterine contractions will progress to cervical dilatation or whether they are just stronger Braxton Hicks contractions. The diagnosis may be assisted by external tocographic measurement of uterine contractions with a semiquantitative external monitor. Any woman thought to be in preterm labour should go to the local maternity unit as soon as possible for further assessment. There tocography may help, and assessment of the cervix may be valuable. About half of the women who present with regular, painful contractions will not

progress to labour. Impending preterm labour may disrupt the cells of the cervix releasing fibronectin. The cells can be detected fairly simply and are the basis of a test to check whether that woman is at risk of going into preterm labour soon. It is more useful in the early treatment of high-risk women but of less use in those at lower risk.

If preterm labour seems inevitable, treatment may be given to postpone it. Otherwise, the woman may be kept in for 24 hours to see if labour follows; if not, she can be discharged home to the care of her general practitioner. It is easy to be wise after the event, but only by sending every woman about whom there is reasonable doubt to the maternity unit will clinicians not miss the occasional woman who goes into very early preterm labour. Ultrasound evaluation of the cervix can sometimes warn of preterm labour. In some women dilatation, funnelling of the internal os and shortening of the canal all can be demonstrated but the specificity of the investigation is not high. A vaginal examination still gives the clearest evaluation of preterm labour.

Inhibition of established preterm labour

If a woman is in real preterm labour a decision has to be made whether labour should be stopped. It is probably wise not to do so if the mother's blood pressure is raised, there is proved infection in the endocervical or decidual regions, or the fetus has a lethal abnormality. Some obstetricians would consider further that it was unwise to inhibit labour in the presence of long-term rupture of the membranes, severe intrauterine growth restriction, or an antepartum haemorrhage. Each of these cases must be decided on their own merits.

Other than these exceptions, in most cases before 28 weeks it is worth trying to stop preterm labour to buy intrauterine time for the fetus. In the short term this can allow emergency treatment such as steroids to help maturation of the fetal respiratory system or allow transfer of the woman to a centre with good neonatal care facilities for a very small baby after delivery. These decisions must be made in consultation with the paediatricians as the practical management of any baby resulting from a preterm labour will depend on their skills and facilities. In a large well equipped obstetric-paediatric unit the borderline comes at about 27 weeks, provided that all other features of the pregnancy are normal.

If it is considered necessary to stop preterm labour a range of agents exist. Alcohol and the progestogens are obsolete.

Before 32 weeks' gestation short-term inhibition of labour allows:

- Transfer to the delivery unit best equipped for special neonatal care
- Steroids to be given to help mature the fetal respiratory system

A third of children born between 32 and 35 weeks' gestation may expect to have problems at school by the age of seven.

ABC of Antenatal Care

Prostaglandin synthesis inhibitors (such as indomethacin) are effective but may have side effects in mother and fetus. Both β antagonists (ritodrine and salbutamol) and calcium antagonists (nifedipine) are used in the United Kingdom to suppress labour. These drugs work equally well on the myometrial cells and may postpone labour for a time. There is little evidence from meta-analyses of many studies that they reduce either perinatal mortality rates or postponement of labour over a long period.² Their use will depend on the ripeness of the cervix—the less ripe the more likely that action will be effective. They are best used before 32 weeks of pregnancy and probably work better in the absence of infection. Though little evidence shows that prophylactic oral β mimetic agents prevent preterm labour, oral maintenance after intravenous inhibition has some effect. Because of this, the recent introduction of oral nifedipine has been popular. The side effect profile is better, with occasional flushing, palpitations, and transient hypotension.

Once treatment with tocolytic agents has been started, the next decision is where the woman is to deliver if labour

proceeds. If the unit cannot cope with very small babies, *in utero* transfer must be considered. The woman should go to a tertiary referral centre in the region that can manage babies of this degree of immaturity. The alternative philosophy is to allow the baby to be delivered in the peripheral centre and, if necessary, transfer the child to the tertiary referral unit by *ex utero* transfer. *In utero* transfer may not be necessary every time; it is used as a precaution but it allows the woman to be in the tertiary referral centre that is able to provide more sophisticated obstetric as well as neonatal care, for example Doppler flow studies. *Ex utero* transfer allows the woman to stay closer to her home at the local hospital she has chosen. However, specialist antenatal tests may not be available, obstetricians may not be as experienced in the delivery of very small babies, and expert paediatric teams may not be available at the time of delivery because of the many other calls on obstetricians' and paediatricians' time. In addition, with road traffic conditions in the UK there is no guarantee that help can get to even the nearest district hospital quickly. At present the

Box 12.3 Expert care for babies expected to be very small

- *In utero* transfer to obstetric/neonatal referral centre
- Delivery in district general hospital and *ex utero* transfer to specialist centre

philosophy is in favour of *in utero* transfer, but it may not stay so for long in the reorganised NHS.

Steroids, given to the mother before delivery, pass across the placenta to the fetus. Between 26 and 34 weeks' gestation, they have been shown to decrease morbidity and mortality associated with the respiratory immaturity of preterm delivery.⁴ They are of optimal use if more than 24 hours passes from the first dose to delivery but often there is not enough time from the admission of the woman to her inevitable delivery. The use of tocolytic agents is used to postpone delivery and so extend the time available for the steroids to work on the fetal lung helping to produce surfactant. The steroids are commonly given as betamethasone in two intramuscular doses at 12-hour intervals. If labour is delayed by more than a week and the woman is still less than 34 weeks' gestation, the course of steroids is often repeated although the evidence of the benefits of this is hard to show.⁵

Conclusion

This and the previous chapter are concerned with the most serious problems of current obstetrics. Getting the best results for very small babies is the most hopeful line of advance at present. It needs coordination from family doctors, obstetricians, midwives, and neonatal paediatricians with individual treatments tailored to individual mothers.

The data for perinatal and neonatal mortality rates for Scotland are taken from the Scottish stillbirths and neonatal deaths report produced by the Information Office of the Scottish Health Service. The figure showing the cumulative distribution of singleton and multiple births is reproduced by permission of the Office of Population Censuses and Surveys from *Three, four and more*, published by HMSO. Other data come from CESDI reports.

Preterm labour and small for gestational age fetuses constitute the most serious current problems in obstetrics.

13 Multiple pregnancy

Multiple pregnancy is a mixed blessing. On the one hand is the instant family, on the other are the increased perinatal mortality and morbidity as well as a much greater load for the mother after delivery.

Types

Multiple pregnancy follows either the division of an oocyte fertilised by one sperm into two separate bodies (identical or monozygotic twins) or the fertilisation of more than one egg by separate sperm (non-identical or dizygotic twins). In higher multiple pregnancies than twins a combination of these two mechanisms happens.

In monozygotic twins, division into two separate bodies was thought to occur only at a very early stage but it can in fact take place up to several days after fertilisation. The later this is, the more likely is the rare abnormality of conjoined twins.

Prevalence

The prevalence of twin births in the UK is 11.3/1000 deliveries, of triplets 0.3/1000, and of quadruplets about 0.01/1000 deliveries. There is a natural variation between races; Japanese women have one of the lowest rate of twins and those from some African countries have a much higher rate, up to one in 30 deliveries. Multiple pregnancies also increase with maternal age. These biological variations are due to an increase in the dizygotic twinning rates, based on the capacity of the woman to produce more than one oocyte at the time of ovulation.

The prevalence of multiple pregnancy has been increasing in the UK in the past decade. For higher multiples than twins the rate trebled from 12 per 100 000 to 40 per 100 000 between 1980 and 1998. Though a part of this is due to the increasing number of mothers over 35, the iatrogenic effect of ovarian stimulation and *in vitro* fertilisation programmes is also important. Concern about this led to the formation of a statutory body, the Human Fertilisation and Embryology Authority which made recommendations about the maximum number of oocytes or embryos transferred at assisted fertilisation, a limit of two.

Figure 13.3 Proportion of maternities resulting in triplets (England and Wales, 1939-98)

Diagnosis

Twin pregnancies used to be diagnosed clinically when the woman reported her symptoms of pregnancy were worse than usual and the uterus was found to be bigger than would be

Figure 13.1 Monozygotic and dizygotic twins

Figure 13.2 Proportion of maternities resulting in multiple births (England and Wales, 1939-98)

Figure 13.4 In early pregnancy twin sacs and embryos can be shown by ultrasonography

expected from gestational dates (after about 20 weeks); sometimes twins were diagnosed for the first time in labour. Often the fetal parts are hard to determine but palpation of more than two poles is suggestive of twins. Now in the UK most women have an ultrasound scan by 16 to 20 weeks and so multiple pregnancies are usually diagnosed much sooner. In the Scottish twin survey, 70% of multiple pregnancies were diagnosed by ultrasonography before 20 weeks and 95% in all were diagnosed in the antenatal period. The rest were diagnosed in labour. When a twin pregnancy is diagnosed by ultrasonography the increased incidence of congenital abnormalities should be remembered and a thorough ultrasound examination of each fetus performed between 20 and 24 weeks.

The increased uterine size leads to greater pressure on venous return. The frequency of the group of conditions that obstetricians (but not women) call minor problems (for example, varicose veins in the leg) is increased. Furthermore, the woman may have more symptoms of nausea in early pregnancy associated with the higher human chorionic gonadotrophin concentrations.

Death of one fetus

When one of a pair of twins dies *in utero* there is a risk to the mother of coagulopathy. For the surviving fetus there is also a risk of neurological lesions, preterm delivery with its problems of immaturity, and even intrauterine death. In very early pregnancy the complete absorption of the fetus that dies is usual (the vanishing twin phenomenon) probably happening in 5–8% of twin pregnancies. When fetal death comes later, it is best managed expectantly with close surveillance of the mother and the remaining fetus. In a dizygous twin pregnancy, the risks to the surviving fetus are relatively low.

One previously underconsidered feature of this problem has been the disaccord of the mother's reaction in grieving for one baby whilst looking forward hopefully to the birth of the other.

Congenital abnormalities

Many congenital abnormalities are more frequent in twins, especially those who are monozygous. Neural tube defects, heart abnormalities, and the incidences of Turner's and Klinefelter's syndromes are all increased. About twice as many live births from multiple pregnancies have a major congenital abnormality compared with singleton pregnancies.

Some of these abnormalities may be detected by ultrasound, others require amniocentesis. In multiple pregnancy this test is associated with a 3% rate of miscarriage compared with about 0.5% in singleton pregnancies. Care must be taken to identify the fluid from each sac, by proper labelling of the sample container, as the abnormality may be in one fetus only. Should severe abnormality be found in one fetus of a multiple pregnancy with two sacs the obstetrician may consider that the normal fetus is at increased risk and recommend selective fetocide. This can be by cardiac puncture, intravenous injection of potassium chloride or clipping the umbilical cord using a hysteroscope. Such management should be at a regional centre well used not just to performing these procedures but to the very important counselling that goes on before and after such an event. The risk of preterm labour in the unaffected pregnancy is increased.

Pregnancy-induced hypertension

The incidence of pregnancy-induced hypertension is increased in multiple pregnancies and eclampsia is also commoner. Antihypertensive treatment should be used as in any other pregnancy complicated by proteinuric hypertension

Figure 13.5 Changes that may follow an overdistended uterus with a multiple pregnancy

Figure 13.6 Twin fetuses at 16 weeks just before amniocentesis. Twin sacs are easily seen

ABC of Antenatal Care

(see Chapter 9), and the ultimate treatment of delivery may be required earlier than for singletons, a more difficult decision as preterm twin babies fare less well than do preterm singletons. A caesarean section is more frequently needed.

Figure 13.7 The greater area of placental implantation on the left of the uterus means that it may encroach on the lower segment

Anaemia

Commonly anaemia is reported as being more frequent in multiple than in singleton pregnancies. Some of this is due to the greater expansion in maternal blood volume with twins whereby the plasma increases more than the red cell bulk, so lowering the haemoglobin concentration. If the mean corpuscular haemoglobin concentration is used as a measure, anaemia is not more frequent in multiple pregnancies than in singletons provided that adequate nutrition and iron and folate intake are maintained. Greater demands of the growing fetuses for folate have led to some reports of megaloblastic anaemia, so folate supplements are commonly given.

Antepartum haemorrhage

Antepartum haemorrhage would be thought to be commoner in multiple pregnancy because of the greater surface area of the placental bed. The Aberdeen twin data set showed rates of antepartum haemorrhage in twin pregnancies to be 6% compared with 4.7% in singleton pregnancies ($p < 0.05$). Much of this difference, however, was made up of antepartum haemorrhage from unknown origin; only a few were caused by placental abruption or placenta praevia.

Intrauterine growth restriction

The growth of each fetus in multiple pregnancies mirrors that of the singleton until about 24 weeks of gestation; thence growth rates for most twins are still as for singletons but occasionally one or both may show a decrease. This is difficult to detect on clinical examination for polyhydramnios may cause imprecision in estimation of fetal size. Repeated serial ultrasound estimations of fetal size are the most useful way to check growth by plotting measurements of individual fetuses longitudinally through pregnancy. These data are not very different from the standard head or abdomen growth curves from singleton pregnancies until the last weeks. The estimation of fetal weight by various formulas based on the diameters of the fetus are not as useful in twin pregnancies as in the singleton.

Twin-to-twin transfusion

Twin-to-twin transfusion may be suspected when there is gross discordance in growth of a pair of twins or if there is

Figure 13.8 Growth of non-identical twins through pregnancy set against the mean (2 SD) singleton growth curve

Figure 13.9 Percentage frequency distribution of length of gestation for singleton and twin pregnancies

polyhydramnios with one twin and oligohydramnios with the other. About 20% of monozygotic twin pregnancies have vascular connections between the two circulations inside the placenta but the imbalance of flow occurs in few of these, probably only 1% of such pregnancies. Clinical signs of stealing circulating blood from one twin by the other occurs less commonly and usually associated with a change in amniotic fluid volume which is quite obvious with ultrasound. If twins of the same sex are diagnosed by about 20 weeks gestation, careful ultrasound examination is made to determine chorionicity by assessing the number of discrete placental masses and the thickness of the membranes and their angle of approach to the decidual bed—the Lambda sign. While this warns of potential anastomoses, it is not of necessity grounds for fetocide, for sometimes the twin-to-twin transfusion can be compensated. It should lead to extra surveillance of both mother and fetus for the rest of the pregnancy.

Laser ablation of the communicating vessels of the placenta with intrauterine amnioscopes and narrow beam YAG laser is used; amnioreductions by amniocentesis may also be helpful.

Onset of preterm labour

The median gestation for human singleton pregnancy is just over 40 weeks whereas that for twins is 37 weeks and that for triplets about 33 weeks. The commonest single cause of perinatal mortality in multiple pregnancies is low birth weight. Though intrauterine growth restriction might also be present, birth weight is low mostly because of a preterm delivery. A measure of this problem is seen in the 30% of all liveborn triplets and 60% of liveborn quadruplets who have to stay in a neonatal intensive care unit for more than a month after delivery. The incidence of preterm labour (before 37 weeks) in twin pregnancies ranges from 20 to 50% compared with from 5 to 10% in singleton pregnancies.

An important part of antenatal care for multiple pregnancy is trying to detect those women who are likely to go into early preterm labour and prevent this if possible; if not, ensuring that they are delivered in the correct surroundings with neonatal unit facilities to look after immature babies. Some obstetricians find the examination of the cervix from 28 weeks gives a clue to its increasing ripeness (length, firmness, and dilatation). This seems to be of more use in primiparous than multiparous women. Others assess the cervix with ultrasound, endeavouring to predict early labour.

An essential element lies in informing the mother; antenatal education of women with twins about the signs of early preterm labour may be helpful.

The greater stretch of the myometrium imposed by multiple pregnancy increases the risk of preterm labour and several measures have been tried in the antenatal period to prevent this. Sympathomimetic drugs such as ritodrine have been given prophylactically, but most controlled trials have shown no benefit of this in twin pregnancy. Cervical cerclage inserted when a twin pregnancy is diagnosed does not seem to confer any increased benefits. Some consider that coitus may tip the balance in a woman who is on the edge of going into preterm labour, because of both the mechanical stimulation and the release into the vagina of prostaglandin-rich fluid. The avoidance of coitus in later pregnancy by women with twin pregnancies, however, does not seem to be associated with any significant prolongation of gestation.

Management

Antenatal care of a woman with a multiple pregnancy needs more vigilance than that of a woman with a singleton

Figure 13.10 Birth weight distribution of singleton and multiple births

Figure 13.11 The extra stretch that twins place on the myometrium usually ensures that labour starts well before term

ABC of Antenatal Care

pregnancy. The woman with a multiple pregnancy will need more social support and advice for she is embarking on an extra load before, during, and after delivery. Her socioeconomic state and its implications should be explored. She needs to be seen more often and will require more ultrasound investigations. Care can be shared with the general practitioner in early pregnancy but after about 24 weeks many obstetricians would prefer the care to be where tests can take place—the hospital antenatal clinic.

Antenatal diagnosis of fetal problems in multiple pregnancy must be preceded by careful counselling. All twins should have a detailed ultrasound scan for anomalies at 18–20 weeks and preferably a detailed fetal cardiac scan at 22–24 weeks. At least monthly ultrasound scans in the last trimester should be performed to monitor fetal growth.

Blood pressure and urinary protein concentration are checked at each clinic, as is the symphysis-fundal height. Palpation is performed by an experienced doctor or midwife.

Because of the increased risk of pregnancy-induced hypertension, women carrying twins were traditionally admitted to hospital from 32 weeks to ensure bedrest. The other justification for this was that it postponed preterm labour and so prolonged pregnancy. It is now realised that antenatal time in bed in hospital is not always the best rest: home is more relaxing. Furthermore, it would be more logical to bring the woman into hospital from 24 to 30 weeks, rather than at a later stage of pregnancy. Neither of the desirable aims has been fulfilled in randomised controlled trials of hospital admission after 32 weeks. Though reports from previous decades seemed to show a benefit in one or other of these aims (preventing raised blood pressure or postponing early labour), truly randomised studies in the 1990s have been unable to show benefit. When the disadvantages of separating the woman from her household, as well as the cost to society, are considered, the disadvantages of a routine policy of hospital admission outweigh the advantages. A woman should be advised, however, to come into hospital at a much lower critical level if, in her individual case, specific symptoms arise. These might include the development of hypertension or the threat of early preterm labour. The woman should be made well aware of the warning signs of preterm labour (see Chapter 12) and be encouraged to come in on a low level of suspicion.

Determination of the exact lie and presentation of each twin is often difficult in the last weeks of pregnancy. In many ways detail is not vital but the examiner should ensure that the leading twin is longitudinal. Nearly always the head or a breech is the lower presenting part. In cases of doubt a vaginal examination will usually give a clearer idea for if a presenting part is in or above the pelvis it can be identified more easily by the vaginal examination than through the abdominal wall. Ultrasonography will always confirm lie and presentation.

Delivery should be in a unit with experienced and sufficient staff to look after the resuscitation of both babies.

Many labours are complicated by the presence of one twin as a breech (up to 50%). Monitoring of each twin separately is necessary. An epidural anaesthetic provides good pain relief and less delay if operative delivery is needed quickly. A full account appears in *ABC of Labour*.

Outcome

Multiple pregnancies have increased risks for both mother and fetuses. Perinatal mortality rates are about four times higher among twins than singletons, being higher still among monozygotic twins. Rates are even greater in triplets and

Figure 13.12 Frequency of antenatal visits

Box 13.2 Management of twin pregnancy

- Detailed ultrasound scan for abnormalities at 18–20 weeks
- Antenatal care at hospital clinic after 24 weeks
- More frequent antenatal visits
- Serial ultrasound scans to monitor fetal growth
- Watch for increased risk of maternal complications

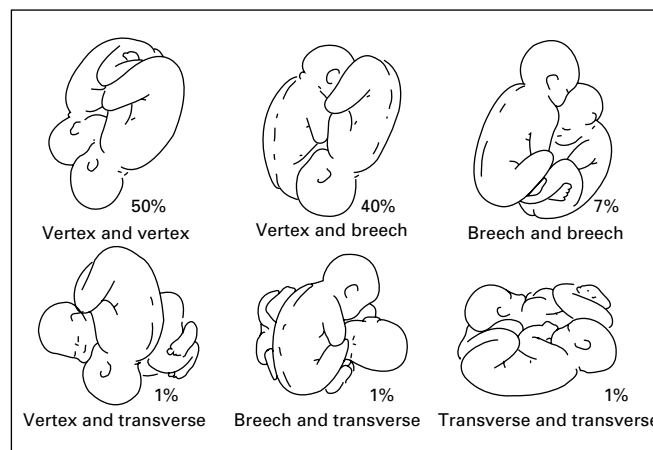

Figure 13.13 Lie and presentation of twins at the start of labour

Figure 13.14 Still birth and early neonatal death rates for singleton and multiple pregnancies (England and Wales, 1998)

quadruplets. About three quarters of the increased mortality is caused by immaturity following preterm delivery, by intrauterine growth restriction or by some combination of the two. The perinatal mortality rate for the second twin at vaginal deliveries is much higher than that of the first, depending on the skills of the professional in charge of the delivery. The perinatal mortality rates associated with antepartum haemorrhage, premature rupture of the membranes, and proteinuric hypertension are increased.

Though some of the increased perinatal mortality rate in twins can be reduced by careful delivery, a large component can be helped by good antenatal care. This includes diagnosing the multiple pregnancy early, carefully managing the woman throughout pregnancy, and either postponing early preterm labour or if it must, ensuring that it takes place in an appropriate hospital with a good neonatal unit.

Triplets and more

With the increasing use of ovarian stimulation and other assorted fertility techniques, more women are becoming

pregnant with higher multiples of fetus. All the complications that apply to twins can happen and more so. The risks are multiplied by the increased number; most triplets deliver before 35 weeks and usually by caesarean section. The survival to live birth of more than five fetuses is most unlikely and many doctors would advise fetal reduction down to two or three babies if the woman wishes this.

14 The audit of birth

Doctors are mostly literate but are commonly innumerate. We are largely ignorant and frightened of the safe and helpful use of figures because we have never been taught to understand them properly. We often try to dismiss them, believing that they are used during medical debate in a biased fashion to support the arguments of the proponents but are put to one side as non-relevant or non-significant by the opponents. This is a head in the sand attitude as statistics are extremely helpful in providing evidence of changes. Obstetricians should be well used to monitoring their activities statistically, having collected and published data long before the current fashion for audit started.

To be useful medical statistics must be:

- collected properly from a prescribed population;
- analysed in a valid fashion so as not to produce bias;
- presented promptly in a digestible, unbiased form.

Birth rates

The number of babies born is counted by two processes, birth registration and birth notification. These are two statutory obligations—registration by parents and notification by professional staff.

Birth rates are often expressed as a ratio of the number of births to the number of people in the existing population, gathered from the decennial census.

$$\text{Birth rate} = \frac{\text{No. of births} \times 1000}{\text{No. of people in the population}}$$

The birth rate in the UK in 1998 was 7.8 per 1000.

The denominator in this birth rate formula includes, however, men, who never give birth, and women under 15 and over 44, who are mostly outside the reproductive age group. Hence the denominator does not relate to the numerator very well; an alternative measure is more commonly used in the Western world:

$$\text{General fertility rate} = \frac{\text{No. of babies born} \times 1000}{\text{No. of women in the population aged 15-44}}$$

The general fertility rate in England and Wales in 1998 was 59 per 1000. International comparisons are harder because only countries with good census systems can break down population data to determine the number of women aged 15-44.

For the less numerically minded, completed family size is a user friendly statistic: we can all imagine the size of a family. Unfortunately, these data depend on uncertain estimates and are usually produced some years after the women concerned have passed their reproductive years and completed their family. Obviously, to increase any population the number in a family needs to be more than two. In much of western Europe it is 1.7 to 2.2, whereas in Kenya it is 6.9, showing a rapidly increasing population.

Perinatal mortality

Deaths of babies around the time of birth are assessed by three sets of statistics.

(1) Stillbirths or late intrauterine deaths occur when a child is delivered after the 24th completed week of pregnancy but shows no signs of life at birth:

$$\text{Stillbirth rate} = \frac{\text{No. of babies born dead after 24 weeks} \times 1000}{\text{Total births (live and stillborn)}}$$

Figure 14.1 Birth rates in England and Wales, 1955-2000

Figure 14.2 General fertility rates in England and Wales, 1840-2000

Figure 14.3 Completed family size

The stillbirth rate for England and Wales in 1998 was 5.3 per 1000 total births.

(2) Neonatal death is recorded when babies who are born alive (regardless of gestation) die in the first 28 days of life; early neonatal deaths refer to babies who die in the first seven days after birth. All babies who die in the first year of life are recorded as infant deaths but those who die after the first four weeks are defined as postneonatal deaths.

$$\text{Neonatal death rate} = \frac{\text{No. of babies dying between 1-28 days} \times 1000}{\text{No. of live births}}$$

Figure 14.5 Neonatal mortality rates in England and Wales, 1983–97

The neonatal death rate for England and Wales in 1998 was 3.8 per 1000 live births.

(3) In the past 50 years perinatal mortality rates have been used to group together all babies whose deaths may have some relation to obstetric events; thus all stillbirths and neonatal deaths in the first week after birth are considered.

$$\text{Perinatal mortality rate} = \frac{\text{Stillbirths} + \text{neonatal deaths in the first 7 days} \times 1000}{\text{Total births (live and stillborn)}}$$

The perinatal mortality rate in England and Wales in 1998 was 7.9 per 1000 total births.

There is some degree of dissatisfaction with the use of perinatal mortality rates as an index of obstetric performance. Many babies born early now survive in neonatal units. Others with congenital lethal malformations may be kept alive in such units until the second or third week and so are not included in the perinatal mortality rate. We may return to looking at stillbirth rates and neonatal death rates as separate statistics. In 1992 in the UK, the gestation stage for viability was reduced from 28 to 24 weeks and so rates increased slightly around this time—a statistical but not a real blip.

The perinatal mortality rate has fallen steadily since the second world war. When data are compared from different countries, rates are falling in most of them at about the same rate, though some countries start worse off and stay there. This reflects the influence of socioeconomic factors and patterns of reproduction more than the quality of obstetric facilities. A similar pattern can be seen to a smaller extent in the regions of the UK.

The three main causes of perinatal mortality in the UK are low birth weight, hypoxia, and congenital abnormalities. Unfortunately, even after careful reexamination of notes and autopsy, some 70% of stillbirths are unexplained. Low birth weight is currently one of the biggest problems in the Western world (see Chapters 11 and 12). Hypoxia is mostly a problem of

Figure 14.4 Stillbirth rates in England and Wales, 1983–97

Figure 14.6 Perinatal mortality rates in England and Wales, 1983–97

Figure 14.7 Early neonatal mortality rates (≤ 7 days) in the 12 countries of the then European community. (Source: Europe en Chiffers, Eurostat Office 1995)

Figure 14.8 Perinatal mortality by father's social class 1979–95. (Source: ONS Mortality Statistics, DH3 series)

labour and to some extent is improved by monitoring women at high risk. Congenital abnormalities may be detected at antenatal examination (see Chapter 5) but the real cure of this problem would be to prevent malformations rather than to detect them and then abort the fetus.

Perinatal mortality rates are not a valid measure of obstetric or midwifery performance. In a developed society they are a mixed measure of a country's educational, social, nutritional, and public health systems as well as of obstetric acute medicine. The rate of deaths in the UK by socioeconomic class of the father has narrowed over the years but still in 1995 PNMR of Social Class I was 6.9 compared with 12.2 in Social Class V, almost double. Probably only a third of the improvement in perinatal mortality statistics is due to improvements in medicine and midwifery. The rest is due to social and economic factors.

A nationwide examination of stillbirths and neonatal deaths together with infant deaths has now been developed, the Confidential Enquiry into Stillbirths and Deaths in Infancy. Reports are made to the regional centres and concentrated in the Health Departments whence they are published each year.

Maternal mortality

Maternal deaths are rare in the Western world but this is not so everywhere: in Kenya a woman has a chance as high as one in 20 of dying during one of her several pregnancies.

Maternal death usually refers to a woman dying in pregnancy, childbirth, or within 42 days of the end of pregnancy. In many countries, including the UK, it includes deaths after an abortion or an ectopic pregnancy but in some countries it does not. The definition in Britain used to include deaths up to one year but has now come in line with World Health Organisation recommendations.

$$\text{Maternal death rate} = \frac{\text{Deaths in pregnancy, childbirth and 6 weeks afterwards} \times 1000}{\text{Total maternities}}$$

Maternal death rates in the UK did not reduce in this century as swiftly as did the rates of perinatal death. Until the mid-1930s maternal mortality was the same as it had been in Victorian times. With the development of antibiotic therapy the rates of puerperal sepsis reduced; to this was added the improvements brought by a proper blood transfusion service catalysed by the Second World War. The founding of the colleges of midwives and obstetricians organised professional training and standards, and the unification of the antenatal and delivery services in the new NHS helped further.

International statistics on maternal mortality are less easy to determine in a comparable way as different countries have different exclusions. In general, however, maternal mortality is an index of medical and midwifery care more than are the perinatal mortality rates. Maternal death rates by region and by country within the UK also vary but differently from perinatal mortality rates.

In Britain the Confidential Enquiry into Maternal Deaths has been set up to provide information about maternal deaths. A complete case history of each maternal death is obtained and published triennially by the Department of Health, keeping all information confidential. The reports are published from the whole UK rather than separately for the four kingdoms.

The maternal mortality in the UK was reported to be 7.4 per 100 000 in 1994–96; principal causes of maternal death in

Figure 14.9 The proportions of babies in different birth weight bands have altered little in the past 30 years

England and Wales are hypertension and pulmonary embolism. To reduce the toll of hypertension the inquiry committee recommends that in each region there should be one or two hospitals with staff skilled at looking after pregnant hypertensive mothers and their fetuses. Women with severe degrees of this condition should be electively transferred to these centres. Pulmonary embolism commonly follows popliteal or pelvic vein thrombosis, which should be watched for, particularly in the puerperium after an operative delivery. An active policy of thromboprophylaxis could reduce this cause of death.

Other major killers in the past were infection and haemorrhage; currently these are much reduced. It must give satisfaction to those who fought for the Abortion Act of 1967 to find that in the last five triennia reported by the confidential inquiry committee (1982–96) there was not a single death from illegal abortion in England and Wales.

Near misses

An audit of serious complications such as haemorrhage over 1000 ml or pulmonary embolism in women who do not die gives an index of morbidity. Such near misses are harder to identify and collect but may be used in local audit. Definitions should be agreed and data collection should be prompt.

Conclusion

Too many doctors think of vital statistics in terms of Disraeli's, "Lies, damn lies and statistics".

Perhaps they should look at statistics in the same way as did Richard Asher: "When something can be expressed in a numerical way, it is an aid to precise and accurate thinking".

Most of the data in England and Wales are derived from the old Office of Population Censuses and Surveys, now the Office for National Statistics. The data on maternal mortality come from the Confidential Enquiries into Maternal Deaths for the UK and those of perinatal data from the Confidential Enquiry into Stillbirths and Deaths in Infancy for England and its parallel body in Wales.

Table 14.2 Major causes of maternal death (UK 1994–96)

		Rate per million maternities
Direct	Thromboembolism	21.8

L'envoi

Patterns of antenatal care shifted more in the last years of the 20th century than ever before. Less frequent visits for women with normal pregnancies and a wider sharing of professional responsibility are overtaking the hospital dominated and regimented patterns of the middle of the last century.

The development of antenatal care reflects what has happened in all of medicine—first came the clinical observations, then the mounting of investigations, each supported by some scientific pedigree, and only later a guilty sideways look at what value these all provided. In an ideal world all the investigations would have been subjected to rigorous scrutiny—randomised controlled trials and careful checks of sensitivity and specificity—but such intellectual disciplines were introduced after many of the antenatal tests had been started. We did not await the more scientifically assessed investigation because babies were still being born and women still needed to know. Meanwhile, we do the best with what we have. Clinical management should reflect the results of research studies and must depend in future more upon evidence based research promptly delivered.

If we were to see women in appropriate circumstances and make proper use of the proven valuable tests we already have, much effort and money would be saved. We could spend more time listening to and talking with the women we care for. The golden age of antenatal care would then have arrived.

Preface

The seeds for this book were sown with the establishment of the haemostasis, thrombosis and vascular biology unit at the university department of medicine, City Hospital, Birmingham—with the coming together of clinicians and scientists interested in thrombosis and vascular biology, bridging the previous divide in thrombosis between basic science research and the application to clinical practice. Indeed, thrombosis is the underlying pathophysiological process in a wide variety of conditions. A greater understanding of the mechanisms leading to thrombosis, and newer developments in the field of antithrombotic therapy make the field all the more dynamic and exciting.

The multidisciplinary team effort and the wide range of research areas studied in our unit forms the core content of the *ABC of Antithrombotic Therapy*. In major textbooks on thrombosis the scope is comprehensive, background details on physiology and pathophysiology are abundant, and treatment options are listed to exhaustion—the patient may sometimes almost disappear in the wealth of information. Our approach in this book—typical of the ABC series in the *British Medical Journal*—tries to synthesise and integrate the extensive research and clinical data that are needed to manage a particular situation as masterly as it is possible. We hope we have produced a patient-oriented guide with relevant information from clinical epidemiology, pathophysiology, common sense clinical judgement, and evidence based treatment options, with reference to recently published antithrombotic therapy guidelines from the American College of Chest Physicians, British Society for Haematology, European Society of Cardiology, American College of Cardiology, and American Heart Association.

Our expectant readers are physicians, general practitioners, medical or nursing students, nurses, and healthcare scientists who care for patients presenting with thrombosis-related problems, and thus, the scope is necessarily wide, ranging from venous thromboembolism to atrial fibrillation and stroke, and to thrombosis in cancer and thrombophilic states. Chapters on clinical pharmacology and bleeding risk, as well as anticoagulation monitoring are included. Furthermore, this book includes additional chapters which were not included in the 14 issues of this series when it first appeared in the *British Medical Journal*.

We thank our excellent colleagues for their help, encouragement and contributions, as well as Sally Carter at BMJ Books for encouraging us to complete the series and book, nearly to schedule.

1 An overview of antithrombotic therapy

Andrew D Blann, Martin J Landray, Gregory Y H Lip

Many of the common problems in clinical practice today relate to thrombosis. The underlying final pathophysiological process in myocardial infarction and stroke is thrombus formation (thrombogenesis). Common cardiovascular disorders such as atrial fibrillation and heart failure are also associated with thrombogenesis. Thrombosis is also a clinical problem in various cancers and after surgery, especially orthopaedic.

Pathophysiology

Over 150 years ago Virchow recognised three prerequisites for thrombogenesis: abnormal blood flow, vessel wall abnormalities, and blood constituent abnormalities. This concept has been extended by modern knowledge of the endothelial function, flow characteristics, and blood constituents including haemorrhological factors, clotting factors, and platelet physiology. As thrombus consists of platelets and fibrin (and often bystander erythrocytes and white blood cells), optimum antithrombotic prophylactic therapy can and should be directed towards both.

Antiplatelet drugs

Aspirin and agents acting on the cyclo-oxygenase pathway

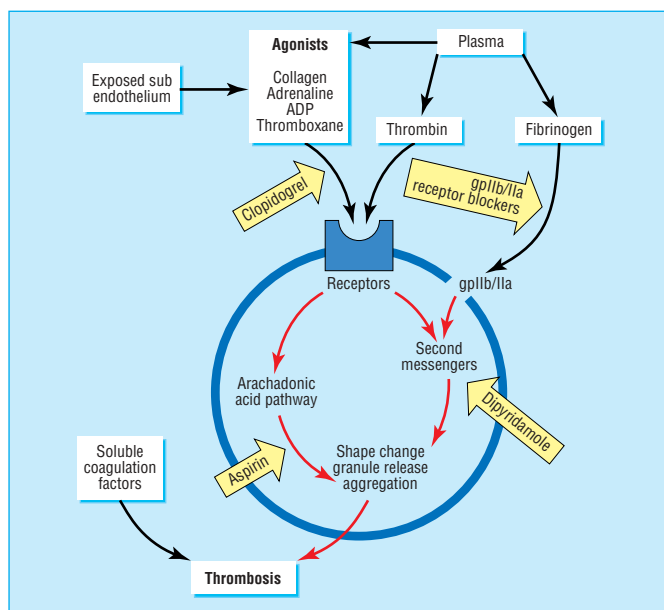

Aspirin irreversibly inhibits cyclo-oxygenase by acetylation of amino acids that are next to the active site. In platelets, this is the rate limiting step in synthesis of thromboxane A_2 , and inhibition occurs in the megakaryocyte so that all budding platelets are dysfunctional. Because platelets are unable to regenerate fresh cyclo-oxygenase in response, the effect of aspirin remains as long as the lifespan of the platelet (generally about 10 days). A severe weakness of aspirin is that its specificity for cyclo-oxygenase means it has little effect on other pathways of platelet activation. Thus aspirin fails to prevent aggregation induced by thrombin and only partially inhibits that induced by ADP and high dose collagen. Antithrombotic doses used in clinical trials have varied widely from less than 50 mg to over 1200 mg/day, with no evidence of any difference in clinical efficacy. Absorption is over 80% with extensive presystemic metabolism to salicylic acid. Only the parent acetylsalicylic acid has any significant effect on platelet function.

Adverse effects of aspirin include haemorrhage, hypersensitivity and skin rashes, alopecia, and purpura.

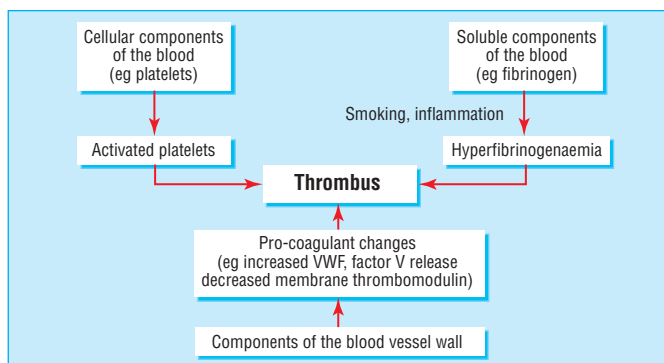

Sulfinpyrazone also inhibits cyclo-oxygenase (thus producing an aspirin-like state), but is reversible, and also inhibits serotonin uptake by platelets. Iloprost is a prostacyclin analogue that exerts its effects by promoting vasodilatation and inhibiting platelet aggregation induced by ADP, thereby opposing the effects of thromboxane A_2 .

Dipyridamole

Dipyridamole inhibits phosphodiesterase, thus preventing the inactivation of cyclic AMP, intraplatelet levels of which are increased, resulting in reduced activation of cytoplasmic second messengers. However, it may also exert its effect in other ways, such as stimulating prostacyclin release and inhibiting thromboxane A_2 formation. The influence of this drug on these pathways causes reduced platelet aggregability and adhesion in

Routes to inhibiting platelet function

Key components of Virchow's triad (VWF= von Willebrand factor)

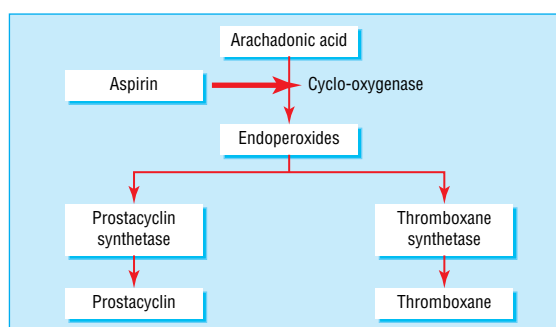

Contraindications to aspirin

Absolute

- Active gastrointestinal ulceration
- Hypersensitivity
- Thrombocytopenia

Relative

- History of ulceration or dyspepsia
- Children under 12 years old
- Bleeding disorders
- Warfarin treatment

Platelet metabolism influenced by aspirin

ABC of Antithrombotic Therapy

vitro with increased platelet survival in vivo. Its effect is relatively short lasting, and repeated dosing or slow release preparations are needed to achieve 24 hour inhibition of platelet function.

Clopidogrel and ticlopidine

These thienopyridine derivatives inhibit platelet aggregation induced by agonists such as platelet activating factor and collagen, and also dramatically reduce the binding of ADP to a platelet surface purinoreceptor. The mechanism of this inhibitory action seems to be independent of cyclo-oxygenase. There is also impairment of the platelet response to thrombin, collagen, fibrinogen, and von Willebrand factor. The peak action on platelet function occurs after several days of oral dosing. Adverse effects include evidence of bone marrow suppression, in particular leucopenia, especially with ticlopidine.

Other receptor blockers

Signal transduction generally occurs when specific receptors on the surface are occupied by ligands such as ADP, leading to structural modification of the glycoprotein IIb/IIIa receptor on the surface of the platelet. This is the commonest receptor on the platelet surface and represents the final common pathway for platelet aggregation, resulting in crosslinking of platelets.

After intravenous administration of glycoprotein IIb/IIIa receptor inhibitors such as abciximab, platelet aggregation is 90% inhibited within two hours, but function recovers over the course of two days. The major adverse effect is haemorrhage, and concurrent use of oral anticoagulants is contraindicated. Eptifibatid is a cyclic heptapeptide that mimics the part of the structure of fibrinogen that interacts with glycoprotein IIb/IIIa. Thus it is a fraction of the size of abciximab and is targeted at the same structure on the platelet surface.

Clinical trials with oral glycoprotein IIb/IIIa receptor inhibitors have been disappointing, with no beneficial effects seen and even some evidence of harm.

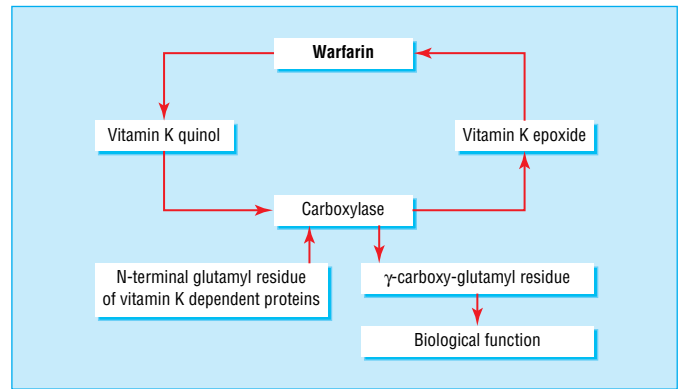

Anticoagulant drugs

Warfarin

This 4-hydroxycoumarin compound, the most widely used anticoagulant in Britain and the Western world, inhibits the synthesis of factors dependent on vitamin K (prothrombin; factors VII, IX, and X; protein C; protein S). Factor VII levels fall rapidly (in < 24 hours) but factor II has a longer half life and only falls to 50% of normal after three days. Warfarin is approximately 97% bound to albumin, and free warfarin enters liver parenchymal cells and is degraded in microsomes to an inactive water soluble metabolite that is conjugated and excreted in the bile. Partial reabsorption is followed by renal excretion of conjugated metabolites.

There is a considerable variability in warfarin's effect on patients, its effectiveness being influenced by age, racial background, diet, and co-medications such as antibiotics. Thus it demands frequent laboratory monitoring, the prothrombin time being compared with a standard to produce the international normalised ratio. The degree of anticoagulation required varies with clinical circumstance, but the target international normalised ratio usually ranges from 2 to 4. Phenindione is an alternative oral vitamin K antagonist, but concerns regarding the potential for hepatotoxicity, nephrotoxicity, and blood dyscrasias have reduced its role largely to individuals with documented hypersensitivity to warfarin.

Adverse effects of warfarin include haemorrhage, hypersensitivity and skin rashes, alopecia, and purpura.

Vitamin K metabolism and the effect of warfarin

Factors that influence the efficacy of warfarin*

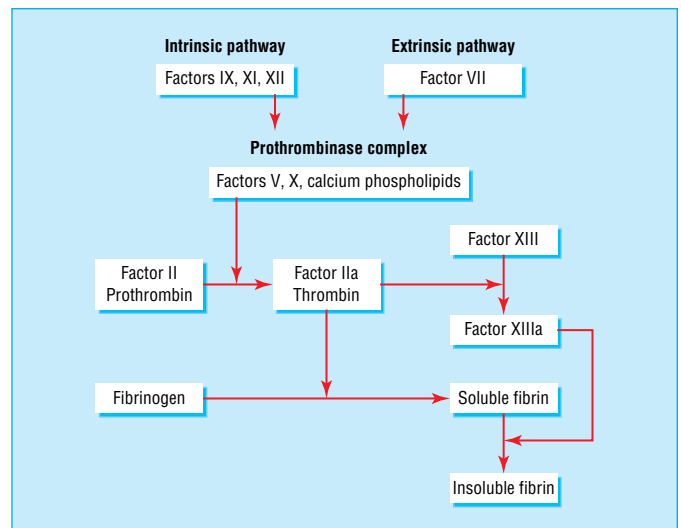

Patient factors

- *Enhanced anticoagulant effect*—Weight loss, increased age (> 80 years), acute illness, impaired liver function, heart failure, renal failure, excess alcohol ingestion
- *Reduced anticoagulant effect*—Weight gain, diarrhoea and vomiting, relative youth (< 40 years), Asian or African-Caribbean background

Examples of drug interactions with warfarin

- *Reduced protein binding*—Aspirin, phenylbutazone, sulfinpyrazone, chlorpromazine
- *Inhibition of metabolism of warfarin*—Cimetidine, erythromycin, sodium valproate
- *Enhanced metabolism of warfarin*—Barbiturates, phenytoin, carbamazepine
- *Reduced synthesis of factors II, VII, IX, X*—Phenytoin, salicylates
- *Reduced absorption of vitamin K*—Broad spectrum antibiotics, laxatives
- *Enhanced risk of peptic ulceration*—Aspirin, NSAIDs, corticosteroids
- *Thrombolytics*—Streptokinase, tissue plasminogen activator
- *Antiplatelet drugs*—Aspirin, NSAIDs

*This list is intended to be illustrative not exhaustive

Simplified coagulation cascade

Melagatran

This oral thrombin inhibitor undergoing phase III trials seems to be well tolerated, with few clinically significant bleeding problems, in patients with venous thromboembolism. Although considerable pharmacokinetic and animal data exist, solid evidence of its effectiveness compared with warfarin and heparin in patients at high or low risk is still awaited.

Heparin

Heparin is a glycosaminoglycan whose major anticoagulant effect is accounted for by a pentasaccharide with a high affinity for antithrombin III. This binding results in a conformational change in antithrombin III so that inactivation of coagulation enzymes thrombin (IIa), factor IXa, and factor Xa is markedly enhanced. Its short half life means it must be given continuously, and its extensive first pass metabolism means it must be given parenterally, preferably by continuous intravenous infusion, and it is therefore inappropriate for home use. The effect on the intrinsic clotting cascade must be monitored carefully by measuring the activated partial thromboplastin time (APTT), generally aiming for a value 1.5 to 2.5 times that of control.

Unfractionated heparin consists of a heterogeneous mixture of polysaccharides with an average molecular weight of 15 000 Da. Low molecular weight heparins (4000-6000 Da) are weaker inhibitors of thrombin but inhibit factor Xa to a similar extent. Different commercial preparations of low molecular weight heparin vary in the ratio of anti-Xa to antithrombin activity, although the clinical relevance of this is uncertain. Better absorption after subcutaneous administration and reduced protein binding result in greatly improved bioavailability. The effective half life after subcutaneous injection is four hours, allowing an injection once daily in most circumstances. These more predictable pharmacokinetics allow the dose to be calculated on the basis of the patient's weight and reduce the requirement for frequent monitoring. In those rare cases where monitoring is deemed necessary, measurement of plasma levels of anti-Xa activity is needed. Tests of APTT are unhelpful.

Major adverse effects of heparin include haemorrhage, osteoporosis, alopecia, thrombocytopenia, and hypersensitivity. At present, the risk of haemorrhage seems to be similar with low molecular weight and unfractionated heparin. However, the risk of heparin induced thrombocytopenia seems to be less with the low molecular weight form.

Hirudin and direct thrombin inhibitors

Hirudin, a 65 amino acid residue anticoagulant peptide with a relative molecular mass of 7000 Da purified from the leech *Hirudo medicinalis*, binds thrombin with high specificity and sensitivity. With a true half life of about an hour and a half life effect on the APTT of two to three hours, it may be seen as an alternative to heparin in indications such as unstable angina and in coronary angioplasty.

Many derivatives are available, with hirulog and argatroban among the best developed. However, trials of the former have been discouraging: no clear benefit over heparin was shown. Conversely, argatroban may have a role in the anticoagulation of patients unable to tolerate heparin as a result of heparin induced thrombocytopenia. Furthermore, in a clinical trial of patients with heparin induced thrombocytopenia, use of argatroban was associated with a reduction in levels of plasma platelet activation markers.

Thrombolytic agents

These agents lyse pre-existing thrombus, either by potentiating the body's own fibrinolytic pathways (such as streptokinase) or

The three low molecular weight heparins that have been evaluated in clinical trials of acute coronary syndromes are shown with their respective anti-Xa and antithrombin activity (PF4=platelet factor 4)

Comparison of low molecular weight and unfractionated heparins

	Unfractionated heparin	Low molecular weight heparin
Action	Anti-XIIa, XIa, IXa, VIIa, antithrombin	Mostly anti-Xa
Route of administration	Subcutaneous Intravenous	Subcutaneous
Absorption from subcutaneous route	Slow	Improved
Protein binding	Proteins in plasma and on endothelium	Reduced
Bioavailability	Subcutaneous—10-30% at low doses, 90% at higher doses Intravenous—100% by definition	>90%
Effective half life	Subcutaneous—1.5 hours Intravenous—30 min	4 hours
Between and within individual variation	Extensive	Minimal
Monitoring	APTT	Not required (anti-Xa activity)
Elimination	Liver and kidney	Kidney

ABC of Antithrombotic Therapy

by mimicking natural thrombolytic molecules (such as tissue plasminogen activator). The common agents in clinical use are derived from bacterial products (streptokinase) or manufactured using recombinant DNA technology (recombinant tissue plasminogen activator). Newer drugs aim to be less antigenic and more thrombus specific in an attempt to increase efficacy and specificity of various agents; on present evidence, however, the differences between thrombolytic agents are only marginal. Because of the lack of site specificity for these drugs, the major adverse effect is that of haemorrhage (gastrointestinal, intracranial, etc). The other important adverse effect is that of hypersensitivity reaction, especially with streptokinase. This usually manifests as flushing, breathlessness, rash, urticaria, and hypotension. Severe anaphylaxis is rare. Hypersensitivity reactions are avoided by using tissue plasminogen activator or recombinant tissue plasminogen activator, which are not antigenic.

Streptokinase

Derived from streptococci, this product is an effective thrombolytic agent for the treatment of acute myocardial infarction and pulmonary thromboembolism. Acting by converting plasminogen to plasmin, the main fibrinolytic enzyme, it potentiates fibrinolysis. However, it is not site specific, lysing thrombus anywhere in the body. Being bacteria derived, it is antigenic, and repeated administration results in neutralising antibodies and allergic reactions. For example, a single administration of 1.5 MU for acute myocardial infarction results in neutralising antibodies that have been shown to persist for up to four years and are sufficient to neutralise a repeat administration of a similar dose of the agent in half of cases.

Tissue plasminogen activator

In clinical use this is produced by recombinant DNA technology and mimics an endogenous molecule that activates the fibrinolytic system. Thus, recombinant tissue plasminogen activator does not elicit an allergic response and is considered more clot specific. Nevertheless, it has a short half life and needs continuous infusion to achieve its greatest efficacy. Accelerated administration of tissue plasminogen activator gives a slight mortality advantage over streptokinase at the cost of a marginal increase in stroke rate.

Fibrinolytic drugs

Examples	Source	Mechanism of action
Streptokinase	Group C β haemolytic streptococci	Complexes with and activates plasminogen
Urokinase	Trypsin-like chemical produced by kidney	Direct acting plasminogen activator
Reteplase (recombinant tissue plasminogen activator)	Recombinant DNA technology	Activates plasminogen, non-immunogenic

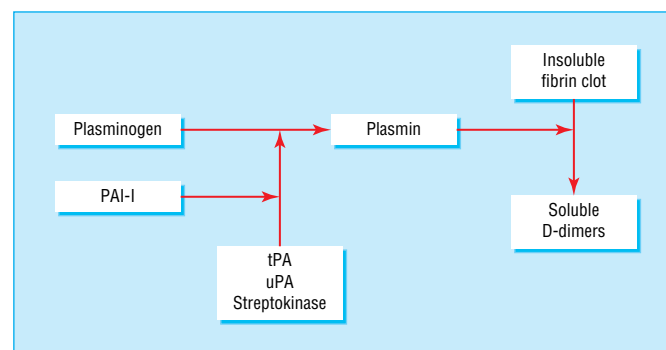

Contraindications to thrombolysis

Absolute

- Recent or current haemorrhage, trauma, or surgery
- Active peptic ulceration
- Coagulation defects
- Oesophageal varices
- Coma
- Recent or disabling cerebrovascular accident
- Hypertension
- Aortic dissection

Relative

- Previous peptic ulceration
- Warfarin
- Liver disease
- Previous use of anistreplase or streptokinase within four years (use alternative agent)
- Hypersensitivity (anistreplase, streptokinase)
- Heavy vaginal bleeding

Simplified fibrinolysis (PAI-1=plasminogen activator inhibitor, tPA=tissue plasminogen activator, uPA=urokinase plasminogen activator)

2 Bleeding risks of antithrombotic therapy

David A Fitzmaurice, Andrew D Blann, Gregory Y H Lip

Many of the common cardiovascular disorders (especially in elderly people) are linked to thrombosis—such as ischaemic heart disease, atrial fibrillation, valve disease, hypertension, and atherosclerotic vascular disease—requiring the use of antithrombotic therapy. This raises questions regarding the appropriate use of antithrombotic therapy in older people, especially because strategies such as anticoagulation with warfarin need regular monitoring of the international normalised ratio (INR), a measure of the induced haemorrhagic tendency, and carry a risk of bleeding. The presence of concomitant physical and medical problems increases the interactions and risks associated with warfarin, and anticoagulation in elderly patients often needs an assessment of the overall risk:benefit ratio.

Physical frailty in elderly people may reduce access to anticoagulant clinics for INR monitoring. The decline in cognitive function in some elderly patients also may reduce compliance with anticoagulation and the appreciation of bleeding risks and drug interactions. However, in recent studies of anticoagulation in elderly people, no significant associations of anticoagulant control were found with age, sex, social circumstances, mobility, domiciliary supervision of medication, or indications for anticoagulation.

Warfarin

Bleeding is the most serious and common complication of warfarin treatment. For any given patient, the potential benefit from prevention of thromboembolic disease needs to be balanced against the potential harm from induced haemorrhagic side effects.

Minor bleeds

Most bleeding problems are clinically minor, although patients are unlikely to view such bleeds in these terms. The problems include nose bleeds, bruising, and excessive bleeding after minor injury such as shaving. Patients should be made aware of these common problems and be reassured that these events are expected in patients receiving warfarin treatment. Menorrhagia is surprisingly rare as a major clinical problem, even though it can be severe.

More serious problems

Patients need access to medical care if they have serious problems. Such problems are generally due to a high INR. Usually, spontaneous bruising, any bleeding that is difficult to arrest, frank haematuria, any evidence of gastrointestinal bleeding, and haemoptysis, need urgent assessment. The definition of minor or major bleeding lacks clarity: in many cases the patient presents with a concern that may need follow up, and a minor bleed can only be defined as such in retrospect. In most cases, evidence of bleeding suggests some underlying pathology but may also be due to drug interactions. For example, a patient with recurrent haemoptysis may be found to have hereditary telangiectasia. Further investigation of the cause of bleeding should always be considered, particularly if the bleeding is recurrent. It is also important in these instances to check for concomitant drug use, particularly drugs received over the counter. Patients should be aware that aspirin and

Questions to ask when considering oral anticoagulation

- Is there a definite indication (such as atrial fibrillation)?
- Is there a high risk of bleeding or strong contraindication against anticoagulation?
- Will concurrent medication or disease states increase bleeding risk or interfere with anticoagulation control?
- Is drug compliance and attendance at anticoagulant clinic for monitoring likely to be a problem?
- Will there be regular review of the patient, especially with regard to risks and benefits of anticoagulation?

$$\text{INR} = \left(\frac{\text{patient's prothrombin time}}{\text{mean normal time}} \right)^{\text{ISI}}$$

ISI=international sensitivity ratio. The mean normal prothrombin time is often generated from samples from local healthy subjects or a commercially available standard. The exact value of the ISI depends on the thromboplastin used in the prothrombin time method

Purpura, petechiae, and haematoma secondary to over-anticoagulation

Sudden, unexplained changes to the efficacy of warfarin may be caused by the consumption of over the counter multivitamin tablets or foodstuffs that contain high levels of vitamin K

ABC of Antithrombotic Therapy

non-steroidal anti-inflammatory drugs are particularly dangerous in combination with warfarin; however, even supposedly safe drugs such as paracetamol can affect a patient's bleeding tendency.

Incidence of bleeding problems

The incidence of severe bleeding problems that may bring patients to an accident and emergency unit has probably been overestimated. The annual incidence of fatality caused by warfarin administration has been estimated to be 1%. However, this is based on old data, and, although difficult to prove, the overall improvement in anticoagulation control in the past 10-15 years means that a more realistic figure is about 0.2%. Methodological problems have hampered the interpretation of previously reported data, particularly with regard to definitions of major and minor bleeding episodes, with some investigators accepting hospital admission for transfusion of up to 4 units of blood as being "minor." Certainly, the most serious "major" bleed is an intracranial haemorrhage. Reviews of observational and experimental studies showed annual bleeding rates of 0-4.8% for fatal bleeding and 2.4-8.1% for major bleeds. Minor bleeds are reported more often, with about 15% of patients having at least one minor event a year.

Risk factors for bleeding

Age is the main factor that increases risk of bleeding. One study showed a 32% increase in all bleeding and a 46% increase in major bleeding for every 10 year increase above the age of 40.

Early studies suggested an increased risk with increasing target INR, but the data were difficult to interpret because results were reported in both INR and prothrombin time. The actual risk of bleeding should be taken into account as well as the degree of anticoagulation (as measured by the INR). One study which achieved point prevalence of therapeutic INRs of 77% reported no association between bleeding episodes and target INR.

Data from an Italian study in 2745 patients with 2011 patient years of follow up reported much lower bleeding rates, with an overall rate of 7.6 per 100 patient years. The reported rates for fatal, major, and minor bleeds were 0.25, 1.1, and 6.2 per 100 patient years respectively. This study confirmed an increased risk with age and found a significantly increased risk during the first 90 days of treatment. Peripheral vascular and cerebrovascular disease carried a higher relative risk of bleeding, and target INR was strongly associated with bleeding with a relative risk of 7.9 (95% confidence interval 5.4 to 11.5, $P < 0.0001$) when the most recent INR recorded was > 4.5 . Data from a trial in a UK community showed 39.8 minor, 0.4 major, and no fatal haemorrhagic events per 100 patient years for the total study population, with 3.9 serious thromboembolic events per 100 patient years, of which 0.79 were fatal.

Warfarin is therefore a relatively safe drug, particularly if therapeutic monitoring is performed well. Analogies are often made between therapeutic monitoring of warfarin and monitoring of blood glucose for diabetic patients. Given the increase in numbers of patients receiving warfarin, particularly for atrial fibrillation, the scale of the problem is likely to be the same. There is no reason why warfarin monitoring cannot become as routine as glucose monitoring in diabetes: relevant small machines are available for generating an INR (with associated standards and quality control).

Overanticoagulation

Excessive anticoagulation without bleeding or with only minor bleeding can be remedied by dose reduction or discontinuation. The risk of bleeding is decreased dramatically by lowering the intended INR from 3-4.5 down to 2-3, although this increases

Patients at high risk of bleeding with warfarin

- Age > 75 years
 - History of uncontrolled hypertension (defined as systolic blood pressure > 180 mm Hg or diastolic blood pressure > 100 mm Hg)
 - Alcohol excess (acute or chronic), liver disease
 - Poor drug compliance or clinic attendance
 - Bleeding lesions (especially gastrointestinal blood loss, such as peptic ulcer disease, or recent cerebral haemorrhage)
 - Bleeding tendency (including coagulation defects, thrombocytopenia) or concomitant use of non-steroidal anti-inflammatory drugs and antibiotics
 - Instability of INR control and INR > 3
-

Computed tomography scan showing intracerebral haemorrhage

Risk of bleeding associated with warfarin treatment

- Rate of bleeding episodes associated in the general patient population is decreasing (possibly due to better management)
 - Risk increases with age
 - Risk of bleeding is directly related to the achieved intensity of INR rather than the target INR (a clear dose-response effect)
 - Temporal association between measured INR and risk of bleeding
 - Relative risk of bleeding is increased in patients with cerebrovascular disease and venous thrombosis
-

the risk of thrombosis. If bleeding becomes substantial, 2-5 mg of oral or subcutaneous vitamin K may be needed. In patients with prosthetic valves, vitamin K should perhaps be avoided because of the risk of valve thrombosis unless there is life threatening intracranial bleeding. Alternatives to vitamin K include a concentrate of the prothrombin group of coagulation factors including II, IX, and X, fresh frozen plasma 15 ml/kg, and recombinant factor VIIa.

Aspirin

Aspirin has little effect in terms of bruising but can cause serious gastrointestinal bleeding. The risk of gastrointestinal bleeding is related to dose and should not be problematic at doses of 75 mg/day given as thromboprophylaxis. There is currently no consensus as to optimal dose of aspirin for stroke prevention in atrial fibrillation. A meta-analysis of randomised controlled trials using aspirin showed that a mean dose of 273 mg/day, increased absolute risk of haemorrhagic stroke to 12 events per 10 000 people. This relatively small increase must be weighed against the reduced risk of myocardial infarction (to 137 events per 10 000) and ischaemic stroke (to 39 events per 10 000). However, in one trial of patients with well controlled hypertension, use of aspirin 75 mg prevented 1.5 myocardial infarctions per 1000 patients a year, which was in addition to the benefit achieved by lowering the blood pressure, with no effect on stroke. Although there was no increase in the number of fatal bleeding events (seven in patients taking aspirin, compared with eight in the placebo group), there was a 1.8% increase in non-fatal, major bleeding events (129 events in patients taking aspirin, compared with 70 in the placebo group) and minor bleeds (156 and 87, respectively).

Risk of bleeding

There have been conflicting results concerning the role of age as an independent risk factor for haemorrhage induced by anticoagulants. Advanced age (>75 years), intensity of anticoagulation (especially INR >4), history of cerebral vascular disease (recent or remote), and concomitant use of drugs that interfere with haemostasis (aspirin or non-steroidal anti-inflammatory drugs) are probably the most important variables determining patients' risk of major life threatening bleeding complications while they are receiving anticoagulation treatment.

Generally elderly people have increased sensitivity to the anticoagulant effect of warfarin, and require a lower mean daily dose to achieve a given anticoagulant intensity. For example, patients aged >75 years need less than half the daily warfarin dose of patients aged <35 for an equivalent level of anticoagulation. Whatever the mechanism it is clear that warfarin therapy needs careful justification for being given to elderly patients, and the dose needs modification and careful monitoring.

As there is an exponential increase in bleeding risk with a linear increase in anticoagulant effect, there will be a substantial increase in bleeding risk with overanticoagulation. For example, the annual risk of bleeding rises from 1.6% in elderly people not treated with anticoagulant drugs (based on the "Sixty-Plus" study), to 5% (relative risk 3) at an INR of 2.5, and to 50% (relative risk 30) at an INR of 4. In another study, total bleeding events were 39% in a group of 31 patients with an INR of 7 compared with 13% in a group of 100 with a stable INR (odds ratio 5.4, 95% CI 2.1-13.9). The greatest risk factor for being in this group was (apart from having a high target INR) antibiotic therapy in the preceding four weeks.

Myocardial infarction, stroke, and bleeding in the hypertension optimal treatment trial (HOT) study (ASP=aspirin, PLA=placebo)

Effect of different doses of aspirin in secondary prevention of vascular events (There is no significant difference in benefit with different aspirin doses, but at higher doses adverse effects are more likely)

Variables that may influence the risk of bleeding in elderly people

- Increased sensitivity to the effect of anticoagulation, perhaps due to increased receptor affinity or lower dietary vitamin K intake
- Concurrent use of drugs that increase bleeding risk
- Associated comorbidity and other diseases that decrease compliance and increase the risk of bleeding

Possible reasons for increased sensitivity to anticoagulation in elderly people

- Lower body weight
- Differences in pharmacokinetics, with a tendency towards reduced drug clearance in the elderly either due to decreases in renal or hepatic blood flow and function with age per se or disease processes
- Change in receptor sensitivity
- Lower dietary vitamin K intake in the elderly may perhaps be the more important cause

Multiple drug therapy or polypharmacy is quite common, with the consequence of adverse drug interactions, the risk of which rises exponentially with the number of drugs given simultaneously and with concurrent diseases. Typical drug interactions include changes in absorption across intestinal mucosae and hepatic metabolism. Patients should be cautioned about the risk of warfarin-drug interactions when their medication list is altered. The decline in cognitive function in some elderly patients may mean they do not realise that some drugs can interact with anticoagulants and so they do not mention their use of oral anticoagulants to doctors or pharmacists. However, elderly patients are likely to attend clinic less often than younger patients, suggesting a greater degree of INR stability.

Many diseases associated with stroke and thromboembolism are more common with increasing age. Older patients are often at highest risk, and appropriate anticoagulation therapy reduces morbidity and mortality. Careful and continuing evaluation of patients is necessary to ensure that the risks of bleeding do not outweigh the benefits from anticoagulation.

The diagram showing the results of the hypertension optimal treatment trial is adapted from Hansson L, et al. *Lancet* 1998;351:1755-62. The figure showing the effect of different doses of aspirin in secondary prevention of vascular events is reproduced from *Clinical Evidence* (June issue 7), BMJ Publishing Group, 2002.

3 Venous thromboembolism: pathophysiology, clinical features, and prevention

Alexander G G Turpie, Bernard S P Chin, Gregory Y H Lip

Venous thromboembolism is a common complication among hospital inpatients and contributes to longer hospital stays, morbidity, and mortality. Some venous thromboembolisms may be subclinical, whereas others present as sudden pulmonary embolus or symptomatic deep vein thrombosis. Ultrasonic Doppler and venographic techniques have shown deep vein thrombosis of the lower limb to occur in half of all major lower limb orthopaedic operations performed without antithrombotic prophylaxis. Deep vein thrombosis of the lower limb is also seen in a quarter of patients with acute myocardial infarction, and more than half of patients with acute ischaemic stroke.

Deep vein thrombosis of the lower limb normally starts in the calf veins. About 10-20% of thromboses extend proximally, and a further 1-5% go on to develop fatal pulmonary embolism. Appropriate antithrombotic measures can reduce this complication. Until recently, some clinicians were reluctant to provide such prophylaxis routinely. As unfounded fears of major bleeding complications from anticoagulant regimens wane, preventive treatments are used more often with medical and surgical patients. However, the risk of bleeding can be serious and this has particular bearing in postoperative patients.

Venous thromboembolism can also arise spontaneously in ambulant individuals, particularly if they have associated risk factors such as thrombophilia, previous thrombosis, or cancer. However, in over half of these patients, no specific predisposing factors can be identified at presentation.

Pathophysiology

Thrombus formation and propagation depend on the presence of abnormalities of blood flow, blood vessel wall, and blood clotting components, known collectively as Virchow's triad. Abnormalities of blood flow or venous stasis normally occur after prolonged immobility or confinement to bed. Venous obstruction can arise from external compression by enlarged lymph nodes, bulky tumours, or intravascular compression by previous thromboses. Increased oestrogens at pharmacological levels, as seen with oral contraceptive use and with hormone replacement therapy in postmenopausal women, have been associated with a threefold increased risk in the small initial risk of venous thromboembolism. Cancers, particularly adenocarcinomas and metastatic cancers, are also associated with increased venous thromboembolism. Indeed, on presentation, some idiopathic venous thromboembolisms have revealed occult cancers at follow up. Both oestrogens at pharmacological levels and cancer can also activate the clotting system.

Clinical presentation and diagnosis

Deep vein thrombosis

Deep vein thrombosis commonly presents with pain, erythema, tenderness, and swelling of the affected limb. Thus, in lower limb deep vein thrombosis, the affected leg is usually swollen with the circumference of the calf larger than the unaffected side. Other causes of leg swelling, erythema, and tenderness include a ruptured Baker's cyst and infective cellulitis. The

Pulmonary angiography showing large pulmonary embolus in left pulmonary artery

Venous thromboembolism often manifests clinically as deep vein thrombosis or pulmonary embolism, and is possibly one of the preventable complications that occur in hospitalised patients

Risk factors and conditions predisposing to venous thromboembolism

- History of venous thromboembolism
- Prolonged immobility
- Prolonged confinement to bed or lower limb paralysis
- Surgery, particularly lower limb orthopaedic operations, and major pelvic or abdominal operations
- Trauma—For example, hip fractures and acute spinal injury
- Obesity
- Major medical illnesses such as acute myocardial infarction, ischaemic stroke, congestive cardiac failure, acute respiratory failure
- Oestrogen use in pharmacological doses—For example, oral contraception pills, hormone replacement therapy
- Cancer, especially metastatic adenocarcinomas
- Age >40 years
- Acquired hypercoagulable states—Lupus anticoagulant and antiphospholipid antibodies, hyperhomocysteinaemia, dysfibrinogenemia, myeloproliferative disorders such as polycythaemia rubra vera
- Inherited hypercoagulable states—Activated protein C resistance (factor V Leiden mutation), protein C deficiency, protein S deficiency, antithrombin deficiency, prothrombin gene mutation

ABC of Antithrombotic Therapy

diagnosis of deep vein thrombosis is therefore more likely when risk factors are present and less so if there are features suggesting alternative diagnoses. For example, ruptured Baker's cysts commonly appear in the context of osteoarthritis and rheumatoid arthritis. Infective cellulitis is unlikely to be bilateral, with clearly demarcated areas of erythema extending proximally. Breaks in the skin, particularly between the toes, and coexistent fungal infection are additional clues to cellulitis.

Objective diagnosis of venous thromboembolism is important for optimal management. Although the clinical diagnosis of venous thromboembolism is imprecise, various probability models based on clinical features have proved to be practical and reliable (interobserver reliability, $\kappa = 0.85$) in predicting the likelihood of venous thromboembolism. These models should be used in conjunction with objective diagnostic tests.

Compression ultrasonography remains the non-invasive investigation of choice for the diagnosis of clinically suspected deep vein thrombosis. It is highly sensitive in detecting proximal deep vein thrombosis although less accurate for isolated calf deep vein thrombosis. In patients with suspected thrombosis and a negative compression ultrasound result, the test should be repeated in seven days because studies have shown that patients with two or more negative tests over a week who are untreated have a less than 2% risk of proximal extension or subsequent deep vein thrombosis.

Impedance plethysmography is slightly less specific and sensitive than ultrasonography but may still have a role in pregnant women and suspected recurrent deep vein thrombosis. The gold standard is invasive contrast venography, which is still used when a definitive answer is needed. Newer imaging techniques are being developed, and tools such as magnetic resonance venography or computed tomography could possibly detect pelvic vein thromboses, but further testing is needed to establish their role in the diagnosis of deep vein thrombosis.

Blood tests such as fibrin D-dimer add to the diagnostic accuracy of the non-invasive tests. In one study, the sensitivity and specificity of a D-dimer concentration of $> 500 \mu\text{g/l}$ for the presence of pulmonary embolism were 98% and 39%, respectively, which give positive and negative predictive values of 44% and 98%. The sensitivity of the test even remained high at three and seven days after presentation (96% and 93%).

Modified pretest probability for deep vein thrombosis

Clinical feature	Score
Tenderness along entire deep vein system	1.0
Swelling of the entire leg	1.0
Greater than 3 cm difference in calf circumference	1.0
Pitting oedema	1.0
Collateral superficial veins	1.0
Risk factors present:	
Active cancer	1.0
Prolonged immobility or paralysis	1.0
Recent surgery or major medical illness	1.0
Alternative diagnosis likely (ruptured Baker's cyst in rheumatoid arthritis, superficial thrombophlebitis, or infective cellulitis)	-2.0

Score > 3 = high probability; 1-2 = moderate probability < 0 = low probability

Plasma D-dimer concentrations on day of presentation according to final diagnosis

Investigations for suspected venous thromboembolism by pretest clinical probability

Pretest probability	Fibrin D-dimer	Other investigations	Comment
Deep vein thrombosis:			
Low	Negative		No further investigations needed
Low or moderate	Positive	Negative ultrasound compression	Consider venography or repeat ultrasound after a week
Moderate or high	Positive	Positive ultrasound compression	Treat with anticoagulants
High	Positive	Negative ultrasound compression	Consider venography to rule out deep vein thrombosis, especially in high risk patients and those with recurrent pulmonary emboli
Pulmonary embolism:			
Low	Negative	No	No further investigation needed
Low or moderate	Positive	Proceed to ventilation-perfusion scan	If non-diagnostic ventilation-perfusion scan consider serial compression ultrasound over two weeks to rule out venous thromboembolism
High	Positive	Proceed to ventilation-perfusion scan (or ultrasound)	If non-diagnostic ventilation-perfusion scans, proceed to venography or pulmonary angiography as needed

Pulmonary embolism

Patients presenting with acute pulmonary embolism often complain of sudden onset of breathlessness with haemoptysis or pleuritic chest pain, or collapse with shock in the absence of other causes. Deep vein thrombosis may not be suspected clinically, but its presence, along with thrombotic risk factors, will make the diagnosis of pulmonary embolism more likely. A similar clinical probability model to that for deep vein thrombosis has been developed for pulmonary embolism.

Pulmonary angiography is the gold standard investigation for pulmonary embolism, but it is invasive and associated with 0.5% mortality. A ventilation-perfusion scan using technetium DTPA (ditriaminopentanic acid) is more widely used. However this investigation is non-specific, and is diagnostic in only 30% of cases. Spiral computed tomography scans are more reliable but diagnosis is limited to emboli in larger vessels only. Measurement of fibrin D-dimer levels, used for deep vein thrombosis, is helpful, as is compression ultrasound in the detection of occult deep vein thrombosis.

Prevention strategies

An appropriate strategy for the prevention of venous thromboembolism include pharmacological or physical methods. To optimise treatment, patients should be stratified into risk categories to allow the most appropriate prophylactic measure to be used.

Prophylactic drugs include unfractionated heparin, low molecular weight heparin, oral anticoagulants (such as coumarins), thrombin inhibitors (such as hirudin), and specific factor Xa inhibitors (such as fondaparinux). The recently approved fondaparinux reduces the risk of venous thromboembolism after orthopaedic surgery by more than half compared with low molecular weight heparin and seems likely to become the treatment of choice after universal availability.

Prophylactic physical methods include the use of compression elastic stockings, intermittent pneumatic compression (which provides rhythmic external compression at 35-40 mm Hg for about 10 seconds every minute), and early mobilisation to improve venous blood flow in conditions predisposing to venous stasis.

General surgery

Patients at low risk undergoing general surgery do not need specific prophylaxis other than early mobilisation. In moderate risk patients, fixed low doses of unfractionated heparin (5000 IU every 12 hours) or low molecular weight heparin (3400 anti-Xa units or equivalent) once daily is sufficient. Higher doses of low molecular weight heparin (more than 3400 IU anti-Xa daily) should be reserved for high risk general surgery and orthopaedic operations. Compression elastic stockings and intermittent pneumatic compression may protect high risk patients when used with anticoagulants. They are also effective when used alone in moderate risk patients where anticoagulants are contraindicated.

Orthopaedic surgery

In very high risk patients, such as those undergoing major orthopaedic operations, high dose low molecular weight heparin or warfarin is appropriate. The current recommended length of anticoagulant prophylaxis is 7-10 days with low molecular weight heparin or warfarin. Extended use may provide additional benefit. Routine screening with duplex ultrasonography is not helpful. Hirudin seems to be superior to low molecular weight heparin and low dose unfractionated

Clinical probability for pulmonary embolism

Clinical feature	Score
Deep vein thrombosis suspected:	
Clinical features of deep vein thrombosis	3.0
Recent prolonged immobility or surgery	1.5
Active cancer	1.0
History of deep vein thrombosis or pulmonary embolism	1.5
Haemoptysis	1.0
Resting heart rate > 100 beats/min	1.5
No alternative explanation for acute breathlessness or pleuritic chest pain	3.0

> 6 = high probability (60%); 2-6 = moderate probability (20%); < 1.5 = low probability (3-4%)

Thromboembolic risk stratification for surgery patients

- *Low risk*—Uncomplicated surgery in patients aged < 40 years with minimal immobility postoperatively and no risk factors
- *Moderate risk*—Any surgery in patients aged 40-60 years, major surgery in patients < 40 years and no other risk factors, minor surgery in patients with one or more risk factors
- *High risk*—Major surgery in patients aged > 60 years, major surgery in patients aged 40-60 years with one or more risk factors
- *Very high risk*—Major surgery in patients aged > 40 years with previous venous thromboembolism, cancer or known hypercoagulable state, major orthopaedic surgery, elective neurosurgery, multiple trauma, or acute spinal cord injury

Ventilation-perfusion scan showing massive pulmonary thromboembolism, showing a mismatch between (left) perfusion and (right) ventilation scans

Key points

- Understanding Virchow's triad aids the treatment of venous thromboembolism
- Numerous situations and risk factors can contribute to venous thromboembolism
- Diagnosis of venous thromboembolism depends upon a combination of history, risk factors, and investigations
- Antithrombotic prophylaxis is safe and effective

ABC of Antithrombotic Therapy

heparin as prophylaxis in patients undergoing elective hip replacements but is still not universally available.

Neurosurgery, multiple traumas, and spinal cord injuries

Intermittent pneumatic compression is the prophylaxis of choice for elective neurosurgery. Among the low molecular weight heparins, only enoxaparin 30 mg twice daily has been shown to reduce venous thromboembolism without excess bleeding after elective neurosurgery, multiple traumas, or spinal cord injuries and so may be used in these situations. Other low molecular weight heparins have either not been tested or have not conclusively been shown to be of benefit in this setting.

Medical conditions

In general medical patients including heart failure and respiratory failure, both unfractionated heparin and low molecular weight heparin have been shown to be effective in reducing the risk of venous thromboembolism. Low molecular weight heparin has been shown to be more effective than heparin in stroke. Low dose heparin has been shown to be effective in acute myocardial infarction but this is now largely historic because myocardial infarction patients receive therapeutic dose anticoagulants.

Other considerations

Combined approaches using drugs and physical methods may be better at preventing thromboembolism than physical methods alone. However, compression elastic stockings and intermittent pneumatic compression may be used for moderate or high risk patients when anticoagulation is contraindicated or best avoided. Inferior vena cava filter placement should be reserved for patients at very high risk of venous thromboembolism where anticoagulation as well as physical methods are contraindicated. Inferior vena cava filter placement tends to cause a long term increase of recurrent deep vein thrombosis, even though the immediate risk of postoperative pulmonary embolism is reduced.

Evidence based use of antithrombotic prophylaxis

General surgery

- *Low risk*—Early mobilisation
- *Moderate risk*—UH 5000 IU 12 hourly starting two hours before surgery, or low molecular weight heparin < 3400 anti-Xa IU daily*, or compression elastic stockings, or intermittent pneumatic compression
- *High risk*—Low molecular weight heparin > 3400 anti-Xa IU daily† plus compression elastic stockings, or unfractionated heparin 5000 IU eight hourly starting two hours before surgery plus compression elastic stockings, or intermittent pneumatic compression if anticoagulation contraindicated
- *Very high risk*—Perioperative warfarin (INR 2-3), low molecular weight heparin > 3400 anti-Xa IU daily† plus compression elastic stockings, or prolonged low molecular weight heparin therapy plus compression elastic stockings

Major orthopaedic surgery

- *Elective hip replacement*—Recombinant hirudin 15 mg twice daily, unfractionated heparin 3500 IU eight hourly with postoperative adjustments (APTT 1.2-1.5), or low molecular weight heparin > 3400 anti-Xa IU daily†, or perioperative warfarin (INR 2-3), or fondaparinux 2.5 mg daily
- *Elective knee replacement*—Low molecular weight heparin > 3400 anti-Xa IU daily†, or perioperative warfarin (INR 2-3), or fondaparinux 2.5 mg daily, intermittent pneumatic compression
- *Surgery for hip fracture*—Low molecular weight heparin > 3400 anti-Xa IU daily†, or perioperative warfarin (INR 2-3), or fondaparinux 2.5 mg daily

Elective neurosurgery

- Intermittent pneumatic compression, enoxaparin 30 mg twice daily

Acute spinal cord injury

- Enoxaparin 30 mg twice daily

Trauma

- Enoxaparin 30 mg twice daily

Acute myocardial infarction

- Low dose unfractionated heparin 5000 IU twice daily, full dose unfractionated heparin 40 000 IU infusion over 24 hours, elastic stockings, and early mobilisation

Ischaemic stroke

- Low dose unfractionated heparin 5000 IU twice daily

Other medical conditions including congestive heart failure

- Enoxaparin 40 mg once daily or 30 U twice daily, dalteparin 2500 IU daily, low dose unfractionated heparin 5000 IU twice daily

Cancer patients receiving chemotherapy

- Low dose warfarin (INR < 2), dalteparin 2500 IU daily

*Dalteparin 2500 IU once daily starting two hours before surgery
Enoxaparin 20 mg once daily starting two hours before surgery
Nadroparin 3100 IU once daily starting two hours before surgery
Tinzaparin 3500 IU once daily starting two hours before surgery
†Dalteparin 5000 IU once daily starting 10-12 hours before surgery
Danaparoid 750 IU twice daily starting one to two hours before surgery
Enoxaparin 40 mg once daily starting 10-12 hours before surgery or 30 mg twice daily starting after surgery
Tinzaparin 50 IU/kg once daily starting two hours before surgery

4 Venous thromboembolism: treatment strategies

Alexander G G Turpie, Bernard S P Chin, Gregory Y H Lip

Pulmonary embolism and deep vein thrombosis are treated using similar drugs and physical methods. The efficacy of intravenous infusion of unfractionated heparin was first proved in a randomised trial in 1960. Subsequently, trials concentrated on the dose, duration of infusion, mode of administration, and combination with warfarin treatment. Later trials have reported the efficacy and cost effectiveness of low molecular weight heparin compared with unfractionated heparin.

Unfractionated heparin

Unfractionated heparin, administered by continuous infusion or subcutaneous injections adjusted to achieve activated partial thromboplastin time (APTT) greater than 1.5, is effective as initial treatment of venous thromboembolism. Initial heparinisation should be followed by long term anticoagulation with oral anticoagulants. APTT is a global coagulation test and not specific for heparin, and it is also influenced by various plasma proteins and clotting factors. Measuring plasma heparin levels is more accurate but it is impractical and expensive. A sensible approach is to standardise the APTT with plasma heparin within each laboratory.

The most common mistake when starting heparin treatment is failure to achieve adequate anticoagulation. APTT ratios of less than 1.5 during the first few days of heparin therapy increase the long term risk of venous thromboembolism recurrence. Hence, the initial bolus dose should be adequate and APTT monitored every six hours during the first 24 hours of heparin infusion.

Oral anticoagulants may be started at the same time and should be continued for at least three to six months, depending on the individual. The optimal duration of intravenous heparin treatment is five to seven days because this is the time needed to obtain an adequate and persistent reduction in the vitamin K dependent clotting factors with oral anticoagulants such as warfarin. Heparin can then be stopped when concomitant use with warfarin has achieved an international normalised ratio (INR) of 2-3 for at least 48 hours. In patients with large iliofemoral vein thromboses or major pulmonary embolism, heparin infusion can be continued for up to 10 days.

Heparin use for more than five to six days is associated with a rare risk of thrombocytopenia. In a recent trial, only one of 308 patients (0.32%) who received unfractionated heparin for acute pulmonary embolism developed a thrombocytopenia, whereas none of 304 patients receiving low molecular weight heparin had this problem. The thrombocytopenia is normally mild, but precipitous falls in platelet count to less than $100 \times 10^9/l$ can occur. When this happens, antibody mediated injury to platelets should be suspected. As this condition may be associated with arterial or venous thromboembolism, heparin should be stopped and warfarin use delayed. Alternative anticoagulation cover should be given by danaparoid, a heparinoid, or hirudin, a thrombin inhibitor, until the platelet count rises above 100 000 and it is safe to start warfarin. Unfractionated heparin has also been reported to increase platelet activation in vivo: low molecular weight heparin had no such effect.

Right iliofemoral deep vein thrombosis

Antithrombotic treatment is often inadequate in the first few days, predisposing to recurrences. Anticoagulation with warfarin after discharge should continue for at least three months, possibly six months. Low molecular weight heparin is as efficacious as unfractionated heparin in prophylaxis and treatment

Initial antithrombotic therapy for deep vein thrombosis with unfractionated heparin

- 1 Check baseline APTT, prothrombin time, full blood count
- 2 Confirm there are no contraindications to heparin therapy
- 3 Intravenous bolus 5000 IU
- 4 Choose between:
 - Continuous unfractionated heparin infusion*—Start infusion at 18 IU/kg/hour (~30 000/24 hours in a 70 kg man)
Check APTT every six hours for first 24 hours, then daily thereafter
Aim for APTT 1.5-2.5 × normal
Recheck APTT at six hours after each adjustment
Continue infusion for five to seven days
 - Subcutaneous*—Start at 17 500 IU every 12 hours (or 250 IU/kg every 12 hours)
- 5 Check platelet count daily for thrombocytopenia
- 6 Warfarin therapy can be started on the first day of heparin therapy according to local protocol
- 7 Continue heparin for at least four to five days after starting warfarin
- 8 Stop heparin when INR greater than 2 for more than 48 hours
- 9 Continue warfarin therapy for at least three months keeping INR between 2 and 3 (target 2.5)

Low molecular weight heparin

Low molecular weight heparin has a more predictable relation between dose and response than unfractionated heparin and does not need monitoring or adjustments if the dose is based on patient body weight. Low molecular weight heparin is also associated with lower risk of thrombocytopenia. Its use in deep vein thrombosis and pulmonary embolism is now firmly established: many trials and meta-analysis have confirmed its superior efficacy, safer profile, and greater cost effectiveness over unfractionated heparins. However, all low molecular weight heparins are different, and trials for one product cannot be extrapolated to another. The introduction of low molecular weight heparin has advanced antithrombotic therapy by providing effective anticoagulation without the need for monitoring or adjustments. It also allows patients with uncomplicated deep vein thrombosis to be treated in the community, saving an average of four to five days' admission per patient.

Coumarins

Warfarin is the most widely used oral anticoagulant for treating venous thromboembolism. It is well absorbed from the gut, metabolised in the liver, and excreted in urine. The lag time for warfarin to take effect may be related to the natural clearance of normal clotting factors from plasma. Of the vitamin K dependent clotting factors, factor II takes the longest to clear. Warfarin monitoring is performed using an INR rather than prothrombin time, which may vary between laboratories. Warfarin interacts with many other drugs and alcohol. It is also teratogenic and may induce spontaneous abortion.

A target INR range of 2-3 is standard for treatment of venous thromboembolism. Higher levels tend to increase incidence of bleeding without reducing recurrent thromboembolism and so are unnecessary. The exception to this is for patients with the antiphospholipid antibody syndrome, where the risk of recurrent venous thromboembolism is high. Here, an INR of 3-4.5 is recommended. Warfarin should be started in conjunction with heparin or low molecular weight heparin when the diagnosis of venous thromboembolism is confirmed, although local protocols may vary in their starting doses and titration schedule. As indicated, heparin should be continued concomitantly for five days and until INR is > 2.

Warfarin therapy should then be maintained for at least three months in all patients. However, it has recently been established that longer treatments (such as six months) may be necessary. Patients without a readily identifiable risk factor (idiopathic venous thromboembolism) have higher rates of recurrences. These recurrences can be reduced by prolonged anticoagulation. However, there is a corresponding rise in bleeding complications with prolonged anticoagulation. Current recommendations advocate anticoagulation for at least six months for the first presentation of idiopathic venous thromboembolism. Patients with recurrent venous thromboembolism and hypercoagulable states (acquired or inherited) or with cancer (especially while receiving chemotherapy) should take anticoagulation therapy for at least a year, and perhaps indefinitely.

Thrombolytic therapy

Unlike heparin and warfarin, which prevent extension and recurrences of thrombosis, thrombolytic agents (including streptokinase, urokinase, and tissue plasminogen activator) lyse the thrombi. It is therefore unsurprising that patients with

Advantages of low molecular weight heparin over unfractionated heparin

- More reliable relation between dose and response
 - Does not need monitoring
 - Does not need dose adjustments
 - Lower incidence of thrombocytopenia
 - No excess bleeding
 - Can be administered by patient at home
 - Saves about five to six days' admission per patient
-

Duration of anticoagulation therapy for venous thromboembolism*

Three to six months

- First event with reversible† or time limited risk factor (patient may have underlying factor V Leiden or prothrombin 20210 mutation)

More than six months

- Idiopathic venous thromboembolism, first event

A year to life time

- First event‡ with cancer (until resolved), anticardiolipin antibody, antithrombin deficiency
- Recurrent event, idiopathic or with thrombophilia

*All recommendations are subject to modification by individual characteristics including patient preference, age, comorbidity, and likelihood of recurrence
 †Reversible or time limited risk factors such as surgery, trauma, immobilisation, and oestrogen use

‡Proper duration of therapy is unclear in first event with homozygous factor V Leiden, homocystinaemia, deficiency of protein C or S, or multiple thrombophilias; and in recurrent events with reversible risk factors

Recent trials with the oral thrombin inhibitor, ximelagatran suggest that, in certain circumstances, this agent may be an alternative to warfarin for the management of venous thromboembolism, without the need for anticoagulation monitoring

Thrombolytic regimens for pulmonary embolism

- 1 Check suitability of patient for thrombolysis
 - 2 Choose between:
 - Streptokinase*—250 000 IU loading dose then 100 000 IU/hour for 24 hours
 - Urokinase*—4400 IU/kg loading dose then 2200 IU/kg/hour for 12 hours
 - Alteplase*—100 mg intravenously over an hour
 - 3 Check APTT two to four hours after starting infusion: > 10 seconds prolongation indicates active fibrinolysis
 - 4 Start heparin at 5000-10 000 IU loading followed by 15-25 units/kg/hour when APTT < 2
 - 5 Adjust according to local protocol to keep APTT 1.5-2.5
-

pulmonary embolism treated with streptokinase and urokinase are three times more likely to show clot resolution than patients taking heparin alone. Even so, thrombolytic therapy of pulmonary embolism does not dissolve the clot completely as it does with acute coronary thrombosis, and increases the risk of bleeding. Occasionally, thrombolytic therapy is administered via a catheter placed in the pulmonary artery. The catheter can be used to “disrupt” the thrombus before starting the drug.

Until there is more evidence that thrombolytic therapy reduces mortality in pulmonary embolism, this treatment should be reserved for patients with massive pulmonary embolism, cardiorespiratory compromise, and low risk of bleeding. Evidence is emerging that streptokinase can decrease swelling and pain in deep vein thrombosis. Again, further trials are needed before this can be recommended routinely.

Physical methods

Non-drug treatments include physically preventing embolisation of the thrombi and extraction of thromboemboli (usually from the pulmonary vasculature).

Inferior vena cava filters may be used when anticoagulation is contraindicated in patients at high risk of proximal deep vein thrombosis extension or embolisation. The filter is normally inserted via the internal jugular or femoral vein. It is then advanced under fluoroscopic guidance to the inferior vena cava. Filters are now available that are easy to insert, and complications are low in skilled hands. For now, this technique should be considered in patients with recurrent symptomatic pulmonary embolism and as primary prophylaxis of thromboembolism in patients at high risk of bleeding (such as patients with extensive trauma or visceral cancer), although the evidence is based on uncontrolled case series. The only randomised trial showed a reduction in pulmonary embolism but no improvement in short or long term survival, because of greater risk of recurrent deep vein thrombosis in patients who received a filter.

Other mechanical and surgical treatments are usually reserved for massive pulmonary embolism where drug treatments have failed or are contraindicated. None of these methods has shown a long term reduction in mortality, but better techniques have led to acceptable complication rates and warrant further evaluation.

Treatment during pregnancy

Unfractionated heparin and low molecular weight heparin do not cross the placenta and are probably safe for the fetus during pregnancy. Oral anticoagulants cross the placenta and can cause fetal bleeding and malformations. Pregnant women with venous thromboembolism can be treated with therapeutic doses of subcutaneous heparin or low molecular weight heparin until after delivery, when warfarin can be used safely. These issues are developed in chapter 14.

The data on duration of anticoagulation therapy for venous thromboembolism is adapted from the 6th ACCP guidelines Hyers TM, et al. Antithrombotic therapy for venous thromboembolic disease. *Chest* 2001;119:176-93S

Indications for inferior vena cava filter placement

- Patients at high risk of proximal deep vein thrombosis extension where anticoagulation is contraindicated
 - Recurrent venous thromboembolism despite adequate anticoagulation
 - Chronic recurrent venous thromboembolism with pulmonary hypertension
 - Simultaneous surgical pulmonary embolectomy or endarterectomy
-

Mechanical and surgical treatment of pulmonary embolism

- Inferior vena cava filter placement
Indications—See box above
 - Pulmonary embolectomy
Indication—Massive pulmonary embolism compromising cardiac output where thrombolysis has failed or is contraindicated
Experienced cardiac surgical cover essential
Where available, catheter transvenous extraction of emboli may be an alternative to pulmonary embolectomy
 - Pulmonary endarterectomy
Indication—Chronic recurrent pulmonary embolism with secondary pulmonary hypertension
-

Vena cavagram showing umbrella delivery device for filter inserted into the inferior vena cava through the jugular vein

5 Antithrombotic therapy for atrial fibrillation: clinical aspects

Gregory Y H Lip, Robert G Hart, Dwayne S G Conway

Atrial fibrillation is the commonest sustained disorder of cardiac rhythm. Although patients often present with symptoms caused by haemodynamic disturbance associated with the rhythm itself, the condition carries an increased risk of arterial thromboembolism and ischaemic stroke due to embolisation of thrombi that form within the left atrium of the heart. Presence of the arrhythmia confers about a fivefold increase in stroke risk, an absolute risk of about 4.5% a year, although the precise annual stroke risk ranges from < 1% to > 12%, according to the presence or absence of certain clinical and echocardiographically identifiable risk factors.

From trial data, patients with paroxysmal atrial fibrillation seem to carry the same risk as those with persistent atrial fibrillation. The same criteria can be used to identify high risk patients, although it is unclear whether the risk is dependent on the frequency and duration of the paroxysms.

Evidence from clinical trials

It is well established that antithrombotic therapy confers thromboprophylaxis in patients with atrial fibrillation who are at risk of thromboembolism. A recent meta-analysis of antithrombotic therapy in atrial fibrillation showed that adjusted dose warfarin reduced stroke by about 60%, with absolute risk reductions of 3% a year for primary prevention and 8% a year for secondary prevention (numbers needed to treat for one year to prevent one stroke of 33 and 13, respectively). In contrast, aspirin reduced stroke by about 20%, with absolute risk reductions of 1.5% a year for primary prevention and 2.5% a year for secondary prevention (numbers needed to treat of 66 and 40, respectively). Relative to aspirin, adjusted dose warfarin reduced the risk by about 40%, and the relative risk reduction was similar for primary and secondary prevention, and for disabling and non-disabling strokes. However, these data, obtained from well planned clinical trials recruiting patients with relatively stable conditions, are unlikely to be fully extrapolable to all patients in general practice, so that some caution is advised.

Overall, warfarin (generally at a dose to maintain an international normalised ratio (INR) of 2-3) is significantly more effective than aspirin in treating atrial fibrillation in patients at high risk of stroke, especially in preventing disabling cardioembolic strokes. The effect of aspirin seems to be on the smaller, non-cardioembolic strokes from which elderly, and often hypertensive, patients with atrial fibrillation are not spared.

Recent clinical trials have suggested that there is no role for minidose warfarin (1 mg/day regardless of INR), alone or in combination with antiplatelet agents or aspirin, as thromboprophylaxis in atrial fibrillation. However, the role of other antiplatelet agents (such as indobufen and dipyridamole) in atrial fibrillation is still unclear. One small trial (SIFA) compared treatment with indobufen, a reversible cyclo-oxygenase inhibitor, with full dose warfarin for secondary prevention and found no statistical difference between the two groups, who were well matched for confounding risk factors. Trials of other antiplatelet and antithrombotic drugs (including low molecular weight heparin) have been performed but have generally been too small and underpowered to show significant differences. Large

Severely damaged left atrial appendage endocardial surface with thrombotic mass in a patient with atrial fibrillation and mitral valve disease

Randomised controlled trials have shown the benefit of warfarin and, to a lesser extent, aspirin in reducing the incidence of stroke in patients with atrial fibrillation without greatly increasing the risk of haemorrhagic stroke and extracranial haemorrhage. However, anticoagulant therapy is still underprescribed in patients with atrial fibrillation, particularly in elderly patients, who stand to benefit most

Meta-analysis of trials comparing warfarin with placebo in reducing the risk of thromboembolism in patients with atrial fibrillation

BAATAF=Boston area anticoagulation trial for atrial fibrillation;
CAFA=Canadian atrial fibrillation anticoagulation study; EAFT=European atrial fibrillation trial; SPAF=Stroke prevention in atrial fibrillation study; SPINAF=Stroke prevention in non-rheumatic atrial fibrillation

multinational trials comparing a direct thrombin inhibitor (ximelagatran) with adjusted dose warfarin in over 7000 patients with atrial fibrillation at high risk of stroke and thromboembolism suggest that this agent may be an alternative to warfarin, without the need for anticoagulation monitoring.

The reduction in relative risk with warfarin applies equally to primary and secondary prevention but, as history of stroke confers an increased annual stroke risk (12% *v* 4.5%), the absolute risk reduction is greater for secondary prevention. The number of patients with atrial fibrillation needing treatment with warfarin to prevent one stroke is therefore about three times greater in primary prevention (37) than in secondary prevention (12).

Treatment with full dose anticoagulation carries the potential risk of major bleeding, including intracranial haemorrhage. Meta-analysis of the initial five primary prevention trials plus a further secondary prevention trial suggests the risk of haemorrhagic stroke is only marginally increased from 0.1% to 0.3% a year. Higher rates of major haemorrhage were seen in elderly patients and those with higher intensity anticoagulation. Further recent trials have confirmed an increased bleeding risk in patients with INR > 3.

Antiplatelet therapy in atrial fibrillation

Several clinical trials have studied the effects of aspirin in atrial fibrillation, with doses ranging from 25 mg twice daily to 1200 mg a day. Overall, aspirin reduces the relative risk of stroke by about 20% (a figure which just reaches statistical significance) with no apparent benefit of increasing aspirin dose. Aspirin seems to carry greater benefit in reducing smaller non-disabling strokes than disabling strokes. This may be due to an effect primarily on carotid and cerebral artery platelet thrombus formation, rather than on formation of intra-atrial thrombus. A meta-analysis of trials directly comparing full dose warfarin with aspirin confirmed significant reductions in stroke risk about three times greater with warfarin. The SPAF III trial demonstrates that addition of fixed low doses of warfarin to aspirin treatment is not sufficient to achieve the benefits of full dose warfarin alone.

Putting the evidence into practice

Despite the evidence from the trials, many doctors are reluctant to start warfarin treatment for patients with atrial fibrillation. This could be due to fears (of patient and doctor) of haemorrhagic complications in an elderly population, logistical problems of INR monitoring, and a lack of consensus guidelines on which patients to treat and the ideal target INR. Such attitudes may result in otherwise avoidable stroke and arterial thromboembolism. A systematic evidence based approach needs to be encouraged, targeting appropriate antithrombotic therapy at those patients who stand to gain most benefit (those at greatest risk of thromboembolism) and using levels of anticoagulation that have been proved both effective and reasonably safe for both primary and secondary prevention of stroke, if we are to realise in clinical practice the large reduction in incidence of stroke achieved in the clinical trials.

Who to treat?

Even though there are impressive figures for relative risk reduction with warfarin, the figures for absolute risk reduction (more important in clinical practice) depend greatly on the underlying risk of stroke if untreated. Elderly patients are often denied anticoagulant therapy because of fears of increased haemorrhage risk. However, the benefits of anticoagulant therapy are greater for elderly patients because of the increased

Independent predictors of ischaemic stroke in non-valve atrial fibrillation

Consistent predictors

- Old age
- Hypertension
- Previous stroke or transient ischaemic attack
- Left ventricular dysfunction*

Inconsistent predictors

- Diabetes
- Systolic blood pressure > 160 mm Hg†
- Women, especially older than 75 years
- Postmenopausal hormone replacement therapy
- Coronary artery disease

Factors which decrease the risk of stroke

- Moderate to severe mitral regurgitation
- Regular alcohol use (> 14 drinks in two weeks)

*Recent clinical congestive cardiac failure or moderate to severe systolic dysfunction on echocardiography
 †In some analyses, systolic blood pressure > 160 mm Hg remained an independent predictor after adjustment for hypertension

ABC of Antithrombotic Therapy

underlying thromboembolic risk. Conversely, young patients at relatively low risk of stroke have less to gain from full dose anticoagulation as there may be little difference between the number of strokes prevented and the number of haemorrhagic complications. Risk stratification is possible using the clinical and echocardiographic parameters and can be used to target treatment at the most appropriate patients.

Risk stratification for thromboprophylaxis can be undertaken in many ways. Clinical risk factors would assist with risk stratification in most cases. Although echocardiography is not mandatory, it would help refine risk stratification in cases of uncertainty. Based on echocardiographic data on 1066 patients, the Atrial Fibrillation Investigators reported that the only independent predictor of stroke risk was moderate or severe left ventricular dysfunction on two dimensional echocardiography. Left atrial size on M mode echocardiography was not an independent predictor on multivariate analysis.

Transoesophageal echocardiography is rarely needed to undertake risk stratification, but “high risk” features include the presence of dense spontaneous echocardiographic contrast

Two dimensional echocardiography showing left atrial thrombus in patient with prosthetic valve

Practical guidelines for antithrombotic therapy in non-valvar atrial fibrillation

Assess risk, and reassess regularly

High risk (annual risk of cerebrovascular accident=8-12%)

- All patients with previous transient ischaemic attack or cerebrovascular accident
- All patients aged ≥ 75 with diabetes or hypertension
- All patients with clinical evidence of valve disease, heart failure, thyroid disease, and impaired left ventricular function on echocardiography*

Treatment—Give warfarin (target INR 2-3) if no contraindications and possible in practice

Moderate risk (annual risk of cerebrovascular accident=4%)

- All patients < 65 with clinical risk factors: diabetes, hypertension, peripheral vascular disease, ischaemic heart disease
- All patients > 65 not in high risk group

Treatment—Either warfarin (INR 2-3) or aspirin 75-300 mg daily. In view of insufficient clear cut evidence, treatment may be decided on individual cases. Referral and echocardiography may help

Low risk (annual risk=1%)

- All patients aged < 65 with no history of embolism, hypertension, diabetes, or other clinical risk factors

Treatment—Give aspirin 75-300 mg daily

*Echocardiogram not needed for routine risk assessment but refines clinical risk stratification in case of moderate or severe left ventricular dysfunction (see figure below) and valve disease. A large atrium per se is not an independent risk factor on multivariate analysis

Effect of left ventricular dysfunction on stroke rate in atrial fibrillation
LV=left ventricle

Different risk stratification schemes for primary prevention of stroke in non-valvar atrial fibrillation

Study	Risk		
	High	Intermediate	Low
Atrial Fibrillation Investigators (1994)	High to intermediate risk: Age > 65 years History of hypertension Diabetes		Age < 65 years No high risk features
American College of Chest Physicians Consensus (1998)	Age > 75 years History of hypertension Left ventricular dysfunction† > 1 moderate risk factor	Age 65-75 years Diabetes Coronary disease (thyrotoxicosis)*	Age < 65 years No risk factors
Stroke Prevention in Atrial Fibrillation	Women aged ≥ 75 years Systolic blood pressure > 160 mm Hg Left ventricular dysfunction‡	History of hypertension No high risk features	No high risk features No history of hypertension
Lip (1999)	Patients aged > 75 years and with diabetes or hypertension Patients with clinical evidence of heart failure, thyroid disease, and impaired left ventricular function on echocardiography§	Patients aged < 65 years with clinical risk factors: diabetes, hypertension, peripheral arterial disease, ischaemic heart disease Patients aged > 65 not in high risk group	Patients aged < 65 years with no risk factors

*Patients with thyrotoxicosis were excluded from participation in the test cohort

†Moderate to severe left ventricular dysfunction on echocardiography

‡Recent congestive heart failure or fractional shortening $\leq 25\%$ by M mode echocardiography

§Echocardiography not needed for routine risk assessment but refines clinical risk stratification in case of impaired left ventricular function and valve disease

(often with low atrial appendage velocities, indicating stasis), the presence of thrombus of the atrial appendage, and complex aortic plaque.

Which INR range?

The evidence suggests that INR levels greater than 3 may result in an excess rate of haemorrhage, whereas low dose warfarin regimens (with INR maintained below 1.5) do not achieve the reductions in stroke of higher doses. An INR range of between 2 and 3 has been shown to be highly effective without leading to excessive haemorrhage and should therefore be recommended for all patients with atrial fibrillation treated with warfarin unless they have another indication for higher levels of anticoagulation (such as a mechanical heart valve). Although INR monitoring is often coordinated by hospital based anticoagulant clinics, general practitioners are likely to play a more important part with the development of near patient INR testing.

Particular care must be taken and INR levels closely monitored when warfarin is used in elderly patients. It has been suggested that an INR of between 1.6 and 2.5 can provide substantial, albeit partial, efficacy (estimated to be nearly 90% of the highest intensities). Given the uncertainty about the safety of INRs >2.5 for atrial fibrillation patients over 75 years, a target INR of 2 (range 1.6-2.5) may be a reasonable compromise between an increased risk of haemorrhage and a reduced risk of thrombotic stroke for some patients within this age group, in the absence of additional risk factors, pending further data about the safety of higher intensities.

The ongoing MRC sponsored Birmingham atrial fibrillation trial of anticoagulation in the aged (BAFTA) is comparing warfarin with aspirin in atrial fibrillation patients over 75 years to further define the relative benefits and risks.

DC cardioversion

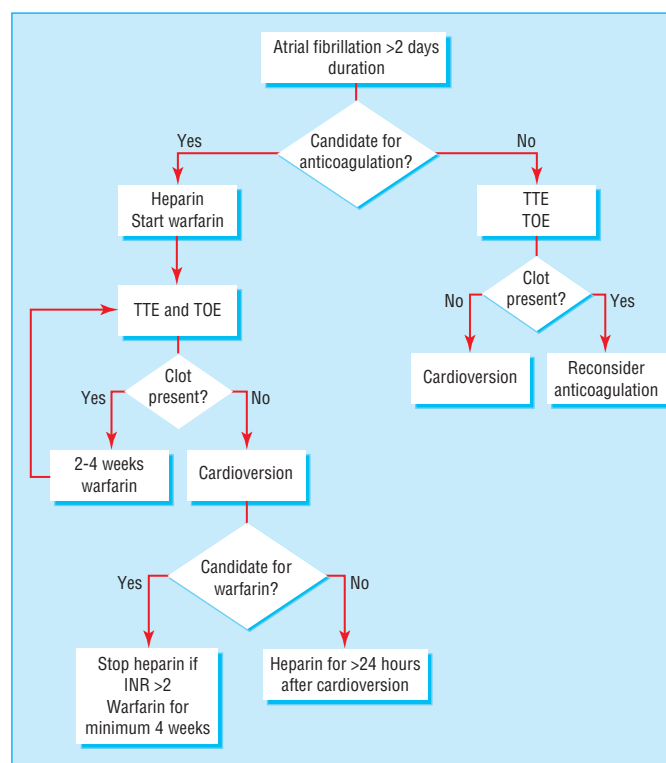

No hard evidence exists in the literature that restoration of sinus rhythm by whatever means reduces stroke risk. Transoesophageal echocardiography performed immediately before cardioversion (to exclude intra-atrial thrombus) may allow DC cardioversion to be performed without prior anticoagulation. However, as the thromboembolic risk may persist for a few weeks postprocedure, it is still recommended that patients receive warfarin for at least four weeks afterwards.

Guidelines for transoesophageal echocardiography guided cardioversion is adapted from the ACUTE Study, *N Engl J Med* 2001;344:1411-20. The recommendations for anticoagulation for cardioversion of atrial fibrillation are based on the 6th ACCP Consensus Conference on Antithrombotic Therapy. Albers GW et al, *Chest* 2001;119:194-206S.

Recommendations for anticoagulation for cardioversion of atrial fibrillation

- For elective cardioversion of atrial fibrillation of >48 hours duration start warfarin treatment (INR 2-3) three weeks before and continue for four weeks after cardioversion
- In urgent and emergency cardioversion administer intravenous heparin followed by warfarin
- Treat atrial flutter similarly
- No anticoagulation treatment is required for supraventricular tachycardia or atrial fibrillation of <48 hours duration
- Continue anticoagulation in patients with multiple risk factors or those at high risk of recurrent thromboembolism

Based on the 6th ACCP Consensus Conference on Antithrombotic Therapy

6 Antithrombotic therapy for atrial fibrillation: pathophysiology, acute atrial fibrillation, and cardioversion

Gregory Y H Lip, Robert G Hart, Dwayne S G Conway

Pathophysiology of thromboembolism in atrial fibrillation

The pathophysiological mechanism for thrombus formation and embolism seems to be abnormalities in blood flow within the fibrillating (and possibly dilated) left atrium. These abnormalities predispose to thrombus formation and arterial embolism, especially in the presence of underlying heart disease. The latter (including valvar heart disease, hypertensive heart disease, and poor left ventricular function) substantially increases the risk for stroke and thromboembolism in patients with atrial fibrillation. For example, the thromboembolic risk of atrial fibrillation is 18 times greater if valvar heart disease is present. In addition, a history of stroke, transient ischaemic attack, or other thromboembolism substantially increases the risk of stroke in atrial fibrillation (by 2.5 times). Hypertension and diabetes are also common risk factors for stroke, increasing the risk of stroke in atrial fibrillation by nearly twofold.

Anatomical aspects

A left atrial diameter of ≥ 4.0 cm was previously regarded as the strongest single predictor of increased risk of thromboembolisation, but atrial dilatation rarely occurs in isolation without associated clinical risk factors such as hypertension. Thus, in the most recent analysis from the Atrial Fibrillation Investigators, isolated left atrial dilatation by M mode echocardiography was not independently predictive of stroke and thromboembolism on multivariate analysis. Nevertheless, patients with lone atrial fibrillation (that is, those who have no underlying cause for their arrhythmia), have been shown to have a low risk of stroke and usually have an atrial size < 4.0 cm. Left atrial enlargement has also been associated with the presence of “spontaneous echocontrast” on transoesophageal echocardiography. With scanning electron microscopy, the endocardium of the left atrial appendage shows evidence of damage in mitral valve disease, especially in the presence of atrial fibrillation.

Mechanical aspects

The loss of atrial systolic function reduces stroke volume, leading to a corresponding reduction in cardiac output and increased atrial stasis. The latter results in increased propensity to thrombus formation. The prevalence of thrombus in the left atrial appendage, detected as an incidental finding during transoesophageal echocardiography, has been reported to be about 10-15% in patients admitted with acute atrial fibrillation and up to 30% in patients with atrial fibrillation and recent stroke.

Indeed, after cardioversion from atrial fibrillation to sinus rhythm, there is risk of thromboembolism of about 7% if anticoagulation is not used, with the highest risk one to two weeks after cardioversion. This may reflect mechanical reasons (embolisation of preformed thrombus), but it is more likely that this increased risk is related to atrial dysfunction after cardioversion (“stunning”) and the delay of the return of atrial systolic function, which can be up to three weeks or more after cardioversion.

Virchow's triad of thrombogenesis needs the presence of structural abnormalities (for example—atherosclerosis, valve disease), abnormal flow (stasis in left atria, heart failure), and abnormal blood constituents (for example—clotting factors, platelets, etc). All are present in “high risk” patients with atrial fibrillation

In patients with paroxysmal atrial fibrillation, thromboembolic events seem to cluster in the transition from atrial fibrillation to sinus rhythm, perhaps reflecting embolisation of a preformed clot

Thrombus in the left atrial appendage of patient with mitral valve disease at surgery

Atrial fibrillation and hypercoagulability

It has been recognised for over 150 years that abnormalities in the blood vessel wall, blood flow, and blood constituents (Virchow's triad) may increase the propensity for thrombus formation. Clinical and echocardiographic criteria can help identify the first two of Virchow's postulates for thrombogenesis—namely, abnormalities of blood flow and vessels, such as valvar heart disease and cardiac impairment. Patients with atrial fibrillation also show abnormalities of haemostatic and platelet markers that are unrelated to aetiology and underlying structural heart disease (and alter with antithrombotic therapy and cardioversion), which point towards the presence of a hypercoagulable state in this common arrhythmia. Thus, atrial fibrillation has been described as an arrhythmia which confers a prothrombotic or hypercoagulable state.

Anticoagulation for atrial fibrillation in special circumstances

Acute atrial fibrillation

In patients presenting with de novo atrial fibrillation, a clear history of arrhythmia onset is needed to guide appropriate antithrombotic therapy and timing of cardioversion.

Although no randomised trials have specifically addressed the issue, there is evidence that cardioversion may be safely performed without anticoagulation if the arrhythmia has been present for < 48 hours. However, in one series intra-atrial thrombus was detected by transoesophageal echocardiography in about 15% of patients presenting with acute atrial fibrillation (apparent duration < 48 hours), raising the possibility that the development of intra-atrial thrombus may be faster than previously suspected, or that in many apparent cases of acute atrial fibrillation the arrhythmia developed asymptotically > 48 hours before. Thus, in cases of uncertainty, anticoagulation is needed. Again, no randomised prospective studies have addressed the use of intravenous unfractionated heparin or subcutaneous low molecular weight heparin derivatives, but both drugs have been used with good results in the acute and pericardioversion periods.

Atrial fibrillation patients presenting with acute stroke

The role of antiplatelet drugs after acute stroke in sinus rhythm is well proved, but there is less certainty about the potential benefits and hazards of anticoagulant treatment in patients with atrial fibrillation, particularly the timing of administration. Although the benefits of secondary stroke prevention using warfarin in atrial fibrillation patients are dramatic, it must be certain that there is no ongoing intracerebral haemorrhage (or risk of new intracerebral haemorrhage) before starting the drug.

Previous consensus guidelines from the American College of Chest Physicians state that before any antithrombotic drug is started computed tomography or magnetic resonance imaging scan should be done to confirm the absence of intracranial haemorrhage and to assess the size of any cerebral infarction. In atrial fibrillation patients with no evidence of haemorrhage and small infarct size (or no evidence of infarction) warfarin (INR 2.0-3.0) can be given with minimal risk, provided patients are normotensive. In atrial fibrillation patients with large areas of cerebral infarction, the start of warfarin treatment should be delayed for two weeks because of the potential risk of haemorrhagic transformation. The presence of intracranial haemorrhage is an absolute contraindication to the immediate and future use of anticoagulation for stroke prevention in atrial fibrillation. The mortality benefits of aspirin treatment in acute stroke seen in the international stroke trial and Chinese acute

The development of intra-atrial thrombus, and thus the immediate risk of thromboembolism, is thought to be temporally related to the duration of the arrhythmia, with minimal risk if the arrhythmia has been present for <48 hours

Benefits of anticoagulant treatment in patients with non-rheumatic atrial fibrillation in preventing stroke

Stroke risk	NNT (95% CI) to prevent one stroke
Low: Age < 65 years, no major risk factors (including previous stroke, systemic embolism, or transient ischaemic attack; hypertension; and poor left ventricular function as determined by a clinical history of heart failure or left ventricular ejection fraction < 50%)	Aspirin 227 (132 to 2500)
Low moderate: Age 65-75 years, no major risk factors	Aspirin 152 (88 to 1667) Warfarin 54 (46 to 69)
High moderate: Age 65-75 years, no major risk factors but either diabetes or coronary heart disease	Warfarin 32 (28 to 42)
High: Age < 75 years with hypertension, left ventricular dysfunction, or both, or age > 75 without other risk factors	Warfarin 14 (12 to 17)
Very high: Age > 75 years with hypertension, left ventricular dysfunction, or both, or any age and previous stroke, transient ischaemic attack, or systemic embolism	Warfarin 8 (7 to 10)

NNT = number needed to treat

ABC of Antithrombotic Therapy

stroke trial were less marked in patients with atrial fibrillation, presumably because of the presence of preformed intra-atrial thrombus rather than new localised platelet thrombus adhering to carotid and cerebral artery atheroma.

Cardioversion of persistent atrial fibrillation

Although there are no randomised studies to show that successful cardioversion of atrial fibrillation reduces the number of subsequent thromboembolic events, the improvement in haemodynamic function and observed reduction in indices of clotting suggest that this may be the case. However, cardioversion is known to increase the short term risk of thromboembolism, and thus, unless the arrhythmia has been present for less than 48 hours, thromboprophylactic measures are needed. The mechanism behind pericardioversion thromboembolism is complex and not entirely understood, but it is likely to be associated with the return of atrial systole, temporary “stunning” of the left atrium before return of systolic function, and possibly an increase in thrombotic tendency caused by the procedure itself. The increase in thromboembolic risk may therefore persist for two weeks or more after successful cardioversion.

The American College of Chest Physicians (ACCP) sixth recommendations for pericardioversion anticoagulation have been summarised in the previous chapter. However, the recent ACUTE study found that by excluding thrombus on transoesophageal echocardiography before cardioversion, the need for prior anticoagulation could be safely avoided. Patients treated in this manner had similar rates of thromboembolism as those treated with the standard antithrombotic regimen but their haemorrhage rates were reduced. Transoesophageal echocardiography guided technique also allowed faster cardioversion of patients and resulted in higher initial success rates, although by eight weeks there was no substantial difference in death rates, maintenance of sinus rhythm, or in functional status between the two groups. Transoesophageal echocardiography guided cardioversion is now regarded by many as the optimum approach to cardioversion and is recognised as a suitable alternative to standard practice by the ACCP. This point is included in the recent American Heart Association (AHA)/American College of Cardiology (ACC)/European Society of Cardiology (ESC) guideline recommendations.

Recent trials comparing a “rate control” strategy with a “rhythm control” strategy for persistent atrial fibrillation showed an excess of thromboembolism in the patients randomised to rhythm control (that is—cardioversion), as such events happened in patients successfully cardioverted, the anticoagulation stopped and on recurrence of atrial fibrillation, thromboembolism occurred. Thus, anticoagulation should be considered long term in patients postcardioversion at high risk of stroke and thromboembolism, or high arrhythmia recurrence risk after cardioversion.

Electrical cardioversion of atrial fibrillation

Recommendations for antithrombotic therapy to prevent ischaemic stroke and systemic embolism in patients with atrial fibrillation undergoing cardioversion*

Class I

- Administer anticoagulation therapy regardless of the method (electrical or pharmacological) used to restore sinus rhythm
- Anticoagulate patients with atrial fibrillation lasting more than 48 hours or of unknown duration for at least three to four weeks before and after cardioversion (INR 2.0-3.0)
- Perform immediate cardioversion in patients with acute (recent onset) atrial fibrillation accompanied by symptoms or signs of haemodynamic instability resulting in angina pectoris, myocardial infarction, shock, or pulmonary oedema, without waiting for prior anticoagulation
 - If not contraindicated, administer heparin concurrently by an initial intravenous bolus injection followed by a continuous infusion in a dose adjusted to prolong the activated partial thromboplastin time at 1.5-2.0 times the reference control value
 - Next, provide oral anticoagulation (INR 2.0-3.0) for at least three to four weeks, as for patients who are undergoing elective cardioversion
 - Limited data from recent studies support subcutaneous administration of low molecular weight heparin in this indication
- Screening for the presence of thrombus in the left atrium or left atrial appendage by transoesophageal echocardiography is an alternative to routine preanticoagulation in candidates for cardioversion of atrial fibrillation
 - Anticoagulate patients in whom no thrombus is identified with intravenous unfractionated heparin by an initial bolus injection before cardioversion, followed by a continuous infusion in a dose adjusted to prolong the activated partial thromboplastin time at 1.5-2.0 times the reference control value
 - Next, provide oral anticoagulation (INR 2.0-3.0) for at least three to four weeks, as for patients who are undergoing elective cardioversion
 - Limited data from recent studies support subcutaneous administration of low molecular weight heparin in this indication
 - Treat patients in whom thrombus is identified by transoesophageal echocardiography with oral anticoagulation (INR 2.0-3.0) for at least three to four weeks before and after restoration of sinus rhythm

Class IIb

- Cardioversion without transoesophageal echocardiography guidance during the first 48 hours after the onset of atrial fibrillation
 - In these cases, anticoagulation before and after cardioversion is optional, depending on assessment of risk
- Anticoagulate patients with atrial flutter undergoing cardioversion in the same way as for patients with atrial fibrillation

ACC/AHA Classification

Class I—Conditions for which there is evidence or general agreement or both that a given procedure or treatment is useful and effective

Class II—Conditions for which there is conflicting evidence or a divergence of opinion about the usefulness and efficacy of a procedure or treatment

Class IIa—Weight of evidence and opinion is in favour of usefulness and efficacy

Class IIb—Usefulness and efficacy is less well established by evidence and opinion

Class III—Conditions for which there is evidence or general agreement or both that the procedure or treatment is not useful and in some cases may be harmful

7 Antithrombotic therapy in peripheral vascular disease

Andrew J Makin, Stanley H Silverman, Gregory Y H Lip

Atherosclerotic peripheral vascular disease is symptomatic as intermittent claudication in 2-3% of men and 1-2 % of women aged over 60 years. However, the prevalence of asymptomatic peripheral vascular disease, generally shown by a reduced ankle to brachial systolic pressure index, is three to four times greater. Peripheral vascular disease is also a significant cause of hospital admission, and is an important predictor of cardiovascular mortality. Pain at rest and critical ischaemia are usually the result of progression of atherosclerotic disease, leading to multilevel arterial occlusion. Other causes of arterial insufficiency—including fibromuscular dysplasia, inflammatory conditions, and congenital malformations—are much rarer. Therapeutic objectives in peripheral vascular disease include relieving symptoms and preventing the disease, and any associated events, progressing.

The symptoms of peripheral vascular disease are progressive. A claudicating patient encouraged to exercise tends to report a symptomatic improvement. This effect is generally not accepted to be an improvement in the diseased segment of blood vessel, but the formation of collateral vessels perfusing the ischaemic tissue.

Vasodilating agents, such as naftidrofuryl, have little value in managing claudication and peripheral vascular disease as their effect is small and does not stop progression of the disease. Cilostazol has been shown to increase absolute walking distance in some patients by up to 47%. However, it has no clear antithrombotic effect and has not been shown to stop disease progression.

Unfortunately, not all progression is amenable to improvement and, without the appropriate risk factor management, progression to rest pain and necrosis can be rapid.

Intermittent claudication

The role of aspirin as an antiplatelet agent has been shown to be beneficial beyond doubt. In peripheral vascular disease it reduces the frequency of thrombotic events in the peripheral arteries and reduces overall cardiovascular mortality in claudicating patients. The dose of aspirin has been the subject of some debate, but 81-325 mg daily has been shown to be of value. Larger doses have no apparent additional benefit but increase the risk of adverse effects. Aspirin has been shown to reduce the progression of atherosclerosis in a few trials, but this remains unsubstantiated.

The role of dipyridamole remains controversial. Several small studies have shown the benefit of giving it in conjunction with aspirin, but it is uncertain if dipyridamole alone is superior to aspirin.

In aspirin intolerant patients there is now a clear role for clopidogrel 75 mg once a day. This is as effective as aspirin in preventing cardiovascular events. If a thrombotic event has occurred (whether the patient is taking aspirin or not) there may be an advantage in using clopidogrel to prevent further events, especially in peripheral vascular disease.

In non-critical peripheral ischaemia, there is no indication for warfarin treatment as the complexities of management and bleeding risks seem to far outweigh the benefits, unless the

Ischaemic ulcer on foot

Antithrombotic therapy in peripheral vascular disease

Clinical problem	Antithrombotic therapy of choice
Intermittent claudication	Aspirin (to reduce risk of stroke and myocardial infarction) Clopidogrel
Diabetes	Aspirin (to reduce risk of stroke and myocardial infarction) Clopidogrel
Embolic arterial occlusion	Intravenous heparin and emergency surgical intervention
Acute on chronic arterial occlusion	Heparin and angioplasty, intra-arterial thrombolysis or early surgery
Intraoperative anticoagulation during vascular surgery	Heparin
Infrainguinal vein bypass and infrainguinal prosthetic bypass	Aspirin (to reduce risk of stroke and myocardial infarction) Clopidogrel (if unable to take aspirin)
Infrainguinal bypass at high thrombotic risk	Aspirin or consider warfarin
Carotid endarterectomy	Aspirin or clopidogrel
Symptomatic carotid stenosis and too unwell for surgery	Consider warfarin or aspirin plus dipyridamole

Survival curve from CAPRIE study showing the benefits of aspirin and clopidogrel on vascular events, with placebo rates from the Antiplatelet Trialists' Collaboration

patient has concomitant problems needing anticoagulation such as atrial fibrillation.

Critical ischaemia

Rest pain and gangrene are markers of critical ischaemia. This is nearly always the result of extensive vessel occlusion with absent pedal pulses. The patient will almost certainly be immobile because of pain and arterial insufficiency making walking impossible. These patients need prophylaxis against venous thromboembolism.

Patients giving a short history of rest pain of sudden onset require full, immediate anticoagulation with low molecular weight heparin or intravenous unfractionated heparin (the latter with a target activated partial thrombin time (APTT) ratio of 1.5-2.5). Warfarin should be avoided initially until investigations and possible interventions are complete.

Patients with chronic, progressive pain at rest also need full anticoagulation. Although the evidence is limited, these patients are often treated with warfarin to prevent progression, especially if remedial surgery is not possible. The international normalised ratio (INR) should be kept in the range of 2-3.

Acute thromboembolic occlusion of the peripheral arteries requires immediate anticoagulation with intravenous unfractionated heparin to prevent propagation of the thrombus and to guard against further embolism. Surgical intervention or, less commonly, thrombolytic therapy is indicated. Once the embolus has been cleared, the source needs to be investigated and this usually requires treatment with warfarin long term.

Gangrenous toe indicating critical ischaemia

Peripheral artery revascularisation

When the ischaemia reaches a state where peripheral artery revascularisation or reconstruction is necessary, the requirements for antithrombotic therapy change.

Neointimal hyperplasia is a considerable problem in the long term survival of a graft as its consequences (reduced blood flow caused by reduced lumen) in some respects mimic those of the original disease. Hyperplasia of smooth muscle cells can occur along the entire length of a vein graft, but particularly does so at the anastomoses of prosthetic grafts.

Aspirin has no apparent effect on graft survival in humans. One trial showed that low molecular weight heparin had a profound beneficial effect on graft patency, when compared with aspirin and dipyridamole over three months, suggesting that early treatment with low molecular weight heparin suppresses neointimal hyperplasia. In the United Kingdom most low molecular weight heparins have licences only for 14 days'

Peripheral angiogram showing chronic occlusions with multiple collateral vessels

Risk of thrombosis with different vein grafts

Site of proximal anastomosis	Site of distal anastomosis	Graft material	Other factors	Thrombotic risk	Recommended antithrombotic therapy
Aorta	Iliac or femoral	Prosthetic		Low	Antiplatelet*
Axilla	Femoral	Prosthetic		Medium	Antiplatelet
Femoral	Popliteal (above knee joint)	Vein		Low	Antiplatelet*
		Prosthetic		Low	Antiplatelet*
	Distal (below knee)	Vein	Good flow (> 100 ml/min) and good distal arteries	Medium	Antiplatelet
		Prosthetic	Poor flow (< 50 ml/min) or poor distal arteries	High	Antiplatelet Consider warfarin
		Prosthetic		High	Antiplatelet Consider warfarin

*Antiplatelet therapy not indicated for graft survival but recommended as prophylaxis against cardiovascular events

ABC of Antithrombotic Therapy

treatment, and, until more data are available, the prolonged use of low molecular weight heparin cannot be recommended.

Infrainguinal bypass

Antiplatelet treatment has no beneficial role for graft patency in short (femoral-popliteal) bypass with native vein grafts because these are high flow and non-thrombogenic. None the less, aspirin has been shown to reduce all cardiovascular end points in patients with peripheral vascular disease, and so should be continued. Anticoagulation with warfarin has not been shown to be of benefit.

Patients with prosthetic femoral-popliteal bypass are a different consideration. Taking aspirin with dipyridamole reduces platelet accumulation at the anastomosis. Starting antiplatelet treatment preoperatively leads to improved patency rates, especially in “high risk” (low flow, prosthetic) grafts once the increased complication rate of postoperative wound haematoma has passed. Again, aspirin (with or without dipyridamole) is recommended.

High risk grafts need to be dealt with cautiously. All patients should continue taking aspirin (or clopidogrel). The use of warfarin needs to be judged carefully. In cases of poor run off, marginal quality vein, and previous graft failure, oral anticoagulation has been shown to improve primary patency and limb salvage rates with a target INR of 2-3. If this is being considered then full heparinisation should begin immediately after the operation while oral anticoagulation is started. Naturally, older patients are more likely to have bleeding complications, including intracranial haemorrhage, and this should be considered.

Aortoiliac and aortofemoral grafts

Large aortoiliac and aortofemoral grafts are at low risk of thrombosis. Primary patency rates of 80-90% can be expected at five to ten years. Thus, specific antithrombotic therapy is not indicated. However, once again, the presence of peripheral vascular disease needs antiplatelet therapy to reduce all cardiovascular end points.

Percutaneous transluminal angioplasty

Almost all patients undergoing percutaneous transluminal angioplasty have atherosclerotic peripheral vascular disease. As such, they should all be treated with aspirin or clopidogrel.

Studies with radiolabelled platelets have found substantial platelet accumulation at the sites of angioplasty, and antiplatelet treatment reduces this. In coronary angiography, this treatment has been shown to reduce the incidence of new thrombus at the site of the angioplasty. However, in similar coronary artery studies, antiplatelet treatment has no effect on restenosis compared with placebo. It is unclear how these results will extrapolate to peripheral angioplasty, and there are insufficient data to make recommendations in peripheral vascular disease.

Similarly there have not been enough studies to recommend the use of dipyridamole, ticlopidine, or clopidogrel as an adjunct to aspirin. Although the long term use of antiplatelet drugs is not known to have any long term effect on restenosis, the drug should be used to prevent cardiovascular mortality in patients undergoing percutaneous transluminal angioplasty.

Carotid stenosis

Evidence for treatment of asymptomatic carotid stenosis of greater than 50% is unclear. One trial showed no reduction in stroke rate in patients treated with aspirin for two to three years. However, it is increasingly accepted that atherosclerosis affects all arteries to a greater or lesser extent. With this in mind, and

Problems in patients undergoing infrainguinal bypass

- The thrombogenic characteristics of prosthetic graft materials
- The poor flow states associated with some grafts, for example, long bypasses passing over the knee joint
- The medium to long term complication of neointimal hyperplasia

Meta-analysis from the Antithrombotic Trialists' Collaboration showing the benefits of antiplatelet treatment in patients with peripheral vascular disease

Among high risk patients, antiplatelet treatment reduces the combined outcome of any serious vascular event by about a quarter, non-fatal myocardial infarction by a third, non-fatal stroke by a quarter, and vascular mortality by a sixth (with no apparent adverse effect on other deaths)

Suggestions from the Antithrombotic Trialists' Collaboration

- Clopidogrel reduced serious vascular events by 10% compared with aspirin, which was similar to the 12% reduction observed with its analogue ticlopidine
- Addition of dipyridamole to aspirin produced no significant further reduction in vascular events compared with aspirin alone

the evidence for using aspirin in lower limb atherosclerosis, it is still recommended that these patients have antiplatelet treatment to prevent all cardiovascular events.

Treating patients who have had a transient ischaemic attack or known ischaemic stroke with aspirin has clear benefit as shown by the Antiplatelet Trialists' Collaboration. The dose is not clear, but 81-325 mg should be effective without unacceptable bleeding risk. Clopidogrel (75 mg daily) is recommended for aspirin intolerant patients. Limited evidence shows that the combination of aspirin and dipyridamole (400 mg daily) may be more beneficial to these patients than aspirin alone.

Inadequate data exist on the use of warfarin in symptomatic carotid stenosis, and so this cannot be recommended because of possible bleeding complications.

Carotid endarterectomy is the treatment of choice for all symptomatic carotid stenosis. Aspirin treatment should be continued in the perioperative period to prevent platelet deposition at the site of the endarterectomy and thus reduce intraoperative and postoperative stroke. Platelet deposition is known to start immediately after the operation, and aspirin started in the first few postoperative days seems to provide much less benefit. In patients with symptomatic disease who are not undergoing endarterectomy antiplatelet therapy is essential to reduce the incidence of ischaemic stroke. Again, warfarin should not be used as not enough evidence exists. In all patients with cerebrovascular or carotid disease, antiplatelet therapy is recommended at all stages to decrease the risk of cardiovascular events.

8 Antithrombotic therapy for cerebrovascular disorders

Gregory Y H Lip, Sridhar Kamath, Robert G Hart

Stroke remains one of the leading causes of death and disability throughout the world. It is the third commonest cause of death in developed countries, exceeded only by coronary artery disease and cancer.

The incidence of stroke is 1-2 cases in 1000 people a year in the Western world, and is probably slightly higher among African-Caribbeans than other ethnic groups. Cerebrovascular disorders are uncommon in people aged <40 years, but there is a definite increase with age, with an incidence of 10 cases in 1000 people aged >75 in a year. Stroke is slightly more common in men, but women tend to have a poorer prognosis because of a higher mean age at onset. The incidence of stroke has been declining in recent decades in many Western countries because of better population control of hypertension, smoking, and other risk factors. However, the absolute number of strokes continues to increase because of the ageing population, which is predicted to peak in 2015. Thus, the present annual incidence of 700 000 strokes in the United States is expected to rise to 1 100 000 in 2015, without further advances in prevention.

About 80-85% of the strokes are ischaemic, with the rest primarily haemorrhagic. Even among patients with ischaemic stroke, there is much heterogeneity in aetiological and pathophysiological factors contributing to the disease.

Atherosclerosis of the major cerebral vessels probably accounts for most ischaemic strokes, either as thrombotic occlusion at the site of atherosclerotic plaques or atherogenic embolism. Embolism from a source in the heart (cardioembolic stroke) and lipohyalinosis of the penetrating small cerebral vessels (lacunar stroke) account for a substantial proportion of ischaemic strokes. In many patients the aetiology remains unknown. The major risk factors for ischaemic stroke include old age, male sex, obesity, hypertension, diabetes, and tobacco smoking.

Management of acute ischaemic stroke

The principles of management of patients with ischaemic stroke include slowing the progression of stroke, decreasing the recurrence of stroke, decreasing death and disability, preventing deep vein thrombosis and pulmonary embolism, and suppressing fever, managing hypertension and controlling glucose levels.

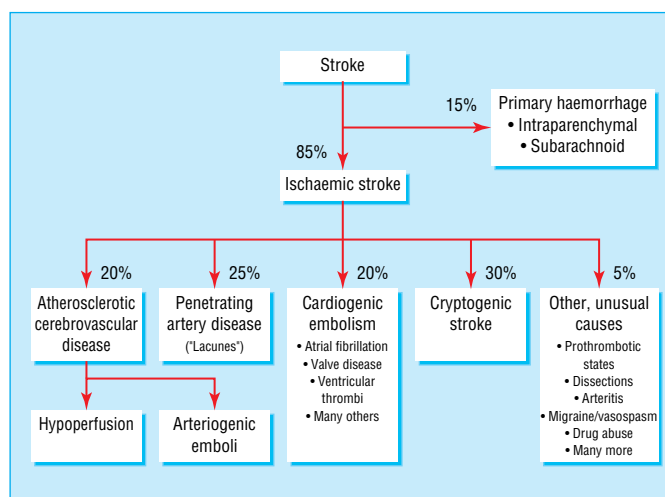

Antiplatelet treatment

Aspirin is the only antiplatelet drug evaluated for the treatment of acute ischaemic stroke and is recommended early in the management at a dose of 160-325 mg daily. Two major randomised trials (the international stroke trial (IST) and the Chinese acute stroke trial (CAST)) have shown that starting daily aspirin promptly (<48 hours after the start rather than the end of the hospital stay) in patients with suspected acute ischaemic stroke reduces the immediate risk of further stroke or death in hospital, and the overall risk of death and dependency at six months later. About 10 deaths or recurrent strokes are avoided in every 1000 patients treated with aspirin in the first few weeks after an ischaemic stroke.

The benefit of aspirin is seen in a wide range of patients irrespective of age, sex, atrial fibrillation, blood pressure, stroke subtype, and computed tomographic findings. In IST 300 mg of

- Traumatic

aspirin was used and in CAST 160 mg. Thus, the two studies show that giving aspirin early in acute stroke is safe, although side effects should always be considered. Other trials have shown that continuing treatment with low dose aspirin gives protection in the longer term. Until further evidence is available, however, aspirin should be withheld from patients receiving other forms of anticoagulant (except low dose heparin (5000 IU twice daily)) or thrombolytic treatment (and for 24 hours after finishing treatment).

The results of the IST and CAST studies apply chiefly to patients who had a computed tomography scan to exclude intracranial haemorrhage. A meta-analysis of subgroups from the trials showed that aspirin was safe and beneficial. Even among patients who did not have a computed tomogram and patients with haemorrhagic stroke, aspirin treatment did not result in net hazard. Thus, aspirin can be started in patients with suspected ischaemic stroke even when computed tomography is not available immediately.

Anticoagulation treatment

Heparin is not routinely recommended for patients with acute ischaemic stroke. There are no randomised trials supporting the use of standard doses of heparin (for example > 10 000 IU daily) even in patients with acute stroke and risk factors for recurrent events. The risk:benefit ratio of heparin administration is narrow, ill defined, and probably depends on the pathophysiological subtype of stroke and the factors that predispose to haemorrhage. For patients with atrial fibrillation and acute ischaemic stroke, there seems to be no net benefit from standard dose heparin (aspirin should be given immediately, then warfarin (INR 2.0-3.0) started for secondary prevention as soon as the patient is medically stable). However, a subgroup analysis from IST showed that in acute ischaemic stroke low dose heparin (5000 IU twice daily) reduced death and recurrence, especially if combined with aspirin, and it is indicated if appreciable leg weakness is present for prevention of venous thromboembolism.

No particular benefit was observed in ischaemic stroke in the vertebrobasilar region with anticoagulation at six months. Trials with low molecular weight heparins or heparinoids have yielded contradictory (but generally negative) results, and they are not recommended for use at the moment.

Thrombolytic treatment

Thrombolytic treatment for acute ischaemic stroke has been in vogue since its immense benefit was seen with myocardial infarction. The National Institute of Neurological Disorders and Stroke (NINDS) rtPA Study Group trial showed that recombinant tissue plasminogen activator administered within three hours of onset of acute cerebral infarct at a dose of 0.9 mg/kg (maximum 90 mg) given over an hour under strict treatment protocols increased the likelihood of minimal or no disability at three months by at least 30%. This benefit was seen in all stroke patients. Recombinant tissue plasminogen activator is licensed for treating acute cerebral infarct in several countries. However, the risk:benefit ratio is narrow because of substantial risk of intracerebral haemorrhage, and the need to start treatment (after computed tomographic assessment) within three hours of stroke onset severely restricts the number of patients who can be treated.

Streptokinase is not approved for use in acute cerebral infarct because of the results of three large trials, which were terminated early due to excessive bleeding. These trials used streptokinase at a dose of 1.5 million units given more than three hours after stroke onset. Intra-arterial thrombolytic treatment for patients with large artery occlusions (such as of

Computed tomogram of the brain showing lacunar infarcts in the anterior limb of the left internal capsule

Thromboembolic and major haemorrhagic events in the International Stroke Trial. ICH=intracranial haemorrhage

Cardiac disorders predisposing to stroke

Major risk

- Atrial fibrillation
- Prosthetic mechanical heart valve
- Mitral stenosis
- Severe left ventricular dysfunction with mobile left ventricular thrombus
- Recent myocardial infarction
- Infective endocarditis

Minor risk*

- Mitral annular calcification
- Mitral valve prolapse
- Patent foramen ovale
- Calcific aortic stenosis
- Atrial septal aneurysm

*Occasionally can cause cardioembolic stroke, but the risk of initial stroke is low and often unrelated when identified during the evaluation of patients with cerebral ischaemia

the internal carotid artery, middle cerebral artery, or basilar artery) remains investigational. In the United Kingdom, thrombolytic treatment is not licensed for treatment of stroke, pending results from ongoing clinical trials (for example, IST-3).

Stroke prevention

In broad terms, antiplatelet agents are more effective in cerebrovascular atherogenic strokes, and anticoagulants are more effective in primary and secondary prophylaxis against cardioembolic stroke.

Antiplatelet agents

Among patients with vascular disorders (such as coronary artery disease, previous stroke or transient ischaemic attack, and peripheral vascular disease) antiplatelet agents substantially reduce the incidence of non-fatal stroke, non-fatal myocardial infarction, vascular mortality, and composite end point of stroke, myocardial infarction, and vascular death.

A variety of antiplatelet drugs with varying mechanisms of action are used to minimise stroke in patients at high risk. These include aspirin (irreversible inhibitor of cyclo-oxygenase), clopidogrel (which inhibits adenosine diphosphate induced platelet aggregation) and dipyridamole (precise mechanism of action not yet clear). Aspirin remains the most commonly used antiplatelet drug, partly because of its cost effectiveness.

Aspirin is effective for stroke prevention in doses ranging from 30 mg/day to 1300 mg/day. Its beneficial effect is seen in all age groups and sexes. The European stroke prevention study II (ESPS II) showed that a combination of aspirin and dipyridamole (sustained release 200 mg tablets twice daily) significantly reduced the risk of stroke and all vascular events compared with aspirin alone. An important ongoing trial (ESPRIT) is seeking to replicate these results.

Clopidogrel is a newer thienopyridine derivative without the adverse effect profile of ticlopidine. The CAPRIE (clopidogrel versus aspirin in patients at risk of ischaemic events) study showed that clopidogrel is slightly more effective than aspirin in reducing the combined outcome of stroke, myocardial infarction, and vascular death among patients with atherosclerotic vascular disease. Although clopidogrel seems to be as safe as aspirin, it is considerably more expensive, and it remains to be seen whether its use in routine practice is cost effective. Its use is justified in patients who are intolerant to aspirin or who develop a stroke while taking aspirin.

Anticoagulation treatment

Anticoagulation in the form of warfarin has a role in a variety of cardiac disorders in primary and secondary prevention of stroke. Cardiac disorders that predispose to stroke and unequivocally seem to benefit from anticoagulation therapy include atrial fibrillation (with additional risk factors putting patients at moderate to high risk), mitral stenosis (with or without atrial fibrillation), and mechanical valve prosthesis. In contrast, recent randomised trials (SPIRIT, WARSS) did not show advantages of warfarin over aspirin for secondary prevention of non-cardioembolic brain ischaemia. At present, warfarin should not be used routinely for patients with common causes of non-cardioembolic stroke, pending results from ongoing randomised trials.

Risk factors for haemorrhagic transformation of ischaemic stroke

- Hypertension
- Concomitant use of two or more antiplatelet or antithrombotic therapies
- Major early infarct signs on pretreatment computed tomography, including brain oedema and mass effect
- Severe neurological deficit

Details of the second European stroke prevention study (ESPS-II)

- Randomised, placebo controlled, double blind trial of aspirin (50 mg), dipyridamole (400 mg), or both versus placebo
- Two year follow up of >6600 patients (secondary prevention of stroke)

Placebo compared with:	Aspirin alone	Dipyridamole alone	Aspirin + dipyridamole
Reduction of stroke risk	18% (P = 0.013)	16% (P = 0.015)	37% (P < 0.001)
Reduction of risk of stroke or death	13% (P = 0.016)	15% (P = 0.015)	24% (P < 0.001)

- Clear additive benefit in stroke reduction (36%) when aspirin and dipyridamole were used in combination

9 Valvar heart disease and prosthetic heart valves

Ira Goldsmith, Alexander G G Turpie, Gregory Y H Lip

Thromboembolism and anticoagulant related bleeding are major life threatening complications in patients with valvar heart disease and those with prosthetic heart valves. In these patients effective and safe antithrombotic therapy is indicated to reduce the risks of thromboembolism while keeping bleeding complications to a minimum.

Assessment

Risk factors that increase the incidence of systemic embolism must be considered when defining the need for starting antithrombotic therapy in patients with cardiac valvar disease and prosthetic heart valves. These factors include age, smoking, hypertension, diabetes, hyperlipidaemia, type and severity of valve lesion, presence of atrial fibrillation, heart failure or low cardiac output, size of the left atrium (over 50 mm on echocardiography), previous thromboembolism, and abnormalities of the coagulation system including hepatic failure.

Secondly, the type, number, and location of prostheses implanted must be considered. For example, mechanical prostheses are more thrombogenic than bioprostheses or homografts, and hence patients with mechanical valves require lifelong anticoagulant therapy. However, the intensity of treatment varies according to the type of mechanical prosthesis implanted. First generation mechanical valves, namely the Starr-Edwards caged ball valve and Bjork-Shiley standard valves, have a high thromboembolic risk; single tilting disc valves have an intermediate thromboembolic risk; and the newer (second and third generation) bileaflet valves have low thromboembolic risks.

In patients with a bioprosthesis in sinus rhythm, antithrombotic therapy with an antiplatelet drug may suffice, whereas patients with homografts in sinus rhythm may not need any antithrombotic therapy. Thromboembolic events are commoner with prosthetic mitral valves than aortic valves and in patients with double replacement valves compared with those with single replaced valves. Moreover, the risk of thromboembolic events is greatest in the first three months after implantation.

Choice of antithrombotic agent

Warfarin is the most used oral anticoagulant, and its dose is guided by achieving a target international normalised ratio (INR) range. The use of heparin is confined to short periods when anticoagulant cover is needed and oral anticoagulants are stopped. The dose of heparin is adjusted to achieve at least twice normal level of activated partial thromboplastin time (APTT) regardless of cardiac rhythm and type or position of prosthesis. Fixed weight-adjusted low molecular weight heparin may be used as an alternative to unfractionated heparin. Antiplatelet drugs, such as low dose aspirin or dipyridamole, are used in patients with bioprosthesis in sinus rhythm and in addition to anticoagulants in the high risk patients with mechanical valves.

Patients with mechanical valves and those with bioprostheses and associated risk factors require lifelong anticoagulant cover. In patients with a bioprosthetic valve in sinus rhythm anticoagulant cover with warfarin for the first three postoperative months may suffice, followed by low dose aspirin treatment for life. Alternatively, some surgeons give only low dose aspirin after

Valve thrombosis of a bileaflet prosthetic mitral valve

Considerations for antithrombotic therapy in patients with valve disease

- Assessment of risk for thromboembolic events, which may be patient related or valve prosthesis related
- Indications for starting treatment
- Choice of antithrombotic agent
- Duration of treatment and optimal therapeutic range
- Antithrombotic therapy in special circumstances (surgical procedures, pregnancy, and resistance to oral anticoagulants)
- Management of treatment failures and complications

Types of prosthetic valves and thrombogenicity

Type of valve	Model	Thrombogenicity
<i>Mechanical</i>		
Caged ball	Starr-Edwards	++++
Single tilting disc	Bjork-Shiley, Medtronic Hall	+++
Bileaflet	St Jude Medical, Sorin Bicarbon, Carbomedics	++
<i>Bioprosthetic</i>		
Heterografts	Carpentier-Edwards, Tissue Med (Aspire), Hancock II	+ to ++
Homografts		+

Risk factors for patients with bioprostheses include previous thromboembolic events, atrial fibrillation, enlarged left atrial cavity, and severe cardiac failure

ABC of Antithrombotic Therapy

surgery in patients with bioprostheses in sinus rhythm (providing aspirin is not contraindicated). Patients with homografts usually do not require any antithrombotic therapy.

Indications for antithrombotic therapy

Native valve disease

Oral anticoagulant treatment is indicated in all patients who have established or paroxysmal atrial fibrillation with native valve disease regardless of the nature or severity of the valve disease. In patients with mitral stenosis in sinus rhythm, treatment is guided by the severity of stenosis, the patient's age, size of the left atrium, and the presence of spontaneous echocontrast or echocardiographic evidence of left atrial appendage thrombus. In these patients a target INR of 2.5 (range 2-3) is recommended. Similarly, in patients with mitral regurgitation treatment is indicated in the presence of congestive cardiac failure, marked cardiomegaly with low cardiac output, and an enlarged left atrium. In the absence of cardiac failure, previous thromboemboli, or heart failure, antithrombotic therapy is not indicated in patients with isolated aortic or tricuspid valve disease.

Mitral valve prolapse per se does not require anticoagulant cover, although sometimes aspirin is recommended because of the association with cerebrovascular events.

Percutaneous balloon valvuloplasty

In patients with mitral stenosis, the presence or absence of left atrial thrombus is first confirmed by transoesophageal echocardiography. In the presence of thrombus, valvuloplasty is deferred and anticoagulant treatment started for two months before the procedure, with a target INR range of 2-3. In the absence of atrial thrombus but in the presence of risk factors—namely, previous thromboembolism, enlarged left atrium, spontaneous echocontrast, or atrial fibrillation—oral anticoagulant treatment should be started a month before the procedure.

During the procedure, intravenous heparin (2000-5000 IU bolus) should be given to all patients immediately after trans-septal catheterisation. After the procedure, subcutaneous heparin should be given for 24 hours and oral anticoagulant treatment restarted 24 hours after the procedure in patients with risk factors, especially in the presence of atrial fibrillation or spontaneous echocontrast.

Patients in sinus rhythm who are undergoing aortic valvuloplasty do not need long term anticoagulant treatment. However, treatment with heparin during the procedure is required.

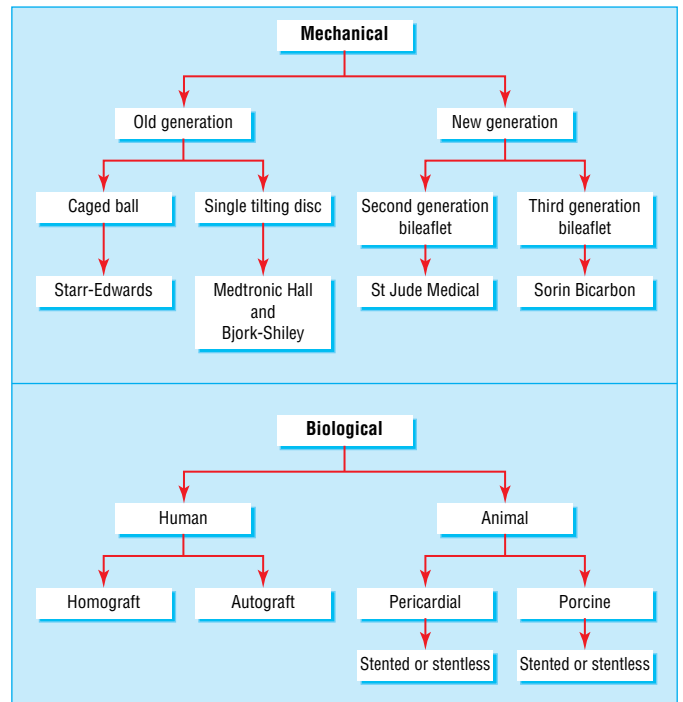

Mitral valve repair

After mitral valve repair, oral anticoagulation (target INR 2.5) is needed for the first six weeks to three months, and thereafter treatment is guided by the presence or absence of risk factors such as atrial fibrillation, heart failure, and enlarged left atrium.

Heart valve replacement

Antithrombotic therapy in patients with replaced heart valves is guided by the type of prosthesis implanted (mechanical or biological), position of the implant, associated risk factors (such as atrial fibrillation), previous thromboembolism, bleeding risk, and the patient's age.

Patients with porcine or pericardial bioprostheses in sinus rhythm may be started on lifelong antiplatelet treatment with low dose aspirin as soon as they can swallow the drugs.

Types of heart valve prostheses

Comparison of mechanical and biological valve prostheses

Mechanical	Biological
Durable—valves lasting 20-30 years	Limited life span—10% of homografts and 30% of heterografts fail within 10-15 years
Thrombogenic—patients require lifelong anticoagulant therapy	Low thrombogenic potential—lifelong anticoagulation is not required
Preferred in younger patients with > 10-15 years life expectancy	Preferred in older patients with < 10-15 years life expectancy
Preferred in patients who require lifelong anticoagulant therapy	Preferred in those who cannot (or will not) take lifelong anticoagulant therapy

Examples of biological and mechanical valve prostheses: (left) stentless porcine valve, (middle) stented porcine valve, (right) Sorin Bicarbon valve

However, many centres start oral anticoagulant treatment the day after implantation, maintaining an INR range of 2-3 for the first three months. Lifelong anticoagulant treatment is recommended for patients with associated risk factors. These factors are previous thromboembolism, left atrial thrombus, marked cardiomegaly, heart failure, dilated left atrium, or spontaneous echocontrast.

Patients with mechanical heart valves require lifelong anticoagulant treatment, and patients with first generation valves (with the highest thromboembolic risk) need a higher target INR than patients with single tilting disc prostheses (intermediate thromboembolic risk) or the newer bileaflet prosthesis (lower thromboembolic risk).

Most centres start (or restart) oral anticoagulant treatment the day after implantation, with or without heparinisation. As the thromboembolic risk is highest in the early postoperative period, it is advisable to give heparin and to continue it until the oral anticoagulant treatment achieves the target INR. The dose of heparin should be adjusted to achieve twice the normal level of APTT regardless of cardiac rhythm and type or position of the valve.

The European and North American guidelines have minor differences. The duration of antithrombotic therapy also varies according to a number of factors. Lifelong anticoagulant treatment is indicated for patients with mechanical valves and those with bioprosthetic valves or native valve disease with additional risk factors.

Antithrombotic therapy in special circumstances

Modification of anticoagulant treatment may be required in patients who have prosthetic valves and are undergoing non-cardiac surgical procedures, who are pregnant, or who have resistance to oral anticoagulants.

Surgical procedures

For minor procedures, such as certain dental surgery or cryotherapy, where blood loss is expected to be minimal and easily manageable, anticoagulant treatment may be continued. After dental extraction bleeding can be stopped with oral tranexamic acid (4.8%) mouth wash. However, before a planned minor surgical procedure, the INR should be adjusted to between 1.5 and 2.0. This can be achieved by stopping or adjusting oral anticoagulant treatment one to three days before the procedure depending on the drug used. In most cases, resumption of oral anticoagulant treatment is possible on the same day as the procedure, and interim heparin treatment is not needed. Patients undergoing endoscopic procedures and in whom an endoscopic biopsy is anticipated should be managed in the same way as patients needing major non-cardiac surgical procedures.

For major non-cardiac surgical procedures, in which there is a substantial risk of bleeding, anticoagulation should be discontinued for several days (generally four to five days) before surgery and the INR should be normalised at 1.0. The risk of thromboembolism increases, and so interim heparin treatment should be given in a dose that prolongs the APTT to twice the control value. However, heparin should be stopped in time to bring the APTT down to near normal at the time of operation and resumed as soon as possible postoperatively. An alternative approach would be to use therapeutic fixed weight-adjusted doses of low molecular weight heparin.

Intensity of anticoagulation guidelines for Europe

	European Society of Cardiology 1995 INR range	British Society of Haematology 1998 INR target

In atrial fibrillation:		
Aortic	2.0-3.0	2.5 (2.0-3.0)
Mitral	2.5-3.5	2.5 (2.0-3.0)

AHA = American Heart Association; ACC = American College of Cardiology; ACCP = American College of Chest Physicians

Pregnancy

In pregnant women with prosthetic valves, the incidence of thromboembolic complications is increased. Hence, adequate antithrombotic therapy is particularly important. Warfarin use in the first trimester of pregnancy is associated with a substantial risk of embryopathy and fetal death, and so warfarin should be stopped when a patient is trying to become pregnant or when pregnancy is detected. Instead, twice daily subcutaneous unfractionated heparin should be given to prolong the APTT to twice the control value, and this treatment may be continued until delivery. Alternatively, unfractionated heparin may be given until the thirteenth week of pregnancy, then a switch made to warfarin treatment until the middle of the third trimester. Then warfarin can be stopped and unfractionated heparin resumed until delivery. Because low dose aspirin is safe for mother and child, it may be used in conjunction with anticoagulant treatment in women at high risk of thromboembolism. However, low molecular weight heparin (which does not cross the placental barrier) may be an alternative to unfractionated heparin in this setting, although there are limited data on its efficacy or safety in pregnancy. Other pregnancy related issues are discussed in chapter 14.

Management of temporary interruption of oral anticoagulants

- Discontinue oral anticoagulation five days before the procedure
 - Measure INR three days before procedure
 - If INR < 2 start low molecular weight heparin in therapeutic doses
 - If INR > 2.5 consider giving Vitamin K₁ 1-2 mg orally and start low molecular weight heparin in therapeutic doses. Repeat INR measurement the day before procedure
 - Continue low molecular weight heparin until evening before procedure (last injection not less than 12 hours preprocedure)
 - Restart warfarin night of or day after procedure
 - Restart low molecular weight heparin 12-24 hours after procedure and when haemostasis is established
-

Indications for lifelong oral anticoagulation in valve disease

- Mechanical prostheses
 - Chronic or paroxysmal atrial fibrillation in the presence of native valve disease, bioprosthesis, valve repair, or valvuloplasty
 - Native valve disease and previous thromboembolism
 - Mitral valve stenosis, irrespective of rhythm, in association with high transmitral valve gradient, left atrial thrombus, spontaneous echocontrast, large left atrium (> 50 mm), low cardiac output, or congestive heart failure
-

10 Antithrombotic therapy in myocardial infarction and stable angina

Gregory Y H Lip, Bernard S P Chin, Neeraj Prasad

Acute Q wave myocardial infarction

The use of thrombolytic treatment in acute myocardial infarction is now established beyond doubt. However, primary angioplasty is now proved to be an effective alternative and is used increasingly in preference to thrombolysis in many centres worldwide.

Thrombolytic treatment

Current key issues relate to the clinical situations in which thrombolysis may be beneficial or contraindicated. For example, all patients with a history suggesting cardiac ischaemia and accompanying electrocardiographic changes indicating acute myocardial infarction should be considered for thrombolysis. However, patients with only ST segment depression on an electrocardiogram or with a normal electrocardiogram do not benefit from thrombolysis, and treatment should therefore be withheld. Exceptions to this are when there is evidence of new development of left bundle branch block or a true posterior myocardial infarction (shown by ST segment depression with dominant R waves present in leads V1 and V2). These situations require thrombolytic treatment.

Thrombolytic treatment should be given within six hours of the onset of symptoms and electrocardiographic changes for patients to derive full benefit. Patients with persisting pain and ST segment elevation may still benefit from thrombolysis up to 12 hours from the onset of symptoms. Beyond that, few patients will benefit, and there is no clear evidence of whether this benefit outweighs the risk of haemorrhage.

Thrombolytic treatment should be offered to all eligible patients presenting with an acute myocardial infarction regardless of age, sex, or site of infarct. In general, patients over 75 years and those with anterior myocardial infarction or previous heart attack have a higher mortality. Therefore, the absolute reduction in mortality in these patients will be greater. Many of the accepted contraindications (absolute and relative) come from observational studies only. Some conditions, such as diabetic proliferative retinopathy and menstruation, are no longer considered to be absolute contraindications.

Reperfusion of the artery affected by infarction occasionally fails with thrombolytic treatment. If this happens patients will have ongoing chest pain or acute electrocardiographic changes. In these instances the optimal management is still uncertain, although readministration of an alternative thrombolytic agent ("rescue thrombolysis") or emergency percutaneous transluminal coronary angioplasty ("rescue" or "salvage" percutaneous transluminal coronary angioplasty) has been advocated. Rescue thrombolysis more than doubles the bleeding complications. Also, the limited data available showed benefit only in cases where plasma fibrinogen concentration was > 1.0 g/l and where recombinant tissue plasminogen activator was given if initial streptokinase did not achieve 25% reduction of maximal ST elevation on the pretreatment electrocardiogram.

All thrombolytic agents are plasminogen activators. Streptokinase is the cheapest widely available agent. However, it is highly antigenic, and neutralising antibodies preclude use of this agent more than once in a patient. Thus, it should not be

Electrocardiogram indicating acute inferior myocardial infarction

Indications and contraindications for thrombolysis in acute myocardial infarction

Indications

- Clinical history and presentation strongly suggestive of myocardial infarction within 6 hours plus one or more of:
 - 1 mm ST elevation in two or more contiguous limb leads
 - 2 mm ST elevation in two or more contiguous chest leads
 - New left bundle branch block
 - 2 mm ST depression in V1-4 suggestive of true posterior myocardial infarction
- Patients presenting with above within 7-12 hours of onset with persisting chest pains and ST segment elevation
- Patients aged < 75 years presenting within 6 hours of anterior wall myocardial infarction should be considered for recombinant tissue plasminogen activator

Contraindications

Absolute

- Aortic dissection
- Previous cerebral haemorrhage
- Known history of cerebral aneurysm or arteriovenous malformation
- Known intracranial neoplasm
- Recent (within past 6 months) thromboembolic stroke
- Active internal bleeding (excluding menstruation)
- Patients previously treated with streptokinase or anisolated plasminogen streptokinase activator complex (APSAC or anistreplase) should receive recombinant tissue plasminogen activator, reteplase, or tenecteplase

Relative

- Severe uncontrolled hypertension (blood pressure $> 180/110$ mm Hg) on presentation or chronic severe hypertension
- Current use of anticoagulants or known bleeding diathesis
- Recent (within past 2-4 weeks) trauma including head injury or traumatic or prolonged (> 10 minutes) cardiopulmonary resuscitation
- Recent (within 3 weeks) major surgery, organ biopsy, or puncture of non-compressible vessel
- Recent (within past 6 months) gastrointestinal or genitourinary or other internal bleeding
- Pregnancy
- Active peptic ulcer disease

ABC of Antithrombotic Therapy

readministered after 48 hours from the initial infusion. Tenecteplase, reteplase, and recombinant tissue plasminogen activator (alteplase) have been shown to be as good as streptokinase in reducing mortality after acute myocardial infarction. They are suitable alternatives if a patient has already received streptokinase. In the GUSTO trial, recombinant tissue plasminogen activator produced greater mortality reduction than streptokinase, especially in patients aged under 75 years who presented within six hours of onset of anterior myocardial infarction. Patients presenting within six hours of inferior myocardial infarction accompanied by right ventricular infarct, haemodynamic compromise, or anterior wall extension may also benefit. Tenecteplase has the advantage of being easily administered as a single bolus injection.

Antiplatelet treatment

The concurrent use of aspirin with a thrombolytic drug reduces mortality far more than either drug alone. In the ISIS-2 trial, streptokinase reduced mortality by 25%, aspirin by 23%, and the combination of aspirin with streptokinase by 42%. In addition, there was no increase in incidence of stroke or major bleeding by giving aspirin and streptokinase in combination.

Anticoagulant treatment

The use of “full dose” heparin, either intravenously or by subcutaneous injections, is not warranted routinely after streptokinase (or anistreplase) infusion, with no difference in mortality during hospitalisation and an increased risk of cerebral haemorrhage and other major bleeding. Patients who may benefit from heparin treatment after streptokinase (or anistreplase) are those at high risk of developing thromboembolism. These patients include those with large infarctions, atrial fibrillation, or congestive cardiac failure.

On the other hand, recombinant tissue plasminogen activator, tenecteplase, and reteplase have short half lives and thus have only small systemic fibrinolytic effects. The high reocclusion rates seen in patients given recombinant tissue plasminogen activator may be stopped by concomitant use of full dose heparin (for at least 24 hours). Several trials of angiographic patency have also reported a favourable synergistic effect of heparin after recombinant tissue plasminogen activator.

For patients with persistent risk factors for systemic embolisation, consideration should be given to starting oral warfarin or continuing heparin treatment as subcutaneous injections beyond 48 hours. All other patients should receive prophylactic heparin (unfractionated or low molecular weight heparin) until they are sufficiently mobile to minimise venous thromboembolism. Finally, trials comparing the use of hirudin and heparin after recombinant tissue plasminogen activator showed hirudin to be no better than heparin at reducing cardiovascular death or reinfarction at 30 days.

Postmyocardial infarction and stable coronary artery disease

Antiplatelet treatment

Data from the Antiplatelet Trialists' Collaboration, which analysed more than 100 trials and 100 000 patients, including 20 000 with acute myocardial infarction, confirmed that antiplatelet treatment reduced cardiovascular events in acute myocardial infarction by 25%, representing a two year treatment benefit in 36 out of 1000 patients treated.

Aspirin is the most widely used antiplatelet drug and is effective at doses from 75 to 300 mg daily in patients who have

Lives saved per thousand people in relation to time of administration of thrombolytic treatment from onset of symptoms of chest pain. Numbers along the curve are the number of people treated at different times

Antithrombotic therapy in acute Q wave myocardial infarction and after myocardial infarction

All patients should receive

- Aspirin 300 mg orally as soon as possible and 75-300 mg daily thereafter
- Consideration for thrombolysis
- β blockers, nitrates, and other standard antianginal drugs as appropriate

Choice of thrombolytic agents

- Streptokinase 1.5 MU intravenously over an hour
- Recombinant tissue plasminogen activator 15 mg intravenous bolus followed by 0.75 mg/kg (maximum 50 mg) infusion over 30 minutes, then at 0.5 mg/kg (maximum 35 mg) over 60 minutes
- Reteplase 10 MU intravenous bolus, repeated once after 30 minutes
- Tenecteplase 30-50 mg (according to body weight) intravenously over 10 seconds

Adjuvant heparin treatment

- In all patients receiving recombinant tissue plasminogen activator—75 U/kg intravenous bolus with recombinant tissue plasminogen activator infusion, followed by 1000-1200 U/hour to maintain APTT ratio 1.5-2.0 for 48 hours
- In all patients receiving reteplase or tenecteplase—75 U/kg intravenous bolus with first reteplase bolus, followed by 1000-1200 U/hour to maintain APTT ratio 1.5-2.0 for 48 hours

Prevention of systemic and venous thromboembolism

- In all patients with acute myocardial infarction—low dose low molecular weight heparin until ambulatory
- In patients receiving streptokinase at high risk of systemic or venous thromboembolism—measure APTT from four hours after thrombolysis. Start intravenous heparin at 1000-1200 U/hour once APTT ratio has fallen to less than 2.0. Continue for 48 hours, maintaining APTT at ratio 1.5-2.0. Alternatively, use low molecular weight heparin
- In all patients at high risk of systemic or venous thromboembolism—heparin infusion may be continued beyond 48 hours or converted to 15 000 U subcutaneously twice daily (alternatively, use low molecular weight heparin) or to warfarin (INR 2-3) for up to three months
- In patients with atrial fibrillation—warfarin treatment after heparin infusion should continue indefinitely

had myocardial infarction and those with stable coronary artery disease. Although there is no substantial difference in efficacy between lower and higher doses of aspirin within the stated range, higher doses are associated with greater side effects.

Dipyridamole and ticlopidine have both been compared with aspirin. Dipyridamole showed no benefit over aspirin in the PARIS trials. Ticlopidine may be slightly better than aspirin treatment but is associated with undesirable side effects such as neutropenia and thrombocytopenia. In the CAPRIE study, which compared clopidogrel with aspirin over two years in patients with vascular disease (ischaemic stroke, myocardial infarction, peripheral vascular disease), clopidogrel was slightly better in reducing the number of vascular events (5.32% *v* 5.83%, *P* = 0.04). Importantly, clopidogrel was as well tolerated as aspirin. Therefore, it would be reasonable to give patients clopidogrel after acute myocardial infarction if aspirin were contraindicated or not tolerated.

The glycoprotein IIb/IIIa antagonists have been tried in conjunction with thrombolysis in acute myocardial infarction, but the various regimens used in recent trials did not confer any additional benefit over conventional treatment. However, there was some evidence of more rapid and complete reperfusion, and these agents warrant further evaluation and refinement.

Anticoagulant treatment

Long term anticoagulation with heparin followed by warfarin is not needed routinely except in patients at higher risk of venous or systemic thromboembolism.

Intracardiac thrombi usually occur within 48 hours after acute myocardial infarction and tend to embolise within the first few weeks. Low dose dalteparin has been shown to reduce the incidence of intramural thrombus (21.9% *v* 14.2%, *P* = 0.03) in patients given thrombolytic treatments, although this is at a risk of small increase in minor bleeding complications. Thus, in patients at high risk of mural thrombus formation, dalteparin should be started as soon as possible after the diagnosis of acute myocardial infarction.

Warfarin should be continued for two to three months, except in the case of atrial fibrillation, when it may be maintained indefinitely. While a patient is taking warfarin, aspirin use may increase the risk of bleeding, but, pending further evidence, many clinicians still continue to use low dose aspirin for its antiplatelet effect. Although thrombus is commonly associated with left ventricular aneurysm (up to 60%), systemic emboli are uncommon (4-5%), and long term anticoagulation does not seem to further reduce the risk of systemic embolisation; thus, anticoagulant treatment is not currently indicated in these patients in the long term.

Venous thromboembolism is often associated with acute myocardial infarction, although its incidence has fallen since the introduction of thrombolytic treatment. Although no trials have compared the efficacy of low molecular weight heparin with unfractionated heparin in preventing venous thromboembolism after acute myocardial infarction per se, it is likely that these agents are equally effective, and are increasingly used in clinical practice.

The box showing antithrombotic therapy in acute Q wave myocardial infarction and after myocardial infarction is adapted from the 6th ACCP consensus conference on antithrombotic therapy. The figure showing lives saved in relation to time of administration of thrombolytic treatment from onset of symptoms of chest pain is adapted from Collins R, et al, *N Engl J Med* 1997;336:847-60.

Risk factors for systemic embolisation when anticoagulation should be considered

- Large anterior wall myocardial infarction
- Myocardial infarction complicated by severe left ventricular dysfunction
- Congestive heart failure
- Echocardiographic evidence of mural thrombus or left ventricular aneurysm
- Previous emboli
- Atrial fibrillation

11 Antithrombotic therapy in acute coronary syndromes

Robert D S Watson, Bernard S P Chin, Gregory Y H Lip

The use of antithrombotic therapy in acute coronary syndromes has reduced the incidence of death and Q wave myocardial infarction dramatically in recent years. Antithrombotic drugs in routine use include antiplatelet drugs (aspirin, clopidogrel, and glycoprotein IIb/IIIa receptor antagonists) and anticoagulants (unfractionated and low molecular weight heparin, warfarin, and direct thrombin inhibitors).

Pathogenesis

Thrombosis is the basic pathophysiological process underlying the acute coronary syndromes. Thus, antithrombotic therapy is the cornerstone of management, and the appropriate choice of antithrombotic drugs to reduce platelet aggregation or interfere with the clotting process can be critical.

Rupture of the fibrous cap of an atheromatous plaque exposes the lipid core, which is highly thrombogenic and contains an abundance of procoagulant tissue factor. Plaque rupture (exposing surface binding glycoproteins) allows platelets to adhere to the plaque, become activated, and release thromboxane A₂, which causes further platelet aggregation and vasoconstriction. As the platelets aggregate around the ruptured plaque, membrane glycoprotein IIb/IIIa receptors undergo a configuration change to bind fibrinogen and form a complex platelet linkage. Further incorporation of fibrin and red blood cells within this platelet-rich thrombus results in a partial or total occlusion of the coronary artery. Alternatively, thrombus may break off from a ruptured plaque and occlude a downstream vessel. Occlusion may also follow from trapping of circulating thrombi formed elsewhere in the circulation.

Antithrombotic drugs

Antiplatelet drugs

Aspirin

Aspirin has been in use for more than 150 years and is cheap and effective. It has been shown to reduce the risk of fatal and non-fatal myocardial infarction by at least 50% in patients with unstable angina. Aspirin blocks cyclo-oxygenase and formation of thromboxane A₂, thus reducing platelet aggregation induced via this pathway.

Aspirin is the cornerstone of treatment in acute coronary syndromes and chronic coronary artery disease. The beneficial effects of aspirin seem to be sustained for at least two years and regardless of the dose used. However, 75-150 mg daily may have a lower incidence of gastrointestinal side effects than the higher doses used in some randomised studies.

ADP receptor antagonists

Ticlopidine and clopidogrel are ADP inhibitors. Evidence exists that ticlopidine reduces mortality, recurrent infarction, stroke, and angina at least to six months after myocardial infarction or unstable angina. Ticlopidine has fewer gastrointestinal effects than aspirin but may cause reversible neutropenia and thrombocytopenia (< 1% of patients), which dictates therapeutic monitoring with regular blood counts.

Clopidogrel is a derivative of ticlopidine that seems to be six times more effective than its predecessor in preventing platelet

Thrombosis in relation to acute coronary syndromes

Thrombus within right coronary artery (arrow) in a patient with unstable angina

Reduction of adverse events in patients treated with aspirin, heparin, or both compared with neither drug

aggregation. Clopidogrel has shown better tolerability with less bleeding than aspirin and fewer haematological side effects than ticlopidine. In the CURE trial—a randomised, double blind, parallel group study of 12 562 patients with acute coronary syndrome or non-Q wave myocardial infarction—patients received aspirin 75-325 mg and then were randomly assigned to additional clopidogrel (300 mg load followed by 75 mg daily) or placebo for three months to a year. Additional clopidogrel resulted in a 20% relative risk reduction in the primary end point (cardiovascular death, myocardial infarction, or stroke) ($P < 0.0001$), mainly caused by a 23% relative reduction in myocardial infarction. However, there was a 34% excess of major bleeding (3.6% *v* 2.7% in placebo; $P = 0.003$).

These observations raise the question of whether combination antiplatelet treatment (such as aspirin with clopidogrel) is preferable to other treatments (such as heparin with glycoprotein IIb/IIIa receptor inhibitors) in the acute phase of acute coronary syndromes and suggest that prolonged antiplatelet treatment is better for high risk patients.

Glycoprotein IIb/IIIa receptor inhibitors

Abciximab is a (large molecule) monoclonal antibody and the first glycoprotein IIb/IIIa receptor antagonist to be developed. Eptifibatide is a peptide receptor antagonist, whereas tirofiban is a non-peptide receptor antagonist. Both eptifibatide and tirofiban are small molecules, apparently non-immunogenic, and therefore suitable for repeat infusions. They have a shorter half life (90-120 minutes) than abciximab (12 hours). Because they are mainly renally cleared, their doses should be adjusted in patients with renal impairment.

In trials with patients with acute coronary syndromes the rate of death, reinfarction, and refractory angina was reduced when glycoprotein IIb/IIIa inhibitors were added to aspirin and heparin. In the largest study, PURSUIT, a bolus injection of eptifibatide followed by a 72 hour infusion resulted in a 9.6% relative risk reduction in death and myocardial infarction when given to patients with acute coronary syndromes already receiving aspirin and heparin. In the PRISM and PRISM-PLUS studies, tirofiban, when given in addition to aspirin and heparin, achieved a 43% relative risk reduction in mortality and reinfarction at seven days. This benefit was sustained at 30 days. Patients taking tirofiban and aspirin without heparin had an excess mortality rate, and this treatment arm was stopped early.

The CAPTURE trial studied patients with acute coronary syndromes scheduled for percutaneous coronary angioplasty. The use of abciximab for about 24 hours before the procedure substantially reduced the risk of mortality, myocardial infarction, or need to proceed to other revascularisation.

The benefits are greatest in patients with elevated levels of troponin T or I, indicating that assessment of subtle indices of cardiac damage predicts patients at higher risk and those most likely to benefit from treatment. Economic evaluations of the costs of using intravenous glycoprotein IIb/IIIa inhibitors suggest that, for patients with elevated troponin levels, 11 are needed to be treated to prevent one death or acute myocardial infarction at 30 days. The equivalent cost effectiveness is about £5000 an outcome.

Using glycoprotein IIb/IIIa inhibitors for acute coronary syndrome in addition to conventional antithrombotic therapy is approved by the British National Institute for Clinical Excellence (NICE). However, interpretation of trial evidence is complicated by patient heterogeneity. Although adjunctive treatment before revascularisation procedures in acute coronary syndromes shows clear benefit, there is some uncertainty of benefit if these drugs are used only as “medical” management without revascularisation.

Anticoagulant treatment

Low molecular weight heparin

Low molecular weight heparins possess more anti-Xa activity than unfractionated heparins. They have a more predictable anticoagulant effect and cause less thrombocytopenia. Titrated appropriately against body weight, low molecular weight heparin provides effective anticoagulation and does not need regular monitoring of the activated partial thromboplastin time. However, platelet count monitoring to detect thrombocytopenia is recommended if treatment is extended beyond a few days. Studies suggest similar safety profiles to unfractionated heparin when used with glycoprotein IIb/IIIa inhibitors.

The therapeutic benefits of low molecular weight heparins are now clear. Recent randomised trials comparing the efficacy of various low molecular weight heparins showed enoxaparin and nadroparin to be more effective in reducing mortality in unstable angina than either aspirin or unfractionated heparin alone. In the ESSENCE study, enoxaparin reduced the incidence of death, myocardial infarction, and recurrent angina at 14 days from 19.6% to 16.6% when compared with unfractionated heparin. This benefit was maintained at 30 days and a year.

Dalteparin in addition to aspirin was more effective than aspirin alone in the FRISC study. It reduced cardiac events and death (1.8% v 4.8%) when used in acute coronary syndromes but was no better than adjusted dose unfractionated heparin.

Low molecular weight heparin is, therefore, at least as good as unfractionated heparin in managing unstable angina (with trials showing enoxaparin and nadroparin to be even better). It has practical advantages because it has more consistent antithrombin effects and is easier to administer, and frequent assessment of antithrombotic effect (activated partial thromboplastin time monitoring) is not necessary. In view of these findings, low molecular weight heparins (enoxaparin and nadroparin) should be used routinely to treat unstable angina concurrently with aspirin in place of unfractionated heparin.

Unfractionated heparin

An uncontrolled study showed that heparin treatment in unstable angina reduced the risk of progression to myocardial infarction by 80%. Other studies show a definite reduction in the incidence of refractory angina and myocardial infarction with the use of unfractionated heparin compared with placebo (risk reduction 0.29). Treatment with heparin and aspirin seems to be more effective than either heparin or aspirin alone. In a meta-analysis on the effect of adding heparin to aspirin in patients with unstable angina, combination treatment resulted in 33% reduction in deaths or myocardial infarction.

Direct thrombin inhibitors

Newer and powerful anticoagulants, such as the direct thrombin inhibitor hirudin, are being investigated. Several trials compared the effects of hirudin with unfractionated heparin and showed a slight reduction in primary end points, and a pooled analysis of these trials showed a 22% relative risk reduction in myocardial infarction or deaths at 72 hours. Bleeding, however, may be a problem. Hirudin is now approved for patients with heparin induced thrombocytopenia but is not yet licensed for treatment of acute coronary syndromes. The direct thrombin inhibitors melagatran and ximelagatran are currently under investigation for use in patients with acute coronary syndromes.

Warfarin

Several trials have investigated using warfarin for unstable angina. In many studies, warfarin was given to patients two days after unfractionated heparin infusion and continued for ten weeks to six months with an international normalised ratio (INR) adjusted

Antithrombotic therapy is the cornerstone of management in acute coronary syndromes

Comparison of low molecular weight heparins with unfractionated heparins in patients with acute coronary syndromes. Results show odds ratio (95% confidence interval) for death and myocardial infarction at long and short term follow up (LMWH=low molecular weight heparin, UH=unfractionated heparin)

Comparison of hirudin therapy with unfractionated heparin in patients with acute coronary syndromes (RR=relative risk)

to between 2.0 and 3.0. Earlier studies showed low fixed doses of warfarin gave no benefit. However, limited evidence suggests that in patients with acute coronary syndromes, combination treatment with aspirin and warfarin adjusted to INR 2.0-3.0 may reduce event rates and hospitalisations.

Pending further trials and in view of potential bleeding risks and need for INR monitoring, warfarin is best reserved for patients with other indications for warfarin use such as coexistent atrial fibrillation, known left ventricular aneurysm with mural thrombus formation, or previous recurrent thromboembolic stroke. Warfarin should not be used as the sole antithrombotic drug in acute cases because of its delayed onset of action.

Thrombolytic treatment

Thrombolytic treatment is not recommended for unstable angina and non-Q wave infarction. It has not been shown to reduce cardiovascular events and death and may worsen clinical outcomes by increasing bleeding complications, as well as increasing bleeding within a ruptured atherosclerotic plaque. This worsens obstruction to coronary flow and exposes clot-bound thrombin to flowing blood, creating an even more prothrombotic environment. In addition, the thrombus in unstable angina is often platelet-rich, unlike the fibrin-rich thrombus seen in infarction, and thus may be less responsive to thrombolytic treatment.

The figure showing reduction of adverse events in patients treated with aspirin, heparin sodium, or both compared with neither drug is adapted from Theroux P et al, *N Engl J Med* 1988;319:1105-11. The effects of clopidogrel plus aspirin in patients with acute coronary syndromes is adapted from the CURE trial investigators, *N Engl J Med* 2001;345:494-502. The figures showing glycoprotein IIb/IIIa inhibitors *v* conventional treatment, comparing the effects glycoprotein IIb/IIIa inhibitors in acute coronary syndrome patients who are undergoing percutaneous coronary intervention with those who are not, and comparing low molecular weight heparin with unfractionated heparin in patients with acute coronary syndrome are all adapted from Bertrand M, et al, *Eur Heart J* 2002;23:1809-40. The figure comparing hirudin treatment with unfractionated heparin in patients with acute coronary syndromes is adapted from Glenn N et al, *Arch Intern Med* 2001;161:937-48

Antithrombotic therapy in acute coronary syndromes: a summary

Aspirin

- Acute treatment with aspirin is used in all patients with suspected acute coronary syndromes in the absence of contraindications and for long term treatment thereafter

Clopidogrel

- In acute coronary syndrome patients clopidogrel is used for acute treatment and for longer term treatment for at least 9-12 months. Beyond this, treatment will depend on the risk status of the patient and individual clinical judgment
- Clopidogrel is used for immediate and long term treatment in patients who do not tolerate aspirin and in patients receiving a stent
- Clopidogrel is given to acute coronary syndrome patients scheduled for angiography unless there is a likelihood that the patient will proceed to urgent surgery (within 5 days)

Low molecular weight heparin

- In aspirin treated patients, low molecular weight heparin is better than placebo. There are also data in favour of low molecular weight heparin (enoxaparin) over unfractionated heparin when administered as an acute regimen

Glycoprotein IIb/IIIa receptor inhibitors

- Treatment with a glycoprotein IIb/IIIa receptor blocker is recommended in all patients with acute coronary syndromes undergoing percutaneous coronary interventions. The infusion should be continued for 12 hours (abciximab) or 24 hours (eptifibatid, tirofiban) after the procedure
- Medical treatment with a glycoprotein IIb/IIIa receptor blocker during the first days after admission, followed by percutaneous coronary intervention or bypass surgery, yields a significant reduction in death and non-fatal myocardial infarction at 72 hours, from 4.3 to 2.9%
- Diabetic patients with acute coronary syndrome derive particular benefit from glycoprotein IIb/IIIa receptor inhibitors

Fibrinolytic treatment

- In contrast to acute coronary syndromes *with* ST segment elevation, thrombolytic therapy is *not* recommended for patients with acute coronary syndromes *without* persistent ST segment elevation
-

12 Antithrombotic strategies in acute coronary syndromes and percutaneous coronary interventions

Derek L Connolly, Gregory Y H Lip, Bernard S P Chin

Acute coronary syndromes

All patients suspected of having acute coronary syndrome should be managed as medical emergencies and monitored in the critical care unit. Baseline tests must include 12 lead electrocardiography, chest x ray examination, and venous blood samples for analyses of haemoglobin and markers of myocardial damage, preferably cardiac troponin T or I.

Initial management

Assessment

Patients with persistent ST segment elevation on 12 lead electrocardiography need immediate reperfusion treatment (thrombolysis or intervention). Patients with ST segment depression, inverted T waves, or pseudonormalisation of T waves on the electrocardiogram, but with a clinical history suggesting cardiac ischaemia should receive initial treatment for angina.

This would include aspirin 300 mg followed by a low dose of 75-150 mg daily. In cases of aspirin intolerance, clopidogrel should be used. β Blockers and nitrates should also be given. Rate limiting calcium antagonists can be used if β blockers are contraindicated or are already being used. Ideally, patients should be given low molecular weight heparin (such as enoxaparin) according to their weight. If low molecular weight heparin is unavailable, unfractionated heparin may be used. A bolus of 5000 U is given, followed by an infusion adjusted to get an activated partial thromboplastin time (APTT) ratio of 1.8 to 2.5. In light of data from the CURE and PCI-CURE study, clopidogrel (given for at least one month and up to nine months) should be considered in addition to aspirin when an early non-interventional approach is planned. The optimal dose of aspirin to limit bleeding is probably 75 mg, particularly with clopidogrel. A glycoprotein IIb/IIIa receptor inhibitor should be added to aspirin and heparin for patients in whom catheterisation and percutaneous coronary intervention are planned. In these patients clopidogrel could be considered if they are not at high risk for bleeding.

Observation

Patients should be observed over the next eight to 12 hours. Patients at high risk of progressing to acute myocardial infarction or death should receive a glycoprotein IIb/IIIa receptor inhibitor (eptifibatid or tirofiban) in addition to heparin and aspirin or clopidogrel (alone or with aspirin). Abciximab would be used in high risk patients undergoing percutaneous coronary intervention. There is no role for thrombolytic therapy in patients without acute ST segment elevation, except in the situations of a true posterior myocardial infarction, or a presumed new left bundle branch block.

Subsequent management

When patients have been free from symptoms and ischaemic electrocardiographic changes for > 48 hours, and any intravenous treatments and heparin have been stopped for > 24 hours, risk assessment with stress testing should be performed unless contraindicated. Stress testing for risk assessment is unnecessary if a patient is already in a high risk category for which coronary angiography is indicated.

High and low risk patients with suspected acute coronary syndromes

High risk

- Recurrent or persistent chest pains with associated electrocardiographic changes (ST segment depression or transient ST elevation) despite anti-ischaemic treatment
- Elevated troponin concentrations
- Age > 65 years
- Comorbidity, especially diabetes
- Development of pulmonary oedema or haemodynamic instability within observation period
- Development of major arrhythmias (repetitive ventricular tachycardia or ventricular fibrillation)
- Early postinfarction unstable angina

Low risk

- No recurrence of chest pains within observation period
 - Troponin or other markers of myocardial damage not elevated
 - No ST segment depression or elevation on electrocardiogram (T wave inversion is classified as intermediate risk)
-

Management strategies for patients with suspected acute coronary syndromes, with risk stratification by troponin and stress tests*

Low risk

Results of tests

- Cardiac troponin result is negative or low (troponin T < 0.01 $\mu\text{g/l}$ or troponin I equivalent) on two occasions
- Stress test indicates a low risk category

Action

- If free from cardiac symptoms, no more cardiac interventions needed
- Subsequent outpatient review appropriate for further investigations and adjustment of drug treatment

Intermediate risk

Results of tests

- Impaired left ventricular function, or haemodynamic abnormalities or arrhythmia during the acute phase *but*
- Normal cardiac troponin result (troponin T < 0.01 $\mu\text{g/l}$, or troponin I equivalent), with a stress test indicating intermediate risk *or*
- Moderately elevated cardiac troponin (troponin T 0.01-0.1 $\mu\text{g/l}$, or troponin I equivalent) with stress test indicating low risk category

Action

- Many cardiologists perform coronary angiography on these patients, but clear evidence of benefit is lacking

High risk

Results of tests

- Maximal cardiac troponin result is high (troponin T > 0.1 $\mu\text{g/l}$, or troponin I equivalent) *or*
- Stress test indicates high risk category

Action

- Coronary angiography should be arranged, unless contraindicated, and performed urgently, before discharge from hospital
- Patients with suitable lesions for percutaneous coronary intervention should be given clopidogrel, which should also be given to patients with coronary lesions not suitable for any revascularisation

*If patient is unable to perform an exercise electrocardiogram, an alternative non-exercise (pharmacological) stress test, such as a stress echocardiograph or isotope myocardial stress perfusion study, should be arranged unless contraindicated. In all cases, aggressive risk factor management and regular aspirin treatment (or clopidogrel, or both, depending on clinical situation) is necessary

Antithrombotic strategies in acute coronary syndromes and percutaneous coronary interventions

Antithrombotic treatment

Low molecular weight heparin should be given for at least two days, and for up to eight days or longer in cases of recurrent ischaemia or where myocardial revascularisation is delayed or contraindicated. Patients requiring a bypass operation may have their glycoprotein IIb/IIIa receptor antagonist infusion stopped before or at the time of cardiac surgery, although clopidogrel should be withheld for five to seven days.

Risk stratification and antithrombotic strategies

Recent trials have shown that patients with elevated troponin benefit from treatment with low molecular weight heparin, glycoprotein IIb/IIIa blockers, or an invasive strategy, whereas patients without troponin elevation showed no such benefit.

In these high risk patients, angiography with a view to revascularisation should be performed on the same admission. Infusion of glycoprotein IIb/IIIa receptor inhibitors should be started while waiting and preparing for angiography and continued for 12 hours (abciximab) or 24 hours (tirofiban) after angioplasty is performed.

Low risk patients can be mobilised and discharged if (at least 12 hours after the onset of symptoms of a suspected acute coronary syndrome) the symptoms have not recurred, cardiac troponin concentrations are normal, electrocardiograms remain normal (or unchanged compared with a recording from before the current presentation), and cardiac enzyme activities are not raised. Risk assessment with stress testing should be performed before a patient is discharged unless contraindicated.

Pros and cons of invasive strategy

There are arguments for and against an invasive approach to acute coronary syndromes. In the FRISC-II trial an invasive strategy had, after a year, saved 1.7 lives in 100 patients and prevented 2.0 non-fatal myocardial infarctions and 20 readmissions. It provided earlier and better symptom relief at the cost of 15 more patients with coronary artery bypass grafting and 21 more with percutaneous transluminal coronary angioplasty, and these results were independent of treatment with dalteparin or placebo. In the BHF RITA3 trial of patients with unstable angina, myocardial infarction, or non-ST segment elevation, an invasive strategy reduced refractory or severe angina, with no increase of death or myocardial infarction, compared with a conservative strategy. Against these benefits is the need to have adequate provision of facilities and trained staff to undertake such procedures.

Percutaneous coronary intervention

Arterial thrombi occur soon after percutaneous coronary interventions for coronary artery disease, usually at the site of the dilated segment. Arterial thrombi are rich in platelets, red blood cells, fibrin, and leucocytes and may contribute to vessel reocclusion with the consequent need for revascularisation. The risk of reocclusion depends on the extent of segment dilatation and vessel injury, as well as local shear forces. Antiplatelet and antithrombin drugs generally reduce the risk of occlusion or the need for further intervention but are not perfect. Where facilities are available, percutaneous coronary angioplasty is an alternative to thrombolytic treatment as a means of reperfusion in acute myocardial infarction.

Antiplatelet treatment

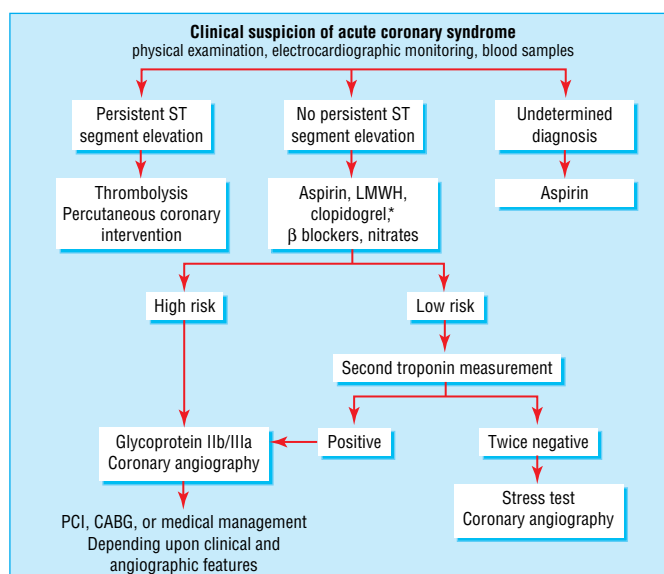

Patients with coronary artery disease undergoing angioplasty should continue taking antiplatelet drugs as usual. For patients not receiving regular antiplatelet treatment, aspirin 100-325 mg should be given orally at least two hours before angioplasty.

Time course of different cardiac biochemical markers

Death or myocardial infarction in patients with elevated troponin concentration or negative troponin result in contemporary trials. The FRISC-II trial also used low molecular weight heparin, and the bars for the TACTICS trial show the strategies used (I=invasive strategy, C=conservative strategy)

European Society of Cardiology recommended strategy for acute coronary syndromes (CABG=coronary artery bypass graft, LMWH=low molecular weight heparin, PCI=percutaneous coronary intervention. *Omit clopidogrel if patient likely to go to CABG within 5 days)

Aspirin substantially reduces the rate of intracoronary thrombus formation at the treatment site and restenoses. The addition of dipyridamole to aspirin adds little extra benefit and is not recommended. Ticlopidine alone has not been shown to be more effective than aspirin alone in patients undergoing percutaneous interventions. Although clopidogrel is marginally better than aspirin in patients with atherosclerotic vascular disease (CAPRIE study), direct comparisons between aspirin and clopidogrel in coronary intervention have not revealed marked differences. Thus, ticlopidine and clopidogrel are useful alternatives for patients scheduled for percutaneous coronary angioplasty who are unable to take aspirin.

After intervention, antiplatelet combination treatment (aspirin plus ticlopidine) is superior to aspirin alone at reducing ischaemic complications and cardiac events, particularly after intracoronary stent placements. The stent anticoagulation restenosis investigators (SARI) trial, compared aspirin-ticlopidine combination treatment with aspirin-warfarin combination treatment and aspirin alone and showed that patients taking aspirin-ticlopidine had the best 30 day mortality (0.5% v 2.7% v 3.6% respectively, $P=0.001$). Total bleeding complications occurred in 5.5% of those taking aspirin-ticlopidine, quite high when compared with 1.8% in those taking aspirin only ($P<0.001$), and the incidence of neutropenia was not significantly different. The CLASSICS trial showed clopidogrel-aspirin combination treatment to be as effective as ticlopidine-aspirin combination treatment after angioplasty and stent placement.

Glycoprotein IIb/IIIa receptor antagonists

Despite adequate treatment with antiplatelet drugs, platelet activation still continues along other pathways not blocked by these agents. This is where the glycoprotein IIb/IIIa receptor antagonists, which block the final common pathways of platelet aggregation, have contributed most to the management of angioplasty and stenting.

Abciximab, eptifibatid, and tirofiban have all been shown to reduce reocclusion and cardiovascular events, including deaths and myocardial infarctions, at 30 days when used in patients undergoing elective and urgent angioplasty and stenting. These benefits are additional to those achieved with antiplatelet drugs, and the effects were most prominent with abciximab. The EPIC, EPILOG, and CAPTURE trials all showed that abciximab infusion reduced major complication rates during balloon angioplasty, a benefit that was sustained at 30 days' follow up. The EPISTENT trial showed that abciximab reduces major complications during stent placement and was superior to a combination of abciximab and balloon angioplasty. In the only direct comparison of glycoprotein IIb/IIIa antagonists, the TARGET trial randomised 5308 patients to tirofiban or abciximab before percutaneous transluminal coronary angioplasty or stent, or both: by six months the primary end point was similar in both treatment arms (14.9% with tirofiban v 14.3% with abciximab, $P>0.05$), as was mortality (1.9% v 1.7%, $P>0.05$). Patients with unstable angina, acute myocardial infarction, and other risk factors (such as diabetes) for postprocedure in stent thrombosis or restenosis stand to benefit most from glycoprotein IIb/IIIa receptor antagonists.

In light of this, glycoprotein IIb/IIIa drugs should be considered in all patients at risk of developing in stent stenosis or with acute coronary syndrome scheduled for percutaneous coronary interventions. If percutaneous coronary intervention is planned in unstable angina, glycoprotein IIb/IIIa receptor antagonist infusions should be started before intervention and continued for 12 hours (abciximab) or 24 hours (tirofiban, eptifibatid) after the procedure.

Meta-analysis of 10 randomised trials that compared thrombolytic treatment with primary angioplasty in acute myocardial infarction (MI=myocardial infarction, IC=intracranial)

Cumulative incidence of primary end points (mortality, target lesion revascularisation or thrombolysis, non-fatal myocardial infarction) in patients treated with aspirin alone (557 patients), aspirin and warfarin (550 patients), or aspirin and ticlopidine (546 patients) after coronary artery stenting

Some factors predisposing to in stent thrombosis after placement

- Underdilation of the stent
- Poor inflow
- Proximal and distal dissections
- Outflow obstruction
- Vessel diameter <3 mm

PRISM-PLUS results showing cumulative incidence of death or myocardial infarction (PTCA=percutaneous transluminal coronary angioplasty, RR=relative risk)

Several economic evaluations have found that routine use of glycoprotein IIb/IIIa drugs after percutaneous coronary interventions is extremely cost effective for patients at high risk of myocardial infarction or death. In such patients, the number needed to treat to save one life or prevent one acute myocardial infarction at 30 days may be as low as 30, or about £5000 per outcome.

Anticoagulant treatment

Most patients with acute coronary syndromes undergoing angioplasty would have been pretreated with heparin. Several small studies have shown that patients with unstable angina who receive heparin before intervention have a higher rate of success and lower postprocedure reocclusion rates.

Increasing numbers of patients with unstable angina are now being treated with low molecular weight heparin. However, such drugs tend to have a longer half life than unfractionated heparin and their effects are not completely reversed by protamine sulphate if necessary. Low molecular weight heparins can be safely substituted for unfractionated heparin as a procedural anticoagulant during percutaneous coronary intervention.

During percutaneous coronary interventions, heparin should be given to avoid postprocedure complications. The dose of unfractionated heparin given should be sufficient to increase the activated clotting time (ACT) to 250-300 seconds as measured with the HemoTec device (or 300-350 seconds with the Hemochron device). Unfractionated heparin dose may need to be adjusted for weight or sex. If glycoprotein IIb/IIIa receptor agonists are being used, then unfractionated heparin boluses should be reduced to achieve a target ACT of about 200 seconds. Although the traditional means of assessing heparin anticoagulation has been with the APTT, the ACT is an assay of whole blood clotting time that can be performed rapidly at the bedside and catheterisation laboratory.

Routine use of unfractionated heparin (either as infusion or subcutaneously) after angioplasty is probably not indicated for uncomplicated procedures. Studies have shown excess bleeding complications with heparin treatment without a reduction in the number of cardiac ischaemic events. Patients who do not receive heparin treatment after coronary interventions can have their femoral sheaths removed earlier, resulting in shorter hospital stays, fewer bleeding complications, at the risk of a similar incidence of cardiac end points including reocclusion.

With the advent of glycoprotein IIb/IIIa receptor antagonists, heparin infusions postprocedure should not be necessary routinely. Femoral sheaths should be removed once the ACT has fallen to less than 150-180 seconds. Adjunctive treatment with low molecular weight heparin or unfractionated heparin may still be warranted after angioplasty and stent implantation in patients at high risk of in stent thrombosis.

Full anticoagulation with heparin followed by warfarin in patients undergoing angioplasty with stenting is no better at reducing the number of adverse effects than combination treatment with aspirin and ticlopidine, but at increased risk of bleeding with warfarin. Use of hirudin, the direct thrombin inhibitor, was associated with a reduction of early cardiac events and restenosis at 96 hours but was no different from the heparin treatment arm at seven months.

Antithrombotic therapy in coronary angioplasty and stent placement procedures

Before procedure

- Aspirin 80-325 mg once daily at least 2 hours before procedure. Ticlopidine 250 mg twice daily or clopidogrel 75 mg once daily started 24 hours before procedure if aspirin contraindicated
- Glycoprotein IIb/IIIa receptor antagonists should be considered in high risk patients with acute coronary syndromes

During and after procedure

- Heparin* bolus to achieve activated clotting time (ACT) ~300 seconds. Give 70-150 U/kg or 7000 U for women and 8000 U for men. If ACT not achieved give extra bolus of 2500-5000 U. Reduce heparin bolus to achieve ACT ~200 seconds if glycoprotein IIb/IIIa receptor agonist is to be used
- In high risk patients, abciximab as bolus and infusion should be given at least 10 minutes before angioplasty and stent placement and continued for 12 hours after procedure

After procedure

- Start clopidogrel 300 mg orally, followed by 75 mg daily for 4 weeks
- Remove femoral sheath as soon as ACT falls below 150-180 seconds
- Heparin infusion is not routinely necessary after uncomplicated angioplasty

Heparin infusion after a procedure is indicated if

- Femoral sheath to be retained—Heparin infusion 1000-1200 U/hour until 4 hours before sheath is to be removed. Check ACT and remove sheath when ACT < 150 seconds
- Patients at high risk for in stent thrombosis
- Patients with other indications for anticoagulation, such as atrial fibrillation or mechanical heart valves

*Details given for unfractionated heparin, but low molecular weight heparin can be used as an alternative in percutaneous coronary interventions

13 Antithrombotic therapy in chronic heart failure in sinus rhythm

Gregory Y H Lip, Bernard S P Chin

Chronic heart failure is one of the few remaining areas in cardiovascular medicine where the use of antithrombotic therapy remains controversial. This is largely because of conflicting outcomes from existing studies, a lack of appropriately conducted randomised clinical trials, and difficulty in defining the syndrome of heart failure and its thromboembolic complications.

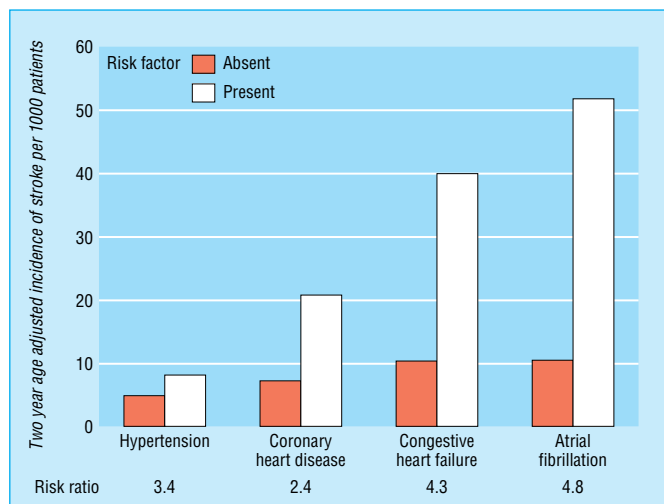

Stroke and systemic embolism in heart failure

Left ventricular dysfunction increases the risk of thrombosis and systemic embolism, and these thromboembolic events add to the high morbidity associated with this condition. In addition, ischaemic and thromboembolic events—particularly stroke, myocardial ischaemia, and myocardial infarction—contribute to the high hospital admission rates in these patients.

The incidence of thromboembolism and the factors associated with a high thromboembolic risk have been addressed in many studies, but the reported incidence of these events seems to vary between studies, depending on study methodology and populations. Retrospective analyses of recent heart failure trials have estimated this risk to be between 1.3% and 4.6% depending on the severity of heart failure. For example, mild to moderate chronic heart failure seems to be associated with an annual stroke risk of about 1.5% (V-HeFT and SOLVD studies), compared with an annual stroke risk in the general population of less than 0.5%. The annual risk of stroke increases to almost 5% in severe chronic heart failure. Evidence from the Framingham study shows that chronic heart failure is a major risk factor for stroke, second only to atrial fibrillation.

Long term oral anticoagulation is beneficial in certain groups of patients with chronic heart failure, but the role of anticoagulation for patients with chronic heart failure in general is less clear. For example, oral anticoagulation is extremely effective in reducing stroke risk and other embolic events in patients with atrial fibrillation and chronic heart failure. Indeed, there is a wide variation in the use of oral anticoagulants in patients with chronic heart failure.

Although oral anticoagulation reduces thromboembolic events in various cardiovascular diseases, the potential risks of bleeding must also be considered. Importantly, the control of

Two year age adjusted incidence of stroke for every thousand patients in the Framingham study

The risk of recurrent strokes in heart failure patients is higher than with initial events. In heart failure patients, second and recurrent stroke rates may be as high as 9% every year

Rates of stroke, pulmonary embolism, myocardial infarction, and total mortality in recent heart failure trials

Study (NYHA)	NYHA	Mean ejection fraction	Mean age	Follow up (years)	Prevalence of atrial fibrillation (%)	Mean (SD) annual risk of events (%)			
						Stroke	Pulmonary embolism	Myocardial infarction	Death
SOLVD	I-III	0.25	60	3.3	6	3.8 (1.3)	5.3 (1.6)	9.6 (2.9)	23.7 (7.2)
V-HeFT-I	II-III	0.30	58	2.3	15	4.1 (1.8)	5.6 (2.5)	—	43.0 (18.7)
V-HeFT-II	II-III	0.29	61	2.6	15	4.7 (1.8)	5.7 (2.2)	5.2 (2.0)	34.7 (13.3)
CONSENSUS	III-IV	—	71	0.5	50	2.3 (4.6)	—	—	46.6 (44)
PROMISE	III-IV	0.21	64	0.5	—	2.0 (3.5)	—	—	27.1 (54)
SAVE	—	0.30	59	3.5	—	4.6 (1.5)	—	13.6 (3.9)	18.9 (5.4)

anticoagulation is reported to be more difficult, and bleeding complications commoner, in chronic heart failure because of hepatic congestion and potential drug interactions that may occur.

Studies have reported stroke incidences in heart failure of up to 11%. However, many of these trials were small, non-randomised and biased towards more severe disease. Importantly, atrial fibrillation was common among participants, many of whom did not receive warfarin during the period of follow up. Nevertheless, given that the risk of stroke in the general population aged 50-75 years is less than 0.5% a year, an estimated stroke incidence of 2% in patients with chronic heart failure represents a fourfold increased risk. With increasing age, the absolute risk of stroke rises, while its risk relative to the general population falls.

The commonest vascular occlusive event in heart failure is not stroke but myocardial infarction. Sudden cardiac death is common in heart failure and has been attributed to fatal arrhythmia. However, pathological studies of sudden cardiac deaths have detected fresh coronary thrombi in many cases, indicating that acute coronary occlusion may have been the primary event in the death. Many heart failure patients with myocardial infarction also die before reaching hospital. Hence, myocardial infarction and acute coronary occlusion may be more common in heart failure than estimated.

Sedentary patients with chronic heart failure patients are also at increased risk of developing venous thromboembolism, particularly in the legs. Pulmonary embolism can originate from deep vein thrombosis of the legs or, rarely, from a thrombus in the right ventricle.

Left ventricular thrombus formation

Chronic heart failure patients in sinus rhythm are at high risk of ventricular thrombus formation because they fulfil Virchow's triad for thrombogenesis. These patients have:

- "Abnormal blood flow" with stasis, with low cardiac output, dilated cardiac chambers, and poor contractility of the heart;
- "Abnormal vessel walls", with endothelial damage or dysfunction or both;
- "Abnormal blood constituents", with abnormalities of haemostasis, platelets, and coagulation.

Autopsy and surgical studies have detected ventricular mural thrombi in 25-50% of heart failure patients. Such mural thrombi have been associated with increased mortality. In chronic heart failure with left ventricular dysfunction, abnormal wall motion leads to alterations in regional blood flow and inflow velocity, whereas impaired ventricular contractility results in further intracavitary blood stasis. Evidence exists for local platelet activation and cytokine recruitment, such as tumour necrosis factor, which can trigger the clotting cascade. This is particularly so after acute myocardial infarction, when high levels of catecholamines are circulating freely. Markers of endothelial injury and dysfunction are also elevated in heart failure, although in many cases these may be caused by underlying atherosclerosis. Endothelial damage promotes monocyte and platelet adhesion to the endothelium, predisposing to thrombosis in situ. The interplay of altered local flow characteristics, heightened clotting factors, and endothelial cell dysfunction gives rise to left ventricular thrombus formation.

Certain conditions are more likely to predispose to left ventricular thrombus formation. Patients with a dyskinetic left ventricular segment or left ventricular aneurysm and those who have had acute and extensive myocardial infarction involving the anterior wall are at highest risk. Left ventricular dilatation and severity of left ventricular dysfunction (measured by

Stroke risk and heart failure

	Annual risk
Stroke in general population aged 50-75 years	0.5%
Stroke in mild chronic heart failure—NYHA II-III	1.3-1.8%
Stroke in severe chronic heart failure—NYHA III-IV	3.5-4.6%
Recurrent stroke rates in chronic heart failure	9%
Stroke in atrial fibrillation	4.5%
Stroke in atrial fibrillation and chronic heart failure	8-12%

Apical thrombus in patient with poor left ventricular function

Factors predisposing to prothrombotic state in heart failure

Endothelial dysfunction

- Impaired nitric oxide release
- Reduced anticoagulant status

Altered flow characteristic

- Left ventricular dilatation
- Abnormal left ventricular wall motion
- Left ventricular aneurysm
- Reduced pump action

Altered coagulation

- Increased platelet activation and aggregation
- Increased clotting
- Reduced fibrinolytic activity

Neurohormonal and inflammatory activation

- Increased catecholamines
- Increased inflammatory cytokines

ejection fraction) also correlate well with risk of thrombus formation. However, mitral regurgitation may have some protective effect.

Risk factors for systemic embolisation

Given the high prevalence of left ventricular thrombus formation in patients with left ventricular aneurysm and heart failure, it is perhaps surprising that the rate of stroke in patients with documented left ventricular thrombi is low. This could be because of the difficulty in determining the presence of thrombus clinically. The best method is by cross sectional echocardiography, but this can only detect thrombi greater than 0.5 cm in diameter. Microthrombi that forms early in myocardial infarction and which pose a serious threat of embolism would not therefore be detected. Conversely, an organised chronic thrombus, which is more easily detectable on echocardiography is less likely to embolise.

A newly formed left ventricular thrombus is likely to embolise as are thrombi that are mobile, protruding, or pedunculated with a narrow stalk. Left ventricular thrombi present for more than three months would have undergone fibrous organisation and endothelialisation and so are more stable.

The only parameters shown by studies to achieve statistical significance as a predictor of thromboembolic events is peak oxygen uptake during symptom limited maximal exercise testing and the severity of heart failure (measured by left ventricular ejection fraction). The left ventricular ejection fraction is a powerful predictor of stroke in patients who have had a myocardial infarction. Patients with left ventricular ejection fraction less than 28% at particularly high risk. Furthermore, for every absolute decrease of 5% in left ventricular ejection fraction, the risk of stroke increases by 18%.

Patients with idiopathic dilated cardiomyopathy tend to have a higher rate of systemic thromboembolism than patients with ischaemic cardiomyopathy. Only women with peripartum cardiomyopathy have higher risks of thromboembolism than patients with idiopathic dilated cardiomyopathy. Atrial fibrillation, age, and previous thromboembolic events are independent risk factors for stroke but confer further risks to patients with heart failure. Atrial fibrillation is associated with a stroke risk of about 5% every year.

Antithrombotic treatment

Warfarin

The need for oral anticoagulation in chronic heart failure has been inferred from mainly observational and retrospective studies of mortality from heart failure. In the PROMISE study, lower incidences of stroke were reported with anticoagulation (1.9% *v* 2.5%). In a follow up study of patients with idiopathic dilated cardiomyopathy, 18% of patients not taking warfarin had a stroke, whereas none occurred among the patients receiving warfarin over 11 years of follow up. Several studies of patients who had myocardial infarction showed that long term warfarin treatment to reduce rates of death, recurrent myocardial infarction, and stroke was effective.

Other studies have also shown that warfarin reduces mortality from sudden coronary death and recurrent myocardial infarction. Both the CONSENSUS and SOLVD studies showed that patients receiving warfarin had a lower mortality than those patients receiving antiplatelet treatment or those without antithrombotic therapy. In a retrospective survey of the SOLVD participants, anticoagulant monotherapy reduced the risk of sudden cardiac death by 32%. Among participants with non-ischaemic heart failure, this risk fell by

Factors predisposing to left ventricular thrombus formation and embolisation

Left ventricular thrombus formation

- After acute extensive myocardial infarction
- Acute anterior myocardial infarction
- Left ventricular aneurysm
- Left ventricular dilatation

Systemic embolisation of left ventricular thrombi

- New or acute thrombus (within two weeks of formation)
 - Protruding segment
 - Normal adjacent wall function
-

Identifying risk factors that predispose to systemic embolisation of left ventricular thrombi is important because it allows patients at highest risk only to be treated. Currently, the identification of risk factors has been inferred from observational data of heart failure trials and smaller non-randomised studies

Major risk factors for cardioembolic stroke in chronic heart failure

- Atrial fibrillation
 - Mitral stenosis
 - Prosthetic mechanical valves
 - Presence of left ventricular mural thrombus
 - Previous thromboembolism (stroke, pulmonary embolism, deep vein thrombosis)
 - Poor left ventricular ejection fraction (<28%)
 - Acute left ventricular wall aneurysm
 - Recent myocardial infarction
 - Idiopathic dilated cardiomyopathy
 - Infective endocarditis
 - Atrial myxoma
 - Reduced peak oxygen uptake at maximal exercise
-

Studies comparing the effect of antithrombotic therapy in heart failure

Study	Treatment (anticoagulation <i>v</i> antiplatelet agents <i>v</i> placebo)	Stroke incidence every 100 patient years	Thromboembolic incidence every 100 patient years	Mortality

nearly 70%. The benefit of warfarin use is not uniform, as for example, the V-HeFTI Trial did not show any substantial benefit with warfarin use. Data from the SOLVD and V-HeFTI studies were observational, without randomisation or control with respect to oral anticoagulation. In addition, interpretation of these data is potentially confounded—patients who were considered to be at highest risk of thromboembolism may have been treated with warfarin, and this would substantially reduce their long term risk of thromboembolic events.

Balanced against its potential benefits, warfarin increases the risk of intracranial haemorrhage by 0.3%. This complication increases with higher therapeutic targets (for example, INR 3.0-4.5). In heart failure patients with sinus rhythm, assuming a 2% risk of ischaemic stroke, warfarin use must reduce the risk by at least 20% to outweigh the threat of intracranial haemorrhages. Recurrent stroke rates in heart failure patients are also high (about 9% a year), and a reduction of only 10% would outweigh the risk of bleeding complications with warfarin. Secondary prevention of ischaemic strokes by warfarin in patients with heart failure should be considered.

Similarly, not all patients with documented left ventricular thrombi carry a high risk of embolisation. “High risk” patients such as those who have had an extensive acute anterior myocardial infarction or who show a new mural thrombus on cross sectional echocardiography should be considered for anticoagulation. Long term therapy (more than three months) is generally not recommended because of low embolisation rates from chronic left ventricular thrombi (unless the mass is mobile and pedunculated or other high risk factors exist).

Despite the limited evidence, some authorities recommend anticoagulation for patients with idiopathic dilated cardiomyopathy, whereas others using the postmyocardial infarction studies and data from SOLVD and CONSENSUS, advocate the use of warfarin in patients with ischaemic cardiomyopathy. A recent Cochrane systematic review does not recommend warfarin routinely for all heart failure patients in sinus rhythm because of conflicting conclusions from retrospective analyses and case series. More evidence is needed from randomised trials, such as the WATCH study (see later).

Aspirin

Use of aspirin in heart failure is controversial, but it is commonly used in patients with chronic heart failure who are in sinus rhythm, because of its general efficacy as an antithrombotic agent in vascular disease. In addition, aspirin in general reduces the incidence of stroke and death in patients with recurrent episodes of cerebral ischaemia. Furthermore, aspirin has been shown to be moderately effective in reducing venous thrombosis and thromboembolism in patients undergoing hip surgery.

Indications for warfarin treatment in chronic heart failure**Strongly recommended**

- Atrial fibrillation
- Previous ischaemic strokes
- New left ventricular mural thrombus formation
- Unstable, mobile left ventricular thrombus

Individual consideration to be given

- Idiopathic dilated cardiomyopathies
- Poor left ventricular ejection fraction (< 28%)
- Acute left ventricular aneurysm

Not recommended

- Sinus rhythm in absence of other risk factors
- Chronic left ventricular aneurysm
- Presence of chronic organised left ventricular mural thrombus

Aspirin has been shown to reduce the incidence of myocardial infarction and death in men and women over 50 years, patients with unstable angina and myocardial infarction, and in patients with atherosclerotic cerebrovascular disease, whereas aspirin improves the patency rates of saphenous-vein aortocoronary bypass grafts

Most trials of angiotensin converting enzyme (ACE) inhibitors, bar the SAVE study, have shown possible attenuation of their protective effects in heart failure after myocardial infarction when combined with aspirin. Several reasons have been put forward, not least because aspirin and ACE inhibitors exert effects on the same prostaglandin pathways. Concomitant aspirin can also limit sodium excretion and impair renal function in patients with chronic heart failure. The justification for using aspirin in chronic heart failure is strongest where an ischaemic aetiology is suspected. Indeed, aspirin reduces rates of death, recurrent myocardial infarction, and stroke when used in or shortly after acute myocardial infarction.

Although observational trials have shown a beneficial reduction of stroke with aspirin in patients with chronic heart failure, in general this reduction is less than that seen with warfarin. Two studies have shown aspirin to be more beneficial than warfarin in preventing strokes in heart failure. Both studies however were not randomised and it is possible that participants in the warfarin arm were more seriously ill or at higher risk of systemic embolism (for example, associated atrial fibrillation). Aspirin had no effect on mortality or risk of systemic embolism in patients with documented left ventricular thrombi.

A recent Cochrane systematic review concluded that there was conflicting evidence to support the use of antiplatelet drugs to reduce the incidence of thromboembolism in patients with chronic heart failure who are in sinus rhythm. There was also no direct evidence to indicate superior effects from oral anticoagulation, when compared with aspirin, in patients with chronic heart failure. Pending further evidence, aspirin cannot be recommended routinely for all patients with chronic heart failure (in sinus rhythm or atrial fibrillation) with or without left ventricular thrombi for the prevention of stroke and thromboembolism. Current guidelines should be tailored to individual risks and benefits.

Other antiplatelet drugs have not been represented in previous trials. Clopidogrel, which inhibits platelet function by inhibiting adenosine-induced platelet aggregation does not inhibit cyclo-oxygenase. Thus, it should not attenuate the beneficial actions of ACE inhibitors in the manner of aspirin. The large, ongoing randomised controlled WATCH study using clopidogrel, aspirin, and warfarin seeks to identify the optimal antithrombotic agent with the best risk:benefit ratio in the prevention of stroke and thromboembolism in heart failure.

Acute heart failure

Patients with acute and decompensated heart failure not only have high levels of circulating catecholamines that may further activate the clotting cascade, but also tend to be less ambulatory and can be confined to bed or chair. The risk of venous thromboembolism is therefore increased and in fact, thromboembolic complications add to the burden of prolonged hospitalisation and mortality in these patients. Giving subcutaneous injections of unfractionated or low molecular weight heparin as prophylaxis can reduce the risk of venous thromboembolism, but trial evidence in chronic heart failure is lacking. No recent clinical trials show that warfarin or aspirin are effective in the primary prevention of venous thromboembolism or systemic complications in patients with acute heart failure who are in sinus rhythm.

14 Antithrombotic therapy in special circumstances. I—pregnancy and cancer

Bernd Jilma, Sridhar Kamath, Gregory Y H Lip

Antithrombotic therapy during pregnancy

Pregnancy predisposes to venous thromboembolism for several reasons. These include a change in the balance between procoagulant and anticoagulant factors in the blood. Any conditions that predispose a woman to thromboembolism when she is not pregnant will also predispose her to thromboembolism when she is pregnant.

Generally, antithrombotic therapy started in a non-pregnant patient for a particular disorder needs to be continued during the pregnancy and in the puerperium. The use and type of antithrombotic therapy depends on the risk:benefit ratio, taking into consideration the potential harm to the mother and the fetus.

The potential risks of antithrombotic therapy during pregnancy can be divided into maternal and fetal risks, and include teratogenicity and bleeding. Unfractionated heparin and low molecular weight heparins do not cross the placenta and are probably safe for the fetus, although bleeding at the uteroplacental junction is possible. Nevertheless, data are sparse for low molecular weight heparin, with no reliable comparative trials or convincing dose assessment.

In contrast to heparin, coumarin derivatives cross the placenta and can cause both bleeding in the fetus and teratogenicity. Coumarin derivatives can cause an embryopathy (which consists of nasal hypoplasia or stippled epiphyses or both) after in utero exposure during the first trimester of pregnancy. In addition, central nervous system abnormalities can occur after exposure to such drugs during any trimester. The main risk of embryopathy occurs if coumarin derivatives are taken between six weeks and 12 weeks of gestation. At the time of delivery, the anticoagulant effect in the fetus can lead to bleeding in the neonate.

Heparin and low molecular weight heparins are not secreted into breast milk and can probably be given safely to nursing mothers. High dose aspirin should be avoided, as it could (theoretically) impair platelet function and produce hypoprothrombinaemia in the infant, if neonatal vitamin K stores are low, as well as cause Reye's syndrome. Warfarin does not induce an anticoagulant effect in an infant who is breast fed and therefore could be used safely in the postpartum period; thus, patients who are receiving long term heparin treatment could be switched over to warfarin post partum if and when considered appropriate. With regard to other agents, phenindione should be avoided, and acenocoumarol requires prophylactic vitamin K for the infant.

Venous thrombosis and pulmonary embolism

Antithrombotic prophylaxis for the prevention of venous thromboembolic disorders in pregnancy is indicated when a patient has experienced a previous thromboembolic episode or is considered to be at particularly high risk because of a predisposing condition.

Unfractionated heparin 5000 IU twice daily is generally adequate in non-pregnant women. Heparin requirements can be highly variable in pregnancy. A once daily dose of low

Disorders during pregnancy for which antithrombotic therapy is commonly considered

- Prophylaxis and treatment of venous thromboembolism
- Prophylaxis in patients with valvar disease (for example, mitral stenosis)
- Prophylaxis in patients with mechanical prosthetic valves
- Antiphospholipid syndrome
- Prophylaxis against pregnancy induced hypertension and intrauterine growth retardation

Potential risks of antithrombotic therapy during pregnancy

Maternal disadvantages and risks

Unfractionated heparin

- Haemorrhage (uteroplacental, especially during labour)
- Heparin induced thrombocytopenia
- Osteoporosis
- Regular monitoring

Low molecular weight heparin

- Bleeding risk, especially during labour

Warfarin

- Bleeding
- Regular monitoring

Risk to the fetus or child

Heparin

- Seems to be safe

Low molecular weight heparin

- Seems to be safe

Warfarin

- Embryopathy, especially if mother is exposed between 6 and 12 weeks
- Central nervous system malformations during any time of the gestation

Low dose aspirin

- Potential risk of birth defects and bleeding risk in the first trimester
- Safe in second and third trimester

Diagnosis of suspected deep vein thrombosis in pregnancy

ABC of Antithrombotic Therapy

molecular weight heparin is a useful alternative to unfractionated heparin and has been shown to be safe and effective in pregnancy.

Patients who develop thromboembolism during pregnancy could be treated initially with at least five days of intravenous heparin treatment, followed by a twice daily subcutaneous dose of unfractionated heparin. The dose is adjusted by maintaining the activated partial thromboplastin time (APTT) within the therapeutic levels. Heparin could temporarily be stopped immediately before delivery and then resumed in the postpartum period to minimise the risk of haemorrhage during labour. The duration of antithrombotic therapy in the postpartum period should be maintained for a minimum of three months, possibly up to six months.

Patients with prosthetic heart valves

The precise safety of warfarin during pregnancy continues to be debated, but it is probably appropriate to withhold warfarin between six and 12 weeks of gestation and for the latter half of the third trimester, because of the risk of causing embryopathy and postpartum haemorrhage respectively. Based on this, the recommended options for use of antithrombotic therapy in patients with a mechanical heart valve during pregnancy include:

- Adjusted dose of unfractionated heparin twice daily to maintain the APTT within therapeutic range, or low molecular weight heparin throughout the pregnancy
- Warfarin throughout the pregnancy, except for the first trimester (either for the entire trimester or between six and 12 weeks) and for the latter half of the third trimester (when warfarin should be replaced by unfractionated or low molecular weight heparin).

The risks and benefits of this approach should be explained to patients, who should be allowed to make an informed choice. There are real concerns over the incidence of abortions and fetal malformations in patients treated with warfarin in the first trimester. Concerns over long term heparin treatment in pregnant women include heparin induced thrombocytopenia and osteoporosis.

Prepregnancy counselling is vital for patients who are receiving long term warfarin treatment, and a cardiologist and obstetrician should explain the risks to patients. Patients who are established on long term warfarin treatment and plan to become pregnant could then take twice daily heparin before getting pregnant. Alternatively, and assuming that the risk of warfarin to the fetus in the first six weeks of gestation is not worrisome, they could continue taking warfarin and have frequent checks to see if they are pregnant. If they are, they should immediately switch over to heparin. Again, close liaison between obstetrician, midwife, general practitioner, cardiologist, and neonatologist is vital.

Antiphospholipid syndrome

Antiphospholipid syndrome predisposes a pregnant woman to thromboembolism and pregnancy losses. Abortion in a previous pregnancy predisposes to further abortions or stillbirths in subsequent pregnancies. A combination of aspirin and heparin to prolong the APTT to within the therapeutic range (APTT ratio 2.0-3.0) throughout the pregnancy would substantially decrease pregnancy losses and other complications. However, one recent trial suggested that low dose aspirin (75 mg) may suffice (see box), but small numbers merit some caution pending further data.

Distribution of warfarin dose and poor outcome according to order of pregnancy. The risk of pregnancy complication in patients treated with warfarin is higher when the mean daily dose exceeds 5 mg ($P < 0.001$)

Antiphospholipid syndrome in pregnancy: a randomised controlled trial of aspirin *v* aspirin plus heparin

	Low dose aspirin (n=47)	Low dose aspirin plus heparin (n=51)
Live birth rate (%)	72	78
Mean (SD) birth weight (g):	3221 (781)	3127 (657)
Range	890-5300	718-4319
Gestation at delivery (%):		
< 30 weeks	1	1
30-36 weeks	3	1
> 36 weeks	30	38
Embryo loss (%)	9	3
Fetal loss (%)	4	8

Antithrombotic therapy in antiphospholipid syndrome

Scenario	Management
History of pregnancy loss	Aspirin plus heparin (APTT in therapeutic range)
History of thromboembolism but no pregnancy loss	Heparin alone (APTT in therapeutic range)
No history of adverse events	Heparin alone 5000 IU twice daily; close observation

Pre-eclampsia and intrauterine growth retardation

On the basis of small, retrospective studies, low dose aspirin (< 150 mg daily) was thought to be useful as prophylaxis in patients with a history of pre-eclampsia and intrauterine growth retardation in preventing similar adverse events during the current pregnancy. However, a large (nearly 10 000 women) randomised controlled trial (CLASP) of aspirin 60 mg compared with placebo, reported that, although aspirin was associated with a 12% reduction in the incidence of pre-eclampsia, this was not significant nor was there any substantial impact on intrauterine growth retardation, stillbirth, or neonatal death. Thus, routine use of low dose aspirin is not recommended. However, some experts recommend its use in patients who are liable to develop early onset (before 32 weeks) pre-eclampsia or in high risk groups for pre-eclampsia, such as women with type 1 diabetes, chronic hypertension, multiple pregnancies, or previous pre-eclampsia. However, the safety of higher doses of aspirin and aspirin ingestion during the first trimester remains uncertain.

Antithrombotic therapy in cancer

Venous thromboembolism is a frequent complication in patients with cancer, and it is a common clinical problem. It can even precede the diagnosis of cancer by months or years. Patients with cancer are nearly twice as likely to die from pulmonary embolism in hospital as those with benign disease, and about 60% of these deaths occur prematurely. Thromboembolism seems to be particularly predominant in patients with mucinous carcinoma of the pancreas, lung, or gastrointestinal tract. This may be because cancer can be associated with raised levels of procoagulants such as fibrinogen, von Willebrand factor, and tissue factor, as well as excess platelet activity. Raised levels of plasminogen activator inhibitor are often present, and this will impair fibrinolysis. Therapeutic interventions in patients with cancer, such as surgery, standard chemotherapy, or hormone based treatment (such as oestrogens for prostatic cancer), further increase the risk for thrombosis. One reason for this may be that certain types of chemotherapy impair the natural anticoagulant properties of the endothelium, thus promoting a procoagulant state. Unfortunately, no standardised protocols exist for the management of patients with cancer and the approaches vary.

Primary prophylaxis

In patients with cancer who are confined to bed or having low risk surgical procedures a low dose of unfractionated heparin or low molecular weight heparin is administered subcutaneously, along with physical measures, as primary prophylaxis to reduce thromboembolic risk. Patients having major abdominal or pelvic surgery for cancer are recommended to receive adjusted dose heparin, low molecular weight heparin, or oral anticoagulants (therapeutic international normalised ratio (INR) 2.0-3.0) similar to those for major orthopaedic surgery.

A low dose warfarin regimen is recommended for patients receiving chemotherapy or those with indwelling venous catheters to decrease the incidence of thromboembolism. For example, one double blind randomised study of patients with metastatic breast cancer receiving chemotherapy showed that a very low dose (1 mg/day) of warfarin for six weeks followed by a dose to maintain the INR at 1.3-1.9 was effective. Low dose low molecular weight heparin (for example, dalteparin 2500 IU/day) is an alternative for patients with indwelling venous catheters.

Study	Aspirin	Placebo	Peto odds ratio (95% CI fixed)	Weight (%)	Peto odds ratio (95% CI fixed)
McParland, 1990	1/48	10/52		18.5	0.18 (0.05 to 0.61)
Morris, 1996	4/52	7/50		18.6	0.52 (0.15 to 1.82)
Bower, 1996	9/31	12/29		26.0	0.59 (0.20 to 1.68)

 Test for overall effect $z=-2.16$, $P=0.03$

Effect of aspirin in preventing pre-eclampsia: meta-analysis of randomised trials showing numbers of cases of pre-eclampsia

Virchow's triad* in cancer

Abnormal blood flow

- Increased viscosity and turbulence
- Increased stasis from immobility

Abnormal blood constituents

- Increased platelet activation and aggregation
- Increased procoagulant factors
- Decreased anticoagulant and fibrinolytic factors

Abnormal blood vessel wall

- Damaged or dysfunctional endothelium
- Loss of anticoagulant nature
- Possibly angiogenesis

*For thrombogenesis (thrombus formation) there needs to be a triad of abnormalities (abnormal blood flow, abnormal blood constituents, and abnormal blood vessel wall)

Risk factors for thromboembolism in patients with cancer

- Prolonged immobility
- Surgical procedures
- Chemotherapy
- Indwelling vascular catheters

Overview of coagulation, fibrinolysis, and angiogenesis in cancer. The activation of platelets leads to their swelling and the release of angiogenic factors. These affect the vascular endothelia of healing and tumour tissues. The blue arrows facilitate angiogenesis and the red arrows are inhibitory (ATIII=antithrombin III, F1 + 2=prothrombin fragments, PAI=plasminogen activator inhibitor, PDGF=platelet derived growth factor, PF4=platelet factor 4, TF=tissue factor, TFPI=tissue factor pathway inhibitor, TSP1/2=thrombospondin 1 and 2, tPA=urokinase type plasminogen activator, uPA=urokinase type plasminogen activator, VEGF=vascular endothelial growth factor)

Treatment and secondary prevention

Patients with cancer who develop a thromboembolism should be treated in a similar manner to patients without cancer. An initial period of therapeutic unfractionated heparin or low molecular weight heparin which is overlapped and followed by warfarin for a minimum of three months is recommended. Anticoagulation should be continued in patients who have active disease or who receive chemotherapy while these risk factors last. The dose should maintain an INR of between 2.0 and 3.0.

Risk of haemorrhage

Patients with cancer who are receiving antithrombotic therapy are thought to be at higher risk of bleeding than patients without cancer. This assumption has been disputed, however, in light of the evidence from some studies in which the risk of major bleeding did not differ greatly between the two groups of patients. For practical purposes, the recommended therapeutic levels of anticoagulation remain the same (for example, if warfarin, then INR 2.0-3.0) as long as patients are educated about the risks and the anticoagulation levels are strictly monitored. The propensity for chemotherapy to be given in cycles or boluses, followed by periods free of chemotherapy, seems likely to frustrate attempts to maintain the INR within its target range.

Definite conclusions cannot be drawn about the safety of antithrombotic therapy in patients with primary or secondary brain malignancy. Some small studies report that it is probably safe to give these patients anticoagulants. However, definite decisions about anticoagulation in such patients have to be individualised and carefully considered. Anticoagulation should probably be avoided in patients with brain metastasis because of the chances of renal cell carcinoma or melanoma, as these tumours are highly vascular.

Recurrent venous thromboembolism

Patients with cancer are at a higher risk than non-cancer patients of recurrence of thromboembolism despite adequate anticoagulation. Again, no strict evidence based guidelines exist for the management of these patients. The recommended options include maintenance of a higher level of anticoagulation (INR 3.0 to 4.5), substitution with adjusted dose heparin or low molecular weight heparin (some evidence suggests heparin is probably better in this situation), and placement of inferior venacaval filters with or without anticoagulation.

Concerns about antithrombotic therapy in cancer

- Recurrent venous thromboembolism
 - Increased tendency for minor and major bleeds
 - Inconsistency in therapeutic anticoagulant levels
 - Procoagulant effects of chemotherapy (for example, endothelial cell dysfunction)
-

15 Antithrombotic therapy in special circumstances. II—children, thrombophilia, and miscellaneous conditions

Bernd Jilma, Sridhar Kamath, Gregory Y H Lip

Treatments for children

Most of the recommendations on antithrombotic therapy in children are based on the extrapolation of results from randomised studies of adults or from small cross sectional, and mainly retrospective, clinical studies of children. Although antithrombotic therapy in children usually follows the same indications as in adults, the distribution of diseases requiring antithrombotic therapy differs in the paediatric population. For example, some predisposing factors for thromboembolism are encountered only in paediatric populations. Most of the indications for antithrombotic therapy in children arise because of an underlying medical disorder or an intervention for the management of the disorder. Management of antithrombotic therapy in children differs from that in adults because of ongoing changes in physiology that may alter the thrombotic process and potentially influence the response of the body to antithrombotic therapy.

Drug treatments

Antiplatelet treatment

Aspirin, dipyridole, and indomethacin are probably the most used antiplatelet treatments among children. Low doses of aspirin (antiplatelet doses) usually have minimal side effects in children, but in general aspirin should not be prescribed to children aged < 16 years unless there are compelling clinical indications. The particular concerns about Reye's syndrome usually seem to be related to higher doses of aspirin (> 40 mg/kg).

Heparin

Heparin is probably the most commonly used antithrombotic drug in children. Varying concentrations of antithrombin in the body during different developmental stages mean that the therapeutic concentration of heparin in children has to be maintained by regular checks of the activated partial thromboplastin time (APTT) or anti-Xa concentrations. The recommended therapeutic level of APTT is the one which corresponds to a heparin concentration of 0.2-0.4 U/ml or an anti-Xa concentration of 0.3-0.7 U/ml.

In children, the advantages of low molecular weight heparin over unfractionated heparin are similar to those in adults. In addition, low molecular weight heparin may be preferred for children with difficult venous access because regular blood checks to monitor the therapeutic levels are not mandatory. The recommended therapeutic dose of a low molecular weight heparin is the one that reflects the plasma anti-Xa concentrations of 0.5-1.0 U/ml four to six hours after injection.

Oral anticoagulants

Certain problems are associated with the use of oral anticoagulants in children. Sensitivity to oral anticoagulants changes during different phases of life, especially during infancy, because of varying concentrations of vitamin K and vitamin K dependent proteins in the body. Neonates (during the first month

Indications for antithrombotic therapy in children

Adjusting low molecular weight heparin in children

Anti-Xa level (U/ml)	Hold next dose?	Dose change?	Repeat anti-Xa measurement
< 0.35	No	Increase by 25%	4 hours after next dose
0.35-0.49	No	Increase by 10%	4 hours after next dose
0.5-1.0	No	No	Next day, then 1 week later, and monthly thereafter while receiving rivaroxaban treatment (4 hours after morning dose)
1.1-1.5	No	Decrease by 20%	Before next dose
1.6-2.0	3 hours	Decrease by 30%	Before next dose then 4 hours after next dose
> 2.0	Until anti-Xa 0.5 U/ml	Decrease by 40%	Before next dose, then every 12 hours until anti-Xa level < 0.5 U/ml

ABC of Antithrombotic Therapy

of life) are especially sensitive because of their relative deficiency of vitamin K, and therefore warfarin should be avoided in such patients if possible. However, formula fed infants are resistant to oral anticoagulants because of a high concentration of vitamin K in their diet. In general, young children need more oral anticoagulation for each kilogram of body weight than older children and adults. Poor venous access (for international normalised ratio (INR) checks) and non-compliance are added problems of anticoagulation in children.

Recommended therapeutic ranges and duration of anticoagulation for a variety of disorders in children are usually similar to those for adults.

Thrombolytic treatment

Thrombolytic treatment is used primarily for maintaining catheter patency and in the management of thromboembolism that threatens the viability of the affected organ. Thrombolytic drugs are used locally or systemically and their concentration can be monitored with plasma fibrinogen levels or total clotting time. Decreased plasma plasminogen levels in newborns may reduce the thrombolytic actions of the drugs. Thrombolytic drugs pose similar risks to children as to adults.

Venous thromboembolism

Venous thromboembolism in children usually occurs secondary to an underlying disorder, such as in the upper arm secondary to a central venous line being inserted. Such lines are usually placed for intensive care management and treatment of cancer. The patency of these lines is traditionally maintained through therapeutic local instillation of urokinase for blocked lines or prophylactic intermittent boluses of heparin (which have doubtful efficacy).

Established venous thromboembolism requires removal of the predisposing factor and anticoagulation similar to that in adults (standard heparin for five days followed by maintenance with oral anticoagulation for at least three months). Oral anticoagulation can be started on the same day as heparin. Low molecular weight heparin is a useful option for maintaining anti-Xa level of 0.5-1.0 U/ml. Patients with a first recurrence of venous thromboembolism or with an initial episode with continuing risk factors either could be closely monitored for any early signs of thromboembolism or should be given anticoagulant drugs prophylactically after the period of initial therapeutic anticoagulation for the episode. Patients with a second recurrence of venous thromboembolism or with a first recurrence with continuing risk factors should be given anticoagulants for life, as in adults.

Arterial thromboembolism

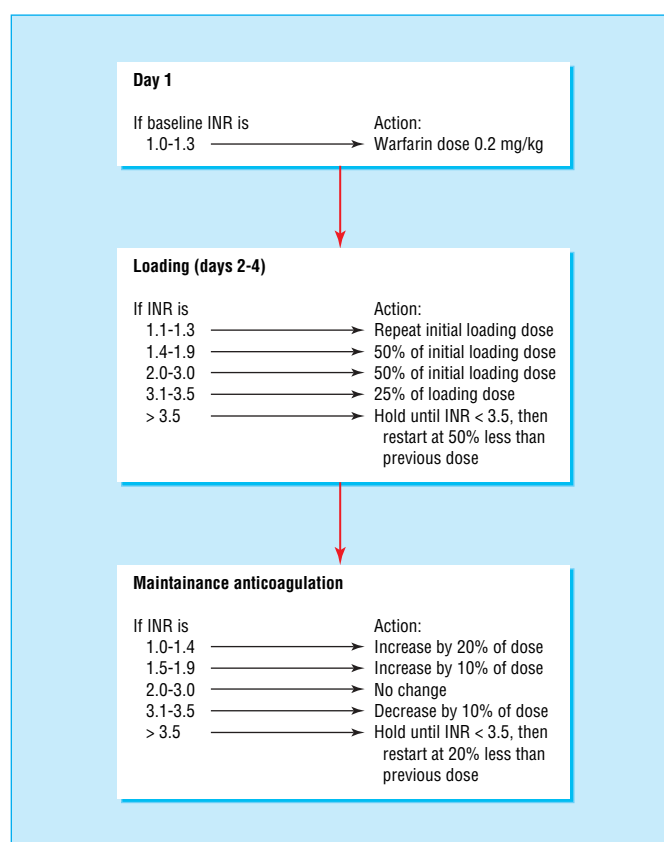

The usual predisposing factors include placement of central and peripheral arterial catheters for cardiac catheterisation and intensive care settings. A bolus of heparin (50-150 U/kg) at the time of arterial puncture and continuous low dose heparin infusion are common methods for cardiac and umbilical artery catheterisation, respectively.

Prosthetic heart valves

Oral anticoagulation is needed in children with mechanical heart valves. An INR of 2.5-3.5 is recommended as the target range. Patients who are predisposed to high risk of thromboembolism despite anticoagulation treatment and those with thromboembolism while taking warfarin could benefit from the addition of antiplatelet drugs, such as aspirin (6-20 mg/kg/day) or dipyridamole (2-5 mg/kg/day), to oral anticoagulation.

Effect of age on dose of warfarin needed to sustain an international normalised ratio (INR) of 2.0-3.0 in 262 children. Younger children required significantly more warfarin than older children ($P < 0.001$)

Protocol for oral anticoagulation treatment to maintain an INR ratio of 2.0-3.0 for children

Commonly used drugs in children that affect INR values

Drug	Usual effect on INR
Amiodarone	Increase
Aspirin	Increase or no change
Amoxicillin	Slight increase
Cefaclor	Increase
Carbamazepine	Decrease
Phenytoin	Decrease
Phenobarbital	Decrease
Cloxacillin	Increase
Prednisone	Increase
Co-trimoxazole	Increase
Ranitidine	Increase

Other cardiac disorders

No universally accepted guidelines or randomised trials exist for the antithrombotic therapy in patients undergoing operations where there is risk of thromboembolism (such as Blalock-Taussig shunts, Fontan operations, and endovascular stents). A variety of antithrombotic regimens have been used after these operations, including intraoperative heparin only and intraoperative heparin followed by oral anticoagulation or aspirin.

Hereditary prothrombotic states

Deficiencies of protein C, protein S, or antithrombin III and factor V Leiden mutation can lead to thromboembolism especially in the presence of a secondary risk factor. Homozygous deficiency of these proteins could lead to fatal purpura fulminans in newborns, which is treated immediately by rapid replacement of these factors with fresh frozen plasma or protein concentrates. This is followed by careful initiation of lifelong oral anticoagulation to maintain the INR at higher levels of 3.0-4.5. Heterozygous patients could be given prophylactic antithrombotic therapy during exposure to secondary risk factors or be followed up with close observation.

Antithrombotic therapy in thrombophilia and miscellaneous conditions

A detailed discussion of management of thrombophilic disorders is beyond the scope of this article. The guidelines on the management of these disorders are based on small and non-controlled series of patients because of the paucity of randomised trials (as reviewed by the Haemostasis and Thrombosis Task Force in 2001).

Inherited thrombophilic disorders are genetically determined, and most of the affected patients are heterozygotes. Homozygotes are extremely rare. Antithrombin III, protein C, and protein S are produced in the liver and act by inactivating coagulation factors. Deficiency of these proteins could lead to uncontrolled activation of the coagulation cascade and therefore thromboembolism.

Activated protein C resistance is the commonest inherited thrombophilic disorder and accounts for 20-50% of cases. Antithrombin III deficiency is the rarest of the mentioned inherited thrombophilic disorders but carries the highest thrombotic risk. High plasma concentration of homocysteine is linked to genetic enzyme deficiencies and low plasma concentrations of folate and vitamin B-6, and an investigation of vitamin B-12 metabolism is warranted.

Though thrombophilic disorders predispose patients to thromboembolism, the routine use of anticoagulation for primary prophylaxis entails greater risks than benefit (except probably in homozygotes). Therefore primary prophylaxis is warranted only in the presence of a second risk factor, and for as long as the risk factor lasts. Common predisposing factors that require prophylaxis include surgery, immobilisation, pregnancy and the puerperium, and oral contraception.

Special caution is needed when giving anticoagulation to patients with protein C deficiency. Because protein C is a vitamin K dependent factor, the administration of warfarin could lead to sudden decrease in protein C before any noticeable decrease in coagulation factors. This could cause enhanced thrombosis and diffuse skin necrosis. This adverse response can be avoided by gradual initiation of oral anticoagulation with low doses of warfarin, preferably overlapped by adequate heparinisation. In cases of severe deficiency, replacement of protein C is indicated before starting warfarin.

Common thrombophilic disorders

Inherited

- Antithrombin III deficiency
- Protein C deficiency
- Protein S deficiency
- Activated protein C resistance (factor V Leiden mutation)
- Inherited hyperhomocysteinaemia
- Raised factor VIII levels
- Prothrombin gene G20210 A variant

Acquired

- Antiphospholipid syndrome
- Acquired hyperhomocysteinaemia

Guidelines for antithrombotic therapy in inherited thrombophilia*

Indication	Treatment
<i>Primary prophylaxis</i>	
Any surgery	Unfractionated heparin subcutaneously 5000 IU three times daily
Malignancy or orthopaedic surgery	Unfractionated heparin subcutaneously 5000 IU three times daily, possibly with replacement of deficient factors
Pregnancy	Unfractionated heparin subcutaneously 5000 IU three times daily
Pregnancy in antithrombin III deficiency	Therapeutic dose of unfractionated heparin to prolong APTT or dose adjusted warfarin (INR 2.0-3.0), except during first trimester and latter part of third trimester, when unfractionated heparin is used
Puerperium (for 4-6 weeks)	Unfractionated heparin subcutaneously 5000 IU three times daily or dose adjusted warfarin (INR 2.0-3.0)
<i>Secondary prophylaxis</i>	
First episode of thrombosis	Dose adjusted warfarin for 6 months
First episode of life threatening thrombosis, multiple deficiencies, continuing predisposing factor	Lifelong oral anticoagulation
Recurrent thrombosis	Lifelong oral anticoagulation
<i>Treatment of established thrombosis</i>	
Treatment of acute thrombosis	Unfractionated heparin to prolong APTT followed by oral anticoagulation treatment, possibly with replacement of the deficient factors

*For full guidelines see Haemostasis and Thrombosis Task Force, *Br J Haematol* 2001;114:512-28
Low molecular weight heparins are increasingly used as alternatives to unfractionated heparin

Little evidence exists to support the use of antithrombotic agents in hyperhomocysteinaemia. Although replacement of folic acid and vitamin B-6 has been shown to reduce plasma homocysteine levels, no study has found reduction in thromboembolic events with this intervention.

Antiphospholipid syndrome

The long term prognosis for this syndrome is influenced by the risk of recurrent thrombosis. As with other thrombophilic disorders, primary prophylaxis is not indicated in the absence of other risk factors. A patient with one episode of thrombosis is at considerable risk of further thrombosis and should be given lifelong anticoagulation with warfarin as secondary prophylaxis. The target INR should be 2.0-3.0 (although some authorities advocate a higher INR level (≥ 3.0)). Patients with this syndrome may be relatively resistant to warfarin and so will need high doses. However, some authorities believe that the antiphospholipid antibodies interfere with the generation of the INR and lead to spurious results. Consequently, other routes to monitoring anticoagulation may be needed.

Low molecular weight heparin is used increasingly in patients with various thrombophilia and seems to be safe and reliable.

Kawasaki disease

Aspirin continues to be used in Kawasaki disease despite a lack of unequivocal evidence from randomised trials of its benefit in reducing coronary artery aneurysm or thrombosis. Aspirin is used in anti-inflammatory doses (50-100 mg/kg/day) during the acute stage of the disease, followed by antiplatelet doses (1-5 mg/kg/day) for seven weeks or longer.

The figure showing effect of age on dose of warfarin in 262 children is adapted from Streif W et al, *Curr Opin Pediatr* 1999;11:56-64. The diagram of protocol for oral anticoagulation for children and the tables showing adjustment of low molecular weight heparin in children and commonly used drugs in children are adapted from Monagle P et al, *Chest* 2001;119:S344-70. The guidelines for antithrombotic therapy in inherited thrombophilia are adapted from the Haemostasis and Thrombosis Task Force, *Br J Haematol* 2001;114:512-28. The box of recommendations from the College of American Pathologists consensus conference on diagnostic issues in thrombophilia is adapted from Olson JD, *Arch Pathol Lab Med* 2002;126:1277-80.

Recommendations from the College of American Pathologists consensus conference XXXVI: diagnostic issues in thrombophilia

- Patients, and especially asymptomatic family members, should provide informed consent before thrombophilia testing is performed
 - Individuals testing positive for a thrombophilia need counselling on:
 - Risks of thrombosis* to themselves and their family members
 - Importance of early recognition* of the signs and symptoms of venous thromboembolism that would require immediate medical attention
 - Risks and benefits* of antithrombotic prophylaxis in situations in which their risk of thrombosis is increased, such as surgery or pregnancy
 - Laboratory testing for other inherited and acquired thrombophilias should be considered even after the identification of a known thrombophilia because more than one thrombophilia could coexist, compounding the risk for thrombosis in many cases
 - When available, World Health Organization (WHO) standards, or standards that can be linked to the WHO standard, should be used to calibrate functional and antigenic assays
 - Effect of age and sex should always be taken into consideration when interpreting the results of antigenic and functional assays
 - Before concluding that a patient has an inherited thrombophilia, diagnostic assays for function or antigen should be repeated after excluding acquired aetiologies of the defect
-

16 Anticoagulation in hospitals and general practice

Andrew D Blann, David A Fitzmaurice, Gregory Y H Lip

Service requirements for warfarin management include phlebotomy or finger pricking, accurate measurement of the international normalised ratio (INR) by a coagulometer (with associated standards and quality control), interpretation of the result, and advice on the warfarin dose. Clinical management of the complications of treatment (predominantly overdose) are also required. Furthermore, almost any drug can interact with oral anticoagulants, and many (such as steroids and antibiotics) often increase the anticoagulant effect.

When introducing a new drug, if the duration of treatment is short (such as an antibiotic for less than five days), then adjustment of dose is often not essential. If, however, the treatment is to last more than five days, then the INR should be checked after starting treatment with the new drug and the warfarin dose adjusted on the basis of the results.

Starting treatment in hospital inpatients

Once the indications for anticoagulation have been confirmed (for example, for suspected deep vein thrombosis do venography or D-dimer measurement), the initial dose of oral anticoagulant depends on a patient's coagulation status, age, clinical situation, and degree of heart failure (if present). In older patients, those with impaired liver function, and those with congestive heart failure oral anticoagulation should be started cautiously and the resulting INR checked often (every three to five days). The dose of warfarin needed to maintain an INR at 2.0-3.0, for example, falls with age and is greater in patients of Indo-Asian or African origin than in Europeans. Where possible, take routine blood samples for prothrombin time and activated partial thromboplastin time (APTT), platelet count, and liver function tests before starting treatment. Oral anticoagulation with warfarin should be started on day one, preferably in conjunction with heparin because the initial period of treatment with warfarin may be associated with a procoagulant state caused by a rapid reduction in protein C concentration (itself a vitamin K dependent protein). Heparin should not be stopped until the INR has been in the therapeutic range for two consecutive days. Patients at a high risk of thrombosis and those with a large atrial thrombus may need longer treatment with heparin.

Similarly, a specific anticoagulant treatment chart that contains the treatment protocol, the results of coagulation tests (INR and APTT ratios), and the prescribed doses based on the results should be the basis of treatment and is a useful way of assessing and monitoring patients' anticoagulation in the follow up period. Daily INR measurement for at least four days is recommended in patients needing rapid anticoagulation (for example, in those with high risk of thrombosis). Adjustment of the oral anticoagulant loading dose may be necessary if baseline coagulation results are abnormal. Some patients may be particularly sensitive to warfarin, such as older people and those with liver disease, congestive cardiac failure, or who are receiving drug treatment (such as antibiotics) likely to increase the effects of oral anticoagulants.

Once the therapeutic INR range is achieved it should be monitored weekly until control is stable. The British Society for Haematology's guidelines suggest that thereafter blood testing can be extended to fortnightly checks, then checks every four

Warfarin tablets used routinely in the United Kingdom

Drug interactions with warfarin*

Enhanced anticoagulant effect—Alcohol, allopurinol, anabolic steroids, analgesics (for example, paracetamol), antiarrhythmics (for example, amiodarone), antidepressants (for example, selective serotonin reuptake inhibitors), antidiabetics, antimalarials, antiplatelets, anxiolytics, disulfiram, influenza vaccine, leukotriene antagonists, levothyroxine, lipid regulating agents, testosterone, uricosurics

Reduced anticoagulant effect—Oral contraceptives, raloxifene, retinoids, rowachol, vitamin K (possibly present in enteral feeds)

Variable effect—Antibiotics (but, generally, more likely to enhance), colestyramine, antiepileptics, antifungals, barbiturates, cytotoxics (for example, effect enhanced by ifosfamide but often reduced by azathioprine), hormone antagonists, ulcer healing drugs

*This list is not exhaustive or definitive but provides perspective: the effect of each particular agent should be observed on each particular patient. Considerable variation exists in different drugs within a single class (for example, antibiotics). Refer to the *BNF* for guidance

Anticoagulation monitoring by fingerprick. Note coagulometer in the background

ABC of Antithrombotic Therapy

weeks, eight weeks, and 12 weeks (maximum). By this time, the checks are most likely to be in the setting of an experienced hospital outpatient clinic.

At the time of discharge from hospital, follow up arrangements for each patient should include sufficient tablets to allow adequate cover until the general practitioner can provide a prescription (two to three weeks' worth) and an appointment for further INR measurements, generally in an outpatient clinic. This period should not exceed seven days and should be detailed in the patient case notes and the yellow Department of Health anticoagulant booklets. Information in the yellow booklet should indicate the target INR range for each patient and other pertinent information, such as the presence of diabetes and indication for anticoagulation.

Starting treatment in outpatients

Without the benefit of the management procedures described above, starting anticoagulant treatment in outpatients can be difficult, especially if patients are referred without their notes or adequate information (such as other drugs prescribed or reason for anticoagulation). Nevertheless, local conditions and guidelines will generally recommend a starting dose, and patients will need to be recalled weekly for INR management until they are deemed to be stable. In many cases the introduction of computer assisted dosing (an algorithm software) is of immense benefit.

Complications and reversal of oral anticoagulation

Bleeding complications while patients are receiving oral anticoagulants increase substantially when INR levels exceed 5.0, and therapeutic decisions depend on the presence of minor or major bleeding. However, in those cases with evidence of severe bleeding or haemodynamic compromise, hospitalisation, intensive monitoring, and resuscitation with intravenous fluids may be needed. Sometimes the bleeding point can be treated (for example, endoscopic treatment of bleeding peptic ulcer). Fresh frozen plasma is recommended when quick reversal of over-anticoagulation is needed. If plasma is unavailable then vitamin K, given by slow intravenous injection at doses of 0.5-1.0 mg or orally at doses of 1-10 mg, may reduce the INR within six to eight hours without the risk of over-correction. However, the effects of vitamin K can last for a week and may delay the restarting of warfarin treatment, although retesting (thus restarting with warfarin) after 48-72 hours is common.

Maintenance in hospital practice

The traditional model of care for patients taking oral anticoagulants requires them to attend a hospital outpatient clinic so that the INR can be estimated. Capillary or venous blood samples are used, with the result being available either immediately or at a later stage. However, the INR derived from capillary (finger prick) blood is likely to be different from that obtained from plasma from a peripheral blood sample, and this should be considered. If possible, it is preferable to use consistently either finger prick or venous blood. Rarely, phlebotomists will visit housebound patients and return a venous sample to the laboratory for INR management. Where INR results are available with the patient present, dosing recommendations are made and the patient is given a date for the next appointment. When there is a delay in the INR estimation, patients receive dosing and recall advice through the

Requirement for daily dose of warfarin to maintain an INR between 2.0 and 3.0 and 3.0 and 4.5

Age (years)	No of patients	Daily dose of warfarin (mg)*
INR to be in range 2.0 to 3.0		
40-49	36	7.3 (6.21 to 8.39)
50-59	76	5.5 (5.0 to 6.0)
60-69	209	4.3 (4.05 to 4.55)
70-79	233	3.9 (3.68 to 4.12)
≥80	107	3.3 (3.01 to 3.59)
INR to be in range 3.0 to 4.5		
40-49	9	6.5 (5.23 to 7.77)
50-59	20	6.0 (5.2 to 6.8)
60-69	45	5.9 (5.13 to 6.67)
70-79	24	4.8 (4.15 to 5.45)
≥80	2	4.2 (2.65 to 5.75)

*Data are presented as mean (95% CI)

Relationship between age and daily dose in INR range 2.0-3.0 is correlation coefficient $r = -0.45$, $P < 0.001$, and for INR range 3.0-4.5 is correlation coefficient $r = -0.23$, $P = 0.022$

Data from Blann AD, et al, *Br J Haematol* 1999;107:207-9

Yellow Department of Health anticoagulant booklet. Columns are provided for the date of each visit, INR result, recommended daily dose, and signature

Treatment of excessive antithrombotic therapy effects

Class	Drug	Antidote
Oral anticoagulants	Warfarin	Oral or intravenous vitamin K; clotting factors or fresh frozen plasma, or both; recombinant factor VII
Intravenous or subdermal anticoagulants	Heparin	Protamine; clotting factors or fresh frozen plasma, or both
Thrombolytics	Streptokinase, tissue plasminogen activator (examples)	Tranexamic acid

post or by telephone. Although this service has been traditionally led by a physician (usually a consultant haematologist) or pathologist, more recently biomedical scientists, nurse specialists, and pharmacists have been taking responsibility for anticoagulant clinics. This model has been widely used in the United Kingdom but has come under more strain because of increasing numbers of patients referred for warfarin treatment, particularly for stroke prophylaxis in atrial fibrillation. However, in terms of INR control, adverse events, or patient satisfaction, long term oral anticoagulant care has traditionally required patients to attend a hospital anticoagulant clinic repeatedly because of the need for laboratory testing, specialist interpretation of the result, and adjustment of warfarin dose.

Anticoagulation in general practice

Concerns over general practice involvement in anticoagulation monitoring have been expressed—namely, lack of resources (machines and reagents to generate the INR) and lack of expertise (experience and training), although these can be overcome. Despite various moves to decentralisation, no large scale development in a primary care setting has occurred. Understandably, general practitioners are anxious that decentralisation of anticoagulation care represents an additional, unwanted, and possibly dangerous burden. Local circumstances vary enormously so the process of decentralisation will need to be modified according to local needs and resources.

The establishment of a local development group consisting of general practitioners and hospital clinicians responsible for the anticoagulant clinic is one way of promoting decentralisation and identifying problem areas. There is increasing evidence that general practitioners or healthcare professionals such as biomedical scientists, pharmacists, and practice nurses, with or without computer assisted dosing, are able to achieve high standards of anticoagulation care with “near patient” testing. As the principle of near patient testing is well developed in glucose monitoring by or for diabetic patients, it seems logical that it can be transferred to oral anticoagulation, provided that adequate levels of accuracy and safety are achievable.

In one of the more widespread models general practitioners take a blood sample and dosing decisions are made by a hospital department, with patients receiving dosing information through the post or by telephone. This model retains the expertise and quality assurance of the laboratory process while decentralising at minimal cost to primary care. Patients can attend their (usually more convenient) general practitioner’s surgery and a venous blood sample is sent to the central laboratory. INR is determined and information on dose and the next appointment is sent to the patient. There are no clinically significant changes in the INR when analysis is delayed for up to three days, and the quality control with near patient sampling is at least equal to that in a hospital based setting. This process requires access to phlebotomy in general practice, and the cost of testing and dosing remains in the central laboratory.

General practices with limited access to hospital clinics are more likely to undertake the second level of care and give dosing advice. General practitioners who do not have access to computer assisted dosing seem to have similar success to hospital clinics in achieving optimum INR control.

The third level of care uses near patient testing for INR estimation and computer assisted dosing for recommendation of dose and recall. Anticoagulant clinics are managed by practice nurses with support from the general practitioner and hospital laboratory. Liaison with the hospital laboratory is

Factors affecting delivery of anticoagulation therapy

Hospital anticoagulation clinics

- Usually busy and congested
- Congestion is an increasing problem caused by the ageing population with more indications for warfarin (especially atrial fibrillation)
- Inconvenient

Domiciliary anticoagulation service

- Depends on resources
- Limited availability
- Useful for those who are immobile or housebound

“Near patient” testing

- Requires considerable resources
 - Dependent on primary care, facilities, and training
-

Potential levels of involvement in general practice for managing anticoagulation treatment

- Phlebotomy in the practice (by practice or hospital staff), blood sent (post or van) to the hospital laboratory with the result returned to the practice (telephone, fax, post, or email), dosing decisions being made in the practice, then communicated to the patient
 - Phlebotomy in the practice, blood sent (post or van) to the hospital laboratory, dosing with INR estimation performed in the hospital and patient managed directly (telephone or post)
 - Phlebotomy, INR estimation (plus dosing) and management all performed in the practice with hospital equipment and by hospital staff
 - Phlebotomy, INR estimation plus dosing and management made by the practice (that is, full near patient testing); minimal input from the hospital
-

The therapeutic “window” is a balance between the best reduction in thromboembolic events and increased risk of bleeding with higher intensities of anticoagulation. Adapted from Hylek EM, et al. *New Engl J Med* 1993;120:897-902

paramount to the success of such a clinic as it needs to provide training and guidance on near patient testing technique, quality assurance, and health and safety issues. In a study by Fitzmaurice, et al (2000), INR therapeutic range analyses as point prevalence, proportion of tests in range, number of serious adverse events, and proportion of time in range all compared well with the hospital control patients. However, the proportion of time spent in the INR range showed substantial improvement for patients in the intervention group.

Computer assisted dosing aids interpretation of results, although it can be over-ridden if the suggestion made is not clinically indicated. For an effective and reliable service it is essential to ensure formal training and quality assurance procedures for near patient testing at the initial stages of the clinic development. This model of care gives an immediately available result, and, with close liaison with a hospital laboratory, it offers patients a complete model of care that would be a useful alternative to traditional care.

Another primary care model that has had limited evaluation is that of anticoagulant clinics that are managed entirely by scientists and pharmacists. These specialist healthcare professionals make use of their expertise in coagulation and pharmacology respectively. Secondary care anticoagulant clinics run by scientists and pharmacists have existed in the United Kingdom since 1979, and in terms of INR control they perform as well as clinics run by pathologists. Patients also prefer general practice management and welcome reduced waiting times and travelling costs. Improved patient understanding may also occur, which can help compliance. Further clinics managed by scientists or pharmacists, or both, are currently being evaluated.

Patient self monitoring and dosing

Diabetic patients have long been able to use portable monitoring machines to check their own blood glucose concentrations and administer insulin accordingly. As equivalent machines for checking INR are now available, increased patient demand is likely to rise. The machine will appeal especially to those receiving long term anticoagulation whose lifestyle is not suited to the inconvenience of attending outpatient clinics. As with diabetic patients, well trained and motivated patients can probably attain a level of control of their own warfarin dose similar to that of the hospital. As yet, there are no comparison data on the safety and reliability of such an approach, so great caution is needed in offering (or even recommending) this option, which will be applicable to a well defined subset of patients. However, most pilot data suggest that patient self management is as safe as primary care management for a selected population, and further study is needed to show if this model of care is suitable for a larger population.

Conclusion

The quality of anticoagulant care has improved in recent years with the development of clinical guidelines (for example, by the haemostasis and thrombosis task force of the British Society for Haematology), adoption of the INR system, quality control assurance, computerised decision support systems, and clinical audit. This allows a gradual movement of dosing from hospital to general practice. New models of delivering care (such as near patient testing) are now being developed to meet the increasing demand from an ageing population, such as from the growing number of patients with atrial fibrillation, whose risk of stroke is markedly reduced by anticoagulant therapy.

Contraindications to warfarin use and management

The patient

- Comorbidity—including comorbid medical conditions, falls, frailty, exposure to trauma
- Impaired cognitive function
- Possibly housebound
- Poor compliance

The doctor

- Poor appreciation of drug interactions
- Inefficient organisation of INR monitoring

The system

- General practice *v* hospital facilities—for example remote location and poor communication and support
 - Inadequate resources and facilities available
-

Preface

The inspiration for this book stemmed from the widely shared optimism of colorectal cancer specialists that after many decades of often painfully slow progress (despite much action), we are at the brink of a new era with several positive developments in the prevention, diagnosis and treatment of colorectal cancer, bringing hope to the hundreds of thousands of people who develop the disease.

It is crucial that this evidence-based sanguinity spreads to the entire multiprofessional colorectal cancer team, in particular to general practitioners who are by and large the first, the intermediate and the last point of contact for our patients. They have the complex task of firstly identifying suspected colorectal cancer and then working in partnership with the patient, carers and the specialists at all stages along the patient pathway. This book is written for them – the primary care physician, the nurses, the junior doctors, the dieticians, the radiographers and countless other healthcare professionals, all caring for colorectal cancer patients.

It isn't just that the book walks us through contemporary knowledge in the prevention, diagnosis, prognosis and modalities of treatment for colorectal cancer (and many other things besides) but it also acknowledges and debates the numerous uncertainties around the disease in a balanced manner, in addition to peering into future approaches towards screening, molecular biology, genetics and therapies.

The book, in short, presents a concise story of the full spectrum of colorectal cancer in a kind of chronological order. All of us who care for colorectal cancer patients, should make it our duty to be acquainted with the detail in order to provide optimal patient care.

Annie Young

1 Epidemiology

Peter Boyle, Michael J S Langman

In countries with a westernised lifestyle about half of all deaths are caused by circulatory disease and a quarter by cancer. Cancer is an important problem in both public health and political terms worldwide, irrespective of a country's development. The most recent estimates of the global cancer burden suggest that there were 8.1 million new cases, excluding non-melanoma skin cancer, worldwide in 1990. About 10 million new cases are now diagnosed each year.

Colorectal cancer is the fourth commonest form of cancer occurring worldwide, with an estimated 783 000 new cases diagnosed in 1990, the most recent year for which international estimates are available. It affects men and women almost equally, with about 401 000 new cases in men annually and 381 000 in women. The number of new cases of colorectal cancer worldwide has been increasing rapidly since 1975 (when it was 500 000).

Worldwide, colorectal cancer represents 9.4% of all incident cancer in men and 10.1% in women. Colorectal cancer, however, is not equally common throughout the world. If the westernised countries (North America; those in northern, southern, and western Europe; Australasia; and New Zealand) are combined, colorectal cancer represents 12.6% of all incident cancer in westernised countries in men and 14.1% in women. Elsewhere colorectal cancer represents 7.7% and 7.9% of all incident cases in men and women respectively.

Large differences exist in survival, according to the stage of disease. It is estimated that 394 000 deaths from colorectal cancer still occur worldwide annually, and colorectal cancer is the second commonest cause of death from any cancer in men in the European Union. Substantial differences in cancer survival seem to exist between Great Britain, Europe as a whole, and the United States. This variation in survival is not easily explained but could be related to stage of disease at presentation or treatment delivery, or both of these.

The numbers of new cases of colorectal cancer worldwide has increased rapidly since 1975

Figure 1.1 Estimated incidence of colorectal cancer in United Kingdom, by age and sex, 1995

Figure 1.2 International comparison of five year relative survival for colon and rectal cancer in adults aged 15-99 at diagnosis (based on Coleman et al, *Cancer survival trends in England and Wales, 1971-1975*; Berrino et al, *Survival of cancer patients in Europe: the EURO-CARE-2 study*; and Surveillance Epidemiology and End Results (SEER) programme, National Cancer Institute, 1998)

Survival and deprivation

The relation between poverty and ill health has been researched for more than 100 years. In Scotland, since the 1851 census, all cause occupational mortality has been routinely reported, and since 1911, inequalities in health, as shown by mortality, have been examined in decennial reports classified by social class (based on occupation) and by occupational group alone.

No single, generally agreed definition of deprivation exists. Deprivation is a concept that overlaps but is not synonymous with poverty. Absolute poverty can be defined as the absence of the minimum resources for physical survival, whereas relative poverty relates to the standards of living in a particular society. Deprivation includes material, social, and multiple deprivation. In Scotland the Carstairs and Morris index of deprivation was derived from 1981 census data with the postcode sector as the basic geographical unit (covering a population of about 5000). This index describes a deprivation category on a scale of 1 (least deprived) to 7 (most deprived) for each household address in Scotland.

The incidence of colorectal cancer is higher in men than women among each of the seven deprivation categories in Scotland, although incidence varies little with deprivation category. Survival, however, clearly improves with decreasing deprivation. At each milestone, there is a notable gradient in survival, with the most affluent doing best and the least affluent doing worst. The reasons that such variations exist are unclear and highlight an important priority for research.

Descriptive epidemiology

Different populations worldwide experience different levels of colorectal cancer, and these levels change with time. Populations living in one community whose lifestyles differ from those of others in the same community also experience different levels of colorectal cancer. Groups of migrants quickly lose the risk associated with their original home community and acquire the patterns of the new community, often starting within one generation of arrival.

Ethnic and racial differences in colorectal cancer, as well as studies on migrants, suggest that environmental factors play a major part in the aetiology of the disease. In Israel male Jews born in Europe or the United States are at higher risk of colon cancer than those born in Africa or Asia. Risk in the offspring of Japanese populations who have migrated to the United States has changed—incidence now approaches or surpasses that in white people in the same population and is three or four times higher than among the Japanese in Japan.

For reasons such as these, colorectal cancer is widely believed to be an environmental disease, with “environmental” defined broadly to include a wide range of ill defined cultural, social, and lifestyle practices. As much as 70-80% of colorectal cancers may owe their appearance to such factors; this clearly identifies colorectal cancer as one of the major neoplasms in which causes may be rapidly identified, and a large portion of the disease is theoretically avoidable.

The move from theoretically avoidable causes to implementation of preventive strategies depends on the identification of risk factors, exposures that have been associated with an increased (or decreased) risk of colorectal cancer, and the smaller subset of risk determinants, whose alteration would lead directly to a reduction in risk. From analytical epidemiology some clear ideas have now emerged about measures for reducing the risk of colorectal cancer.

Data taken from Parkin et al. eds (*Cancer incidence in five continents*. Vol 7. IARC Scientific Publications, 1997:120)

Dietary and nutritional practices

Evidence from epidemiological studies seems to show consistently that intake of dietary fat and meat is positively related to risk of colorectal cancer. This evidence is obtained from ecological studies, animal experiments, and case-control and cohort studies.

In 1990 Willett et al published the results from the US nurses health study involving follow up of 88 751 women aged 34-59 years who were without cancer or inflammatory bowel disease at recruitment. After adjustment for total energy intake, consumption of animal fat was found to be associated with increased risk of colon cancer. The trend in risk was highly significant ($P = 0.01$), with the relative risk in the highest compared with the lowest quintile being 1.89 (95% confidence interval 1.13 to 3.15). No association was found with vegetable fat. The relative risk in women who ate beef, pork, or lamb as a main dish every day was 2.49 (1.24 to 5.03) compared with women reporting consumption less than once a month. The authors suggested that their data supported the hypothesis that a high intake of animal fat increases the risk of colon cancer, and they supported existing recommendations to substitute fish and chicken for meats high in fat.

Intake of vegetables, fruit, and fibre

Dietary fibre has been proposed as accounting for the differences in the rates of colorectal cancer between Africa and westernised countries—on the basis that increased intake of dietary fibre may increase faecal bulk and reduce transit time. Various other factors, related to risk of colorectal cancer, are now thought to contribute to explaining these differences.

Fibre has many components, each of which has specific physiological functions. The components are most commonly grouped into insoluble, non-degradable constituents (mainly found in cereal fibre) and soluble, degradable constituents, such as pectin and plant gums (mainly found in fruits and vegetables). Epidemiological studies have reported differences in the effect of these components. Many studies, however, found no protective effect of fibre in cereals but have consistently found a protective effect of fibre in vegetables and perhaps fruits. This might reflect an association with other components of fruits and vegetables, with fibre intake acting merely as an indicator of consumption.

Physical activity, body mass index, and energy intake

Evidence from epidemiological studies is strong that men with high occupational or recreational physical activity seem to have a decreased risk of colon cancer. Such evidence comes from follow up studies of cohorts who are physically active or who have physically demanding jobs, as well as from case-control studies that have assessed physical activity by, for example, measurement of resting heart rate or questionnaire. The association remains even after potential confounding factors, such as diet and body mass index, are controlled for.

The available data, however, show no consistent association between obesity and risk of colorectal cancer (analysis and interpretation of this factor is difficult in retrospective studies, where weight loss may be a sign of the disease), although evidence now suggests an association between obesity and adenomas. This increased risk associated with energy intake does not seem to be the result merely of overeating; it may reflect differences in metabolic efficiency. If the possibility that the association with energy intake is a methodological artefact is excluded (as such a consistent finding is unlikely to emerge from such a variety of study designs in diverse population groups), it would imply that individuals who use energy more efficiently may be at a lower risk of colorectal cancer.

Figure 1.5 Intake of dietary fat and meat may increase risk of colorectal cancer

Figure 1.6 Fruits are a good source of fibre and may protect against cancer

Box 1.1 Physical activity and colorectal cancer

- Giovannucci et al examined the role of physical activity, body mass index, and the pattern of adipose distribution in the risk of colorectal adenomas
- In the nurses health study, 13 057 female nurses, aged 40-65 years in 1986, had an endoscopy during 1986-92. During this period, adenoma of the distal colorectum was newly diagnosed in 439 nurses
- After age, prior endoscopy, parental history of colorectal cancer, smoking, aspirin use, and dietary intake were controlled for, physical activity was associated inversely with the risk of large adenomas (≥ 1 cm) in the distal colon (relative risk 0.57 (95% confidence interval 0.30 to 1.08)) when high and low quintiles of average weekly energy expenditure from leisure activities were compared
- Much of this benefit came from activities of moderate intensity, such as brisk walking

Hormone replacement therapy

Increasing evidence supports an (originally unexpected) association between hormone replacement therapy and a reduced risk of colorectal cancer.

Of 19 published studies of hormonal replacement therapy and risk of colorectal cancer, 10 support an inverse association and a further five show a significant reduction in risk. The risk seems lowest among long term users. Although some contradictions still exist in the available literature, hormone replacement therapy seems likely to reduce the risk of colorectal cancer in women. The risk seems to halve with 5-10 years' use. The role of unopposed versus combination hormone replacement therapy needs further research.

Whether this association is causal or is associated with some selection factor that directs women to using hormone replacement therapy is, however, not known. This question is important; if the link is indeed causal, women who are at high risk of colorectal cancer could be offered the therapy to lower their risk.

Control of colorectal cancer

Prospects for preventing death from colorectal cancer are now more promising than even 10 years ago. To achieve this goal public health decisions have to be taken, and part of this decision process involves deciding at which point enough epidemiological evidence is available to change focus comfortably from information generation to health actions.

To turn research findings into public health strategies for controlling the incidence of and mortality from colorectal cancer requires a profound change of mentality in the epidemiological community. It is easy to say that more studies are needed, but they would be unlikely to alter existing conclusions. Moreover, the implementation of strategies to control cancer must be considered separately from research into the control of cancer.

One consequence of epidemiological research into the contribution of lifestyle factors to cancer risk has been to blame the individual who develops cancer. Smoking, alcohol, dietary imprudence, and exposure to sunlight tend to assign responsibility to the individual. The individual is often not principally responsible for decisions about factors that influence his or her risk of cancer, and society—including government and industry—could do more to discourage lifestyles associated with cancer risk. Government legislation, including taxation policy and other actions, could have profound effects on smoking habits, for example.

The goal of all cancer research and treatment is to prevent people dying from the disease. Knowledge has been accruing rapidly about actions and interventions that could lead to a reduction in death from colorectal cancer by reducing the risk of developing the disease, identifying the disease at a stage when it is more curable, or improving the outcome of treatment.

Box 1.2 How individuals can reduce their risk of colorectal cancer

- Increase intake of vegetables and fruits (eat five servings of fruits and vegetables each day); replace snacks such as chocolate, biscuits, and crisps with an apple, orange, or other fruit or vegetable
 - Reduce intake of calories (animal fats in particular); often replace beef, lamb, and pork with fish and poultry
 - Increase physical activity—by activities of moderate intensity, such as brisk walking
 - Participate in population screening programmes; when these are not in place, strongly consider having a colonoscopy with polyp removal once between ages 50 and 59
 - Consult a doctor as soon as possible if a noticeable and unexplained change in bowel habits occurs, blood is present in the stool, colicky pain occurs in the abdomen, or a sensation of incomplete evacuation after defecation recurs
-

2 Molecular basis for risk factors

Robert G Hardy, Stephen J Meltzer, Janusz A Jankowski

Evidence for the molecular basis of colorectal cancer comes from genetic analysis of tissues either from patients with a family history of the disease or from patients with sporadic adenomatous colorectal polyps or extensive ulcerative colitis. The traditional view is that background rates of genetic mutation, combined with several rounds of clonal expansion, are necessary for a tumour to develop. It has recently been argued, however, that inherent genetic instability not only is necessary but may also be sufficient for cancer to develop.

Sporadic colorectal adenomas

More than 70% of colorectal cancers develop from sporadic adenomatous polyps, and postmortem studies have shown the incidence of adenomas to be 30-40% in Western populations. Polyps are asymptomatic in most cases and are often multiple. Flat adenomas, which are more difficult to detect at endoscopy, account for about 10% of all polyps and may have a higher rate of malignant change or may predispose to a more aggressive cancer phenotype.

Figure 2.1 Proposed adenoma to carcinoma sequence in colorectal cancer. Adenomatous polyposis coli (APC) gene mutations and hypermethylation occur early, followed by k ras mutations. Deleted in colon cancer (DCC) and p53 gene mutations occur later in the sequence, although the exact order may vary

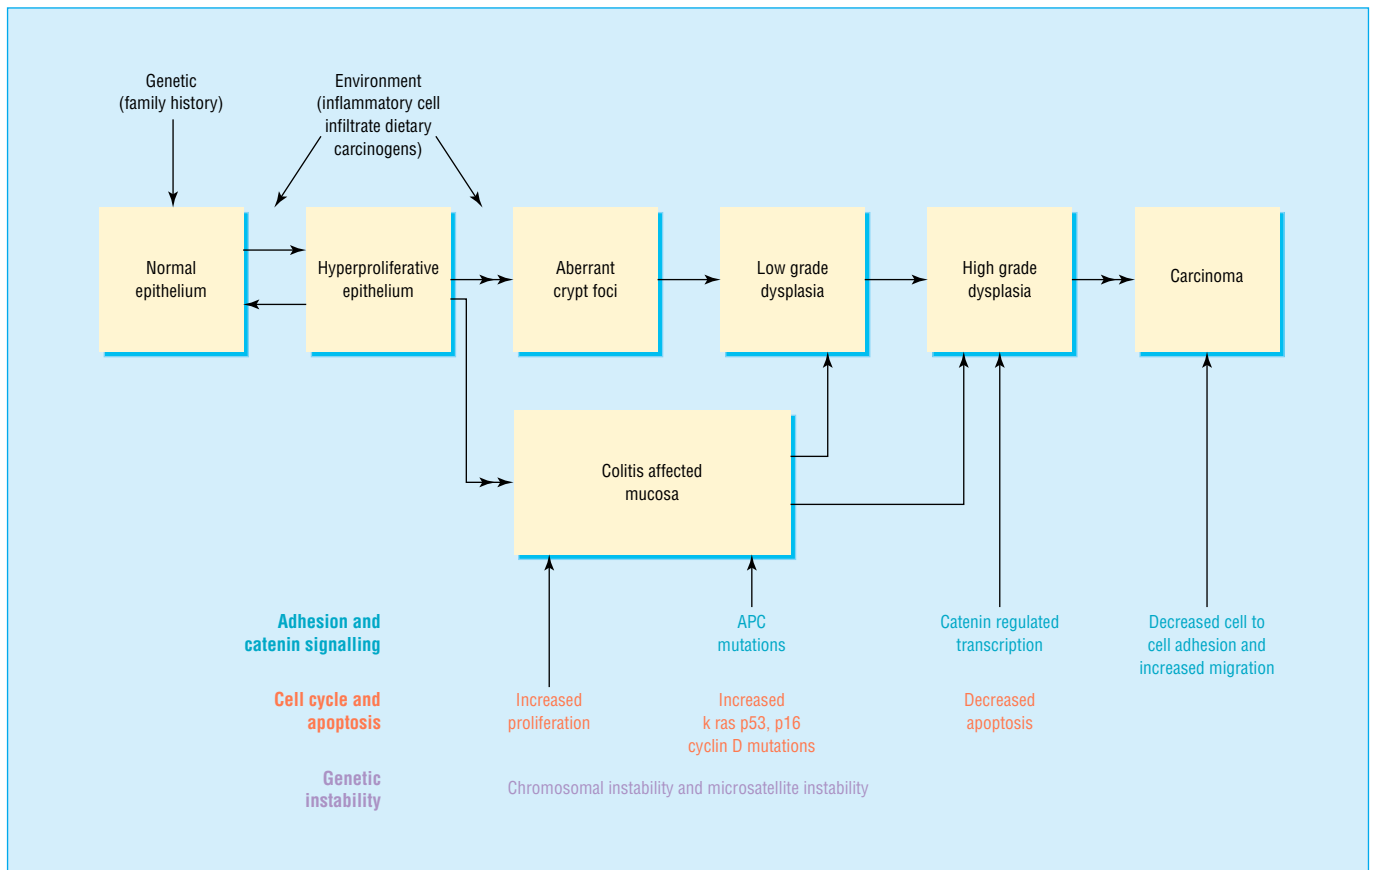

Figure 2.2 Key molecular events in colorectal premalignancy: comparisons between the adenoma carcinoma sequence and ulcerative colitis associated neoplasia

Family history

Recognised familial syndromes account for about 5% of colorectal cancers. The commonest hereditary syndromes are familial adenomatous polyposis and hereditary non-polyposis colon cancer. Patients with these syndromes usually have a family history of colorectal cancer presenting at an early age. Attenuated familial adenomatous polyposis, juvenile polyposis syndrome, and Peutz-Jeghers syndrome are rarer, mendelian causes of colorectal cancer. In familial adenomatous polyposis (a mendelian dominant disorder with almost complete penetrance) there is a germline mutation in the tumour suppressor gene for adenomatous polyposis coli (APC) on chromosome 5.

Hereditary non-polyposis colon cancer also shows dominant inheritance, and cancers develop mainly in the proximal colon. Patients with hereditary non-polyposis colon cancer show germline mutations in DNA mismatch repair enzymes (which normally remove misincorporated single or multiple nucleotide bases as a result of random errors during recombination or replications). Mutations are particularly demonstrable in DNA with multiple microsatellites (“microsatellite instability”).

In addition to the well recognised syndromes described above, clusters of colorectal cancer occur in families much more often than would be expected by chance. Postulated reasons for this increased risk include “mild” APC and mismatch repair gene mutations, as well as polymorphisms of genes involved in nutrient or carcinogen metabolism.

Box 2.1 Factors determining risk of malignant transformation within colonic adenomatous polyps

High risk

Large size (especially > 1.5 cm)
Sessile or flat
Severe dysplasia
Presence of squamous metaplasia
Villous architecture
Polyposis syndrome (multiple polyps)

Low risk

Small size (especially < 1.0 cm)
Pedunculated
Mild dysplasia
No metaplastic areas
Tubular architecture
Single polyp

The immediate family members of a patient with colorectal cancer will have a twofold to threefold increased risk of the disease

Table 2.1 Clinical and molecular correlates of familial adenomatous polyposis coli; attenuated familial adenomatous polyposis coli/hereditary flat adenoma syndrome; hereditary non-polyposis colon cancer/Lynch forms of hereditary colorectal cancer; and ulcerative colitis associated neoplasia

	FAP	AFAP/HFAS	HNPCC/Lynch	UCAN
Mean age at diagnosis of colorectal cancer	32-39	45-55	42-49	40-70
Distribution of cancer	Random	Mainly right colon	Mainly right colon	Mainly left colon
No of polyps	> 100	1-100	1 (ie tumour)	
Sex ratio (male:female)	1:1	1:1	1.5:1	1:1
Endoscopic view of polyp	Pedunculated	Mainly flat	Pedunculated (45%); flat (55%)	None
Lag time (years) from early adenoma to occurrence of cancer	10-20	10	5	? < 8
Proportion (%) of colonic cancer	1	0.5	1-5	< 0.5
Superficial physical stigmata	80% have retinal pigmentation	None	Only in Muir-Torre syndrome	None
Distribution of polyps	Distal colon or universal	Mainly proximal to splenic flexure with rectal sparing	Mainly proximal to splenic flexure	None
Carcinoma histology	More exophytic growth	Non-exophytic but very variable	Inflammation increased mucin	Mucosal ulceration and inflammation
Other associated tumours	Duodenal adenoma cerebral and thyroid tumours, medulloblastoma and desmoids	Duodenal adenoma	Endometrial ovarian, gastric cancer, glioblastoma, many other cancers	
Gene (chromosome) mutation	APC (5q 21) distal to 5	APC (5q 21) proximal to 5	MHS2 (2p), MLH1 (3p21), PMS1 (2q31), PMS2 (7p22)	Multiple mutations, 17p (p53), 5q (APC), 9p (p16)

FAP = familial adenomatous polyposis coli; AFAP = attenuated familial adenomatous polyposis coli; HFAS = hereditary flat adenoma syndrome; HNPCC = hereditary non-polyposis colon cancer; UCAN = ulcerative colitis associated neoplasia.

Risk from ulcerative colitis

Several studies have indicated that patients with ulcerative colitis have a 2-8.2 relative risk of colorectal cancer compared with the normal population, accounting for about 2% of colorectal cancers. One of the factors influencing an individual's risk is duration of colitis—the cumulative incidence of colorectal cancer is 5% at 15 years and 8-13% at 25 years. The extent of disease is also important: patients with involvement of right and transverse colon are more likely to develop colorectal cancer (the relative risk in these patients is 15 compared with the normal population). Coexisting primary sclerosing cholangitis independently increases the relative risk of ulcerative colitis associated neoplasia (UCAN) by 3-15%. In addition, high grade dysplasia in random rectosigmoid biopsies is associated with an unsuspected cancer at colectomy in 33% of patients.

Molecular basis of adenoma carcinoma sequence and UCAN

Cancers arising in colitis versus those in adenomas

Important clinical and biological differences exist between the adenoma carcinoma sequence and ulcerative colitis associated neoplasia. Firstly, cancer in ulcerative colitis probably evolves from microscopic dysplasia with or without a mass lesion rather than from adenomas. Secondly, the time interval from the presence of adenoma to progression to carcinoma probably exceeds the interval separating ulcerative colitis associated dysplasia from ulcerative colitis associated neoplasia. Thirdly, patients with a family history of colorectal cancer (but not ulcerative colitis associated neoplasia) and who also have ulcerative colitis are at further increased risk, suggesting additive factors.

Chromosomal instability

Aneuploidy indicates gross losses or gains in chromosomal DNA and is often seen in many human primary tumours and premalignant conditions. It has been shown that aneuploid "fields" tend to populate the epithelium of patients with ulcerative colitis even in histologically benign colitis. These changes may occur initially in some cases by loss of one allele at a chromosomal locus (loss of heterozygosity) and may imply the presence of a tumour suppressor gene at that site. Loss of both alleles at a given locus (homozygous deletion) is an even stronger indicator of the existence of a tumour suppressor gene. Loss of heterozygosity occurs clonally in both the adenoma carcinoma sequence and ulcerative colitis associated neoplasia. Many of these loci are already associated with one or more known candidate tumour suppressor genes. These include 3p21 (β catenin gene), 5q21 (APC gene), 9p (p16 and p15 genes), 13q (retinoblastoma gene), 17p (p53 gene), 17q (BRCA1 gene), 18q (DCC and SMAD4 genes), and less frequently 16q (E cadherin gene).

The p53 gene locus is the commonest site demonstrating loss of heterozygosity. p53 is a DNA binding protein transcriptional activator and can arrest the cell cycle in response to DNA damage—hence its title "guardian of the genome." The effect of normal (wild-type) p53 is antagonised by mutation or by action of the antiapoptotic gene Bcl-2, which is significantly less frequently overexpressed in ulcerative colitis associated neoplasia than in the adenoma carcinoma sequence. Most mutations in p53 cause the protein to become hyperstable and lead to its accumulation in the nucleus.

A second tumour suppressor gene necessary for development of sporadic colorectal cancer is APC, which is

Box 2.2 Factors affecting risk of colorectal cancer in patients with ulcerative colitis

High risk

Long duration of disease (especially > 10 years)
Extensive disease
Dysplasia
Presence of primary sclerosing cholangitis
Family history of colorectal cancer
Coexisting adenomatous polyp

Low risk

Short duration of disease (especially < 10 years)
Proctitis only
No dysplasia
No primary sclerosing cholangitis
No family history of colorectal cancer
No coexisting adenomatous polyp

Box 2.3 Chromosomal and microsatellite instability

- Molecular alterations in colorectal cancer can be grouped into two broad categories: chromosomal instability (subdivided into aneuploidy and chromosomal alterations) and microsatellite instability
- As a consequence of these two phenomena, other specific genetic events occur at increased frequency
- These include inactivation of tumour suppressor genes by deletion or mutation, activation of proto-oncogenes by mutation, and dysregulated expression of diverse molecules, such as the cell to cell adhesion molecule E cadherin and mucin related sialosyl-Tn antigen

Figure 2.3 Downregulation of E cadherin (arrowed) within colonic adenoma. Normal membranous E cadherin staining (brown) is seen in non-dysplastic crypts in the right of the picture

inactivated in >80% of early colorectal cancers. Consequently this gene has been termed the “gatekeeper” for adenoma development as adenoma formation requires perturbation of the APC gene’s function or that of related proteins such as catenins. An important function of the APC gene is to prevent the accumulation of molecules associated with cancer, such as catenins. Accumulation of catenins can lead to the transcription of the oncogene c-myc, giving a proliferative advantage to the cell. APC mutations occur later and are somewhat less common in ulcerative colitis associated neoplasia (4-27%) than in sporadic colorectal adenomas and carcinomas. Catenins also bind E cadherin, which functions as a tumour suppressor gene in the gastrointestinal tract. It is currently thought that mutated catenins may not bind to APC and thus accumulate.

Microsatellite instability

A further important category of alteration studied in the adenoma carcinoma sequence and ulcerative colitis associated neoplasia is microsatellite instability. This comprises length alterations of oligonucleotide repeat sequences that occur somatically in human tumours. This mechanism is also responsible for the germline defects found in hereditary non-polyposis colon cancer. The incidence of microsatellite instability has been noted to be about 15% for adenomas and 25% for colorectal cancers overall. Microsatellite instability also occurs in patients with ulcerative colitis and is fairly common in premalignant (dysplastic) and malignant lesions (21% and 19% respectively). Indeed it has also been reported in “histologically normal” ulcerative colitis mucosa. It can therefore be considered to be an early event in the adenoma carcinoma sequence and in ulcerative colitis associated neoplasia.

Prognosis

The prognosis of colorectal cancer is determined by both pathological and molecular characteristics of the tumour.

Pathology

Pathology has an essential role in the staging of colorectal cancer. There has been a gradual move from using Duke’s classification to using the TNM classification system as this is thought to lead to a more accurate, independent description of the primary tumour and its spread. More advanced disease naturally leads to reduced disease-free interval and survival. Independent factors affecting survival include incomplete resection margins, grade of tumour, and number of lymph nodes involved (particularly apical node metastasis—main node draining a lymphatic segment).

Molecular biology

Reports on correlations between tumour genotype and prognosis are currently incomplete. However, analysis of survival data from patients with sporadic colorectal cancer and from those with colorectal cancer associated with familial adenomatous polyposis and hereditary non-polyposis colon cancer has not shown any reproducible significant differences between these groups. In premalignancy, however, the onset of p53 mutations in histologically normal mucosa in ulcerative colitis suggests that detection of such mutations may be a useful strategy in determining mucosal areas with a high risk of dysplastic transformation.

E cadherin mutations are not commonly associated with the adenoma carcinoma sequence, but loss of heterozygosity and, rarely, missense mutations have been reported in 5% of ulcerative colitis associated neoplasia

Table 2.2 Staging and survival of colorectal cancers

TNM classification	Modified Duke’s classification	Survival (%)
Stage 0—Carcinoma in situ		
Stage I—No nodal involvement, no metastases; tumour invades submucosa (T1, N0, M0); tumour invades muscularis propria (T2, N0, M0)	A	90-100
Stage II—No nodal involvement, no metastases; tumour invades into subserosa (T3, N0, M0); tumour invades other organs (T4, N0, M0)	B	75-85
Stage III—Regional lymph nodes involved (any T, N1, M0)	C	30-40
Stage IV—Distant metastases	D	< 5

3 The role of clinical genetics in management

T R P Cole, H V Sleightholme

Before 1990 the role of inherited factors in the aetiology of adult cancer was relatively poorly understood and aroused little interest among doctors and the public alike—although familial adenomatous polyposis (the autosomal dominant colon cancer syndrome) was an exception in this respect. In the past decade, however, interest has increased markedly. In the West Midlands, for example, familial cancer referrals constituted < 1% (< 20 cases) of all clinical genetic referrals in 1991, whereas now they represent over 30% of cases (> 1000).

Despite the estimate that 5-10% of colorectal cancer has an inherited basis, only a small percentage of referred families have mutations in one of the currently identified genes. Furthermore, mutation studies are usually possible only if DNA is available from an affected patient, so molecular investigation will facilitate the management of only a small minority of cases. The remaining referrals must be managed with clinically derived strategies. This article discusses the clinical features and management of dominant colon cancer syndromes and provides referral guidelines and screening protocols for more common familial clusters.

Genetic counselling for families with a history of cancer requires a full and accurate family history. When possible, histological confirmation of the reported tumours should be obtained. It should then be possible to recognise the specific cancer syndromes. It is important to emphasise to families that however extensive the family history of cancer (unless present on both sides), a person will always have a greater than 50% chance of not developing that particular tumour. This may surprise but greatly reassure many families.

Familial adenomatous polyposis

Familial adenomatous polyposis, previously called polyposis coli (or Gardner's syndrome if extra colonic manifestations were present), is the best recognised of the colorectal cancer syndromes but accounts for less than 1% of all colorectal cancers and has an incidence of 1 in 10 000. It is characterised by the presence of 100 or more tubovillous adenomas in the colon, with intervening microadenoma on histological examination. The mean age of diagnosis of polyps is during teenage years, and almost all of gene carriers have polyps by the age of 40. If these polyps are left untreated, malignant transformation is inevitable, with a mean age of colorectal cancer occurring during the patients' mid-30s, often with synchronous tumours.

This condition is an autosomal dominant disorder, with the offspring of affected individuals at 50% risk of being gene carriers. The diagnosis of familial adenomatous polyposis should always result in a careful and full evaluation of the family history. Wherever possible, parents should have at least one colonoscopy, irrespective of age. In most cases without a family history, parental examination will be negative and the proband will probably be one of 30% of cases that represent new mutations. The siblings of all probands, however, should be offered annual flexible sigmoidoscopy up to the age of 40 or until proved to be non-gene carriers.

The cloning of the causative gene (APC) on chromosome 5 in 1991 dramatically changed the management of familial adenomatous polyposis. If DNA is available from an affected

Figure 3.1 Number of referrals of patients with cancer (except familial adenomatous polyposis) to West Midlands regional clinical genetics service, 1988-98

Figure 3.2 Features of familial adenomatous polyposis: colon with multiple polyps (top) and jaw cysts (bottom)

ABC of Colorectal Cancer

individual, mutation detection is possible in about 70% of families. In these families first degree relatives should be offered predictive testing with appropriate genetic counselling. In families with no identified mutation, linkage studies to identify the “high risk” chromosome 5 are possible in many cases. Non-gene carriers should be reassured and surveillance stopped. Gene carriers should be offered annual flexible sigmoidoscopy from the age of 12. Once several polyps have been identified, the timing and type of surgery available should be discussed (a sensitive issue in teenagers and young adults). The two most common options are ileal-rectal anastomosis with annual surveillance of the remaining rectal tissue; and ileal-anal anastomosis with reconstruction of a rectal pouch using terminal small bowel.

Molecular testing is usually offered to “at risk” children at age 10-14 before starting annual sigmoidoscopy. However, parental pressure for earlier testing (before the child can give consent) is not uncommon, and ongoing studies may help to clarify when to proceed with testing.

Cloning APC explained several clinical features and aided studies of genotypes and phenotypes. For example, congenital hypertrophy of the retinal pigment epithelium, an attenuated phenotype (that is, fewer than 100 polyps or late onset), and non-malignant but debilitating and potentially lethal desmoid disease each show an association with mutations in specific exon regions. The cloning also confirmed clinical findings that familial adenomatous polyposis and Gardner’s syndrome were different manifestations of the same disease spectrum that could coexist within the same family.

With greater clinical awareness, regular surveillance, and the advent of molecular investigation, almost all colorectal cancer deaths in inherited cases of familial adenomatous polyposis can be avoided. Increased survival has revealed later complications, in particular periampullary or duodenal adenocarcinoma (present in about 12% of postcolectomy cases). Also important are aggressive desmoid disease and other rare malignant disease.

Chemoprophylactic approaches to reduce polyp growth (for example, aspirin and non-digestible starch) are the subject of multicentre trials.

Hereditary non-polyposis colon cancer

Hereditary non-polyposis colon cancer (also known as Lynch syndrome) became more widely recognised about 30 years ago in families manifesting mainly colorectal cancer segregating in an autosomal dominant fashion. Many families also exhibit extracolonic tumours, particularly gynaecological, small bowel, or urinary tract carcinomas, and these became known as Lynch type 2 to distinguish them from site specific colorectal cancers, designated Lynch type 1. The subsequent name change to hereditary non-polyposis colon cancer is potentially misleading as many gene carriers will develop a small number of tubovillous adenomas, but not more than 100, as seen in familial adenomatous polyposis. The proportion of colorectal cancers due to hereditary non-polyposis colon cancer is controversial, and estimates range from 1% to 20%; most observers, however, suggest about 2%.

The diagnosis of hereditary non-polyposis colon cancer is made on the family history as the appearance of the bowel, unlike in familial adenomatous polyposis, is not diagnostic. To improve the recognition of hereditary non-polyposis colon cancer, diagnostic criteria were devised in Amsterdam in 1991 and were subsequently modified to include non-colonic tumours.

Figure 3.3 Congenital hypertrophy of the retinal pigmentary epithelium is a feature of familial adenomatous polyposis

Box 3.1 Early and late extracolonic tumours in familial adenomatous polyposis

- Hepatoblastoma (early)
- Adrenal adenoma (early or late)
- Desmoid disease (early or late)
- Papillary thyroid cancer—females only (late)
- Periampullary carcinoma (late)

Figure 3.4 Site of tumours and frequency in hereditary non-polyposis colon cancer (upper figures in ranges may be overestimates owing to ascertainment bias)

Box 3.2 Modified Amsterdam criteria

- Three or more cases of colorectal cancer in a minimum of two generations
- One affected individual must be a first degree relative of the other two (or more) cases
- One case must be diagnosed before age 50
- Colorectal cancer can be replaced by endometrial or small bowel adenocarcinoma
- Familial adenomatous polyposis must be excluded

In 1994 the first of the genes for hereditary non-polyposis colon cancer (hMSH2 on chromosome 2) was cloned, and since then four further genes have been identified; all are mismatch repair genes. If both copies of the genes are mutated, as postulated in Knudson's "two hit" hypothesis, that cell and all its daughter cells are missing a vital mechanism for repair of DNA in somatic tissue. Failure to repair mutations in tumour suppressor genes will in some instances result in initiation of the adenoma carcinoma sequence. Molecular studies showed that about 30% of colorectal cancers with early onset (under age 35) are due to the mismatch repair genes, and the typical age of onset and the spectrum of tumours in families with hereditary non-polyposis colon cancer were revised.

The limited available evidence suggests that screening for colorectal cancer in hereditary non-polyposis colon cancer is beneficial. In 1999 Vasen et al published figures showing clinical benefit and cost effectiveness of screening in hereditary non-polyposis colon cancer after a Finnish study reporting reduced morbidity and mortality in a non-randomised observational study of colonoscopy versus no screening.

The optimal surveillance frequency has not yet been defined in families with hereditary non-polyposis colon cancer. The method of choice, however, is colonoscopy rather than flexible sigmoidoscopy as 80% of cancers are proximal to the rectum (compared with only 57% in sporadic colorectal cancer). The screening interval should be at most three years and probably every 18-24 months in gene carriers. Failure to reach the caecum should be followed by barium enema examination, although surveillance using radiological techniques should probably be used sparingly owing to the theoretical mutagenic consequences in patients with DNA repair defects. Patients should understand that the strategy of colonoscopy is the removal of polyps and prevention of tumours or early diagnosis, but that complete prevention is impossible.

Familial clusters with no recognisable single gene disorder

Families whose cancers do not meet the diagnostic criteria of familial adenomatous polyposis, hereditary non-polyposis colon cancer, or rarer colorectal cancer syndromes (such as syndromes related to the PTEN gene, Turcot's syndrome, Peutz-Jeghers syndrome, or juvenile polyposis) make up the largest and most difficult group of patients requesting management. There is rarely any indication of the aetiological basis of the cluster of colorectal cancer, and many instances will be coincidental occurrences. Other tumours clusters may be due to common environmental exposures, the effect of multiple low penetrance genes, or an interaction of both these elements. The risk of colorectal cancer may be assessed with empirical risk figures. These figures are estimates, however, and do not take into account factors such as the number of unaffected relatives. Further enquiry is usually justified if features such as multiple relatives with the same tumour or early onset of tumours are present in a family.

Concerns about not having precise risk figures may be misguided as many patients have difficulty interpreting risk figures and are often requesting only general guidance on risk and a discussion of management options. Many different screening protocols have been suggested in the past, however, and the lack of consistency and long term audit in these families is a problem.

To manage familial cancer in the West Midlands (population 5.2 million), a protocol has been developed that builds on the Calman-Hine model for cancer services and maximise the role

No large series of patients fulfilling the Amsterdam criteria has a mutation detection rate >70%. The figure is much lower for families that do not meet the criteria described here. Case selection using tumour DNA instability or immunohistochemical studies can improve mutation detection rates

- Screening of other organ systems has not yet been proved beneficial
- It is prudent to screen for gynaecological tumours in mutation positive families, irrespective of family history, as 40% of female gene carriers develop endometrial carcinomas
- If tumours have been identified in the gynaecological or urinary tract in the family, surveillance should be offered (see the West Midlands guidelines)

Box 3.3 West Midlands site specific screening strategies in hereditary non-polyposis colon cancer

Colorectal (all cases)—colonoscopy every two years at age 25-65

*Endometrial**—annual pipelle biopsy (suction curettage) and ultrasound at age 30-65

Ovarian†—annual transvaginal ultrasound and serum Ca125 concentration at age 30-65

Transitional cell carcinoma in the urinary tract—annual haematuria test at age 25-40; annual urine cytology at age 40-65 (with or without cystoscopy every one to two years); annual renal ultrasound at age 40-65

*Families with history of endometrial cancer and mutation positive families.
†Families with history of ovarian cancer.

Table 3.1 Lifetime risk of colorectal cancer in first degree relatives of patient with colorectal cancer (from Houlston et al, 1990)

Population risk	1 in 50
One first degree relative affected (any age)	1 in 17
One first degree and one second degree relative affected	1 in 12
One first degree relative affected (age <45)	1 in 10
Two first degree relatives affected	1 in 6
Autosomal dominant pedigree	1 in 2

Box 3.4 Four pointers to recognition of familial cancer clusters

- High frequency of the same tumour in the family
- Early age of onset of tumours
- Multiple primary tumours
- Recognised associations—for example, colorectal and endometrial adenocarcinomas

of primary care. The protocol provides clear inclusion and screening guidance for cancer units and centres. This has promoted a consistency of management in and between families and is now allowing data collection for audit.

Figure 3.5 Algorithm for West Midlands family cancer strategy

It may be wise for general practitioners to use a reactive approach to patient enquiries until evidence exists to support a proactive approach. In the West Midlands, patients requesting advice are asked to complete a data collection sheet at home. This form and the inclusion criteria are available at www.bham.ac.uk/ich/clingen.htm. Completion of the form in the patient's own time, at home, facilitates discussion with relatives to clarify the relevant information and has saved time in primary care if a referral is required.

After histological confirmation in suspected familial cases, the data are evaluated centrally to identify high risk families requiring specialist investigation or referral to a cancer unit.

In a pilot study (population 200 000) the protocol reduced referrals from primary care by 50%, with a greater reduction in screening owing to a fall in low risk referrals to cancer units. This was associated with an increased referral rate for high risk referrals to clinical genetics departments. Central coordination prevents unnecessary investigations for different branches of any one family and facilitates audit.

Reports from general practitioners and patients suggest that individuals at no or minimal increased risk of cancer avoid unnecessary outpatient appointments and screening and for the most part are reassured by standardised protocols with explanations on the data collection forms. Such systems need to be studied further but seem to be preferable to continuing the current exponential rise of ad hoc responses from individual clinicians without long term audit.

Table 3.2 West Midlands inclusion and screening criteria for a family history of colorectal cancer

Inclusion criteria	Screening method	Age range (years) for surveillance
One first degree relative aged >40	Reassure, plus general advice on symptoms	Not applicable
One first degree relative aged <40	Colonoscopy every 5 years; appointment at local screening unit	25-65, or 5 years before tumour if later
Two first degree relatives average age >70	Reassure, plus general advice on symptoms	Not applicable
Two first degree relatives average age 60-70	Single colonoscopy; appointment at local screening unit	About 55
Two first degree relatives average age 50-60	Colonoscopy every 5 years; appointment at local screening unit	35-65
Two first degree relatives average age <50	Colonoscopy every 3-5 years; referral to genetics unit	30-65
Three close relatives but not meeting Amsterdam criteria	Colonoscopy every 3-5 years; referral to genetics unit	Begin age 30-40; stop at 65
Three close relatives meeting Amsterdam criteria	Colonoscopy every 2 years; referral to genetics unit	25-65
Familial adenomatous polyposis	Annual sigmoidoscopy; referral to genetics unit	12-40

4 Screening

John H Scholefield

Colorectal cancer is the third commonest malignancy in the United Kingdom, after lung and breast cancer, and kills about 20 000 people a year. It is equally prevalent in men and women, usually occurring in later life (at age 60-70 years). The incidence of the disease has generally increased over recent decades in both developed and developing countries. Despite this trend, mortality in both sexes has slowly declined. This decrease in mortality may reflect a trend towards earlier diagnosis—perhaps as a result of increased public awareness of the disease.

Why screen?

Most colorectal cancers result from malignant change in polyps (adenomas) that have developed in the lining of the bowel 10-15 years earlier. The best available evidence suggests that only 10% of 1cm adenomas become malignant after 10 years. The incidence of adenomatous polyps in the colon increases with age, and although adenomatous polyps can be identified in about 20% of the population, most of these are small and unlikely to undergo malignant change. The vast majority (90%) of adenomas can be removed at colonoscopy, obviating the need for surgery. Other types of polyps occurring in the colon—such as metaplastic (or hyperplastic) polyps—are usually small and are much less likely than adenomas to become malignant.

Colorectal cancer is therefore a common condition, with a known premalignant lesion (adenoma). As it takes a relatively long time for malignant transformation from adenoma to carcinoma, and outcomes are markedly improved by early detection of adenomas and early cancers, the potential exists to reduce disease mortality through screening asymptomatic individuals for adenomas and early cancers.

Which screening test for population screening?

Education about bowel cancer is poor. A survey in 1991 showed that only 30% of the British population were aware that cancer of the bowel could occur. Such ignorance only adds to the difficulties of early detection for this form of cancer.

For a screening test to be applicable to large populations it has to be inexpensive, reliable, and acceptable. Many different screening tests for detecting early colorectal cancer have been tried. The simplest and least expensive is a questionnaire about symptoms, but this has proved predictably insensitive and becomes reliable only when the tumour is relatively advanced. Digital rectal examination and rigid sigmoidoscopy both suffer from the limitation that they detect only rectal or rectosigmoid cancers and are unpleasant and invasive.

Flexible sigmoidoscopy

Flexible sigmoidoscopy can detect 80% of colorectal cancers as it examines the whole of the left colon and rectum. A strategy of providing single flexible sigmoidoscopy for adults aged 55-65 years—with the aim of detecting adenomas—may be cost effective. A multicentre trial of this strategy for population screening is currently under evaluation.

Although flexible sigmoidoscopy is more expensive than rigid sigmoidoscopy, it is generally more acceptable to patients (it is less uncomfortable) and has much higher yield than the

Surgery remains the mainstay of treatment for colorectal cancer, but early diagnosis makes it more likely that the tumour can be completely resected and thereby improves the chance of cure

Figure 4.1 Colon cancer

Figure 4.2 Flexible sigmoidoscope: used for endoluminal visualisation and therapeutic removal of adenomas

ABC of Colorectal Cancer

rigid instrument. Many nurses are now trained to perform flexible sigmoidoscopy, making potential screening programmes using this technique more cost effective. In a population screening programme, uptake of the offer of the screening test is crucial. Uptake is likely to be around 45%, and, of these, 6% will subsequently need full colonoscopy. The effect that this will have on the incidence of and mortality from colorectal cancer is uncertain until the completion of the multicentre trial in 2003.

Colonoscopy

Colonoscopy is the gold standard technique for examination of the colon and rectum, but its expense, the need for full bowel preparation and sedation, and the small risk of perforation of the colon make it unacceptable for population screening. Colonoscopy is, however, the investigation of choice for screening high risk patients (those at risk of hereditary non-polyposis colon cancer or with longstanding ulcerative colitis).

Barium enema

Barium enema, like colonoscopy, examines the whole colon and rectum, and, although it is cheaper and has a lower complication rate than colonoscopy, it is invasive and requires full bowel preparation. Whereas colonoscopy may be therapeutic (polypectomy), barium enema does not allow removal or biopsy of lesions seen. There are no population screening studies using barium enema.

Faecal occult blood tests

Faecal occult blood tests are the most extensively studied screening tests for colorectal cancer. These tests detect haematin from partially digested blood in the stool. Their overall sensitivity for colorectal neoplasia is only 50-60%, though their specificity is high. In screening studies of faecal occult blood tests, individuals are invited to take two samples from each of three consecutive stools. Compliance is around 50-60%, but with population education this might be improved. Individuals with more than four out of six positive tests (about 2% of participants) need colonoscopy.

Several large randomised studies have shown that screening with faecal occult blood testing is feasible, and two studies have shown that such screening reduces the mortality from colorectal cancer. In a study in Nottingham, for every 100 individuals with a positive test result, 12 had cancer and 23 had adenomatous polyps. The cancers detected at screening tended to be at an earlier stage than those presenting symptomatically (Dukes's A classification: 26% screen detected *v* 11% in controls). The disadvantage of screening with faecal occult bloods is its relatively low sensitivity—a third to a half of cancers will be missed on each round of screening. The Nottingham data suggest that screening every two years detects only 72% of cancers. This could be improved by testing annually and using more sensitive immunologically based faecal occult blood tests.

Who should be screened?

Although about 20% of the population will develop adenomatous polyps, only 5% of these will develop colorectal cancer. This equates to a 1 in 20 lifetime risk for colorectal cancer. The cancer occurs most often in the age group 65-75 years, but for adenomas the peak incidence is in a slightly earlier age group (55-65 years). Thus population screening for colorectal cancer should target both these age groups.

In addition, some people inherit a much higher susceptibility to colorectal cancer. Some inherit a well

Figure 4.3 Colonoscopic view of colonic adenoma (about 1.5 cm diameter)

Figure 4.4 Double contrast barium enema showing carcinoma of sigmoid colon

Box 4.1 CT colography

- CT (computed tomographic) colography—virtual colonoscopy—is a new radiological technique that may have a role in population screening
- Although it requires full bowel preparation, highly expensive computed tomography scanners, and computing facilities, it is minimally invasive, and views of the whole colon can be obtained in five minutes
- Preliminary data suggest that this technique is as sensitive as colonoscopy or barium enema for detecting large polyps and cancers
- As yet, no trials of CT colography in population screening have been published
- CT colography has the potential to be cost effective and to reduce the need for colonoscopy in population screening

recognised single gene disorder, such as familial adenomatous polyposis or hereditary non-polyposis colon cancer, whereas most inherit an undetermined genetic abnormality. These people tend to develop colorectal cancer before the age of 50, and therefore screening in this high risk population needs to be tailored to each individual's risk pattern. They may also be at risk for cancers at other sites, and screening for ovarian, breast, and endometrial cancers may be appropriate in some of these cases. The advice of clinical geneticists in these cases can be invaluable.

Cost effectiveness of screening

If screening for colorectal cancer is to be acceptable to healthcare providers it must be shown to be cost effective. Estimates of the cost of screening for colorectal cancer range from £1000 to £3000 per life year saved, depending on the screening technique used. The cost of using faecal occult blood testing would be the lowest—similar to estimates for breast cancer screening.

Cost estimates are associated with several unknown factors. The factors that cause greatest concern to those considering funding screening programmes are the cost of cancers missed and the potential damage caused to asymptomatic individuals by invasive procedures such as colonoscopy.

Potential harm from screening

Although it has been suggested that considerable anxiety and psychological morbidity may be caused by inviting populations to participate in screening for colorectal cancer, little evidence exists to substantiate this. Indeed in the Nottingham trial no longstanding psychological morbidity from the screening programme was found. Similarly, no evidence exists that screening for colorectal cancer leads to false reassurance from negative tests.

Complications from colonoscopy (perforation and haemorrhage), however, can occur. The incidence of these complications is around 1 in 2000 procedures, and complications usually occur in therapeutic colonoscopy (endoscopic polypectomy) rather than in diagnostic procedures. Mortality from such events is rare.

Conclusions

- Screening for colorectal cancer using faecal occult blood tests is feasible; increasingly compelling evidence shows that such programmes can save lives at a cost similar to that of the existing breast cancer screening programme
- Once-only flexible sigmoidoscopy presents a promising alternative to faecal occult blood screening, but conclusive data will not be available for about five years
- For a screening programme to operate in the United Kingdom, considerable investment in colonoscopy facilities and expertise would be needed
- Several countries, including the United States, have screening programmes that use faecal occult blood tests or once-only flexible sigmoidoscopy, or both of these procedures. The United Kingdom has undertaken a pilot study in three areas to determine the feasibility of delivering a practicable, population based screening programme

Box 4.2 Inherited risk of colorectal cancer

High risk

- Familial adenomatous polyposis
- Hereditary non-polyposis colon cancer

Medium risk

- One first degree relative with colorectal cancer presenting at < 45 years
- Two or more first degree relatives with colorectal cancer

Low risk

- Only one first degree relative with colorectal cancer presenting at > 55 years
- No family history of colorectal cancer

Figure 4.5 Estimates of costs for different methods of screening for colorectal cancer. Costs are based on biennial testing (faecal occult blood), testing at intervals of 5 years (barium enema and colonoscopy), or once-only testing (sigmoidoscopy)

5 The role of primary care

F D Richard Hobbs

Every general practitioner in the United Kingdom will on average see one new case of colorectal cancer each year. For most primary care doctors the most important contributions they make to the care of patients with colorectal cancer relate to early diagnosis of the condition (including the point of referral) and to palliation of symptoms in those with established disease. Further roles in the future primary care service are screening for colorectal cancer (possibly using faecal occult blood testing) and a greater involvement in monitoring patients after curative procedures.

Early diagnosis and referral guidelines

Early diagnosis of colorectal cancer is essential in view of the stage related prognosis. Three potential levels of delay occur in the diagnosis of the disease: delay by the patient in presenting to the general practitioner; delay in referral by the general practitioner to a specialist; and delay by the hospital in either establishing the diagnosis or starting treatment. Detrimental differences between England and Wales and the rest of western Europe in survival rates for colorectal cancer arise primarily in the first six months after diagnosis, suggesting that these differences relate to late presentations or delays in treatment.

Patients presenting with symptoms

Most patients developing colorectal cancer will eventually present with symptoms. Primary symptoms include rectal bleeding persistently without anal symptoms and change in bowel habit—most commonly, increased frequency or looser stools (or both)—persistently over six weeks. Secondary effects include severe iron deficiency anaemia and clear signs of intestinal obstruction. Clinical examination may show a definite right sided abdominal mass or definite rectal mass.

Unfortunately, many large bowel symptoms are common and non-specific and often present late. Recently published guidelines, however, make specific recommendations about which patients should be urgently referred—within two weeks—for further investigation in the NHS. The guidelines also indicate which symptoms are highly unlikely to be caused by colorectal cancer.

The risk of colorectal cancer in young people is low (99% occurs in people aged over 40 years and 85% in those aged over 60). In patients aged under 45, therefore, initial management will depend on whether they have a family history of colorectal cancer—namely, a first degree relative (brother, sister, parent, or child) with colorectal cancer presenting below the age of 55, or two or more affected second degree relatives. Patients aged under 45 presenting with alarm symptoms and a family history of the disease should also be urgently referred for further investigation.

In patients suspected of having colorectal cancer, referral should be indicated as urgent (with an appointment expected within two weeks); the referral letter should include any relevant family history and details about symptoms and risk factors. An increasing number of general practitioners will have direct access to investigations, often via a rapid access rectal bleeding clinic. The usual investigations needed will be flexible colonoscopy or barium enema studies.

As colorectal cancer is the sixth most common cause of mortality in the United Kingdom, a general practitioner will on average care for a patient dying from colorectal cancer every 18 months

Box 5.1 Guidelines for urgent referral of patients with suspected colorectal cancer based on symptoms presented*

These combinations of symptoms and signs, when occurring for the first time, should be used to identify patients for urgent referral (that is, within two weeks). Patients need not have all symptoms

All ages

- Definite, palpable, right sided, abdominal mass
- Definite, palpable, rectal (not pelvic) mass
- Rectal bleeding with change in bowel habit to more frequent defecation or looser stools (or both) persistent over six weeks
- Iron deficiency anaemia (haemoglobin concentration <110 g/l in men or <100 g/l in postmenopausal women) without obvious cause

Age over 60 years (maximum age threshold could be 55 or 50)

- Rectal bleeding persistently without anal symptoms (soreness, discomfort, itching, lumps, prolapse, pain)
- Change of bowel habit to more frequent defecation or looser stools (or both), without rectal bleeding, and persistent for six weeks

*Adapted from the NHS Executive's *Referral Guidelines for Suspected Cancer* (London: Department of Health, 2000)

Figure 5.1 The NHS Executive's *Referral Guidelines for Suspected Cancer*

Box 5.2 Symptoms associated with low risk of malignancy*

Patients with the following symptoms but with no abdominal or rectal mass are at very low risk of colorectal cancer

- Rectal bleeding with anal symptoms (soreness, discomfort, itching, lumps, prolapse, pain)
- Change in bowel habit to less frequent defecation and harder stools
- Abdominal pain without clear evidence of intestinal obstruction

*Adapted from *Referral Guidelines for Suspected Cancer*

In the absence of a family history of the disease, younger patients with a negative physical examination, including a digital rectal examination, can be initially treated symptomatically. If symptoms persist, however, patients should be considered for further investigation.

Patients with genetic predisposition

All patients registering with a practice for the first time should provide details of their medical history. Patients with a history of familial adenomatous polyposis should be referred for DNA testing after the age of 15. Familial adenomatous polyposis accounts for about 1% of cases of colorectal cancer, with the defect gene identified on chromosome 5. Patients with a positive result should enter a programme of surveillance with flexible sigmoidoscopy.

The second common genetic predisposition to colorectal cancer is hereditary non-polyposis colon cancer. This condition should be suspected in patients describing three or more cases of colorectal cancer (or adenocarcinoma of the uterus) within their family. Such patients should be referred for endoscopic screening at the age of 25. Genetic testing for this condition is currently not feasible.

In patients with a first degree relative with colorectal cancer aged under 45 or with two first degree relatives with the disease, the lifetime risk of the cancer rises to over 1 in 10. Such patients should be referred for lower endoscopy screening once they are 10 years younger than the age at which the disease was diagnosed in the youngest affected relative. An earlier article in this series gives more detail on the genetics of colorectal cancer.

Population screening in primary care

The United Kingdom currently has no national screening programme for colorectal cancer. Several studies in the United States and Europe have shown that screening with faecal occult blood testing will reduce the overall mortality of colorectal cancer by about 15%. Such testing is a fairly simple procedure: only two small samples from different sites of a stool need to be collected on each of three consecutive days. In the United States, the specimens are then normally hydrated, whereas research in the United Kingdom and Denmark advocates using dry samples. The latter technique results in a lower sensitivity, but higher specificity—desirable test performance characteristics for an asymptomatic population screening procedure.

Faecal occult blood testing is therefore a cheap and easy method of screening, with reasonable levels of acceptability to the population. The main disadvantages of this test are the low sensitivity—with about 40% of cancers missed by a single screen, leading to the need for frequent faecal occult blood tests—and the fact that bleeding tends to occur late in the development of the disease. Furthermore there are no direct studies to guide on the most cost effective method of establishing a national screening programme using faecal occult blood testing. However, evidence from the cervical screening programme suggests that general practice led “call/recall” programmes would have the greatest impact.

A large Medical Research Council trial is currently evaluating once-only flexible sigmoidoscopy as a method of screening patients aged 50-60 years. The results of this trial will not be available for several years.

The American Cancer Society recommends an annual digital rectal examination for people aged over 40, an annual faecal occult blood test for people aged over 50, and flexible sigmoidoscopy every three to five years for people aged over 50. More detail on screening for colorectal cancer appears in an earlier article in this series.

Most (85-90%) colorectal cancers arise in people with no known risk factors, so opportunistic asymptomatic screening is of little value in colorectal cancer

Box 5.3 Patients with iron deficiency

- Patients aged 45 and over presenting with iron deficiency anaemia should be investigated to determine the cause of anaemia
- This will normally require both upper and lower bowel endoscopy
- In patients aged under 45, the cause of the anaemia should also be established, although the likelihood of this being colorectal cancer is low

Figure 5.2 Haemoccult (SmithKline Beecham) has been the faecal occult blood test most often used in studies of the feasibility of screening for colorectal cancer

Managing patients with established disease

After confirmation of diagnosis, the role of the primary care doctor revolves around advice, support, possibly monitoring for recurrence, and palliative care. Some general practices are involved with home based chemotherapy, usually coordinated by specialist outreach nurses.

In the United Kingdom primary care does not currently have a formal role in monitoring for disease recurrence after curative treatments. Data on this option are limited (see a later article in this series) but suggest that such surveillance could be safely conducted in primary care. Ideally, this monitoring should be accompanied by adequate infrastructure and training in primary care, with good liaison between the practice and secondary (or tertiary) care.

Limited evidence from other types of shared care indicate that certain factors are likely to improve outcomes: structured and planned discharge policies; the use of shared (preferably patient held) cards that document patient information (disease progress and drug treatments, as a minimum); locally agreed guidelines specifying the appropriate follow up and delineating responsibilities; and access to rapid referral clinics. As with follow up in all chronic diseases, the more communication between doctors and with the patients (and their families), the better the quality of care.

Where appropriate, the doctor should also counsel patients on any possible familial risk and the need for genetic counselling of relatives. The primary care doctor may also advise patients with diagnosed colorectal cancer about practical considerations, including access to social security benefits. In the United Kingdom eligibility for attendance allowance may be immediately available in the exceptional circumstance of cancer with a short terminal prognosis of less than six months.

For some patients, especially those with rectal tumours, the diagnosis of cancer is also accompanied by the necessity for either colostomy or ileostomy. Such patients will often require further specialised support, and liaison between the primary care team and specialist stoma nurses is important.

As the disease progresses, management will shift towards palliative care. Ideally, this would be delivered jointly by the primary care team and specialist palliative care services, such as those based at a hospice or provided by Macmillan nurses. Few data exist to guide on the most effective models for palliative care in colorectal cancer. However, non-randomised studies have shown high satisfaction among patients when they are kept fully involved in understanding the progression of their disease and their treatment options, when shared care cards are used, and when home care teams are provided.

The main priorities in palliative care in colorectal cancer include the management of pain, jaundice, ascites, constipation, and nausea. The importance of attempting to correct these symptoms cannot be overstated: as much distress may be caused by constipation or nausea as by pain. Full explanations of signs such as jaundice are likely to be reassuring. Moreover, the advent of specialist home care teams (with access to specialist equipment—such as bed aids to preserve pressure areas or syringe drivers for pain control) and skilled counsellors for patients and their families, enables virtually all patients who wish it to remain at home.

Such an option is further enhanced by relief admission—when necessary for the patient or the family—to specialist palliative care wards or, more likely, to a hospice. In the United Kingdom only a minority of patients with colorectal cancer currently die from their disease in hospital or in a hospice.

Figure 5.3 Macmillan nurses have an important role in community palliative care, liaising with both professionals and patients

6 Primary treatment—does the surgeon matter?

Colin McArdle

The dominant factor contributing to the relatively poor prognosis for colorectal cancer is the advanced stage of the disease at the time of initial presentation: up to a third of patients have locally advanced or metastatic disease, which precludes surgical cure. Even in the patients who undergo apparently curative resection, almost half die within five years.

In the west of Scotland, for example, about a third of 1842 patients presenting with colorectal cancer to seven hospitals between 1991 and 1994 presented as emergencies. Potentially curative resection was achieved in about 70% of patients presenting electively; the curative resection rate was lower in those presenting as emergencies. Five per cent of patients admitted for elective surgery and 13% of those admitted as emergencies died. Almost 60% of elective patients survived two years, compared with 44% of patients admitted as emergencies. These results are typical of population based studies in the United Kingdom.

Variation among surgeons

Most surgeons acknowledge that the incidence of postoperative complications varies widely among individual surgeons. It is now almost 20 years since Fielding and his colleagues in the large bowel cancer project drew attention to differences in anastomotic leak and local recurrence rates after resection for large bowel cancer.

In the original Glasgow Royal Infirmary study, which was conducted in the 1980s, similar differences in postoperative morbidity and mortality were noted. Furthermore, after apparently curative resection, survival at 10 years varied threefold among surgeons.

One might argue that these are historical data and therefore bear little relevance to the current situation. In the current west of Scotland study, however, although overall 33% of patients presented as emergencies, the proportion varied among hospitals from 24% to 41% and among surgeons from 10% to 50%.

Similarly, the proportion of patients undergoing curative resection varied among surgeons from 45% to 82%; postoperative mortality, in patients presenting electively, also varied, from 0% to 17%. Several out of the 16 surgeons studied performed less well than their colleagues.

Several factors apart from the individual surgeon's skill might influence these measurements of immediate and long

Table 6.1 Presentation, type of surgery, and postoperative mortality, by hospital and surgeon (n=1842), west of Scotland study. Values are percentages

	All (mean)	Hospital (range)	Surgeon (range)
Emergency admission	33	24-41	10-50
Dukes's classification A or B	49	43-56	29-68
Curative resection	68	63-75	45-82
Palliative resection	25	15-29	11-48
Postoperative mortality:			
Elective	5	0-7	0-17
Emergency	13	9-24	4-38

Figure 6.1 Colorectal adenoma and tumour—does a patient's survival depend on which surgeon operates?

Table 6.2 Variation in outcome, by surgeon, after curative resection (n=338)

	Overall rate (%)	Range among surgeons (%)
Anastomotic leak	9	0-25
Local recurrence	11	0-21
Postoperative mortality	6	0-20
Survival (10 years)	41	20-63

Data are from the original Glasgow Royal Infirmary study (McArdle et al, *BMJ* 1991;302:1501-5)

Figure 6.2 95% confidence intervals for relative risk of outcome, for all resections, by surgeon (n=16), west of Scotland study

term outcome: case mix; surgical philosophy; assessment of cure; quality of pathological reporting; other prognostic factors; small numbers (see box). Despite these factors it seems likely that the differences in the immediate postoperative morbidity and mortality observed among surgeons in the above studies are genuine. There have now been several analyses of immediate outcome after colorectal cancer surgery, and in each study, the results have been broadly comparable.

Effect of volume of surgery

Two explanations are possible for the differences in outcome among surgeons—namely, the number of patients treated by individual surgeons and whether these surgeons are specialists.

Although good evidence exists for other types of surgery that volume of work is important, in colorectal cancer convincing evidence that volume affects outcome is lacking. In the Lothian and Borders study, 5 of 20 consultants were responsible for 50% of the rectal cancer procedures. These five surgeons had a significantly lower anastomotic leak rate, but this may reflect specialisation rather than volume of work. In the German multicentre study, a group of surgeons with low work volume and performing only a few rectal cancer procedures had local recurrence rates well within the range of results obtained by individual surgeons with high work loads. Furthermore, in a recent analysis of outcome in 927 patients treated in the Manchester area, after correction for non-prognostic variables no relation between volume and outcome was noted.

Role of specialisation

The question of specialisation is more complex. Clearly rectal cancer surgery represents a greater technical challenge than colonic surgery. It therefore seems reasonable to expect—but it is remarkably difficult to show (largely because of the small numbers of patients treated by individual surgeons)—that specialist surgeons achieve better outcome. Analysis of outcome in almost 1400 patients with rectal cancer randomised in the Swedish preoperative radiotherapy studies, suggested that local recurrence and death rates were significantly lower in those patients operated on by surgeons with more than 10 years' experience as a specialist.

Perhaps the best information, however, comes from the Canadian study in which 683 patients with rectal cancer were treated by 52 different surgeons, five of whom were trained in colorectal surgery. These five surgeons performed 109 (16%) of the procedures. Independent of the type of training received by the surgeons, 323 procedures (47%) were performed by surgeons who each did fewer than 21 resections over the study period. Multivariate analysis showed that the risk of local recurrence was increased in patients treated both by surgeons not trained in colorectal surgery and by surgeons performing fewer than 21 resections. Similarly, disease specific survival was lower in the patients treated by these two groups of surgeons. These results suggest that both specialisation and volume may be important independent factors determining outcome.

Surgeons are currently under intense scrutiny, partly because readily available measures of outcome exist and partly because outcome seems to differ substantially among surgeons. The issues, however, are complex. Small numbers, annual accounting, and failure to take into account case mix, surgical intent, quality of staging, and prognostic factors may lead to inappropriate conclusions.

Box 6.1 Influences, apart from surgeon's skill, on immediate and long term outcome of colorectal surgery

Case mix

Non-specialist surgeons tend to have a high proportion of elderly patients, often with concomitant disease, who present as emergencies with advanced lesions; specialist surgeons may have fewer emergencies, with most patients being younger, fitter, and with less advanced disease

Surgical philosophy

Faced with the same problem, an aggressive surgeon might undertake radical surgery, thereby risking technical complications, in an attempt to improve quality and duration of life, whereas a conservative surgeon might opt for limited surgery, thereby minimising the risk of postoperative complications (but in doing so, he or she may compromise long term survival)

Assessment of cure

The decision on whether a resection is curative or palliative is often based on the surgeon's subjective impression at the time of laparotomy. In patients in whom the adequacy of resection was borderline an optimistic surgeon might believe a cure had been achieved, whereas a more pessimistic surgeon might believe that only palliation had been achieved

Quality of pathological reporting

Limited sampling might suggest that the lymph nodes and the lateral resection margins were clear of tumour, whereas more rigorous sampling might show the presence of more extensive disease. The resultant pathological stage migration might therefore alter expectation of outcome and lead to inappropriate interpretation of the results

Other prognostic factors

Other factors—for example, socioeconomic deprivation—should be taken into consideration

Small numbers

Most surgeons at times have a cluster of patients who do less well than expected. This will vary from year to year. Any conclusion based on a small sample is likely to be misleading as it pertains to the individual surgeon

Table 6.3 Local recurrence and disease specific survival (n=683), according to specialisation and volume of work. Values are percentages

Training in colorectal surgery	Surgeons performing <21 resections (323 procedures)	Surgeons performing ≥21 resections (360 procedures)
No (n = 574):		
Local recurrence	44.6	27.8
Survival	39.2	49
Yes (n = 109):		
Local recurrence	21.1	10.4
Survival	54.5	67.3

Data are from the Canadian study (Porter et al, *Ann Surg* 1998;227:157-67)

Even if confounding variables are taken into account, some surgeons seem to be less competent than others, with poorer outcomes

Nevertheless, the results of the studies discussed here suggest that some surgeons are less competent than their colleagues and that these factors may compromise survival. Considerable effort and resources are currently being poured into large multicentre studies of adjuvant chemotherapy and radiotherapy in an effort to provide a marginal improvement in the survival of patients with colorectal cancer. If, by specialisation, the overall results of surgery could be improved—and evidence suggests that this is so—the impact on survival might be greater than that of any of the adjuvant therapies currently under study.

7 Adjuvant therapy

Rachel S J Midgley, D J Kerr

Despite substantial improvements in surgical technique and postoperative care, colorectal cancer continues to kill 95 000 people in Europe alone each year.

Of the annual 150 000 newly diagnosed cases, about 80% have no macroscopic evidence of residual tumour after resection. More than half of patients, however, develop recurrence and die of their disease. This is a result of occult viable tumour cells that have metastasised before surgery and which are undetectable by current radiological techniques (the limit of detection of standard computed tomography is about 1cm³, equivalent to 10⁹ cells).

Adjuvant treatment (chemotherapy and radiotherapy) has developed as an auxiliary weapon to surgery and is aimed at eradicating these micrometastatic cancer cells before they become established and refractory to intervention. As the presence of the primary tumour can exert an inhibitory influence on micrometastases, theoretically the removal of the tumour might stimulate growth of any residual cells, increasing the proliferating fraction and rendering them more susceptible to the cytotoxic effects of the widely used cytotoxic agent, fluorouracil.

It is reasonable to predict therefore that the earlier chemotherapy is started after surgery, the greater the potential benefit, although this has not yet been formally addressed in adjuvant trials. Implicit in this belief is a necessity for a multidisciplinary effort between surgeon, oncologist, and the community care team to provide seamless, streamlined cancer care for the individual patient.

Pharmacology of fluorouracil

Fluorouracil has remained the cornerstone chemotherapy for colorectal cancer for over 40 years. It is a prodrug that is converted intracellularly to various metabolites that bind to the enzyme thymidylate synthase, inhibiting synthesis of thymidine, DNA, and RNA. Increasing understanding of the molecular pharmacology of fluorouracil has led to the development of strategies to increase its efficacy.

The first strategy to be tested was coadministration with the immunostimulatory, antihelminthic drug levamisole, but despite promising early results, recent trials have not convincingly shown significant improvements in outcome compared with fluorouracil alone. In addition, no persuasive mechanism for the assumed synergism between fluorouracil and levamisole has been found.

In contrast, addition of folinic acid increases and prolongs the inhibition of the target enzyme (thymidylate synthase) and seems to confer improved clinical outcome compared with fluorouracil alone in advanced disease and when used in adjuvant therapy.

The side effects of chemotherapy based on fluorouracil vary according to the regimen (most commonly given as bolus intravenously daily for 5 days every 4 weeks or bolus weekly). They include nausea, vomiting, an increased susceptibility to infection, oral mucositis, diarrhoea, desquamation of the palms and soles, and, rarely, cardiac and neurological toxic effects.

Adjuvant—helpful, assisting, auxiliary (from Latin *ad* to, and *juvare* to help)

Figure 7.1 Optimising adjuvant therapy requires careful coordination between general practice, surgical, and oncology teams

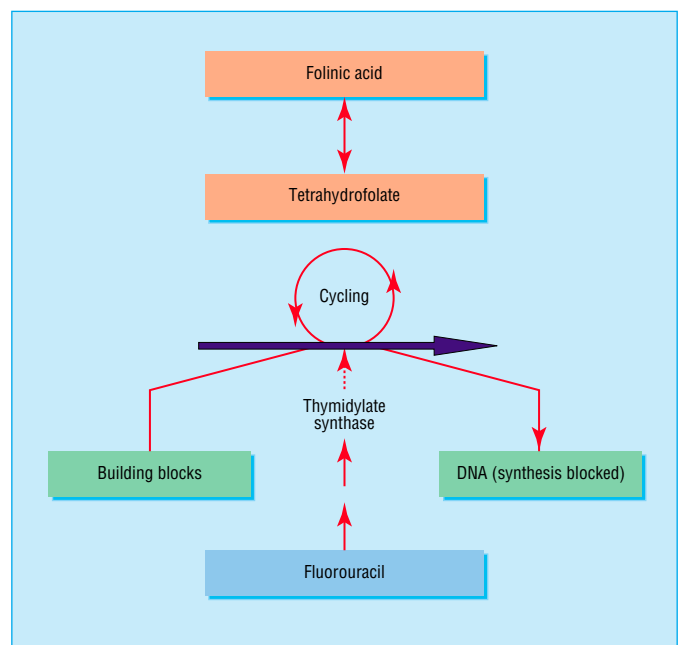

Figure 7.2 Intracellular metabolism and mechanism of action of fluorouracil and modulation by folinic acid

Established benefits of fluorouracil based adjuvant chemotherapy

Early adjuvant trials were retrospective and underpowered and failed to show any therapeutic benefit with respect to recurrence rate or survival. In 1990, however, the results of the intergroup trial were published. In this study 318 patients with stage B colorectal malignancy were randomised for surgical treatment alone or surgery followed by fluorouracil plus levamisole. In addition, 929 patients with stage C malignancy received surgery alone, surgery plus levamisole, or surgery plus fluorouracil and levamisole. For these patients there was a 33% reduction in the odds of death and a 41% decrease in recurrence among those treated with fluorouracil plus levamisole compared with surgery alone or surgery plus levamisole.

In contrast with levamisole, combining folinic acid with fluorouracil is pharmacologically rational, and documented benefit in advanced disease led to the logical extension of this combination into adjuvant therapy. Three large randomised adjuvant phase III trials produced confirmatory evidence of improved, disease-free survival at three years and improved overall survival in patients treated with fluorouracil plus folinic acid, with a 25-30% decrease in the odds of dying from colon cancer (or an absolute improvement in survival of 5-6% compared with controls).

Recently a meta-analysis of updated individual data from all unconfounded randomised studies of adjuvant chemotherapy (including the above three trials) has been undertaken (Colorectal Cancer Collaborative Group, unpublished). Overall, there was a 6-7% absolute improvement in survival with chemotherapy compared with surgery alone (SD 2.3, $P = 0.01$). The analysis advised that on current evidence the combination of fluorouracil plus folinic acid should be accepted as "standard" adjuvant chemotherapy for patients with Dukes's type C colon cancer.

Controversies in adjuvant therapy

Despite convincing evidence that adjuvant chemotherapy improves disease-free survival and overall survival in Dukes's type C colon cancer (an estimated six deaths prevented for 100 patients treated), several controversies surrounding the application of this form of treatment still exist.

Length of treatment and optimal dose of fluorouracil plus folinic acid

Lengthy adjuvant treatment has adverse effects on patients' quality of life as well as financial implications. A recent North American study, however, has shown that six months' treatment is as effective as 12 months'.

Determining the optimal dose is important: high dose folinic acid is 10 times as expensive as low dose. This issue has been addressed in the "certain" arm of the United Kingdom Co-ordinating Committee on Cancer Research's QUASAR ("quick and simple and reliable") trial (patients with Dukes's type C colon cancer). The trial uses the principle of randomising according to certain or uncertain indication: if, for a particular subgroup of patients the worth in receiving some form of adjuvant chemotherapy is definitely established from published randomised controlled trials (for example, patients with Dukes's type C colon cancer) then these patients are randomised to the certain indication arm (with a choice of different drugs and regimens); if, however, no definitive evidence exists of worth in a particular subgroup (for example, in patients with Dukes's type B colon cancer or with rectal

Box 7.1 Controversies still surrounding adjuvant therapy

- For how long should adjuvant therapy be continued, and what is the optimal dose of fluorouracil plus folinic acid?
- What is the role of adjuvant chemotherapy in lower risk groups?
- Is adjuvant therapy useful in rectal cancer?
- What is the role of new agents (eg irinotecan and oxaliplatin)?

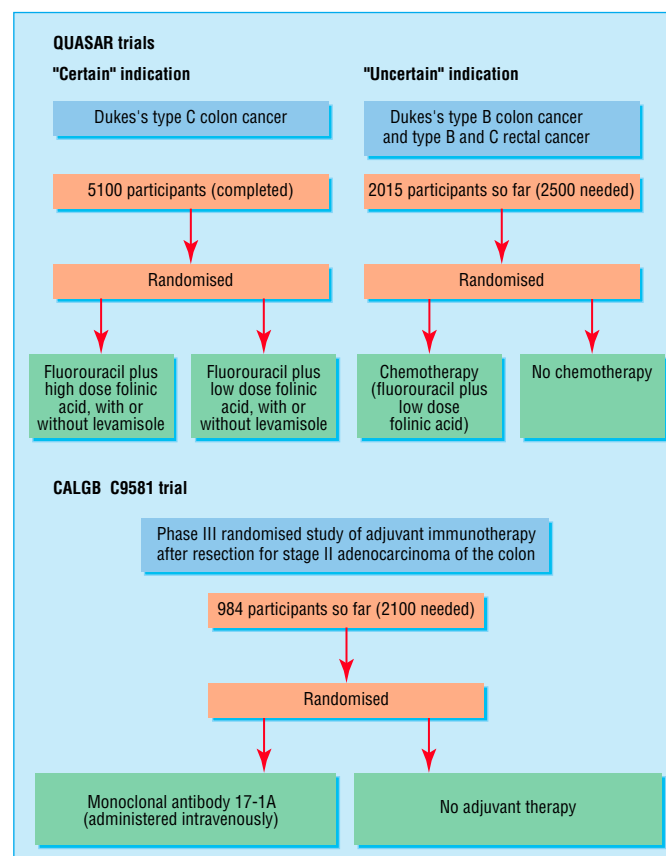

Figure 7.3 Ongoing adjuvant trials in colorectal cancer

ABC of Colorectal Cancer

cancer) then the patients are randomised into the uncertain indication arm (chemotherapy *v* no chemotherapy). The results from QUASAR's certain arm show that neither high dose folinic acid nor levamisole contribute to improved survival.

Role of adjuvant chemotherapy in lower risk groups

Inadequate data exist on the effect of chemotherapy in stage B colon cancer. The proportional reduction in annual risk is probably similar for stage B and stage C patients. If the proportional reductions in mortality are similar, the absolute benefits in terms of five year survival would be somewhat smaller for stage B patients than for stage C patients because of lower risk of recurrence (perhaps two to three lives saved per 100 patients treated).

Patients with stage B cancers who have prognostic indicators that suggest a high risk of recurrence (for example, perforation, vascular invasion, poor differentiation) might benefit proportionately more than patients with stage B cancer without high risk indicators and these variables might define a subgroup of patients who might merit adjuvant chemotherapy. Little evidence exists, however, on the prognostic predictability of these various features.

Use of adjuvant therapy in rectal cancer

Insufficient evidence exists to support the routine use of systemic chemotherapy in either Dukes's type B or type C rectal cancer. Anatomical constraints make the rectum less accessible to the surgeon, so it is much more difficult to achieve wide excision of the tumour, and about 50% of recurrences are in the pelvis itself rather than at distant sites. This means that locally directed radiotherapy is a useful adjuvant weapon, and this has been assessed for rectal cancer both before and after surgery.

In the largest trial of preoperative radiotherapy (the Swedish rectal cancer trial), radiotherapy produced a 61% decrease in local recurrence and an improvement in overall survival (58% *v* 48%) compared with surgery alone. Radiotherapy after surgery seems to be less effective, even at higher doses, possibly because of rapid repopulation of tumour cells after surgery or relative hypoxia around the healing wound.

Only one trial, the Uppsala trial in Sweden, has directly compared radiotherapy before and after surgery. Despite a higher dose after surgery, a significant reduction occurred in local recurrence rates among patients treated before surgery (12% *v* 21%, $P < 0.02$).

Animal studies have suggested that fluorouracil may prime the tumour cells and increase the cytotoxic effect of subsequent radiotherapy. Some clinical data support the role of chemoradiotherapy combinations in rectal cancer, but further clinical evidence of benefit needs to be provided before this treatment could be considered for routine use. The uncertain arm of the QUASAR trial will help to resolve this issue.

Figure 7.4 Five year survival for 4927 patients with colorectal cancer randomised to high dose or low dose folinic acid with fluorouracil

The uncertain arm of the QUASAR trial is aiming to establish whether chemotherapy is justified in Dukes's type B colon cancer and to define which factors might help to predict chemotherapeutic benefit

Figure 7.5 Microscopic metastasis in a draining lymph node from a rectal cancer

Table 7.2 Benefits of adjuvant therapy

Site and stage	Chemotherapy	Radiotherapy
Dukes's type C colon cancer	Worth established; fluorouracil plus folinic acid optimal to date; six lives per 100 treated saved; new drugs entering trial	No benefit
Dukes's type B colon cancer	Worth not established; particular subgroups of patients may benefit (on basis of histological and other prognostic factors)	No benefit
Dukes's type B or C rectal cancer	Worth not established	Worth established; preoperative may be superior to postoperative in terms of both efficacy and reducing toxicity

Role of portal venous infusional therapy

Fluorouracil is an S phase specific drug, and yet its active metabolites have a half life of about 10 minutes, which limits its target, when given as a bolus, to the small fraction of cells in the S phase at the time of administration. Infusional therapy can therefore affect a greater proportion of cells. In addition, the most common site for micrometastases after resection of a colorectal tumour is the liver. In contrast with macroscopically identifiable metastases of advanced disease, which derive their blood supply from the hepatic artery, these micrometastases are thought to be supplied by the portal vein. Therefore delivering chemotherapy via the portal vein should provide high concentrations of the drug at the most vulnerable site and lead to substantial first pass metabolism, which should attenuate any systemic toxicity. The established regimen for portal fluorouracil in adjuvant therapy is a course of 5-7 days starting immediately after surgery. A meta-analysis of 10 randomised trials showed a 4.7% improvement in absolute survival with portal venous infusion therapy compared with surgery alone; however, the confidence intervals were wide and the statistical benefit is not robust. Indeed the AXIS trial, the largest single trial of portal venous infusion to date, randomising 4000 patients after surgery either to the infusion therapy or to observation alone at five years, suggests no significant differences in overall survival.

Future role of adjuvant therapy

The use of adjuvant therapy in colorectal cancer over the past 40 years has centred on fluorouracil, alone and in combination, and on the fine tuning of regimen and route of administration. Current trials are considering new drugs (eg irinotecan and oxaliplatin) and their sequencing, as well as innovative techniques, such as immunotherapy and gene therapy. These techniques will be considered in detail later in the series. Gene therapy and immunotherapy are likely to function optimally, however, when cellular load is low, blood supply is good, and small clusters of cells are surrounded by effectors of the immune system; these therapies may therefore be most suitable as adjuvant therapy rather than for use in advanced disease.

All cytotoxic agents are rigorously tested and applied in advanced disease before being used in adjuvant therapy. New agents that are now entering adjuvant trials will be fully described in the next article in this series.

The United Kingdom Co-ordinating Committee on Cancer Research's AXIS study, in which 4000 patients have been randomised to portal vein infusion versus surgery alone, will contribute substantially to the debate on this type of therapy

8 Treatment of advanced disease

Annie M Young, Daniel Rea

Advanced colorectal cancer can be defined as colorectal cancer that at presentation or recurrence is either metastatic or so locally advanced that surgical resection is unlikely to be carried out with curative intent. Despite most patients undergoing potentially curative surgery and the availability of adjuvant chemotherapy, about 50% of patients presenting with colorectal adenocarcinoma die from subsequent metastatic disease. The five year survival rate for advanced colorectal cancer is lower than 5%.

In the past few years several therapeutic advances—underpinned by multiprofessional, site specialised team working—have finally changed the view that advanced colorectal cancer is an untreatable disease. Although cytotoxic chemotherapy is not suitable for all patients, widespread use in appropriate situations can improve survival and quality of life

Clinical presentation

Local recurrence of a tumour is more common in rectal than colon primaries. It may be identified early in the asymptomatic phase by follow up monitoring or may present with similar symptoms to the primary lesion. Blood loss through the rectum, mucous discharge, altered bowel habit, and straining are common features of recurrent rectal cancer. Pain and urinary symptoms are features of localised pelvic recurrence. Recurrent intra-abdominal disease can present as small or large bowel obstruction, and recurrence at other sites may be indicated by focal features such as hepatic capsular pain, jaundice, dyspnoea, localised bone pain, or neurological symptoms. Systemic features of weight loss, anorexia, nausea, and asthenia are symptoms commonly associated with advanced colorectal cancer. The tumour is often palpable on rectal or abdominal examination, and malignant ascites may also be evident.

Referral

Despite clear evidence of the value of chemotherapy and the apparent willingness of cancer patients to have chemotherapy, in the United Kingdom only about 25% of patients with advanced disease are referred to an oncology tertiary centre for consideration of chemotherapy. Referral patterns and treatment policies for patients with advanced colorectal cancer vary widely in the United Kingdom. Currently many regions are in the throws of reorganising their cancer services as part of the implementation of the Calman report, *A Policy Framework for Commissioning Cancer Services*. It is envisaged that referrals to oncologists will increase considerably owing to the publication in 1997 of guidelines for managing colorectal cancer.

Overview of management

The management of patients with advanced colorectal cancer involves a combination of specialist active treatment, symptom control measures, and psychosocial support. Active treatment comprises an individual plan (often combining palliative surgery), cytotoxic chemotherapy, and radiation therapy.

The outcome measures of the impact of active treatment have traditionally been survival, response, and toxicity. Alternative end points—for example, quality of life, convenience, acceptability to patients, and patients' preferences—assume greater importance in those with advanced disease, and they should now also be incorporated into the assessment of the relative worth of treatments.

Box 8.1 Clinical presentation

- About 20% of colorectal cancer cases will present with advanced disease
 - About 50% of patients treated with curative surgery will develop advanced disease
 - About 80% of relapses will occur within three years of primary surgery
 - About 50% of patients with advanced disease will present with liver metastasis
 - About 20% of patients with advanced disease have disease confined to the liver
-

Box 8.2 Which patients should be referred for palliative chemotherapy*?

Patients in whom chemotherapy should be considered

- Able to carry out all normal activity without restriction
- Restricted in physically strenuous activity but able to walk about and carry out light work
- Able to walk about and capable of all self care but unable to carry out any work; out of bed or chair for more than 50% of waking hours

Patients unlikely to benefit from chemotherapy

- Capable only of limited self care; confined to bed or chair for more than 50% of waking hours
- Severely disabled; cannot carry out any self care; totally confined to bed or chair

*Based on the World Health Organization's criteria for functional performance status

Box 8.3 Current status of chemotherapy

- Many patients with advanced colorectal cancer die without having received chemotherapy
 - Chemotherapy improves survival by an average of about six months, compared with supportive care alone
 - Chemotherapy improves overall quality of life
 - Stabilisation of disease with chemotherapy improves both survival and disease related symptoms
 - Early chemotherapy treatment (rather than waiting until symptoms appear) prolongs survival
-

Surgery

Palliative surgical procedures for advanced colorectal cancer are commonly used to overcome obstructing lesions and to alleviate pelvic symptoms. The liver is the most frequent site of metastasis, and in selected patients with no extrahepatic metastases surgical resection offers the only hope of cure. Five year survival rates of 25-35% have been reported with this highly specialised procedure (Cady and Stone, 1991).

Radiotherapy

In advanced colon cancer, radiotherapy is rarely indicated. In locally advanced rectal disease, localised radiation may render some tumours resectable. Radiotherapy can also be effective in palliation of symptoms—it can improve pain, stop haemorrhage, and lessen straining. In the absence of distant metastases, radiation may afford long term control of the tumour. Pain from isolated bone metastases can also be alleviated with short courses of radiation.

Conventional chemotherapy

In patients with advanced colorectal cancer, chemotherapy is delivered with palliative rather than curative intent. For over four decades fluorouracil has been the mainstay of treatment for advanced colorectal cancer. Folinic acid is given intravenously before fluorouracil to enhance the fluorouracil's cytotoxicity. Large randomised trials of chemotherapy versus best supportive care have shown that fluorouracil based chemotherapy adds about 4-6 months to the remaining life of patients with advanced colorectal cancer. Chemotherapy delays the occurrence or progression of symptoms by about six months and improves symptoms, weight gain, and functional performance in about 40% of patients. Palliative chemotherapy in advanced colorectal cancer should not be restricted by chronological age but by fitness and activity level.

Is failure to respond a failure of treatment?

Less than a third of patients receive an objective tumour response—complete or partial—with fluorouracil based therapy. In a further 20-30% of patients, the disease is stabilised during chemotherapy. The patients with stable disease ("no change" category) also derive a symptomatic and survival advantage from chemotherapy.

Which regimen?

Current evidence supports the use of infusional fluorouracil regimens over bolus schedules in terms of both toxicity and efficacy, but infusional chemotherapy is more complex to administer, requiring permanent vascular access technology or admission to hospital. In the United Kingdom a 48 hour regimen of fluorouracil plus folinic acid repeated every 14 days is commonly used. Ideally, chemotherapy for advanced colorectal cancer should be given within the umbrella of a clinical trial to help resolve outstanding questions of optimal type, duration, and scheduling of therapy.

Tailoring treatment

The optimum duration of chemotherapy is unknown and is currently being tested in clinical trials. The current approaches are either to treat for a fixed period (usually six months) or to treat until progression occurs. Irrespective of which of these approaches is adopted, the overriding need is to monitor rigorously the effect of treatment in terms of response, palliative

Figure 8.1 Abdominal computed tomogram showing a hepatic metastasis (arrow) before chemotherapy (top) and 17 weeks after chemotherapy (bottom); the later image shows a substantial reduction in the bulk of the hepatic tumour

Box 8.4 Definitions for assessing response and progression after chemotherapy

Complete response—Disappearance of all known disease, determined by two observations not less than four weeks apart
Partial response—Decrease of at least 50% of the sum of the products of the largest perpendicular diameters of all measurable lesions as determined by two observations not less than four weeks apart
No change—Less than 50% decrease and less than 25% increase in the sum of the products of the largest perpendicular diameters of all measurable lesions; no new lesions should appear
Progressive disease—More than 25% increase in the size of at least one lesion or appearance of a new lesion

Data from trials by the Nordic Gastrointestinal Tumour Therapy Group support the early use of chemotherapy, before the patient's condition deteriorates

ABC of Colorectal Cancer

benefit, and toxicity. This ensures that any toxicity or disease progression is recognised as soon as possible and that the appropriate individualised treatment or cessation of chemotherapy can be implemented without delay.

Chemotherapy toxicity

Chemotherapy for advanced colorectal cancer should be prescribed by experienced oncologists familiar with the toxicity profile of the drug regimens used. Despite concerns over toxicity, currently used infusional regimens are remarkably well tolerated. Management of toxicities in the community requires close liaison with the hospital team, and severe toxicity requires immediate admission. The most common effects of toxicity from chemotherapies for advanced colorectal cancer are diarrhoea, mucositis, asthenia, and neutropenia. Nausea, alopecia, and anorexia can also be experienced. Diarrhoea can be substantially relieved with oral antimotility drugs. Mucositis should be managed with antiseptic mouthwash and prophylactic or early treatment of oral candidiasis. Neutropenia is less common with current infusional regimens but must always be suspected in patients with fever. Prolonged treatment with fluorouracil can produce painful blistering erythema of palms and soles of the feet (palmar plantar erythrodysesthesia), which often improves with pyridoxine.

Cost effectiveness

In 1995 Glimelius et al showed that the overall cost of early intervention with chemotherapy in patients with advanced colorectal cancer is similar to that of no treatment or delayed chemotherapy, indicating that chemotherapy as part of the management of the advanced disease is indeed cost effective. Inevitably, it is becoming increasingly difficult for the health service to fund modern drugs to treat advanced colorectal cancer. The NHS is struggling to fund the new chemotherapy treatments that are proved to extend life by only a few months or to improve the quality of life only.

Ambulatory and domiciliary chemotherapy

The emergence of primary care health teams, together with developing technology, has allowed for more complex care to be carried out in the community or at home.

Ambulatory infusional chemotherapy is administered via a small pump (battery assisted and disposable elastomeric infuser). The chemotherapy may be connected and disconnected at the hospital outpatient clinic by oncology nurses, or patients can be taught to do this themselves.

A feasibility study of home chemotherapy has been undertaken in Birmingham for patients with advanced colorectal cancer. This shows that a nurse led service (backed up by oncology medical and nursing staff from both primary and secondary health care) is safe and that patients and carers find home therapy of immeasurable value. Early analysis shows that the cost of this home service is similar to and often cheaper than the current hospital based service.

New drugs

In recent years the availability of several new drugs has revived interest in the treatment of advanced colorectal cancer. New treatments include alternative fluoropyrimidines, new thymidylate synthase inhibitors, new modulators of fluorouracil and also mechanistically new drugs.

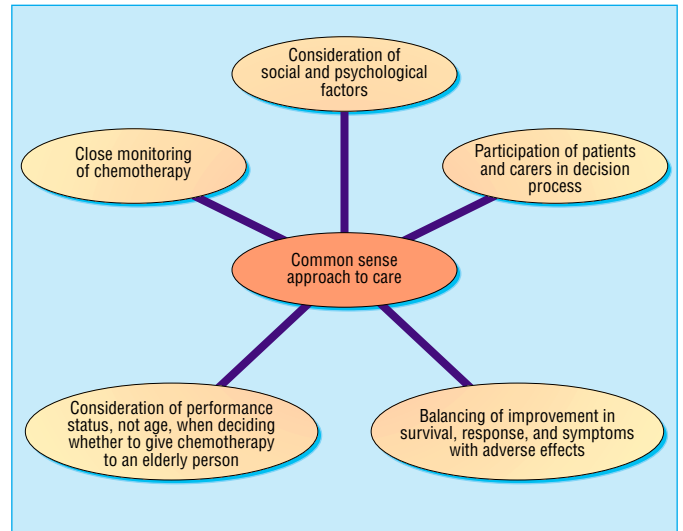

Figure 8.2 Basic elements of caring for patients with advanced colorectal cancer

Figure 8.3 Patient receiving chemotherapy through central venous catheter in hospital outpatient department (top); and small, battery assisted pump, worn on the waist and used to deliver chemotherapy through a central venous catheter (bottom). Patients are free to perform many normal activities during “ambulatory” chemotherapy

Box 8.5 Current controversies in advanced colorectal cancer

- For how long should chemotherapy be given?
- Are new delivery routes for fluorouracil—for example, orally and by intrahepatic arterial administration—superior to conventional intravenous fluorouracil?
- Should newer agents with similar efficacy but more convenient intravenous regimens be used in place of fluorouracil?
- What is the optimum combination and sequence for fluorouracil based therapies and the new chemotherapy drugs?
- Is home chemotherapy viable?
- How are the new, more expensive drug therapies to be funded?

New thymidylate synthase inhibitors

Raltitrexed is a quinazoline analogue antifolate that gains entry to cells via the reduced folate carrier and is polyglutamated to a potent, long acting, specific inhibitor of thymidylate synthase. Its regimen—a short intravenous infusion every three weeks—has similar efficacy to that of fluorouracil plus folinic acid and is clearly more convenient, although potentially more toxic.

Oral fluorouracil prodrugs and modulators

Fluoropyrimidine analogues have been developed with reliable oral bioavailability. In addition, oral inhibitors of fluorouracil catabolism can facilitate oral dosing. Preliminary data show similar effectiveness and lower toxicity compared with fluorouracil. Given the convenience and potential cost savings, oral therapy may soon find a place in routine practice.

Irinotecan and oxaliplatin

Irinotecan is a camptothecin analogue that acts through the inhibition of a DNA unwinding enzyme, topoisomerase I, resulting in replication arrest with breaks in single strand DNA. It is useful in advanced colorectal cancer, even after resistance to fluorouracil has developed, and is associated with a survival benefit (about three months) compared with best supportive care. This drug can be associated with severe late onset diarrhoea, which must be treated immediately. Selection of patients, therefore, plays an important part in the safe use of this agent.

Oxaliplatin is a new platinum derivative analogue that crosslinks DNA and induces apoptotic cell death. It shows synergism with fluorouracil. The dominant toxic effect is cumulative neurotoxicity.

Fluorouracil plus either irinotecan or oxaliplatin is superior to fluorouracil alone as a first line treatment for advanced colorectal cancer, with improvement in progression-free survival and, in the case of irinotecan, overall survival. Questions about the optimum sequence and combination of these agents remain and are the subject of ongoing clinical trials.

Intrahepatic arterial chemotherapy

For patients with unresectable hepatic metastases, intrahepatic arterial chemotherapy should be considered. This approach greatly increases drug delivery to the liver and doubles the rate at which tumours shrink, with tolerable toxicity. Owing to the complexity of placing the delivery catheter, intrahepatic arterial chemotherapy is usually administered at specialist centres. Current trials should offer definitive proof of whether intrahepatic arterial chemotherapy offers survival benefits compared with conventional intravenous therapy.

Supportive care

All patients with advanced colorectal cancer need continual evaluation of symptoms and appropriate measures for controlling symptoms. Dietary advice and nutritional supplements can stop weight loss, and corticosteroids may be used for their anabolic effect. Psychosocial aspects of care should incorporate evaluation of and provision for the needs of both the patient and the family. Supportive care needs to be tailored to the individual's circumstances and should involve the close collaboration of locally available palliative care services (both in the community and in hospitals). The initial contact between the patient and the palliative team should ideally be made at the time of diagnosis rather than at a crisis point when urgent input from palliative care services is required.

Figure 8.4 Liver with over 50% hepatic replacement by metastatic colorectal cancer

The Colorectal Forum is a worldwide educational service for healthcare professionals working with patients with colorectal cancer. Its website provides news on conferences and events, recommendations on management of advanced colorectal cancer, articles and visual images, reviews of recent publications, and the opportunity to debate controversial clinical issues. It can be accessed at www.colorectal-forum.org

9 Effectiveness of follow up

Colin McArdle

Population based studies show that for rectal cancer the incidence of local recurrence after apparently curative resection is about 20%. Local recurrence after surgery for colon cancer is less common. The liver is the commonest site of distant spread, followed by the lungs; brain and bone metastases are relatively rare. Most recurrences are within 24 months of surgery.

Aim of follow up

Traditionally surgeons have reviewed their patients at regular intervals after apparently curative resection. Recent surveys, however, have highlighted the lack of consensus among surgeons about the optimal modality and intensity of follow up; surveillance strategies range from a single postoperative visit to lifelong surveillance. Enthusiasts believe that intensive follow up and early intervention will lead to a reduction in the number of deaths from colorectal cancer; others point to the fact that the value of follow up is unproved. With so many tests available and no consensus on their value, it is not surprising that individual clinicians have tended to devise their own protocols.

Results of meta-analysis

A meta-analysis in the mid-1990s did little to clarify the situation. The researchers evaluated the results of seven non-randomised studies (covering over 3000 subjects in total) that compared intensive follow up with minimal or no follow up. Clearly several potential biases could and did exist. In the intensive group, investigations included clinical examination, faecal occult blood testing, liver function tests, measurement of the carcinoembryonic antigen, sigmoidoscopy, and either colonoscopy or barium enema examination. Liver ultrasonography was performed in only three studies and even then infrequently. In the intensive group more asymptomatic recurrences were detected, more patients underwent "second look" laparotomy, and more patients had a second potentially curative resection; more metachronous tumours were also detected and resected. However, although there were fewer deaths in the group receiving intensive follow up, this difference did not reach significance.

Results of randomised clinical trials

Since the meta-analysis, four randomised trials of intensive follow up have been reported. Ohlsson and his colleagues randomised 107 patients to no follow up or to intensive follow up, similar to that described above. No liver imaging was performed routinely. No differences were found in recurrence rates or in overall or cancer specific mortality.

Mákelá and his associates compared conventional with intensive follow up in 106 patients. In the intensive group flexible sigmoidoscopy was performed every three months, ultrasonography every six months, and colonoscopy and abdominal computed tomography at yearly intervals. Recurrences were detected at an earlier stage (median 10 months *v* 15 months) in the intensive group. Despite this, no difference in survival was found between the two groups.

Symptomatic recurrence of colorectal cancer is seldom amenable to curative surgery

Box 9.1 Aims of follow up

- Early detection and treatment of recurrent disease
- Detection of a second, or metachronous, tumour in the large bowel
- Provision of psychological support and advice
- Facilitation of audit

Figure 9.1 Results of meta-analysis of seven non-randomised trials that compared intensive with minimal or no follow up (Bruinvels et al, 1994)

The results of the four randomised controlled trials of intensive follow up should be interpreted with caution. Despite consistently fewer deaths in the intensive group in each study, the numbers in each were small, and no study had sufficient power to detect a survival advantage

Kjeldsen and his colleagues randomised almost 600 patients to either six monthly follow up or to follow up visits at five and 10 years only. Investigations included chest x ray and colonoscopy; no routine liver imaging was performed. Recurrence rates were similar (26%) in both groups, but the recurrences in the intensive group were detected on average nine months earlier, often at an asymptomatic stage. More patients with local recurrence underwent repeat surgery with curative intent. No difference existed, however, in overall survival (68% v 70%) or cancer related survival.

More recently, Schoemaker and his colleagues evaluated the addition of annual chest radiography, colonoscopy, and computed tomography of the liver to a standard follow up based on clinical examination, faecal occult blood testing, liver function tests, and measurement of the carcinoembryonic antigen, with further investigations as clinically indicated. At five years, fewer patients in the intensive group had died, but the result was not significant. At the cost of 505 additional investigations, annual colonoscopy failed to detect any asymptomatic local recurrences; only one asymptomatic metachronous colon tumour was detected. Six hundred and eight additional liver computed tomograms detected only one asymptomatic patient with liver metastases who might have benefited from liver resection.

Carcinoembryonic antigen

Carcinoembryonic antigen concentrations have also been used to predict recurrence. About three quarters of patients with recurrent colorectal cancer have a raised carcinoembryonic antigen concentration before developing symptoms.

An alternative approach therefore would be to monitor this concentration regularly during follow up and, in those patients showing a rising concentration, undertake second look laparotomy. However, although early non-randomised studies suggested that surgery that was prompted by this method resulted in more potentially curative repeat operations for recurrence, more recent studies have failed to show a survival advantage.

Moertel analysed outcome in patients included in trials of adjuvant therapy, according to whether the patient underwent carcinoembryonic antigen testing. Of 1017 patients whose concentrations were monitored, 417 (41%) developed recurrence. A comparison of those patients whose follow up included measurements of carcinoembryonic antigen with those whose follow up did not, failed to show any difference in disease-free survival. Among 29 laparotomies performed solely on the basis of a raised concentration of carcinoembryonic antigen, only one patient remained alive and disease-free after one year.

In the randomised study by Northover and his colleagues, 1447 patients undergoing potentially curative surgery were randomised to an intervention group or a control group. Carcinoembryonic antigen was measured in all patients at frequent intervals. In the intervention group, a rising antigen concentration prompted further investigation, including second look laparotomy, if appropriate.

Preliminary analysis showed no difference in survival between the two groups. The failure to show a survival advantage in the intervention group may be due to the fact that a rising antigen concentration is a relatively poor predictor of local recurrence; furthermore, even in patients with liver metastases a rising concentration is a relatively late phenomenon.

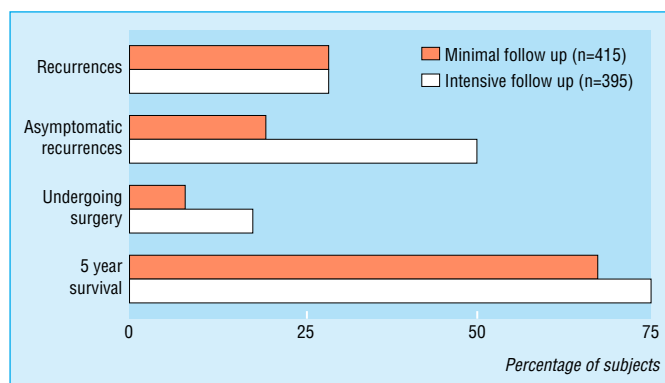

Figure 9.2 Combined results of three randomised trials of intensive follow up

Table 9.1 Results of intensive follow up*

Follow up	Colonoscopy	Chest x ray	Liver CT
Standard (n = 158)	72	17	66
Intensive (n = 167)	577	650	674
No of extra investigations	505	633	608
No of asymptomatic recurrences resulting from extra investigations	0	0	10
No of cures resulting from extra investigations	0	1	1

CT = computed tomography.

*Data from Schoemaker et al, 1998 (see Further reading box).

Carcinoembryonic antigen concentrations have been used to predict recurrence of colorectal cancer, but recent evidence does not support this approach

Table 9.2 Results of "second look" surgery according to measurement of carcinoembryonic antigen (CEA)*

CEA concentration	No of patients	No (%) of "curative" resections	% of patients free of recurrence at 1 year
Raised	345	47 (14)	2.9
Normal	672	38 (6)	1.9
Not measured	200	23 (12)	2.0

*Data from Moertel et al, 1993.

Cost effectiveness

Concern is also increasing about the cost of follow up. A review of the published literature suggests a 28-fold difference in costs between the least intensive and most intensive, published, five year follow up protocols.

Wrong target?

Clearly, follow up as currently practised is ineffective. Why, therefore, should we continue to follow patients up after apparently curative resection for colorectal cancer? There are several reasons. Firstly, we should do so to provide psychological support and advice; many patients welcome the reassurance that regular check up provides. Secondly, routine follow up facilitates audit of outcome measures after surgery, ensures quality control and facilitates evaluation of trials of new treatments and strategies.

There may, however, be a more fundamental reason that current follow up practices are ineffective. On theoretical grounds, attempts to identify potentially resectable local recurrences or metachronous tumours were never likely to have a significant impact on survival. Isolated resectable anastomotic recurrences are uncommon. Most local recurrences arise from residual disease left at the time of surgery and therefore, by definition, are unlikely to be amenable to further curative surgery. Metachronous tumours, although potentially amenable to surgery, are relatively uncommon.

Wrong intervention?

In contrast, liver metastases are much more common. Furthermore, these metastases are confined to the liver in about a quarter of patients.

Perhaps, therefore, the emphasis should shift towards the early detection of liver metastases. It is worth noting that in contemporary studies of liver resection, mortality is less than 5% and about 35% of patients survive five years. These figures are better than the results obtained after primary surgery for many types of gastrointestinal cancer. Furthermore recent studies have shown that patients with disseminated disease who receive systemic chemotherapy at an asymptomatic stage have higher response rates, better quality of life, and improved survival compared with those in whom the administration of chemotherapy is delayed until symptoms appear. Therefore if liver metastases were diagnosed in more patients at a point at which they were amenable to resection or chemotherapy, more long term survivors might be anticipated.

To date only two randomised studies have included liver imaging. In both these studies the numbers were small and liver imaging was infrequent. In neither study was a survival advantage noted. However, intensive liver imaging for the first three years after surgery may be more effective: at the Royal Infirmary in Glasgow more than 80% of patients who developed liver metastases as the initial site of recurrence were detected at an asymptomatic stage.

Hospital or community coordination of follow up?

Most patients with colorectal cancer are followed up in hospital. Yet overwhelming evidence from previous studies shows that few curable recurrences are detected at routine follow up based on history, physical examination, and routine blood tests. Few patients are followed up by their general practitioners, although

Box 9.2 Costs of follow up, suggested by recent study from Italy

- £2530 per patient over five years
- £9050 per recurrence detected
- £39 890 for each case undergoing further surgery
- £91 190 for each “cured” patient

Figure 9.3 Contrast enhanced computed tomogram (arterial phase) showing solitary liver metastasis

Table 9.3 Comparison of results of trial of early versus delayed chemotherapy in patients with advanced colorectal cancer

Treatment group	No of patients	Median symptom-free survival (months)	Median survival (months)	Survival at 1 year (%)
Early	92	10	14	55
Delayed	91	2	9	38

Early chemotherapy was given when patients were asymptomatic; delayed chemotherapy was given when patients were symptomatic. Data from the Nordic Gastrointestinal Tumor Group, 1992.

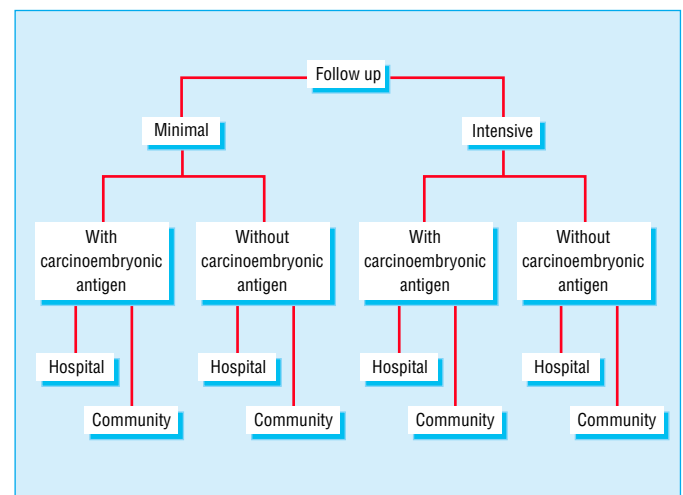

Figure 9.4 Suggested study outline to test three follow up strategies: intensive v minimalist; role of carcinoembryonic antigen; and general practitioner (community) coordinated v hospital coordinated

good evidence exists that, in other tumours at least, such follow up is as effective (or ineffective) as hospital follow up. Furthermore, provided that general practitioners have access to a “fast track” referral system for patients in whom they suspected recurrent disease, follow up coordinated by general practitioners might offer several advantages. It might be more acceptable to and convenient for patients and might reduce costs.

Perhaps it is time to reassess follow up. Formal studies to assess the value of these strategies might include:

- A comparison of the value of intensive versus minimalist follow up
- A re-evaluation of the role of carcinoembryonic antigen
- A comparison of the effectiveness of follow up that is coordinated by general practitioners rather than by hospitals.

Conclusion

Current methods of follow up, aimed at the early detection and treatment of local recurrence or metachronous tumours, have yet to be shown to be cost effective.

As liver metastases are common, a protocol that includes regular liver imaging to detect potentially resectable lesions may prove more effective. Further studies are needed to assess the value of this approach in patients undergoing apparently curative resection for colorectal cancer.

10 Innovative treatment for colon cancer

G A Chung-Faye, D J Kerr

Despite advances in treatment for colon cancer, the five year survival has not significantly altered over the past decade. Survival could improve in several key areas:

- Preventive measures—such as diet and chemoprevention with agents such as non-steroidal anti-inflammatory drugs
- Screening strategies—such as faecal occult blood testing and flexible sigmoidoscopy
- Optimisation of current chemotherapy and radiotherapy regimens and the development of more effective antineoplastic agents
- New therapeutic approaches—such as immunotherapy and gene therapy.

This article will focus on prevention with non-steroidal anti-inflammatory drugs and on new strategies for treating colon cancer.

Non-steroidal anti-inflammatory drugs

Evidence strongly suggests a protective effect of non-steroidal anti-inflammatory drugs in colon cancer. Several cohort and case-control studies have consistently shown dose related reductions of colorectal cancer in regular users of these drugs. Furthermore, patients with familial adenomatous polyposis who took the non-steroidal anti-inflammatory sulindac had reductions in the number and size of their polyps. Gene knockout studies in mice suggest that inhibition of the cyclo-oxygenase type 2 pathway by non-steroidal anti-inflammatory drugs may be important in the mechanism of action.

The only randomised controlled trial examining the effect of aspirin in primary prevention of colon cancer did not show any benefit after five years of aspirin use. A recent prospective cohort study suggested, however, that five years may be insufficient to show any benefit and that 10-20 years is needed to show an effect.

The predominant side effect from using non-steroidal anti-inflammatory drugs is the increased incidence of gastrointestinal bleeds. On the current evidence, the mortality risk from such bleeding would be outweighed by the reduction in mortality from colon cancer. To maximise the benefit to risk ratio, however, targeting individuals at high risk of colon cancer may prove more fruitful.

Non-steroidal anti-inflammatory drugs could be used as secondary prevention after surgical resection of colonic tumours, but this approach has yet to be tested in a large randomised controlled trial.

Immunotherapy

Many cancers can be destroyed by a tumour specific, cell mediated immune response, usually by CD8 (cytotoxic) lymphocytes. However, colorectal tumours are poorly immunogenic and may evade immune destruction by various mechanisms, such as tumour “tolerance.” To overcome these problems, several immunostimulatory approaches have been advocated to augment the innate immune response against tumours.

Dietary modifications to reduce the incidence of colon cancer may be difficult to implement (dietary interventional studies have shown this to be the case for cardiovascular disease); the roles of screening, chemotherapy, and radiotherapy have been covered earlier in this series

Figure 10.1 Use of non-steroidal anti-inflammatory drugs (NSAID) and relative risk of colorectal cancer

Figure 10.2 Cell mediated immunity against tumours. Tumour antigens are taken up and processed by antigen presenting cells (APC) and re-presented to class II receptors on T helper cells. This requires a costimulatory signal, B7, which binds to the CD28 ligand, causing T helper cell activation. This leads to secretion of cytokines, which in turn activates cytotoxic lymphocytes to bind to tumour cells via class I receptors and causes tumour lysis

Vaccination with autologous tumour cells

This approach uses cells derived from the patient’s tumour to elicit a cell mediated immune response against the tumour. To increase the efficacy of this response, tumour cells are coadministered with an immunomodulatory adjuvant, such as BCG. This approach has been tested in three randomised, controlled trials in an adjuvant setting in colorectal cancer, after resection of the tumour. No serious side effects were encountered in any of the studies.

Vaccination against tumour associated antigens

An alternative approach is vaccination against a tumour associated antigen, such as the carcinoembryonic antigen, which is overexpressed in 90% of colon cancers. A phase I immunisation study of a recombinant vaccinia virus, encoding the gene for carcinoembryonic antigen, in patients with advanced colorectal cancer, showed HLA specific, cytolytic T cell responses to carcinoembryonic antigen epitopes in vitro. This study did not show any clinical benefit, but several trials are under way, using optimal vaccination approaches in patients with minimal residual disease where clinical responses may be observed.

Monoclonal antibodies directed against tumour antigens

Monoclonal antibodies against tumour antigens have been shown to elicit immune responses against the tumour, which may previously have induced immunogenic tolerance. The 17-1A antigen is a surface glycoprotein with a putative role in cell adhesion and is present in over 90% of colorectal tumours.

In a study among patients with Dukes’s stage C colon cancer the patients were randomised to receive either surgery alone or surgery plus repeat administrations of a monoclonal antibody against the 17-1A antigen. Side effects of the treatment were infrequent, consisting mainly of mild constitutional and gastrointestinal symptoms. Four patients experienced an anaphylactic reaction, which required intravenous steroids but no hospital admission.

Gene therapy

Gene therapy represents a new treatment approach for colon cancer. It is at a developmental stage, and preclinical studies are only just being translated into clinical trials. Two gene therapy strategies are currently used, gene correction and enzyme-prodrug systems.

Gene correction

The most logical approach to gene therapy is the correction of a single gene defect, which causes the disease phenotype. In colon cancer, as in many other cancers, this goal is elusive as malignant transformation is usually accompanied by a series of genetic mutations. However, some of these mutations, such as the p53 gene mutation, are important for the propagation of the malignant phenotype, and the corollary is that correcting these mutations may inhibit the growth of tumour cells.

P53 gene

The p53 gene regulates the cell cycle and can cause growth arrest or apoptosis in response to DNA damage. Loss of p53 control leads to uncontrolled growth and is associated with more aggressive tumours. Restoration of wild-type p53 in p53 mutated tumours inhibits growth. In a phase I trial an adenovirus encoding wild-type p53 was delivered by hepatic artery infusion to 16 patients with p53 mutated colorectal liver metastases. This procedure was well tolerated, with the side

Box 10.1 Immunostimulatory approaches for augmenting the innate immune response against tumours

- Vaccination with autologous tumour cells
- Vaccination against tumour associated antigens, such as carcinoembryonic antigen
- Use of monoclonal antibodies directed against tumour antigens

Box 10.2 Vaccination with autologous tumour cells

Hoover et al, 1993

- 98 patients with colon or rectal cancer were randomised to surgery alone or to surgery plus vaccination with autologous tumour cells
- No significant improvement in the recurrence or the survival rate
- Subgroup analysis of patients with colon cancer showed a significant improvement in survival and disease-free survival in those who received vaccination (P = 0.02, P = 0.039 respectively)

Harris et al, 1994

- 412 patients with Dukes’s stage B and C colon cancer were postoperatively randomised to vaccination with autologous tumour cells or to no further treatment
- No significant differences between treated and untreated groups

Vermorken et al, 1999

- 254 postoperative patients with stage II or III colon cancer were randomised to vaccination with autologous tumour cells or to no further treatment. Those randomised to receive vaccination received a 4th booster vaccine after six months (in contrast with the patients in the two previous studies, who received only three doses)
- In those receiving vaccination, there was a significant reduction in recurrence (44%, 95% confidence interval 7% to 66%) and a reduction in overall survival, although this did not reach significance
- The main benefit was in stage II disease, with a non-significant reduction in recurrence in stage III disease; this was thought to be due to the increased tumour burden in more advanced stages

Figure 10.3 Results of a study of monoclonal antibody against 17-1A as adjuvant therapy in Dukes’s C colon cancer (Riethmuller et al, 1998)

The p53 gene mutation is present in most colon cancers

effects of fever and transiently damaged liver function. Although gene expression was detected in subsequently resected tumours, no radiographic responses were seen at 28 days. This study has now proceeded to a phase II trial, in combination with intrahepatic floxuridine based chemotherapy, in which 11 out of 12 patients have had partial responses.

Virus directed enzyme-prodrug treatment

Enzyme-prodrug systems are used to localise the toxic drug effects to tumour cells. This involves gene transfer of an enzyme into tumour cells, which converts an inactive prodrug into a toxic metabolite, leading to cell death. An important feature of enzyme-prodrug systems is the "bystander effect," whereby surrounding cells (not expressing the enzyme) are also killed by active metabolites. Gene transfer is achieved by viral vectors, such as retroviruses or adenoviruses. One such enzyme-prodrug combination is the bacterial enzyme cytosine deaminase, which converts the antifungal agent fluorocytosine into the antineoplastic agent fluorouracil. Fluorouracil induces apoptosis by inhibition of the enzyme thymidylate synthase during DNA replication. In murine models with colon cancer xenografts expressing cytosine deaminase, 75% of mice were cured by administration of fluorocytosine, whereas no anti-tumour effect was seen with the maximally tolerated dose of fluorouracil.

New therapeutic agents

The matrix metalloproteinases are a group of enzymes involved in the physiological maintenance of the extracellular matrix. They degrade the extracellular matrix and promote the formation of new blood vessels and are involved in tissue remodelling processes, such as wound healing and angiogenesis. Matrix metalloproteinases are overexpressed, however, in various tumours, including colorectal cancers, and have been implicated in facilitating tumour invasion and metastasis. The matrix metalloproteinase inhibitor, marimastat, has shown reductions in levels of tumour markers in phase I studies, and its clinical efficacy is currently being tested in phase III trials.

Conclusions

Non-steroidal anti-inflammatory drugs seem to be the most promising drug for prevention of colon cancer; case-control and prospective cohort studies strongly suggest they reduce the risk of colon cancer. This is further supported by studies in familial cancer patients and animal data. However, this effect of non-steroidal anti-inflammatory drugs is unproved in randomised controlled trials, and the issue remains to be addressed.

Immunotherapy seems to be well tolerated and effective in an adjuvant setting in colon cancer with limited residual disease. Its effect in stage II disease is comparable to that of adjuvant chemotherapy in Dukes's C colon cancer. In more advanced disease it may have a role in combination with chemotherapy, and this approach is being explored in ongoing trials.

Gene therapy for colon cancer is still at an early stage of development. Preclinical studies have prompted several phase I trials. However, significant problems remain, such as low efficiency in gene transfer and the inhibitory effect of the host immunity, which may be addressed by developments in vector technology. As our understanding of the molecular biology of cancer increases, gene therapy is likely to have an increasingly important role in the expanding array of treatment options for colon cancer.

Figure 10.4 Virus directed enzyme-prodrug treatment

Two current phase I trials are using a virus directed enzyme-prodrugs approach for treating colorectal liver metastases by direct injection into the tumour of an adenovirus encoding a therapeutic enzyme. One study is using nitroreductase plus the intravenous prodrug CB1954; the other is using cytosine deaminase plus fluorocytosine

BMJ
Books

ABC OF DERMATOLOGY

Fourth Edition

ABC of Dermatology CD Rom

Features

ABC of Dermatology PDF eBook

- Bookmarked and hyperlinked for instant access to all headings and topics
- Fully indexed and searchable text—just click the “Search Text” button

Artwork slideshow

- Every diagram and photograph from the book, organised by chapter
- Hover over a image thumbnail and the caption will appear in a pop-up window
- Click on the image thumbnail to view at full-screen size, then use the left and right cursor keys to view the previous or next figure

PDA Edition sample chapter

- A chapter from *ABC of Dermatology*, adapted for use on handheld devices such as *Palm and Pocket PC*
- Click on the underlined text to view an image (or images) relevant to the text concerned
- Uses Mobipocket Reader technology, compatible with all PDA devices and also available for Windows
- Follow the on-screen instructions on the relevant part of the CD Rom to install Mobipocket for your device
- Full title available in this format for purchase as a download from <http://www.pda.bmjbooks.com>

BMJ Books catalogue

- Instant access to BMJ Books full catalogue, including an order form

Instructions for use

The CD Rom should start automatically upon insertion, on all Windows systems. The menu screen will appear and you can then navigate by clicking on the headings. If the CD Rom does not start automatically upon insertion, please browse using “Windows Explorer” and double-click the file “BMJ_Books.exe”.

Tips

To minimise the bookmarks pane so that you can zoom the page to full screen width, simply click on the “Bookmarks” tab on the left of your screen. The bookmarks can be accessed again at any time by simply clicking this tab again.

To search the text simply click on “Search Text”, then type into the window provided. You can stop the search at any time by clicking “Stop Search”, and can then navigate directly to a search result by double-clicking on the specific result in the Search pane. By clicking your left mouse button once on a page in the PDF ebook window, you “activate” the window. You can now scroll through pages using the scroll-wheel on your mouse, or by using the cursor keys on your keyboard.

Note: the ABC of Dermatology PDF eBook is for search and reference only and cannot be printed. A printable PDF version as well as the full PDA edition can be purchased from <http://www.bmjbookshop.com>

Troubleshooting

If any problems are experienced with use of the CD Rom, we can give you access to all content* via the internet. Please send your CD Rom with proof of purchase to the following address, with a letter advising your email address and the problem you have encountered:

Acknowledgements

Professor R StC Barnetson, University of Sydney, Australia, wrote the original chapter on the sun and the skin, which is included in this edition. Professor Barbara Leppard, Regional Dermatology Training Centre, Moshi, Tanzania, has contributed a chapter on tropical dermatology with her own illustrations and some from Professor Barnetson. Professor R Hay, St Johns Institute of Dermatology, UMDS, Guy's Hospital, London, extensively revised the section on bacterial and fungal infections and provided some illustrations. Dr JA Savin, Lothian University NHS Trust, Edinburgh, rewrote the section on genetics and skin disease. Dr MA Waugh, consultant in GU medicine, The Leeds Teaching Hospitals NHS Trust, provided material and illustrations on AIDS. Dr Robin Balfour and Dr Ewan Crawford, general practitioners in Edinburgh, provided contributions on dermatology in general practice.

Material from contributors to earlier editions has been retained, particularly that supplied by Dr DJ Gawkrödger, consultant dermatologist, Royal Hallamshire Hospital, Sheffield (autoimmunity), Dr DWS Harris, consultant dermatologist, Whittington Hospital, London (practical procedures), Dr D Kemmett, consultant dermatologist, Lothian University NHS Trust, Edinburgh (diseases of hair and scalp), Dr AL Wright, consultant dermatologist, Bradford Royal Infirmary (diseases of nails).

The illustrations come from the Fife hospitals, the Royal Infirmary Edinburgh and the author's own collection. Some specific illustrations have been donated by Dr JA Savin (flea bites on the ankle); Dr Peter Ball (rubella); Professor CV Ruckley (varicose veins); Dr GB Colver (spider naevus); Dr MA Waugh and Dr M Jones (AIDS); Dr PMW Copemen (dermatoses in black skin). Miss Julie Close made the diagrams of the nail and types of immune response. The illustrations for dermatology in general practice were produced by Sister Sheila Robertson, Dermatology Liaison Nurse in Fife and Julie Close. The text of the third edition, on which this one is based, was typed by Mrs Mary Henderson. I would also like to thank Pat Croucher, who proofread the third edition, for copy-editing the script for this edition with perception and patience. Sally Carter and the editorial staff at BMJ Books gave great help and support.

Finally thanks are due to all the hospital staff—and particularly the patients—without whom dermatology could not be practised at all.

Preface

The remit for the first edition of the *ABC of Dermatology* in 1987 was that it should concentrate on common conditions and give down to earth advice. The ABC format proved well suited for this and there has been a steady demand for the book since then. In this edition the same approach is maintained while taking into account advances in diagnosis and treatment. Research in genetics and immunology is providing ever-increasing insights into the mechanisms that underlie clinical changes, and has led to more accurate diagnosis and more rational treatment. Specialised techniques that may not be relevant to common conditions can be of the greatest importance to an individual patient with a rare disease. In epidermolysis bullosa, for example, the ability to differentiate accurately between the different types with electronmicroscopy and immunohistochemistry is of considerable significance. Generally research increases our understanding of *how* diseases arise, but we have to admit to ourselves and our patients that *why* they occur remains as elusive as ever.

In recent years the management of inflammatory skin conditions has become both more effective and less demanding for the patient. In addition there is greater recognition of the impact of skin diseases on the patient's life. Major advances in treatment include more effective and safer phototherapy and the use of immunosuppressive drugs that enable inflammatory dermatoses to be managed without the need to attend for dressings or admission to hospital. This is just as well, since dermatology inpatient beds are no longer available in many hospitals. As a consequence, more dermatology patients are managed in the community with a greater role for the community nurse and general practitioner or family doctor. Dermatology liaison nurses play a very important part in making sure that the patients are using their treatment effectively at home and in maintaining the link between the hospital department, the home situation, and the general practitioner. Self-help groups are a valuable resource of support for patients, and there is now much more information available to the public on the recognition and management of skin disease.

Progress has been made in increasing the awareness of the general public and the politicians (who control the resources for health care) of the importance of skin diseases. In countries with minimal medical services there are immense challenges—particularly the need for training medical workers in the community who can recognise and treat the most important conditions. This has a major impact on the suffering and disability from skin diseases. The International Foundation for Dermatology and the pioneering Regional Dermatology Training Centre in Moshi, Tanzania, have set an important lead in this regard.

All the chapters have been revised for this new edition and a number of new illustrations included. A new chapter on tropical dermatology, which was previously included in the “hot climates” Australasian edition, is incorporated. In addition, there is a chapter on dermatology in general practice. Colleagues with special areas of expertise have been generous in giving advice and suggestions for this edition, which I trust will be a means of introducing the reader to a fascinating clinical discipline, covering all age groups and relevant to all areas of medicine.

Edinburgh, 2003, Paul Buxton

1 Introduction

The object of this book is to provide the non-dermatologist with a practical guide to the diagnosis and treatment of skin conditions. One advantage of dealing with skin conditions is that the lesions are easily examined and can be interpreted without the need for complex investigations, although a biopsy may be required to make or confirm the diagnosis. An understanding of the microscopic changes underlying the clinical presentation makes this interpretation easier and more interesting.

In the early chapters the relationship between the clinical presentation and the underlying pathological changes is discussed for a few important conditions, such as psoriasis. These are then used as a model for comparison with other skin diseases. This approach is suitable for skin conditions that present with characteristic lesions.

In other disorders a variety of causes may produce the same type of lesion. In this case it is more helpful to describe the characteristic clinical pattern that results. For example, similar inflammatory changes may result from drug allergy, autoimmune disease, or infection.

Tumours, acne, and leg ulcers are covered as separate subjects, as are diseases of the hair and nails.

The same condition is sometimes dealt with in more than one section, for example, fungal infections are discussed under “Rashes with epidermal changes” and again under “Fungal and yeast infections”, giving different perspectives of the same disorder.

Skin lesions are sometimes an indication of internal disease and may be the first clinical sign. For example, the girl in the photograph presented with a rash on her face, made worse by sunlight. She then mentioned that she was aware of lassitude, weight loss, and vague musculoskeletal symptoms which, in conjunction with the appearance of the rash, suggested lupus erythematosus. This was confirmed by further investigations and appropriate treatment was initiated. Other dermatological associations with systemic disease are discussed in the relevant sections.

The significance of skin disease

A large proportion of the population suffers from skin diseases, which make up about 10% of all consultations in primary care in the United Kingdom. However, community studies show that over 20% of the population have a medically significant skin condition and less than 25% of these consulted a doctor.

The skin is not only the largest organ of the body, it also forms a living biological barrier and is the aspect of ourselves we present to the world. It is therefore not surprising that there is great interest in “skin care”, with the associated vast cosmetic industry. The impairment of the normal functions of the skin can lead to acute and chronic illness with considerable disability and sometimes a need for hospital treatment.

A wide variety of tumours, both benign and malignant, arise in the skin. Fortunately the majority are harmless and most moles never develop dysplastic change.

Most cancers arising in the skin remain localised and are only invasive locally, but others may metastasise. It is important therefore to recognise the features of benign and malignant tumours, particularly those, such as malignant melanoma, that

Psoriasis—large lesions

Lupus erythematosus

Skin tags—examples of benign tumours

ABC of Dermatology

can develop widespread metastases. Recognition of typical benign tumours saves the patient unnecessary investigations and the anxiety involved in waiting for results.

Although a wide range of internal diseases produce physical signs in the skin, most skin diseases do not themselves have serious physical effects. However there can be significant psychological effects and problems with personal relationships, employment, and sporting activity. It is therefore important to use what Dr Papworth called “wide angle lenses” in assessing the patient and their disease. So, in addition to concentrating on the skin changes, the overall health and demeanour of the patient should be taken into account. This also means making sure that there are no other signs, such as involvement of the nails, mucous membranes, or other parts of the skin. The general physical condition and psychological state of the patient should be assessed, with more specific examination if indicated.

Section through skin

Descriptive terms

All specialties have their own common terms, and familiarity with a few of those used in dermatology is a great help. The most important are defined below.

Macule

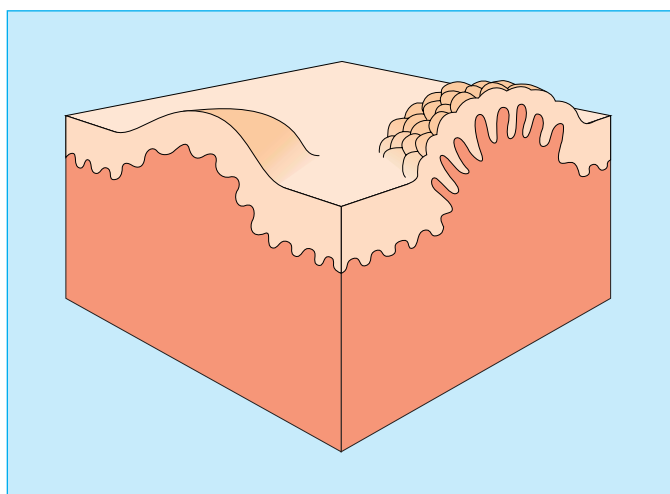

Derived from the Latin for a stain, the term macule is used to describe changes in colour or consistency without any elevation above the surface of the surrounding skin. There may be an increase of melanin, giving a black or blue colour depending on the depth of the pigment. Loss of melanin leads to a white macule. Vascular dilatation and inflammation produce erythema.

Papules and nodules

A papule is a circumscribed, raised lesion, conventionally less than 1 cm in diameter. It may be due to either epidermal or dermal changes.

Eythema

Section through skin with a papule

A papule surrounded by a depigmented macule

A nodule is similar to a papule but over 1 cm in diameter.
 A vascular papule or nodule is known as an haemangioma.

Plaque

Plaque is one of those terms which conveys a clear meaning to dermatologists but is often not understood by others. To take it literally, one can think of a commemorative plaque stuck on the wall of a building, with a large area relative to its height and a well defined edge. Plaques are most commonly seen in psoriasis.

Papule

Haemangioma

Section through skin with plaque

Plaques in psoriasis

Vesicles and bullae

Vesicles and bullae are raised lesions that contain fluid. A bulla is a vesicle larger than 0.5 cm. They may be superficial within the epidermis or situated in the dermis below it.

Acute reaction to insect bite—bullae

Section through skin showing situations of vesicle and bulla

Lichenification

Lichenification is another term frequently used in dermatology as a relic of the days of purely descriptive medicine. Some resemblance to lichen seen on rocks and trees does occur, with hard thickening of the skin and accentuated skin markings. It is most often seen as a result of prolonged rubbing of the skin in localised areas of eczema.

Lichen simplex

ABC of Dermatology

Nummular lesions

Nummular literally means a “coin-like” lesion. There is no hard and fast distinction from *discoïd* lesions, which are flat disc-like lesions of variable size. It is most often used to describe a type of eczematous lesion.

Pustules

The term pustule is applied to lesions containing purulent material—which may be due to infection, as in the case shown—or sterile pustules, which are seen in pustular psoriasis.

Atrophy

Atrophy refers to loss of tissue which may affect the epidermis, dermis, or subcutaneous fat. Thinning of the epidermis is characterised by loss of the normal skin markings, and there may be fine wrinkles, loss of pigment, and a translucent appearance. There may be other changes as well, such as sclerosis of the underlying connective tissue, telangiectasia, or evidence of diminished blood supply.

Ulceration

Ulceration results from the loss of the whole thickness of the epidermis and upper dermis. Healing results in a scar.

Erosion

An erosion is a superficial loss of epidermis that generally heals without scarring.

Nummular lesion as a response to a vaccination site in the arm

Pustule due to infection

Epidermal atrophy

Tropical ulcer

Bullous pemphigoid causing erosion

Excoriation

Excoriation is the partial or complete loss of epidermis as a result of scratching.

Fissuring

Fissures are slits through the whole thickness of the skin.

Excoriation of epidermis

Hyperkeratosis with fissures

Desquamation

Desquamation is the peeling of superficial scales, often following acute inflammation.

Annular lesions

Annular lesions are ring shaped lesions.

Reticulate

The term reticulate means “net-like”. It is most commonly seen when the pattern of subcutaneous blood vessels becomes visible.

Desquamation

Ring-shaped annular lesion

Reticulate pattern on skin

Psoriasis of both legs

Rashes

Approach to diagnosis

A skin rash generally poses more problems in diagnosis than a single, well defined skin lesion such as a wart or tumour. As in all branches of medicine a reasonable diagnosis is more likely to be reached by thinking firstly in terms of broad diagnostic categories rather than specific conditions.

There may have been previous episodes because it is a constitutional condition, such as atopic eczema. In the case of contact dermatitis, regular exposure to a causative agent leads to recurrences that fit with the times of exposure and this is usually apparent from the history. Endogenous conditions such as psoriasis can appear in adults who have had no previous episodes. If there is no family history and several members of the household are affected, a contagious condition, such as scabies, should be considered. A common condition with a familial tendency, such as atopic eczema, may affect several family members at different times.

A simplistic approach to rashes is to clarify them as being from “inside” or “outside”. Examples of “inside” or endogenous rashes are atopic eczema or drug rashes, whereas fungal infection or contact dermatitis are “outside” rashes.

Symmetry

Most endogenous rashes affect both sides of the body, as in the atopic child or a man with psoriasis on his knees. Of course, not all exogenous rashes are asymmetrical. A seamstress who uses scissors in her right hand may develop an allergy to metal in this one hand, but a hairdresser or nurse can develop contact dermatitis on both hands.

Diagnosis of rash

- Previous episodes of the rash, particularly in childhood, suggest a constitutional condition such as atopic eczema
- Recurrences of the rash, particularly in specific situations, suggests a contact dermatitis. Similarly a rash that only occurs in the summer months may well have a photosensitive basis
- If other members of the family are affected, particularly without any previous history, there may well be a transmissible condition such as scabies

Contact dermatitis as a response to mascara

Irritant dermatitis

ABC of Dermatology

Distribution

It is useful to be aware of the usual sites of common skin conditions. These are shown in the appropriate chapters. Eruptions that appear only on areas exposed to sun may be entirely or partially due to sunlight. Some are due to a sensitivity to sunlight alone, such as polymorphous light eruption, or a photosensitive allergy to topically applied substances or drugs taken internally.

Morphology

The appearance of the skin lesion may give clues to the underlying pathological process.

The surface may consist of normal epidermis overlying a lesion in the deeper tissues. This is characteristic of many types of erythema in which there is dilatation of the dermal blood vessels associated with inflammation. The skin overlying cysts or tumours in the dermis and deeper tissues is usually normal. Conditions affecting the epidermis will produce several visible changes such as thickening of the keratin layer and scales in psoriasis or a more uniform thickening of the epidermis in areas lichenified by rubbing. An eczematous process is characterised by small vesicles in the epidermis with crusting or fine scaling.

The margin of some lesions is very well defined, as in psoriasis or lichen planus, but in eczema it merges into normal skin.

Blisters or vesicles occur as a result of (a) oedema between the epidermal cells or (b) destruction of epidermal cells or (c) the result of separation of the epidermis from the deeper tissues. Of course, more than one mechanism may occur in the same lesion. Oedema within the epidermis is seen in endogenous eczema, although it may not be apparent clinically, particularly if it is overshadowed by inflammation and crusts. It is also a feature of contact dermatitis.

Allergic reaction producing photosensitivity

Lesion in deeper tissue with normal epidermis

Small vesicles of eczema

Eczema—*intraepidermal vesicle*

Pemphigus—*destruction of epidermal cells*

Pemphigoid—*blister forming below epidermis*

Blisters occur in:

- *viral diseases* such as chickenpox, hand, foot and mouth disease, and herpes simplex
- *bacterial infections* such as impetigo
- eczema and contact dermatitis
- *primary blistering disorders* such as dermatitis herpetiformis, pemphigus and pemphigoid as well as metabolic disorders such as porphyria.

Herpes simplex

Impetigo

Pemphigoid

Impetigo

Bullae, blisters over 0.5 cm in diameter, may occur in congenital conditions (such as epidermolysis bullosa), lichen planus, and pemphigoid without much inflammation. However, those forming as a result of vasculitis, sunburn, or an allergic reaction may be associated with pronounced inflammation. In pustular psoriasis there are deeper pustules, which contain polymorphs but are sterile and show little inflammation. Drug rashes can appear as a bullous eruption.

Induration is thickening of the skin due to infiltration of cells, granuloma formation, or deposits of mucin, fat, or amyloid.

Inflammation is indicated by erythema, which may be accompanied by increased temperature if acute—for example, in cellulitis or erythema nodosum. There may be a chronic inflammatory infiltrate in, for example, conditions such as lichen planus or lupus erythematosus.

Assessment of the patient

As well as assessing the clinical changes, the effect of a skin condition on the patient's life and their attitude to it must always be taken into account. For example, severe pustular psoriasis of the hands can be devastating for a self-employed electrician and total hair loss from the scalp very distressing for a 16-year-old girl.

Fear that a skin condition may be due to cancer or infection is often present and reassurance should always be given whether asked for or not. If there is the possibility of a serious underlying cause that requires further investigation, it is part of good management to answer any questions the patient has and provide an explanation that he or she can understand. It is easy to forget this aspect of medical practice at times.

The significance of occupational factors must be taken into account. In some cases, such as an allergy to hair dyes in a hairdresser, it may be impossible for the patient to continue their job. In other situations the allergy can be easily avoided.

Patients understandably ask whether psoriasis can be cured and often want to know the cause. The cause is unknown and the best answer is that the tendency to develop psoriasis is part of a person's constitution and some factor triggers the development of the clinical lesions. Known factors include physical or emotional stress, local trauma to the skin (Koebner's phenomenon), infection (in guttate psoriasis), drugs (β blockers, lithium, and antimalarial drugs).

To illustrate the use of these basic concepts in the diagnosis of lesions in practice two common skin diseases are considered—*psoriasis*, which affects 1–2% of the population, and *eczema*, an even more common complaint. Both are rashes with distinctive epidermal changes. The difficulty arises with the unusual lesion: Is it a rarity or a variation of a common disease? What should make us consider further investigation? Is it safe to wait and see if it resolves or persists? The usual clinical presentations of psoriasis and eczema are also used as a basis for comparison with variations of the usual pattern and other skin conditions.

A relevant history should be taken in relation to occupational and environmental factors

- Where? Site of initial lesion(s) and subsequent distribution
- How long? Has condition been continuous or intermittent?
- Prognosis—Is it getting better or worse?
- Previous episodes—How long ago? Were they similar? Have there been other skin conditions?
- Who else? Are other members of the family affected? Or colleagues at work or school?
- Other features—Is there itching, burning, scaling, or blisters? Any association with drugs or other illnesses?
- Treatment—By prescription or over the counter? Have prescribed treatments actually been used?

The following points are helpful when examining skin lesions

Distribution

- This may give the essential clue, so a full examination is necessary. For example, there are many possible causes for dry thickened skin on the palms, and finding typical psoriasis on the elbows, knees, and soles may give the diagnosis

Morphology

- Are the lesions dermal or epidermal? Macular (flat) or forming papules? Indurated or forming plaques? With a well defined edge? Forming crusts, scabs, or vesicles?

Pattern

- This is the overall clinical picture of both morphology and distribution. For example, an indeterminate rash may be revealed as pityriasis rosea when the "herald patch" is found

Factors possibly affecting development of skin disease such as psoriasis

2 Psoriasis

The familiar pink or red lesions with a scaling surface and well defined edge are easily recognised. These changes can be related to the histological appearance:

Increased epidermal proliferation—nuclei found ... throughout the epidermis

- The increased thickness of the epidermis, presence of nuclei above the basal layer, and thick keratin are related to increased epidermal turnover.
- Because the epidermis is dividing it does not differentiate adequately into normal keratin scales. These are readily removed to reveal the tortuous blood vessels beneath, appearing clinically as “Auspitz sign”. The psoriatic plaque can be likened to a brick wall badly built by a workman in too much of a hurry—it may be high but it is easily knocked down.
- The polymorphs that migrate into the epidermis form sterile pustules in pustular psoriasis. These are most commonly seen on the palms and soles.
- The dilated blood vessels can be a main feature, giving the clinical picture of intense erythema.

Pitting of the nail

The equivalent changes in the nail cause thickening and “pits” 0.5–1.0 mm in diameter on the surface; these are thought to be due to small areas of psoriatic changes in the upper layer of the nail plate that then fall out. Onycholysis, in which the nail plate is raised up, also occurs in psoriasis.

Clinical appearance

The main characteristics of psoriatic lesions, which reflect the pathological processes listed above, follow.

Plaques consisting of well defined raised areas of psoriasis. These may be few or numerous, covering large areas of the trunk and limbs. Sometimes there are large confluent lesions.

Small lesions

Large lesions

Plaques

Plaques

Scaling may predominate, giving a thick plaque, which is sometimes likened to limpets on the sea shore, hence the name “rupioid”. Scratching the surface produces a waxy appearance—the “tache de bougie” (literally “a line of candle wax”).

Erythema may be conspicuous, especially in lesions on the trunk and flexures.

Pustules are rare on the trunk and limbs, but deep seated pustules on the palms and soles are fairly common. In the form of *palmoplantar pustulosis* they may occur without psoriasiatic lesions elsewhere.

The *size* of the lesions varies from a few millimetres to very extensive plaques.

Rupoid lesions

The typical patient

Psoriasis usually occurs in early adult life, but the onset can be at any time from infancy to old age, when the appearance is often atypical.

The following factors in the history may help in making a diagnosis:

- There may be a family history—if one parent has psoriasis 16% of the children will have it, if both parents, the figure is 50%.
- The onset can occur after any type of stress, including infection, trauma, or childbirth.
- The lesions may first appear at sites of minor trauma—Koebner’s phenomenon.
- The lesions usually clear on exposure to the sun.
- Typically, psoriasis does not itch.
- There may be associated arthropathy—affecting either the fingers and toes or a single large joint.

Clinical presentation

Patients usually present with lesions on the elbows, knees, and scalp. The trunk may have plaques of variable size and which are sometimes annular. Patients with psoriasis show Koebner’s phenomenon with lesions developing in areas of skin trauma such as scars or minor scratches. Normal everyday trauma such as handling heavy machinery may produce hyperkeratotic lesions on the palms. In the scalp there is scaling, sometimes producing very thick accretions. Erythema often extends beyond the hair margin. The nails show “pits” and also thickening with separation of the nail from the nail bed (onycholysis).

Widespread pustular psoriasis

Common patterns of distribution in psoriasis

Scalp psoriasis

Annular lesions

ABC of Dermatology

Koebner's phenomenon: psoriasis in surgical scar

Psoriasis of the nail

Psoriasis of the hand

Guttate psoriasis—from the Latin *gutta*, a drop—consists of widespread small pink macules that look like drops of paint. It usually occurs in adolescents and often follows an acute β haemolytic streptococcal infection. There may be much distress to both parent and child when a previously healthy adolescent erupts in spots. Fortunately it also resolves quite rapidly.

Pustular lesions occur as either chronic deep seated lesions or generalised pustular psoriasis.

Chronic deep seated lesions occur on the palms and soles with surrounding erythema which develops a brown colour and scaling. It is important to reassure the patient that, despite their appearance, these pustules are not infectious—they consist of sterile collections of polymorphs.

These lesions occur in an older age group than psoriasis, and psoriasis may not be present elsewhere. It is more common in smokers. *Acrodermatitis pustulosa* is a variant that occurs in a younger age group in which there are pustules and inflammation around the nails and the fingertips.

Generalised pustular psoriasis is uncommon. Pustules develop in association with erythema. It may be precipitated by the use of steroids.

Flexural psoriasis produces well defined erythematous areas in the axillae and groins and beneath the breasts. Scaling is minimal or absent. It must be distinguished from a fungal infection and it is wise to send specimens for mycology if there is any doubt.

Guttate psoriasis

Pustules on the foot

Napkin psoriasis

Flexural psoriasis

Napkin psoriasis in children may present with typical psoriatic lesions or a more diffuse erythematous eruption with exudative rather than scaling lesions.

Erythrodermic psoriasis is a serious, even life threatening, condition with erythema affecting nearly the whole of the skin. Diagnosis may not be easy as the characteristic scaling of psoriasis is absent, although this usually precedes the erythroderma. Less commonly the erythema develops suddenly without preceding lesions. There is a considerable increase in cutaneous blood flow, heat loss, metabolism, and water loss.

It is important to distinguish between the *stable*, chronic, plaque type of psoriasis, which is unlikely to develop exacerbations and responds to tar, dithranol, and ultraviolet treatment, and the more *acute* erythematous type, which is unstable and likely to spread rapidly. The use of tar, dithranol, or ultraviolet light can irritate the skin and will make it more widespread and inflamed.

Erythrodermic psoriasis

Joint disease in psoriasis

Patients with seronegative arthropathy of the non-rheumatoid type show double the normal (2%) incidence of psoriasis. Psoriatic arthropathy commonly affects the distal interphalangeal joints, sparing the metacarpophalangeal joints, and is usually asymmetrical. Radiological changes include a destructive arthropathy with deformity. Rheumatoid nodules are absent. The sex ratio is equal but a few patients develop a "rheumatoid-like" arthropathy, which is more common in women than in men. A third rare group have arthritic changes in the larger joints, where there is considerable resorption of bone. Other members of the families of those with psoriatic arthropathy are affected in 40% of cases.

There may be pustular psoriasis of the fingers and toes associated with arthropathy which can be sufficiently severe to immobilise the patient.

Both psoriatic arthropathy and Reiter's syndrome are associated with the presence of HLA B27. Reiter's syndrome is characterised by polyarthritis and the development of urethritis, inflammatory changes in the conjunctivae, and skin lesions including pustulosis hyperkeratosis of the soles.

Acute arthropathy

Acute arthropathy—X ray signs

Causes of psoriasis

The cause is unknown but there is an inherited predisposition. The strong genetic influence may result from a single dominant gene with poor penetrance or a number of genetic influences. Other factors such as local trauma, general illness and stress are also involved, so the cause of psoriasis is best regarded as being multifactorial. HLA-Cw6 is the phenotype most strongly associated with psoriasis, particularly the early onset variety in which hereditary factors seem to play the greatest part. There is an increase in HLA expression in psoriatic arthropathy.

Local trauma, acute illness, and stress may be factors in causing the appearance of clinical lesions. β Haemolytic streptococcal throat infection is a common precipitating factor in guttate psoriasis. Antimalarial drugs, lithium, and β blockers can make psoriasis worse. There is evidence that psoriasis occurs more readily and is more intractable in patients with a high intake of alcohol. Smoking is associated with palmo-plantar pustulosis.

Acute arthropathy—X ray signs

ABC of Dermatology

There is evidence that both hormonal and immunological mechanisms are involved at a cellular level. The raised concentrations of metabolites of arachidonic acid in the affected skin of people with psoriasis are related to the clinical changes. Prostaglandins cause erythema, whereas leukotrienes (LTB₄ and 12 HETE) cause neutrophils to accumulate. The common precursor of these factors is phospholipase A₂, which is influenced by calmodulin, a cellular receptor protein for calcium. Both phospholipase A₂ and calmodulin concentrations are raised in psoriatic lesions.

T helper lymphocytes have been found in the dermis as well as antibodies to the basal cell nuclei of psoriatic skin. In addition, dermal factors contribute to the development of psoriatic lesions.

The detailed treatment of psoriasis is covered in the next chapter. The only point to be made here is the importance of encouraging a positive attitude with expectation of improvement but not a permanent cure, since psoriasis can recur at any time. Some patients are unconcerned about very extensive lesions whereas to others the most minor lesions are a catastrophe.

3 Treatment of psoriasis

It vanished quite slowly, beginning with the end of the tail, and ending with the grin, which remained some time after the rest of it had gone.

Lewis Carroll, *Alice in Wonderland*

To ignore the impact of the condition on the patient's life is to fail in treating psoriasis. Like the Cheshire cat that Alice met, it tends to clear slowly and the last remaining patches are often the hardest to clear. This is frustrating enough, but there is also the knowledge that it will probably recur and need further tedious courses of treatment, so encouragement and support are an essential part of treatment.

In an attempt to quantify the impact of psoriasis on the life of the individual patient the Psoriasis Disability Index (PDI) has been developed. This takes the form of a questionnaire and covers all aspects of the patient's work, personal relationships, domestic situation, and recreational activities. It can be helpful in assessing the effectiveness of treatment as perceived by the patient.

Patients understandably ask whether psoriasis can be cured and often want to know the cause. The cause is unknown and the best answer is that the tendency to develop psoriasis is part of an affected person's constitution and some factor triggers the development of the clinical lesions. Known factors include physical or emotional stress, local trauma to the skin (Koebner's phenomenon), infection (in guttate psoriasis), drugs (β blockers, lithium, and antimalarial drugs).

Treatment comprises ointments and pastes, systemic drugs, or various forms of ultraviolet light. The treatment should suit the type of psoriasis. The age and health of the patient, social and occupational factors need to be taken into consideration. The motivation of the individual patient is also important.

The preparations mentioned in the text are listed in the formulary in chapter 26. It is estimated that 80% of patients with psoriasis do not consult a doctor, as the lesions are minimal.

Preparation applied to affected area (left). Application of stockinette (right)

Bandages being applied to larger areas (left). Patient now prepared for contact treatment (right)

Treatment of psoriasis

Type of psoriasis	Treatment	Alternative treatment
Stable plaque psoriasis	Tar preparations Calcipotriol + topical steroids Tacalcitol Ultraviolet B (TL 01)	Short contact dithranol
Extensive stable plaques	As above. If not responding: Ultraviolet B (TL01) psoralen with ultraviolet A + etretinate	Methotrexate Ciclosporin A Tacrolimus
Widespread small plaque	Ultraviolet B	Tar
Guttate psoriasis	Emollients then ultraviolet B	Weak tar preparations
Facial psoriasis	1% hydrocortisone ointment	
Flexural psoriasis	Local mild to moderate strength steroids + antifungal	
Pustular psoriasis of hands and feet	Moderate to potent strength topical steroids	Acitretin
Acute erythrodermic, unstable, or general pustular psoriasis	Inpatient treatment Short term local steroids for acutely inflamed lesions	Methotrexate Acitretin Ciclosporin or other immunosuppressants

Local treatment

Local treatments entail the use of ointments and pastes, usually containing tar in various forms. It is much easier to apply them in hospital than at home if patients can make the time for hospital visits. Inpatient treatment can be more intensive and closely regulated; it also has the advantage of taking the patient completely away from the stresses of the everyday environment. In some units a “five day ward” enables patients to return home at weekends, which is particularly important for parents with young children.

Coal tar preparations are safe and effective for the stable plaque-type psoriasis but will irritate acute, inflamed areas. However, tar may not be strong enough for thicker hyperkeratotic lesions. Salicylic acid, which helps dissolve keratin, can be used in conjunction with tar for thick plaques. Refined coal tar extracts can be used for less severe areas of psoriasis.

Ichthammol, prepared from shale rather than coal tar, is less irritating and has a soothing effect on inflamed skin. It is therefore useful for “unstable” or inflamed psoriasis, when tar would not be tolerated.

Dithranol, obtained originally from the Goa tree in south India, is now made synthetically. It can easily irritate or burn the skin, so it has to be used carefully and should be kept from contact with normal skin as far as possible. For hospital treatment pastes are used and the lesions surrounded by petroleum jelly to protect the normal skin. Dithranol creams can be used at home—they are applied for 30 minutes and then washed off. A low concentration (0.1%) is used initially and gradually increased to 1% or 2% as necessary. All dithranol preparations are irritants and produce a purple-brown staining that clears in time. If used in the scalp dithranol stains red or fair hair purple.

Emollients soften dry skin and relieve itching. They are a useful adjunct to tar or dithranol.

Corticosteroid preparations produce an initial clearing of psoriasis, but there is rapid relapse when they are withdrawn and tachyphylaxis (increasing amounts of the drug having a diminishing effect) occurs. Strong topical steroids should be avoided. Only weak preparations should be used on the face but moderately potent steroids can be used elsewhere:

- (a) if there are only a few small lesions of psoriasis;
- (b) if there is persistent chronic psoriasis of the palms, soles, and scalp (in conjunction with tar paste, which is applied on top of the steroid at night); and (c) in the treatment of psoriasis of the ears, flexures, and genital areas. In flexural psoriasis secondary infection can occur and steroid preparations combined with antibiotics and antifungal drugs should be used, such as Terra-Cortril with nystatin and Trimovate.

Systemic corticosteroids should not be used, except in life threatening erythroderma, because of the inevitable “rebound” that occurs when the dose is reduced. The management of psoriasis in patients taking steroids for an unrelated condition may require inpatient or regular outpatient attendances to clear the skin lesions.

Calcipotriol and *tacalcitol*, vitamin D analogues, are calmodulin inhibitors used topically for mild or moderate plaque psoriasis. They are non-staining creams that are easy to use but can cause irritation. Sometimes a plateau effect is seen with the treatment becoming less effective after an initial response. If so, other agents, such as tar preparations, have to be used as well to clear the lesions completely. It is important not to exceed the maximum recommended dose so as to prevent changes in calcium metabolism.

Short contact dithranol

Indications

- Stable plaque psoriasis on the trunk and limbs

Suitable preparations

- Those available are in a range of concentrations such as Dithrocream (0.1%, 0.25%, 0.5%, 1.0%, 2.0%) or Anthranol (0.4%, 1.0%, 2.0%)

Method

- Start with the lowest concentration and increase strength every five to six days if there are no problems
- Apply cream to affected areas and then wash it off completely 20–30 minutes later
- Apply a bland emollient immediately after treatment

Cautions

- Do not apply to inflamed plaques, flexures, or the face
- Avoid contact of the dithranol with clothing and rinse the bath well after use to avoid staining
- Never leave the cream on for longer than 30 minutes (60 minutes is not twice as effective)

Psoriasis suitable for short contact dithranol treatment

Ultraviolet treatment (phototherapy)

Ultraviolet B is short wavelength ultraviolet light and is used for widespread thin lesions or guttate psoriasis. The dose has to be accurately controlled to give enough radiation to clear the skin without burning. Recently, "narrow waveband" ultraviolet B treatment has been developed, which increases the therapeutic effect and diminishes burning. It can be used instead of psoralen with ultraviolet A in many cases.

Ultraviolet A is long wavelength ultraviolet light, which activates psoralens in the skin. This results in diminished DNA synthesis and hence reduced epidermal turnover. The combination of psoralen with ultraviolet A is known as PUVA therapy: a dose of 8-methoxypsoralen (8MOP), 0.6–0.8 mg/kg body weight, is taken one to two hours before treatment. 5-Methoxypsoralen is also used, particularly in patients develop itching or nausea with 8MOP.

Other long term cumulative side effects of ultraviolet treatment include premature ageing of the skin, lentigenes, and eventually cutaneous malignancies. For this reason the total cumulative dose is kept below 1000 Joules.

After medical assessment treatment is given two or three times a week, with gradually increasing doses of ultraviolet A. Once the psoriasis has cleared maintenance treatments can be continued once every two or three weeks. Protective goggles are worn during treatment with ultraviolet A and dark glasses for 24 hours after each treatment. The glasses are tested for their effectiveness in screening ultraviolet A light.

A variable degree of erythema and itching may occur after treatment. Longer term side effects include a slight risk of epitheliomas developing, premature ageing of the skin, and cataract formation (which can be prevented by wearing ultraviolet A filtering goggles during and after treatment). The total cumulative dosage is carefully monitored and kept as low as possible to reduce the risk of side effects.

Guttate psoriasis suitable for ultraviolet B treatment

Ultraviolet B cabinet

Systemic treatment

Extensive and inflamed psoriasis that is resistant to local treatment may require systemic treatment. A number of antimetabolite drugs (such as azathioprine and hydroxyurea) and immunosuppressive drugs (such as ciclosporin A) are effective, but the most widely used are methotrexate and acitretin.

Methotrexate inhibits folic acid synthesis during the S phase of mitosis and diminishes epidermal turnover in the lesions of psoriasis. Because it is hepatotoxic liver function has to be assessed initially and at regular intervals during treatment. The dosage must be monitored, and when a total of 1.5 g is reached a liver biopsy is indicated to exclude significant liver damage.

Although it is rare, bone marrow suppression can occur insidiously and rapidly in some patients. In order to detect this an initial test dose is followed by a full blood count. If this gives normal results a weekly dose of 7.5–15 mg is used. As it is excreted in the urine, the dose must be reduced if renal function is impaired. Aspirin and sulphonamides diminish plasma binding.

Before phototherapy

After phototherapy

ABC of Dermatology

Methotrexate may interact with barbiturates, para-aminobenzoic acid, phenytoin, probenecid, phenylbutazone, oral contraceptives, and colchicine.

Acitretin is a vitamin A derivative that can be prescribed only in hospital in the United Kingdom. It is useful in pustular psoriasis and has some effect on other types of psoriasis. However, the effect is increased when combined with PUVA. Minor side effects include drying of the mucous membranes, crusting in the nose, itching, thinning of the hair, and erythema of the palms and nail folds. These are usually not severe and settle when treatment stops. More serious side effects include hepatotoxicity and raised lipid concentrations. Liver function tests and serum lipid (cholesterol and triglyceride) concentrations have to be carefully monitored. Etretinate is teratogenic and should only be taken by women during reproductive years if effective contraception is used during treatment and for two years afterwards, as the half life is 70–100 days.

Ciclosporin A is an immunosuppressant widely used following organ transplantation. It is effective in suppressing the inflammatory types of psoriasis. Blood tests should be carried out before starting treatment, particularly serum creatinine, urea, and electrolytes, as ciclosporin A can interfere with renal function.

Erythematous psoriasis suitable for methotrexate treatment, having failed to respond to phototherapy

Psoriasis of the scalp

This condition can be very difficult to clear, particularly if there are thick scales

Scalp psoriasis

- 3% salicylic acid in a suitable base and left on for four to six hours or overnight and then washed out with a tar shampoo
- Dithranol preparations are effective but will tint blonde or red hair purple
- Steroid preparations can be used to control itching

4 Eczema and dermatitis

The terms eczema and dermatitis are interchangeable, covering a wide variety of conditions from the child with atopic eczema to the adult with an allergy to cement. If patients are told they have dermatitis they may assume that it is related to their employment with the implication that they may be eligible for compensation. It is not unusual for industrial workers to ask “Is it dermatitis, doctor?”, meaning “is it due to my job?”

Clinical appearance

Eczema is an inflammatory condition of the skin characterised by groups of vesicular lesions with a variable degree of exudate and scaling. In some cases dryness and scaling predominate, with little inflammation. In more acute cases there may be considerable inflammation and vesicle formation, in keeping with the Greek for “to boil out”, from which the word eczema is derived. Sometimes the main feature may be blisters that become very large.

Eczema commonly itches and the clinical appearance may be modified by scratching, which with time may produce lichenification (thickening of the skin with increased skin markings). Also as a result of scratching the skin surface may be broken and have excoriations, exudate, and secondary infection.

Pathology

The characteristic change is oedema between the cells of the epidermis, known as *spongiosis*, leading to formation of vesicles. The whole epidermis becomes thickened with an increased keratin layer. A variable degree of vasodilatation in the dermis and an inflammatory infiltrate may be present.

Types of eczema

The many causes of eczema are not consistently related to the distribution and clinical appearance. In general there are either external factors acting on the skin producing inflammatory changes or it is an endogenous condition. It is important to remember there can be more than one cause—for example, in atopic eczema or varicose eczema on the ankle an allergic reaction may develop to the treatments used.

Atopic eczema affects mainly the flexor surfaces of the elbows and knees as well as the face and neck. To a variable degree it can affect the trunk as well.

The typical patient with atopic eczema is a fretful, scratching child with eczema that varies in severity, often from one hour to the next. In the older child or adult, eczema is more chronic and widespread and its occurrence is often related to stress. Atopic eczema is common, affecting 3% of all infants, and runs a chronic course with variable remissions. It normally clears during childhood but may continue into adolescence and adult life as a chronic disease. It is often associated with asthma and rhinitis. Sufferers from atopic eczema often have a family history of the condition.

Variants of atopic eczema are pityriasis alba—white patches on the face of children with a fair complexion—and chronic juvenile plantar dermatosis—dry cracked skin of the forefoot in children. This does not affect the interdigital spaces and is not due to a fungal infection.

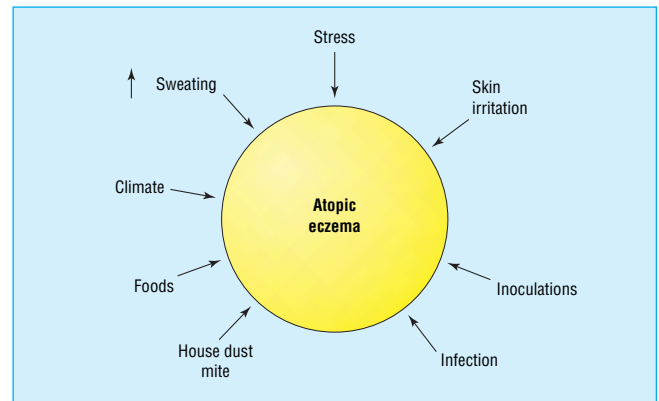

Eczema herpeticum. Children with atopic eczema are particularly prone to herpes virus infection, which may be life

Eczema

Pathology of eczema

Factors leading to development of atopic eczema

Atopic eczema—distribution

Atopic eczema

Plantar dermatosis

Nummular eczema

threatening. Close contact with adults with “cold sores” should therefore be avoided.

Nummular eczema appears as coin shaped lesions on legs and trunk.

Stasis eczema occurs around the ankles, where there is impaired venous return.

Paget’s disease of the breast. Whereas bilateral eczema of the nipples and areolae occur in women, any unilateral, persistent, areas of dermatitis in this region may be caused by Paget’s disease, in which there is underlying carcinoma of the ducts. In such cases a biopsy is essential.

Lichen simplex is a localised area of lichenification produced by rubbing.

Neurodermatitis is a term often used synonymously with lichen simplex. It is also used to describe generalised dryness and itching of the skin, usually in those with atopic eczema.

Asteatotic eczema occurs in older people with a dry, “crazy paving” pattern, particularly on the legs.

Pompholyx is itching vesicles on the fingers, with lesions on the palms and soles in some patients.

Infection can modify the presentation of any type of eczema or contact dermatitis.

Nummular eczema—distribution

Classification of eczema

Endogenous (constitutional) eczema	Exogenous (contact) eczema	Secondary changes
Atopic	Irritant	Lichen simplex
Nummular or discoid	Allergic	Neurodermatitis
Pompholyx	Photodermatitis	Asteatosis
Stasis		Pompholyx
Seborrhoeic (discussed later)		Infection

Stasis eczema

Paget’s disease of the nipple

Lichen simplex

Asteatosis

Pompholyx

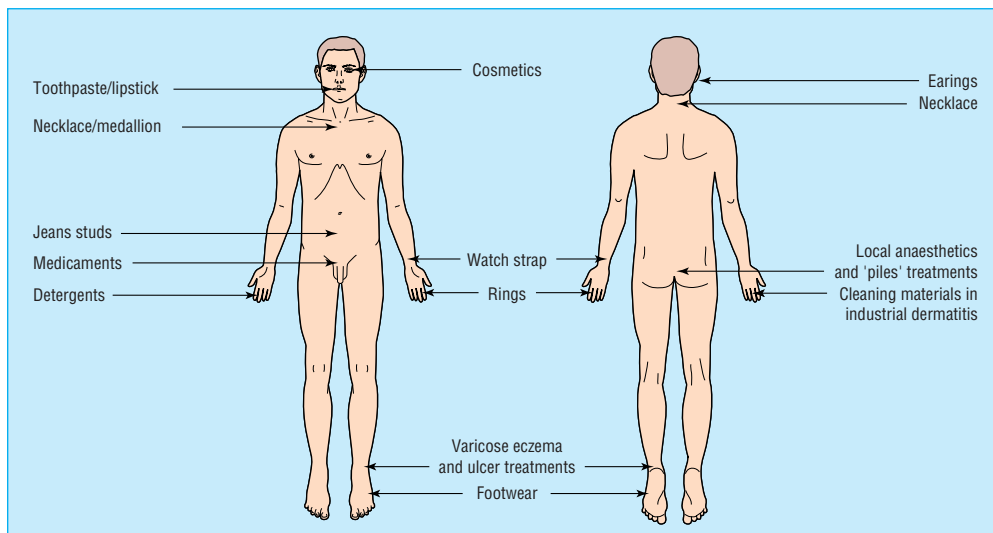

Infected eczema

Contact dermatitis

The skin normally performs its function as a barrier very effectively. If this is overcome by substances penetrating the epidermis an inflammatory response may occur leading to epidermal damage. These changes may be due to either (a) an allergic response to a specific substance acting as a sensitiser or (b) a simple irritant effect. An understanding of the difference between these reactions is helpful in the clinical assessment of contact dermatitis.

Common sources of allergic contact dermatitis

- Jewellery, clothing, wristwatch, scissors, cooking utensils
- Cement, leather
- Hair dyes, tights, shoes
- Rubber gloves and boots
- Creams, ointments, cosmetics
- Nickel—and cobalt occasionally
- Chromate
- Paraphenylenediamine—used in hair dyes
- Rubber preservative chemicals
- Preservatives (parabenz, quarternium), balsam of Peru, fragrances, lanolin, neomycin, benzocaine in medicated ointments

Contact dermatitis—common sources

Allergic contact dermatitis

The characteristics of allergic dermatitis are:

- Previous exposure to the substance concerned.
- 48–96 hours between contact and the development of changes in the skin.
- Activation of previously sensitised sites by contact with the same allergen elsewhere on the body.
- Persistence of the allergy for many years.

The explanation of the sequence of events in a previously sensitised individual is as follows: The antigen penetrates the epidermis and is picked up by a Langerhans cell sensitised to it. It is then transported to the regional lymph node where the paracortical region produces a clone of T cells specifically programmed to react to that antigen. The sensitised T cells accumulate at the site of the antigen and react with it to produce an inflammatory response. This takes 48 hours and is amplified by interleukins that provide a feedback stimulus to the production of further sensitised T cells.

Immunological response leading to contact dermatitis

ABC of Dermatology

Allergic contact dermatitis can be illustrated by the example of an individual with an allergy to nickel who has previously reacted to a wrist watch. Working with metal objects that contain nickel leads to dermatitis on the hands and also a flare up at the site of previous contact with the watch. The skin clears on holiday but the dermatitis recurs two days after the person returns to work.

Sensitisers in leg ulcer treatments

- Neomycin
- Lanolin (wool alcohol)
- Formaldehyde
- Tars
- Chinaform (the “C” of many proprietary steroids)

Allergic response to sulfapyridine

Allergic response to Solarcaine and sun

Allergic response to topical neomycin (left). After stopping ointment (right)

Irritant contact dermatitis

This has a much less defined clinical course and is caused by a wide variety of substances with no predictable time interval between contact and the appearance of the rash. Dermatitis occurs soon after exposure and the severity varies with the quantity, concentration, and length of exposure to the substance concerned. Previous contact is not required, unlike allergic dermatitis where previous sensitisation is necessary.

Photodermatitis

Photodermatitis, caused by the interaction of light and chemical absorbed by the skin, occurs in areas exposed to light. It may be due to (a) drugs taken internally, such as sulphonamides, phenothiazines, and dimethylchlortetracycline, or (b) substances in contact with the skin, such as topical antihistamines, local anaesthetics, cosmetics, and antibacterials.

Morphology

The clinical appearance of both allergic and irritant contact dermatitis may be similar, but there are specific changes that help in differentiating them. An acute allergic reaction tends to produce erythema, oedema, and vesicles. The more chronic lesions are often lichenified. Irritant dermatitis may present as slight scaling and itching or extensive epidermal damage resembling a superficial burn, as the child in the illustration shows.

Pathology

The reaction to specific allergens leads to a typical eczematous reaction with oedema separating the epidermal cells and blister formation. In irritant dermatitis there may also be eczematous changes but also non-specific inflammation, thickening of keratin, and pyknotic, dead epidermal cells.

Allergic response to dithranol

Photodermatitis

The distribution of the skin changes is often helpful. For example, an itchy rash on the waist may be due to an allergy to rubber in the waistband of underclothing or a metal fastener. Gloves or the rubber lining of goggles can cause a persisting dermatitis. An irritant substance often produces a more diffuse eruption, as shown by the patient who developed itching and redness from dithranol.

An allergy to medications used for treating leg ulcers is a common cause of persisting dermatitis on the leg.

Acute irritant dermatitis

Allergic response to elastic in underpants

Allergic reaction to cosmetics

Substances commonly causing allergic occupational dermatitis

- Chromate—in cement and leather
- Biocides, for example, formaldehyde and isothiazolinones, used in cutting oils in engineering
- Epoxy resins (uncured monomers)
- Rubber chemicals
- Hair dressing chemicals—particularly dyes and setting lotions
- Plant allergens

Allergic reaction to epoxy resin

Patch testing

Patch testing is used to determine the substances causing contact dermatitis. The concentration used is critical. If it is too low there may be no reaction, giving a false negative result, and if it is too high it may produce an irritant reaction, which is interpreted as showing an allergy (false positive). Another possible danger is the induction of an allergy by the test substance. The optimum concentration and best vehicle have been found for most common allergens, which are the basis of the “battery” of tests used in most dermatology units.

The test patches are left in place for 48 hours then removed, the sites marked, and any positive reactions noted. A further examination is carried out at 96 hours to detect any further reactions.

Acutely infected eczema

ABC of Dermatology

It is most important not to put a possible causative substance on the skin in a random manner without proper dilution and without control patches. The results will be meaningless and irritant reactions, which are unpleasant for the patient, may occur.

Test patches in place

Positive reactions marked

Patches being removed after 48 hours

Occupational dermatitis

Dermatitis, which is simply inflammation of the skin, can arise as a result of:

- Inherited tendency to eczema (atopy)
- Contact dermatitis, which may be either irritant or allergic
- Infection.

In the workplace, all three factors may contribute to dermatitis. For example, a student nurse or trainee hairdresser is exposed to water, detergents, and other factors that will exacerbate any pre-existing eczema. In addition, there may be specific allergies and, as a result of the broken skin, secondary infection can occur making the situation even worse. The following points are helpful in determining the role of occupational causes.

- If the dermatitis first occurred during employment or with a change of employment and had not been present before, then occupational factors are more likely.
- If the condition generally clears during holidays and when away from the workplace, this suggests an occupational cause, but chronic irritant dermatitis may persist when the patient is away from the workplace.
- If there is exposure to substances that are known to induce dermatitis and protective measures are inadequate at the workplace then an occupational cause is likely.
- If secondary infection is present, this can keep a dermatitis active even when away from the workplace and sometimes allergen exposure continues at home; for example, an allergy

Progression of acute and chronic dermatitis

to rubber gloves at work will also occur when rubber gloves are used for domestic work at home.

Whatever the cause of the dermatitis, the end result may seem the same clinically, because the inflammation and blisters of atopic eczema may be indistinguishable from an allergic reaction to rubber gloves. Generally, contact dermatitis is more common on the dorsal surface of the hands whereas atopic eczema occurs on the palms and sides of the fingers.

Irritant contact dermatitis can occur acutely as mentioned above and there is usually a definite history of exposure to irritating chemicals.

Chronic irritant dermatitis can be harder to assess as it develops insidiously in many cases. Often it starts with episodes of transient inflammation that clear up, but with each successive episode the damage becomes worse with an escalation of inflammatory changes that eventually become chronic and fixed.

Once chronic damage has occurred the skin is vulnerable to any further irritation, so the condition may flare up in the future even after removal of the causative factors. Individuals with atopic eczema are particularly liable to develop chronic irritant dermatitis and secondary infection is an additional factor.

Allergic contact dermatitis occurs as an allergic reaction to specific substances. As this involves a cell mediated response the inflammatory reaction occurs about two days after exposure and once the allergy is present further exposure will inevitably produce a reaction. Some substances are much more likely to produce an allergy, such as epoxy resin monomer, than others, such as cement, which characteristically requires exposure over many years before an allergy develops. In addition to the capacity of the substance to produce an allergic reaction, individuals also vary considerably in the capacity to develop allergies.

Immediate type sensitivity is sometimes seen as a reaction to food protein and sensitivity to latex gloves. This can produce a very severe reaction, particularly in atopic individuals.

The itching skin (pruritus)

It is sometimes very difficult to help a patient with a persistently itching skin, particularly if there is no apparent cause. Pruritus is a general term for itching skin, whatever the reason.

Itching with skin manifestations

Eczema is associated with itching due to the accumulation of fluid between the epidermal cells that are thought to produce stretching of the nerve fibres. As a result of persistent scratching there is often lichenification which conceals the original underlying areas with eczema. Exposure to irritants and persistent allergic reactions can produce intense itching and should always be considered.

“Allergic reactions” due to external agents often cause intense itching. Systemic allergic reactions such as a fixed drug eruption, erythema multiforme, and vasculitis are less likely to cause pruritus.

Psoriasis, which characteristically has hyperkeratotic plaques, usually does not itch but sometimes there can be considerable itching. Occasionally this is due to secondary infection of breaks in the skin surface.

Lichen planus presents with groups of flat-topped papules which often cause an intense itch. Blistering disorders of the skin may itch.

In *herpes simplex* there is usually burning and itching in the early stages.

Treatment of occupational dermatitis

The exact cause of the dermatitis should be identified as far as possible. It is important to ascertain exactly what an individual's job entails; for example, a worker in a plastics factory had severe hand dermatitis but the only positive result on patch testing was to nickel. On visiting the factory it became clear that the cause was a nickel plated handle that he used several thousand times a day and not the plastic components that the machine was making. It is also important to assess the working environment because exposure to damp and irritants (for example, on an oil rig or in a coal mine) can irritate the skin.

If occupational factors are suspected, then a full assessment and investigation in a dermatology department is important as the patient's future working life may be at stake

Systemic causes

- Endocrine diseases—diabetes, myxoedema, hyperthyroidism
- Metabolic diseases—hepatic failure, chronic renal failure
- Haematological—polycythaemia, iron deficiency anaemia
- Malignancy—lymphoma, reticulosis, carcinomatosis
- Psychological—anxiety, parasitophobia
- Tropical infection—filariasis, hookworm
- Drugs—alkaloids

Investigations

- Skin scrapings for mycology
- Patch testing for allergies
- Full blood count, erythrocyte sedimentation rate, liver and renal function tests
- Urine analysis
- Stools for blood and parasites

In *herpes zoster* there may be a variable degree of itching, but this is overshadowed by the pain and discomfort of the fully developed lesions.

By contrast, *bullous impetigo* causes few symptoms, although there may be extensive blisters. Itching is usually not present.

Dermatitis herpetiformis is characterised by intense persistent and severe itching that patients often describe as being unendurable. Usual measures such as topical steroids and antihistamines have little if any effect.

By contrast, the blisters of *pemphigoid* do not itch although the earlier inflamed lesions can be irritating.

Parasites. Fleas and mites cause pruritic papules in groups. The patient may not realise that they may have been acquired after a walk in the country or encountering a dog or cat.

Nodular prurigo may develop after insect bites and is characterised by persistent itching, lichenified papules, and nodules over the trunk and limbs. The patient attacks them vigorously and promotes a persisting "itch-scratch-itch" cycle which is very difficult to break.

Parasitophobia is characterised by the patient reporting the presence of small insects burrowing into the skin which persists despite all forms of treatment. The patient will produce small flakes of skin, fibres of clothing, and pieces of dust, usually in carefully folded pieces of paper, for examination. These should always be examined and the patient gently informed that no insect could be found but this will not be believed. Treatment is therefore very difficult and sometimes recourse has to be had to psychotropic drugs (see page 106).

Infestations with lice cause irritation and a scabies mite can cause widespread persistent pruritus, even though only a dozen or so active scabies burrows are present. It is always acquired by close human contact and the diagnosis may be missed unless an adequate history of personal contacts and a thorough clinical examination is carried out. However, a speculative diagnosis of scabies should be avoided.

Itching with no skin lesions

If no dermatological lesions are present generalised pruritus or itchy skin may indicate an underlying internal cause. In elderly patients, however, the skin may itch simply because it is dry. Hodgkin's disease may present with pruritus as a sign of the internal malignancy long before any other manifestations.

A 35 year old ambulance driver attended the dermatology clinic with intense itching but a normal skin and no history of skin disease. His general health was good and both physical examination and all blood tests were normal. However, a chest x ray examination showed a mediastinal shadow that was found to be due to Hodgkin's lymphoma. Fortunately this was easily treated. Other forms of carcinoma rarely cause pruritus.

Metabolic and endocrine disease

Biliary obstruction and *chronic renal disease* cause intense pruritus. *Thyroid disease* can be associated with an itching skin. In hyperthyroidism the skin seems normal but in hypothyroidism there is dryness of the skin causing pruritus.

Blood diseases. Polycythaemia and iron deficiency are sometimes associated with itching skin.

Treatment

Treatment of the cause must be carried out when possible. Calamine lotion cools the skin with 0.5% menthol or 1% phenol in aqueous cream. Camphor-containing preparations and crotamiton (Eurax) are also helpful. Topical steroid ointments and occlusive dressings may help to prevent scratching and may help to break the itch-scratch-itch cycle. Emollients should be used for dry skin.

Topical local anaesthetics may give relief but intolerance develops and they can cause allergic reactions. Sedative antihistamines at night may be helpful. In liver failure cholestyramine powder may help to relieve the intense pruritus, as this is thought to be due to bile salts in the skin.

Antihistamines can be helpful both for their antipruritic effect and because many are sedative and enable the itching patient to sleep.

Pruritus ani is a common troublesome condition and the following points may be helpful:

- Advise gentle cleaning once daily and patients should be advised to avoid excessive washing.
- Avoid harsh toilet paper, especially if coloured, because cheap dyes irritate and cause allergies. Olive oil and cotton wool can be used instead.
- Weak topical steroids will help to reduce inflammation, with zinc cream or ointment as a protective layer on top.
- Anal leakage from an incompetent sphincter, skin tags, or haemorrhoids may require surgical treatment.
- There may be an anxiety or depression and pruritus ani itself can lead to irritability and depression.

Pruritus vulvae is a persistent irritation of the vulva which can be most distressing and is most common in postmenopausal women. It is important to eliminate any factors that may be preventing resolution. These include:

- Secondary infection with pyogenic bacteria or yeasts
- Eczema or contact dermatitis
- Lichen sclerosus atrophicus.

The adjacent vaginal mucosa should be examined to exclude an intraepithelial neoplasm or lichen planus. Treatment includes suitable antiseptic preparations such as 2% eosin, regular but not excessive washing, emollients, and topical steroids, bearing in mind the possibility of infection.

5 Treatment of eczema and inflammatory dermatoses

Treat the patient, not just the rash. Many patients accept their skin condition with equanimity but others suffer much distress, especially if the face and hands are affected. Acceptance by the doctor of the individual and his or her attitudes to the disease goes a long way to helping the patient live with the condition.

The common inflammatory skin diseases can nearly always be improved or cleared, but it is wise not to promise a permanent cure.

Be realistic about the treatment people can apply in their own homes. It is easy to unthinkingly give patients with a widespread rash a large amount of ointment to apply twice daily, which is hardly used because: (a) they have a busy job or young children and simply do not have time to apply ointment to the whole skin; (b) they have arthritic or other limitations of movement and can reach only a small part of the body; (c) the tar or other ointment is smelly or discolours their clothes. Most of us have been guilty of forgetting these factors at one time or another.

Dry skin tends to be itchy, so advise minimal use of soap. Emollients are used to soften the skin, and the simpler the better. Emulsifying ointment BP is cheap and effective but rather thick. By mixing two tablespoons in a kitchen blender with a pint of water, the result is a creamy mixture that can easily be used in the bath. A useful preparation is equal parts of white soft paraffin and liquid paraffin. Various proprietary bath oils are available and can be applied directly to wet skin. There are many proprietary emollients.

Wet weeping lesions should generally be treated with creams rather than ointments (which remain on the surface).

Steroid ointments are effective in relieving inflammation and itching but are not always used effectively. Advise patients to use a strong steroid (such as betamethasone or fluocinolone acetonide) frequently for a few days to bring the condition under control; then change to a weaker steroid (dilute betamethasone, fluocinolone, clobetasone, hydrocortisone) less frequently. Strong steroids should not be continued for long periods, and, as a rule, do not prescribe any steroid stronger than hydrocortisone for the face. Strong steroids can cause atrophy of the skin if used for long periods, particularly when applied under occlusive dressings. On the face they may lead to florid telangiectasia and acne-like pustules. Avoid using steroids on ulcerated areas. Prolonged use of topical steroids may mask an underlying bacterial or fungal infection.

Immunosuppressants are a valuable adjunct in severe cases not responding to topical treatment and antibiotics. Ciclosporin is usually given on an intermittent basis, with careful monitoring for side effects. Azathioprine is also used, provided the thiopurine methyl transferase (TPMT) level is normal.

Tacrolimus is an immunosuppressant that has recently become available in two strengths as an ointment. It promises to be a successful treatment but is relatively expensive.

Specific treatment

Wet, inflamed, exuding lesions

- (1) Use wet soaks with plain water, normal saline, or aluminium acetate (0.6%). Potassium permanganate (0.1%) solution should be used if there is any sign of infection.

Treatment guidelines

- Treat the patient, not just the rash
- Complete cure may not be possible
- Be realistic about the problems of applying treatments at home
- Make sure the patient understands how to carry out the treatment
- Advise using emollients and minimal soap
- Provide detailed guidance on using steroids

Weeping eczema

Acute erythema

ABC of Dermatology

- (2) Use wet compresses rather than dry dressings (“wet wraps”).
- (3) Steroid *creams* should be used as outlined above. Greasy ointment bases tend to float off on the exudate.
- (4) A combined steroid–antibiotic cream is often needed as infection readily develops.
- (5) Systemic antibiotics may be required in severe cases. Take swabs for bacteriological examination first.

Dry, scaling, lichenified lesions

- (1) Use emollients.
- (2) Use steroid *ointments*, with antibiotics if infection is present.
- (3) A weak coal tar preparation or ichthammol can be used on top of the ointments. This is particularly useful at night to prevent itching. 1–2% coal tar can be prescribed in an ointment. For hard, lichenified skin salicylic acid can be incorporated and the following formulation has been found useful in our department:
 - (a) Coal tar solution BP 10%, salicylic acid 2%, and unguentum drench to 100%.
 - (b) 1% ichthammol and 15% zinc oxide in white soft paraffin is less likely to irritate than tar and is suitable for children.
- (4) In treating psoriasis start with a weaker tar preparation and progress to a stronger one.
- (5) For thick, hyperkeratotic lesions, particularly in the scalp, salicylic acid is useful. It can be prescribed as 2–5% in aqueous cream, 1–2% in arachis oil, or 6% gel.

It is often easiest for the patient to apply the preparation to the scalp at night and wash it out the next morning with a tar shampoo.

Infection

Remember that secondary infection may be a cause of persisting lesions.

Hand dermatitis

Hand dermatitis poses a particular problem in management and it is important that protection is continued after the initial rash has healed because it takes some time for the skin to recover its barrier function. Ointments or creams should be reapplied each time the hands have been washed.

It is useful to give patients a list of simple instructions such as those shown in the box on the right.

Lichenified eczema

Infected eczema: before (left) and after (right) treatment

Hand dermatitis: hints on management

- Hand washing: use tepid water and soap without perfume or colouring or chemicals added; dry carefully, especially between fingers
- When in wet work: wear cotton gloves under rubber gloves (or plastic if you are allergic to rubber); try not to use hot water and cut down to 15 minutes at a time if possible; remove rings before wet or dry work; use running water if possible
- Wear gloves in cold weather and for dusty work
- Use only ointments prescribed for you
- Things to avoid on unprotected skin:
 - Shampoo
 - Peeling fruits and vegetables, especially citrus fruits
 - Polishes of all kinds
 - Solvents, for example, white spirit, thinners, turpentine
 - Hair lotions, creams, and dyes
 - Detergents and strong cleansing agents
 - “Unknown” chemicals
- Use “moisturisers” or emollients which have been recommended by your doctor to counteract dryness

6 Rashes with epidermal changes

Familiarity with the clinical features of psoriasis and eczema, which all clinicians see from time to time, provides a basis for comparison with other rather less common conditions. The characteristics that each condition has in common with psoriasis and eczema are highlighted in the relevant tables.

Lichen planus

Like psoriasis, the lesions are well defined and raised. They also occur in areas of trauma—the Koebner’s phenomenon. There is no constant relation to stress.

Unlike psoriasis, there is no family history. Itching is common. The distribution is on the flexor aspects of the limbs, particularly the ankles and wrists, rather than on the extensor surfaces, as in psoriasis. It also occurs on the trunk. However, localised forms of lichen planus can occur on the shin, palm, and soles or elsewhere.

Nail involvement is less common than in psoriasis. There may be thinning and atrophy of part or all of a nail and these often take the form of a longitudinal groove, sometimes with destruction of the nail plate. The oral mucosa is commonly affected with a white, net-like appearance and sometimes ulceration.

The typical flat topped lesions have a shiny hyperkeratotic lichenified surface with a violaceous colour, interrupted by milky white streaks—Wickham’s striae.

Less commonly, very thick hypertrophic lesions occur and also follicular lesions. Lichen planus is one cause of localised alopecia on the scalp as a result of hair follicle destruction.

Lichen planus usually resolves over many months to leave residual brown or grey macules. In the oral mucosa and areas subject to trauma ulceration can occur.

Characteristics of lichen planus

Clinical features of psoriasis	Clinical features of eczema
Possible family history	Possible family history
Sometimes related to stress	Sometimes worse with stress
Itching—rare	Usually itching
Extensor surfaces and trunk	Flexor surfaces and face
Well defined, raised lesions	Poorly demarcated lesions
Hyperkeratosis	Oedema, vesicles, lichenification
Scaling, bleeding points beneath scales	Secondary infection sometimes present
Koebner’s phenomenon	
Nails affected	
Scalp affected	
Mucous membranes not affected	

Lichen planus—wrist

Lichen planus (left). Lichen planus—oral mucosa (right)

Lichen planus—nails

ABC of Dermatology

Treatment

There is usually a gradual response to topical steroids, but in very extensive and inflamed lesions systemic steroids may be needed. Localised hypertrophic lesions can be treated with intralesional injections.

Similar rashes

Lichenified eczema

This is also itchy and may occur on the ankles and wrists. The edge of the lesion is less well defined and is irregular. The flat topped, shiny papules are absent.

Lichenified eczema

Guttate psoriasis

Guttate psoriasis is not as itchy as lichen planus. Scaling erythematous lesions do not have the lichenified surface of lichen planus.

Pityriasis lichenoides

The lesions have a mica-like scale overlying an erythematous papule.

Drug eruptions

Rashes with many features of lichen planus can occur in patients taking:

- Chloroquine
 - Chlorpropamide
 - Chlorothiazide
- } The three "C"s
- Anti-inflammatory drugs
 - Gold preparations

It also occurs in those handling colour developers.

Treatment

The main symptom of itching is relieved to some extent by moderately potent steroid ointments. Very hypertrophic lesions may respond to strong steroid preparations under polythene occlusion. Careful intralesional injections may be effective in persistent lesions. In very extensive, severe lichen planus systemic steroids may be indicated.

Lichen planus—skin

Guttate psoriasis—section through lesion (left); lichenified eczema—section through lesion (right)

Guttate psoriasis

Lichen planus

- Flexor surfaces
- Mucous membranes affected
- Itching common
- Violaceous colour
- Wickham's striae
- Small discrete lesions
- Lichenified

Pathology of lichen planus

As expected from the clinical appearance, there is hypertrophy and thickening of the epidermis with increased keratin. The white streaks seen clinically occur where there is pronounced thickness of the granular layer and underlying infiltrate. Degenerating basal cells may form “colloid bodies”. The basal layer is being eaten away by an aggressive band of lymphocytes, the remaining papillae having a “saw toothed” appearance.

Lichen planus—pathology

Seborrhoeic dermatitis

Seborrhoeic dermatitis has nothing to do with sebum or any other kind of greasiness. There are two distinct types, adult and infantile.

Adult seborrhoeic dermatitis

The adult type is more common in men and in those with a tendency to scaling and dandruff in the scalp. There are several commonly affected areas:

- Seborrhoeic dermatitis affects the central part of the face, scalp, ears, and eyebrows. There may be an associated blepharitis, giving some red eyes and also otitis externa.
- The lesions over the sternum sometimes start as a single “medallion” lesion. A flower-like “petaloid” pattern can occur. The back may be affected as well.
- Lesions also occur in well defined areas in the axillae and groin and beneath the breasts.

Typically the lesions are discrete and erythematous and they may develop a yellow crust. The lesions tend to develop from the hair follicles. It is a persistent condition that varies in severity.

Clinically and pathologically the condition has features of both psoriasis and eczema. There is thickening of the epidermis with some of the inflammatory changes of psoriasis and the intercellular oedema of eczema. Parakeratosis—the presence of nuclei above the basement layer—may be noticeable. Recently, increased numbers of *Pityrosporum ovale* organisms have been reported.

Treatment

Topical steroids produce a rapid improvement, but not permanent clearing. Topical preparations containing salicylic acid, sulphur, or ichthammol may help in long term control. Triazole antifungal drugs by mouth have been reported to produce clearing and can be used topically. These drugs clear yeasts and fungi from the skin, including *P. ovale*, which is further evidence for the role of this organism.

Seborrhoeic dermatitis

Characteristics of seborrhoeic dermatitis

Clinical features of psoriasis	Clinical features of eczema
Possible family history	Possible family history
Sometimes related to stress	Sometimes worse with stress
Itching—rare	Usually itching
Extensor surfaces and trunk	Flexor surfaces and face
Well defined, raised lesions	Poorly, demarcated lesions
Hyperkeratosis	Oedema, vesicles, lichenification
Scaling, bleeding points beneath scales	Secondary infection sometimes, present
Koebner’s phenomenon	
Nails affected	
Scalp affected	
Mucous membranes not affected	

Seborrhoeic dermatitis affecting centre of face

Seborrhoeic dermatitis under breasts

Seborrhoeic dermatitis—distribution pattern

Infantile seborrhoeic dermatitis

In infants less than six months old a florid red eruption occurs with well defined lesions on the trunk and confluent areas in the flexures associated with scaling of the scalp. There is no consistent association with the adult type of seborrhoeic dermatitis. It has been suggested that infantile seborrhoeic dermatitis is a variant of atopic eczema. It is said to be more common in bottle fed infants. A high proportion of affected infants develop atopic eczema later but there are distinct differences.

Itching is present in atopic eczema but not in seborrhoeic dermatitis.

The *clinical course* of atopic eczema is prolonged with frequent exacerbation, whereas seborrhoeic dermatitis clears in a few weeks and seldom recurs.

Treatment comprises emollients, avoiding soap, and applying hydrocortisone combined with an antibiotic plus nystatin (for example, Terra-Cortril plus nystatin cream). Hydrocortisone can be used on the scalp.

Allergy

IgE concentrations are often raised in atopic eczema and food allergy is common, but not in seborrhoeic dermatitis.

Perioral dermatitis

Perioral dermatitis is possibly a variant of seborrhoeic dermatitis, with some features of acne. Papules and pustules develop around the mouth and chin. It occurs mainly in women.

Pityriasis rosea

The word “pityriasis” is from the Greek for bran, and the fine bran-like scales on the surface are a characteristic feature. The numerous pale pink oval or round patches can be confused with psoriasis or discoid eczema. The history helps because this condition develops as an acute eruption and the patient can often point to a simple initial lesion—the herald patch.

There is commonly slight itching. Pityriasis rosea occurs mainly in the second and third decade, often during the winter months. “Clusters” of cases occur but not true epidemics. This suggests an infective basis. There may be prodromal symptoms with malaise, fever, or lymphadenopathy. Numerous causes have been suggested, from allergy to fungi; the current favourite is a virus infection.

The typical patient is an adolescent or young adult, who is often more than a little concerned about the sudden appearance of a widespread rash. The lesions are widely distributed, often following skin creases, and concentrated on the trunk with scattered lesions on the limbs. The face and scalp may be affected.

Early lesions are red with fine scales—usually 1–4 cm in diameter. The initial herald patch is larger and may be confused with a fungal infection. Subsequently the widespread eruption develops in a matter of days or, rarely, weeks. As time goes by the lesions clear to give a slight pigmentation with a collarette of scales facing towards the centre.

Similar rashes

Discoid eczema presents with itching and lesions with erythema, oedema, and crusting rather than scaling. Vesicles may be present. The rash persists unchanged.

A *drug eruption* can sometimes produce similar lesions.

In *guttate psoriasis* the lesions are more sharply defined and smaller (0.5–1.0 cm) and have waxy scales.

Infantile Seborrhoeic dermatitis

Perioral dermatitis

Pityriasis rosea—herald lesions

Characteristics of pityriasis rosea

Clinical features of psoriasis	Clinical features of eczema
Possible family history	Possible family history
Sometimes related to stress	Sometimes worse with stress
Itching—rare	Usually itching
Extensor surfaces and trunk	Flexor surfaces and face
Well defined, raised lesions	Poorly demarcated lesions
Hyperkeratosis	Oedema, vesicles, lichenification
Scaling, bleeding points beneath scales	Secondary infection sometimes present
Köebner's phenomenon	
Nails affected	
Scalp affected	
Mucous membranes not affected	

Pathology

Histological changes are non-specific, showing slight inflammatory changes in the dermis, oedema, and slight hyperkeratosis.

Pityriasis lichenoides

Pityriasis lichenoides is a less common condition occurring in acute and chronic forms.

The *acute* form presents with widespread pink papules which itch and form crusts, sometimes with vesicle formation suggestive of chickenpox. There may be ulceration. The lesions may develop in crops and resolve over a matter of weeks.

The *chronic* form presents as reddish brown papules—often with a “mica”-like scale that reveals a smooth, red surface underneath, unlike the bleeding points of psoriasis. In lichen planus there is no superficial scale and blistering is unusual.

The distribution is over the trunk, thighs, and arms, usually sparing the face and scalp.

The underlying pathology—vascular dilatation and a lymphocytic infiltrate with a keratotic scale—is in keeping with the clinical appearance. The cause is unknown.

Treatment is with topical steroids. Ultraviolet light treatment is also helpful.

Characteristics of pityriasis lichenoides

Clinical features of psoriasis	Clinical features of eczema
Possible family history	Possible family history
Sometimes related to stress	Sometimes worse with stress
Itching—rare	Usually itching
Extensor surfaces and trunk	Flexor surfaces and face
Well defined, raised lesions	Poorly demarcated lesions

Scaling, bleeding points beneath scales	Secondary infection sometimes present
Koebner’s phenomenon	
Nails affected	
Scalp affected	
Mucous membranes not affected	

Pityriasis lichenoides—distribution pattern

Pityriasis lichenoides showing acute erythematous rash

A mica scale pityriasis lichenoides

Pityriasis versicolor

Pityriasis versicolor is a skin eruption that usually develops after sun exposure with white macules on the tanned skin but pale brown patches on the covered areas, hence the name versicolor, or variable colour. The lesions are: (a) flat; (b) only partially depigmented—areas of vitiligo are totally white; and (c) do not show inflammation or vesicles.

The causative organism is a yeast, *Pityrosporum orbiculare*, that takes advantage of some unknown change in the epidermis and develops a proliferative, stubby, mycelial form, *Malassezia furfur*. This otherwise incidental information can be simply put to practical use by taking a superficial scraping from a lesion on to a microscope slide—add a drop of potassium hydroxide or water with a coverslip. The organisms are readily seen under the microscope as spherical yeast forms and mycelial rods, resembling “grapes and bananas” (“spaghetti and meatballs” in the United States).

Treatment is simple: selenium sulphide shampoo applied regularly with ample water while showering or bathing will clear the infection. The colour change may take some time to clear.

Pityriasis versicolor skin lesions

Ketoconazole shampoo is an effective alternative. Oral terbinafine, which is very effective in other fungal infections, has no effect.

Desquamating stage of generalised erythema

Any extensive acute erythema, from the erythroderma of psoriasis to a penicillin rash, commonly shows a stage of shedding large flakes of skin—desquamation—as it resolves. If only this stage is seen it can be confused with psoriasis.

Desquamation

Localised lesions with epidermal changes

Psoriasis, seborrhoeic dermatitis, atopic eczema, and contact dermatitis can all present with localised lesions.

Psoriasis may affect only the flexures, occur as a genital lesion, or affect only the palms. The lack of itching and epidermal changes with a sharp edge help in differentiation from infective or infiltrative lesions.

Seborrhoeic dermatitis can occur in the axillae or scalp with no lesions of other areas.

In *atopic eczema* the “classical” sites in children—flexures of the elbows and knees and the face—may be modified in adults to localised vesicular lesions on the hands and feet in older patients. Some atopic adults develop severe, persistent generalised eczematous changes.

Contact dermatitis is usually localised, by definition, to the areas in contact with irritant or allergen. Wide areas can be affected in reactions to clothing or washing powder, and sometimes the reaction extends beyond the site of contact.

Flexural seborrhoeic dermatitis

Fungal infections

Apart from athlete’s foot, toenail infections, and tinea cruris (most commonly in men), “ringworm” is in fact not as common as is supposed. The damp, soggy, itching skin of athlete’s foot is well known. An itching, red diffuse rash in the groin differentiates tinea cruris from psoriasis. However, erythrasma, a bacterial infection, may be confused with seborrhoeic dermatitis and psoriasis—skin scrapings can be taken for culture of *Corynebacterium minutissimum* or, more simply, coral pink fluorescence shown with Wood’s light. The scaling macules from dog and cat ringworm (*Microsporum canis*) itch greatly, whereas the indurated pustular, boggy lesion (kerion) of cattle ringworm is quite distinctive.

Fungal infection of the axillae is rare; a red rash here is more likely to be due to erythrasma or seborrhoeic dermatitis.

Tinea cruris is very unusual before puberty and is uncommon in women.

In all cases of suspected fungal infection skin scrapings should be taken on to black paper, in which they can be folded and sent to the laboratory. Special “kits” are available, which contain folded black paper and Sellotape strips on slides for taking a superficial layer of epidermis.

Corynebacterium minutissimum (erythrasma)

Lupus erythematosus

There are two forms of this condition: discoid, which is usually limited to the skin, and systemic, in which the skin lesions are associated with renal disease, arthritis, and other disorders. There is also a subacute type with limited systemic involvement.

Characteristics of systemic and discoid lupus erythematosus

Systemic lupus erythematosus, which is much more common in women than men, can be an acute, fulminating, multisystem disease that requires intensive treatment, or a more chronic progressive illness. Characteristically there is malar erythema with marked photosensitivity and a butterfly pattern. It may be transient. There may be scalp involvement as well with alopecia and also telangiectasia of the perifungal blood vessels. Mouth ulcers may also be present. Systemic involvement may cause nephritis, polyarteritis, leukopenia, pleurisy, myocarditis, and central nervous system involvement.

Systemic lupus erythematosus can present in many forms and imitate other diseases. The facial rash can resemble rosacea, cosmetic allergy, or sun sensitivity. Systemic involvement may present with lassitude, weight loss, anaemia, arthritis, renal failure, dyspnoea, or cardiac signs among others.

Criteria for making a diagnosis of systemic lupus erythematosus have been established, of which at least four must be present.

In the subacute variety there is less severe systemic involvement, with scattered lesions occurring on the face, scalp, chest, and arms.

Treatment is with systemic steroids, with immunosuppressive agents if necessary. Antimalarial drugs, such as hydroxychloroquine, are more effective in the subacute type.

In *discoid lupus erythematosus* there are well defined lesions with a combination of atrophy and hyperkeratosis of the hair follicles giving a “nutmeg grater” appearance. They occur predominantly on the cheeks, nose, and forehead. It is about three times as common in women as men, which is a lower ratio than in the systemic variety. There is a tendency for the skin lesions to gradually progress and to flare up on sun exposure. It is rare for progression to the systemic type to occur.

Treatment is with moderate to very potent topical steroids and hydroxychloroquine by mouth, together with suitable sun screens.

Fixed drug eruptions

Generalised drug eruptions are considered under erythema, but there is a localised form recurring every time the drug is used. There is usually a well defined, erythematous plaque, sometimes with vesicles. Crusting, scaling, and pigmentation occur as the lesion heals. It is usually found on the limbs, and more than one lesion can occur.

Systemic lupus erythematosus—subacute

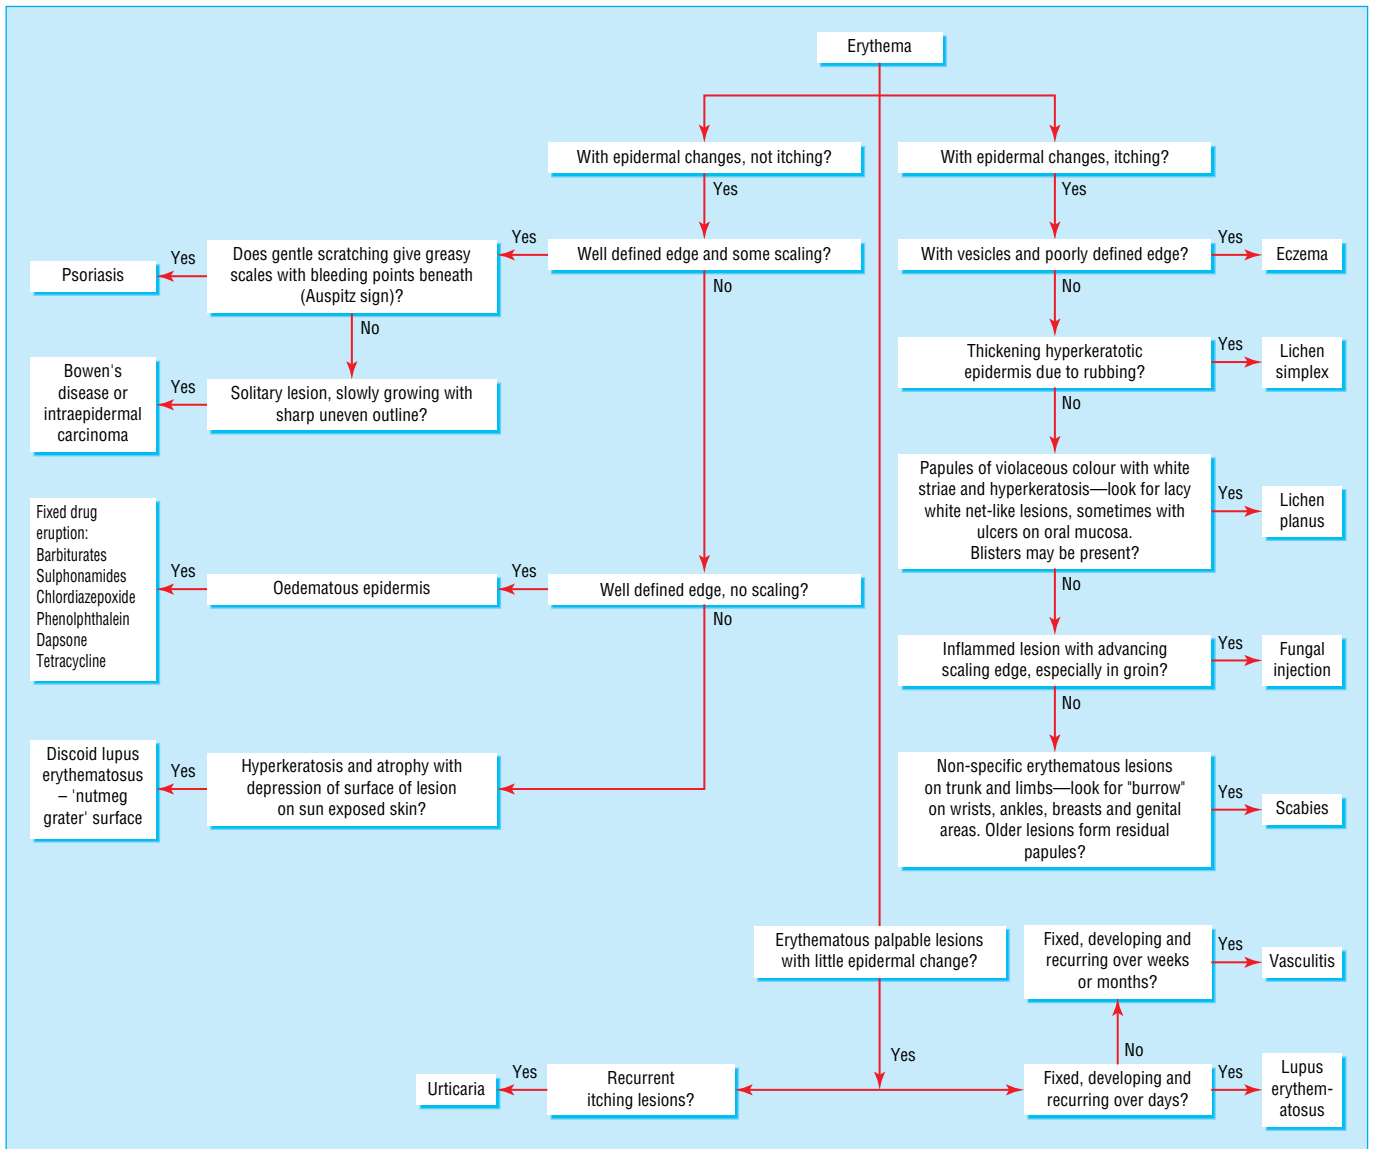

Discoid lupus erythematosus

Fixed drug eruption

Criteria for diagnosing systemic lupus erythematosus

- Malar rash
- Discoid plaques
- Photosensitivity
- Mouth ulcers
- Arthritis
- Serositis
- Renal disease
- Neurological disease
- Haematological changes
- Immunological changes
- Antinuclear antibodies

Causes of epidermal rashes

7 Rashes arising in the dermis

The erythemas

Complex reactions occurring in the capillaries and arterioles of the skin cause erythema, which is simply redness of the skin. This may present as flat macules or as papules, which are raised above the surrounding skin. The lesions may be transient or last for weeks, constant or variable in distribution, with or without vesicles.

It is possible to recognise specific patterns within this plethora of clinical signs, but even the most experienced dermatologist may be reduced to making a general diagnosis of “toxic” erythema. The best we can do therefore is to recognise the common types of erythema and list the possible causes. It is then a matter of deciding on the most likely underlying condition or group of conditions—for example, bacterial infection or autoimmune systemic disease.

Morphology and distribution

Because there can be the same cause for a variety of erythematous rashes detailed descriptions are of limited use. None the less, there are some characteristic patterns.

Morbilliform

The presentation of measles is well known, with the appearance of Koplik’s spots on the mucosa, photophobia with conjunctivitis, and red macules behind the ears, spreading to the face, trunk, and limbs. The prodromal symptoms and conjunctivitis are absent in drug eruptions. Other viral conditions, including those caused by echoviruses, rubella, infectious mononucleosis, and erythema infectiosum, may have to be considered.

Scarlatiniform

These rashes are similar to that in scarlet fever, when an acute erythematous eruption occurs in relation to a streptococcal infection. Characteristically erythema is widespread on the trunk. There is intense erythema and engorgement of the pharyngeal lymphoid tissue with an exudate and a “strawberry” tongue. Bacterial infections can produce a similar rash, as can drug rashes, without the systemic symptoms.

Figurate erythemas

These are chronic erythematous rashes forming annular or serpiginous patterns. There may be underlying malignancy or connective tissue disease.

Erythema multiforme

Erythema multiforme is sometimes misdiagnosed because of the variety of lesions and number of possible precipitating causes; some of these are listed in the box on the right.

Erythema from antibiotics

Causes of “toxic” erythema

Drugs

- Antibiotics, barbiturates, thiazides

Infections

- Any recent infections such as streptococcal throat infection or erysipelas; spirochaetal infections; viral infections

Systemic causes

- Pregnancy; connective tissue disease; malignancy

Erythema multiforme: precipitating causes

Infections

- Herpes simplex—the commonest cause
- Mycoplasma infection
- Infectious mononucleosis
- Poliomyelitis (vaccine)
- Many other viral and bacterial infections
- Any focal sepsis
- BCG inoculation

Collagen disease

- Systemic lupus erythematosus
- Polyarteritis nodosa

Neoplasia

- Hodgkin’s disease
- Myeloma
- Carcinoma

Chronic inflammation

- Sarcoidosis
- Wegener’s granuloma

Drugs

- Barbiturates
- Sulphonamides
- Penicillin
- Phenothiazine and many others

Erythema multiforme

Erythema multiforme

ABC of Dermatology

Clinical picture

The usual erythematous lesions occur in crops on the limbs and trunk. Each lesion may extend, leaving a cyanotic centre, which produces an “iris” or “target” lesion. Bullae may develop in the lesions and on the mucous membranes. A severe bullous form, with lesions on the mucous membranes, is known as the Stevens–Johnson syndrome. There may be neural and bronchial changes as well. Barbiturates, sulphonamides, and other drugs, are the most common cause.

Histologically there are inflammatory changes, vasodilatation, and degeneration of the epidermis.

A condition that may be confused is Sweet’s syndrome, which presents as acute plum coloured raised painful lesions on the limbs—sometimes the face and neck—with fever. It is more common in women. The alternative name, “acute febrile neutrophilic dermatosis”, describes the presentation and the pathological findings of a florid neutrophilic infiltrate. There is often a preceding upper respiratory infection. Treatment with steroids produces a rapid response but recurrences are common.

Erythema induratum

Erythema induratum occurs on the lower legs posteriorly, usually in women, with diffuse, indurated dusky red lesions that may ulcerate. It is more common in patients with poor cutaneous circulation. Epithelioid cell granulomas may form.

This erythema was originally described in association with tuberculous infection elsewhere in the body (Bazin’s disease). It represents a vasculitic reaction to the infection, and when there is no tuberculous infection another chronic infection may be responsible.

Erythema nodosum

Erythema nodosum occurs as firm, gradually developing lesions, predominantly on the extensor aspect of the legs. They are tender and progress over four to eight weeks from an acute erythematous stage to residual lesions resembling bruises.

Single or multiple lesions occur, varying in size from 1 to 5 cm. The lesions are often preceded by an upper respiratory tract infection and may be associated with fever and arthralgia. Infections (streptococcal, tuberculous, viral, and fungal) and sarcoidosis are the commonest underlying conditions. Drugs can precipitate erythema nodosum, the contraceptive pill and the sulphonamides being the commonest cause. Ulcerative colitis, Crohn’s disease, and lymphoma may also be associated with the condition.

Annular lesions of erythema multiforme

Annular lesions of erythema multiforme

Blistering lesions of erythema multiforme

Erythema induratum

Rashes due to drugs

There is an almost infinite variety of types of drug reaction.

External contact with drugs can cause a contact dermatitis presenting with eczematous changes. This occurs commonly with neomycin and bacitracin. Chloramphenicol and sulphonamides from ophthalmic preparations can also cause dermatitis around the eyes. Penicillin is a potent sensitiser so is not used for topical treatment.

Topical neomycin allergy

Same patient after withdrawing neomycin

Erythema nodosum

Drugs used systemically can cause a localised fixed drug eruption or a more diffuse macular or papular erythema, symmetrically distributed. In the later stages exfoliation, with shedding scales of skin, may develop. Antibiotics, particularly penicillins, are the most common cause. They also cause erythema multiforme as already mentioned.

Penicillins are the most common cause of drug rashes, which range from acute anaphylaxis to persistent diffuse erythematous lesions. Joint pains, fever, and proteinuria may be associated, as in serum sickness.

Ampicillin often produces a characteristic erythematous maculopapular rash on the limbs seven to 20 days after the start of treatment. Such rashes occur in nearly all patients with infectious mononucleosis who are given ampicillin.

Fixed drug eruption

Vasculitis

Inflammation associated with immune complexes in the capillaries and small blood vessels is part of the pathological changes of many of the conditions described above. The term vasculitis is also used clinically to describe a variable clinical picture with red macules and papules and with necrosis and bruising in severe cases. In children purpura is more prominent and these cases are classified as Henoch–Schönlein purpura. The legs and arms are usually affected. Skin signs are preceded by malaise and fever with arthropathy and there may be associated urticaria. As a high proportion of cases are associated with systemic lesions, it is essential to check for renal, skeletal, gastrointestinal, and central nervous system disease. In children with Henoch–Schönlein purpura nephritis is common.

Vasculitis

Drug reactions

Blistering eruptions

- Barbiturates
- Sulphonamides
- Iodines or bromides
- Chlorpropamide
- Salicylates
- Phenylbutazone

Lichen planus like reactions

- Chloroquine
- Chlorothiazide
- Chlorpropamide

Photosensitivity (seen on areas exposed to light)

- Thiazide diuretics
- Sulphonamides
- Tetracyclines

Vasculitis

- Inflammation around dilated capillaries and small blood vessels
- A common component of the erythemas
- May occur as red macules and papules with necrotic lesions on the extremities
- In children a purpuric type (Henoch–Schönlein purpura) occurs in association with nephritis
- Systemic lesions may occur, with renal, joint, gastrointestinal, and central nervous system involvement

Purpura

Is seen on the skin as a result of:

- Thrombocytopenia—platelet deficiency
- Senile purpura—due to shearing of capillaries as a result of defective supporting connective tissue
- Purpura in patients on corticosteroid treatment—similar to senile purpura
- Schamberg's disease—brown macules and red spots resembling cayenne pepper on the legs of men
- Associated vasculitis

Some conditions associated with vasculitis

- Infection—streptococcal, hepatitis
- Drugs—numerous, including sulphonamides, penicillin, phenothiazine, phenacitin
- Chemicals—insecticides, weed killers, phenolic compounds
- Connective tissue diseases—systemic lupus erythematosus, rheumatoid arthritis
- Lymphoma and leukaemia
- Dysproteinemias

Acute vasculitis with necrosis

Necrotising angitis

Urticaria

In this condition itching red weals develop; they resemble the effects of stinging nettle (*Urtica dioica*) on the skin. The condition may be associated with allergic reactions, infection, or physical stimuli, but in most patients no cause can be found. Similar lesions may precede, or be associated with, vasculitis (urticarial vasculitis), pemphigoid, or dermatitis herpetiformis.

The histological changes may be very slight but usually there is oedema, vasodilatation, and a cellular infiltrate of lymphocytes, polymorphs, and histiocytes. Various vasoactive substances are thought to be involved, including histamine, kinins, leukotrienes, prostaglandins, and complement.

Angio-oedema is due to oedema of the subcutaneous tissues; it can occur rapidly and may involve the mucous membranes. Hereditary angio-oedema is a rare form with recurrent severe episodes of subcutaneous oedema, swelling of the mucous membranes, and systemic symptoms. Laryngeal oedema is the most serious complication.

The *physical urticarias*, which account for about 25% of cases, include dermatographism and the pressure, cold, heat, solar, cholinergic, and aquagenic urticarias.

Dermatographism is an exaggerated release of histamine from stroking the skin firmly with a hard object, such as the end of a pencil. *Pressure urticaria* is caused by sustained pressure from clothing, hard seats, and footwear; it may last some hours. *Cold urticaria* varies in severity and is induced by cold, particularly by cold winds or by the severe shock of bathing in cold water. It appears early in life—in infancy in the rare familial form. In a few cases abnormal serum proteins may be found. *Heat urticaria* is rare, but warm environments often make physical urticaria worse. *Solar urticaria* is a rare condition in which sunlight causes an acute urticarial eruption. Tolerance to sun exposure may develop in areas of the body normally exposed to sun. There is sensitivity to a wide spectrum of ultraviolet light. *Cholinergic urticaria* is characterised by the onset of itching urticarial papules after exertion, stress, or exposure to heat. The injection of cholinergic drugs induces similar lesions in some patients. *Aquagenic urticaria* occurs on contact with water, regardless of the temperature.

Non-physical urticaria may be acute in association with allergic reactions to insect bites, drugs, and other factors. Chronic recurrent urticaria is fairly common. Innumerable causes have been suggested but, to the frustration of patient and doctor alike, it is often impossible to identify any specific factor.

Treatment of urticaria

- Eliminate possible causative factors, such as aspirin, and by a diet free from food additives
- Antihistamines. Also, H₂ blockers, for example, cimetidine
- Adrenaline can be used for acute attacks, particularly if there is angio-oedema of the respiratory tract
- Systemic corticosteroids should not be used for chronic urticaria but may be needed for acute urticarial vasculitis

Urticaria

Angio-oedema

Some reported causes of non-physical urticaria

- Food allergies—fish, eggs, dairy products, chocolate, nuts, strawberries, pork, tomatoes
- Food additives—for example, tartrazine dyes, sodium benzoates
- Salicylates—both in medicines and foods
- Infection—bacterial, viral, and protozoal
- Systemic disorders—autoimmune and “collagen” diseases; reticuloses, carcinoma, and dysproteinaemias
- Contact urticaria—may occur from contact with meat, fish, vegetables, plants, and animals, among many other factors
- Papular urticaria—a term used for persistent itching papules at the site of insect bites; it is also sometimes applied to urticaria from other causes
- Inhalants—for example, house dust, animal danders

Dermatographism

8 Blisters and pustules

Development, duration, and distribution

Several diseases may present with blisters or pustules. There is no common condition that can be used as a “reference point” with which less usual lesions can be compared in the same way as rashes can be compared with psoriasis. A different approach is needed for the assessment of blistering or pustular lesions, based on the history and appearance, and is summarised as the three Ds: development, duration, and distribution.

Development

Was there any preceding systemic illness—as in chickenpox, hand, foot, and mouth disease, and other viral infections? Was there a preceding area of erythema—as in herpes simplex or pemphigoid? Is the appearance of the lesions associated with itching—as in herpes simplex, dermatitis herpetiformis, and eczematous vesicles on the hands and feet?

Duration

Some acute blistering arises rapidly—for example, in allergic reactions, impetigo, erythema multiforme, and pemphigus. Other blisters have a more gradual onset and follow a chronic course—as in dermatitis herpetiformis, pityriasis lichenoides, and the bullae of porphyria cutanea tarda. The rare genetic disorder epidermolysis bullosa is present from, or soon after, birth.

Distribution

The distribution of blistering rashes helps considerably in making a clinical diagnosis. The most common patterns of those that have a fairly constant distribution are shown.

Itching is a very useful symptom. If all the accessible lesions are scratched and it is hard to find an intact blister it is probably an itching rash.

Clinical features: widespread blisters

Chickenpox

Chickenpox is so well known in general practice that it is rarely seen in hospital clinics and is sometimes not recognised. The prodromal illness lasts one to two days and is followed by erythematous lesions that rapidly develop vesicles, then pustules, followed by crusts in two to three days. Crops of lesions develop at the same sites—usually on the trunk, face, scalp, and limbs. The oral mucosa may be affected. The condition is usually benign.

Dermatitis herpetiformis

Dermatitis herpetiformis occurs in early and middle adult life and is characterised by symmetrical, intensely itching vesicles on the trunk and extensor surfaces. The vesicles are superficial. The onset is gradual, but may occur rapidly. The distribution is shown in the diagram.

Variants of dermatitis herpetiformis are larger blisters forming bullae and erythematous papules and vesicles.

Associated conditions

Coeliac disease with villous atrophy and gluten intolerance may occur in association with dermatitis herpetiformis. Linear IgA

The differential diagnosis of blistering eruptions

Widespread blisters

- Eczema—lichenification and crusting, itching
- Dermatitis herpetiformis—itching, extensor surface, persistent
- Chickenpox—crops of blisters, self limiting, prodromal illness
- Pityriasis lichenoides—pink papules, developing blisters
- Erythema multiforme—erythematous and “target” lesions, mucous membranes affected
- Pemphigoid—older patients, trunk, and flexures affected. Preceding erythematous lesions, deeply situated, tense blisters
- Pemphigus—adults, widespread superficial blisters, mucous membranes affected (erosions)
- Drug eruptions—history of drugs prescribed, overdose (barbiturates, tranquillisers)

Localised blisters

- Eczema—“pompholyx” blisters on hand and feet, itching
- Allergic reactions, including topical medication, insect bites
- Psoriasis—deep, sterile, non-itching blisters on palms and soles
- Impetigo—usually localised, staphylococci and streptococci isolated
- Herpes simplex—itching lesions developing turbid blisters

Diseases presenting with blisters and pustules

Itching	Non-itching
Eczema pompholyx on hands and feet	Erythema multiforme
Allergic reactions	Pemphigus vulgaris
Dermatitis herpetiformis	Bullous pemphigoid
Chickenpox	Bullous impetigo
Herpes simplex	Insect bite allergy
	Pustular psoriasis on hands and feet

Dermatitis herpetiformis

Dermatitis herpetiformis

Dermatitis herpetiformis—distribution pattern

ABC of Dermatology

disease is a more severe, widespread disease, in which there are “linear” deposits of IgA along the basement membrane of the epidermis and not only at the tips of the papillae as in dermatitis herpetiformis. Treatment is with dapsone or sulfapyridine together with a gluten free diet.

Erythema multiforme with blisters

Blisters can occur on the lesions of erythema multiforme to a variable degree; when severe, generalised, and affecting the mucous membranes it is known as Stevens–Johnson syndrome. The typical erythematous maculopapular changes develop over one to two days with a large blister (bulla) developing in the centre of the target lesions. In severe progressive cases there is extensive disease of the mouth, eyes, genitalia, and respiratory tract. The blisters are subepidermal, although some basement membrane remains on the floor of the blister.

Pityriasis lichenoides varioliformis acuta

As the name implies lichenified papules are the main feature of pityriasis lichenoides varioliformis acuta (or Mucha–Habermann disease), but vesicles occur in the acute form. Crops of pink papules develop centrally, with vesicles, necrosis, and scales—resembling those of chickenpox—hence the “varioliformis”. There is considerable variation in the clinical picture, and a prodromal illness may occur. The condition may last from six weeks to six months. No infective agent has been isolated. The pathological changes parallel the clinical appearance with inflammation around the blood vessels and oedema within the dermis.

Pemphigoid

The bullous type of pemphigoid is a disease of the elderly in which tense bullae develop rapidly, often with a preceding erythematous rash, as well as on normal skin. It is mainly seen in the elderly and is slightly more common in women. The flexural aspects of the limbs and trunk and flexures are mainly affected. The bullae are subepidermal and persistent, with antibodies deposited at the dermo-epidermal junction. Unlike pemphigus there is a tendency for the condition to remit after many months.

Another type of pemphigoid occurs in which there is scarring of the oral mucous membrane and the conjunctiva. Occasionally localised lesions are seen on the legs with evidence of an immune reaction, but often the absence of circulating antibasement membrane antibodies. This is a relatively benign condition and often responds to topical steroids.

Treatment is with corticosteroids by mouth, 40–60 mg daily in most patients, although higher doses are required by some. Azathioprine aids remission, with reduced steroid requirements, but takes some weeks to produce an effect. It is essential to check the serum thiopurine methyl transferase (TPMT) level before starting treatment. Patients with low levels have impaired ability to metabolise azathioprine and are likely to suffer toxic effects. Topical steroids can be used on developing lesions.

Chronic scarring pemphigoid affects the mucous membranes with small bullae that break down, leading to erosions and adhesions in the conjunctivae, mouth, pharynx, and genitalia.

There is also a localised type of pemphigoid occurring on the legs of elderly women that runs a benign self-limiting course.

Erythema multiforme in Stevens–Johnson syndrome

Erythema multiforme showing blisters

Pityriasis lichenoides

Bullous pemphigoid

Mucous membrane pemphigoid

Bullous pemphigoid—distribution pattern

Pemphigus

The most common form of pemphigus vulgaris is a chronic progressive condition with widespread superficial bullae arising in normal skin. In about half of the cases this is preceded by blisters and erosions in the mouth. The bullae are easily broken, and even rubbing apparently normal skin causes the superficial epidermis to slough off (Nikolsky sign). These changes are associated with the deposition of immunoglobulin in the epidermal intercellular spaces. It is a serious condition with high morbidity, despite treatment with steroids and azathioprine. Pemphigus vegetans and pemphigus erythematosus are less common variants.

Differential diagnosis of ulcers in the mouth

- Trauma (dentures)
- Aphthous ulcers
- *Candida albicans* infection
- Herpes simplex
- Erythema multiforme (from drugs)
- Pemphigus
- Lichen planus
- Carcinoma

Pemphigus—distribution pattern

Clinical features: localised blisters

Pompholyx, which means “a bubble”, is characterised by persistent, itchy, clear blisters on the fingers, which may extend to the palms, with larger blisters. The feet may be affected. Secondary infection leads to turbid vesicle fluid. Pompholyx may be associated with a number of conditions— atopy, stress, fungal infection elsewhere, and allergic reactions. It may occur as a result of ingesting nickel in nickel sensitive patients and a similar reaction has been reported to neomycin.

Pustular psoriasis is characterised by deep seated sterile blisters, often with no sign of psoriasis elsewhere—hence the term palmopustular pustulosis. Foci of sepsis have long been considered a causative factor and recent studies have shown a definite association with cigarette smoking. The pattern of HLA antigens indicates that this may be a separate condition from psoriasis.

Bullous impetigo is seen in children and adults. Staphylococci are usually isolated from the blister fluid. The blisters are commonly seen on the face and are more deeply situated than in the non-bullous variety.

Herpes simplex. Primary infection with type I virus occurs on the face, lips, and buccal mucosa in children and young adults. Type II viruses cause genital infection. Itching may be severe.

Pemphigus vulgaris

Nikolsky sign

Pompholyx

Pustular psoriasis

Bullous impetigo

Herpes simplex—type I virus infection

Herpes simplex—type II virus infection

ABC of Dermatology

Herpes zoster is due to varicella virus producing groups of vesicles in a dermatome distribution, usually thoracic, trigeminal, or lumbosacral. It is more common after the fourth decade of life.

Insect bite allergy. Large blisters, which are usually not itching, can occur on the legs of susceptible individuals.

Bullous drug eruptions. Fixed drug eruptions can develop bullae, and some drugs can cause a generalised bullous eruption, particularly:

- Barbiturates (particularly if taken in overdose)
- Sulphonamides
- Penicillins
- Penicillamine } pemphigus-like blisters
- Captopril }
- Frusemide (may be phototoxic)

Remember that there may be an associated erythematous eruption.

Herpes zoster

Herpes zoster

Insect bite allergy

9 Leg ulcers

Although the patient will not probably die of this disease, yet, without great care, it may render her miserable. The disease may be very much relieved by art, and it is one of very common occurrence.

Sir Benjamin Brodie (1846)

Despite the great increase in our understanding of the pathology of leg ulcers, their management is still largely “art”. Consequently there are numerous treatments, each with their enthusiastic advocates. There are, however, basic concepts which are helpful in management. As about 95% of leg ulcers are of the “venous” or gravitational variety these will be considered first.

Venous leg ulcers

Pathology of venous ulcers

The skin

Ulcers arise because the skin dies from inadequate provision of nutrients and oxygen. This occurs as a consequence of (a) oedema in the subcutaneous tissues with poor lymphatic and capillary drainage and (b) the extravascular accumulation of fibrinous material that has leaked from the blood vessels. The result is a rigid cuff around the capillaries, preventing diffusion through the wall, and fibrosis of the surrounding tissues.

The blood vessels

Arterial perfusion of the leg is usually normal or increased, but stasis occurs in the venules. The lack of venous drainage is a consequence of incompetent valves between the superficial veins and the deeper large veins on which the calf muscle “pump” acts. In the normal leg there is a superficial low pressure venous system and deep high pressure veins. If the blood flow from superficial to deep veins is reversed then the pressure in the superficial veins may increase to a level that prevents venous drainage, Venose veins with “back pressure” causing stasis and oedema.

Incompetent valves

Incompetent valves leading to gravitational ulcers may be preceded by:

- (1) deep vein thrombosis associated with pregnancy or, less commonly, leg injury, immobilisation, or infarctions in the past
- (2) primary long saphenous vein insufficiency
- (3) familial venous valve incompetence that presents at an earlier stage—there is a familial predisposition in half of all patients with leg ulcers—or
- (4) deep venous obstruction.

Varicose veins

Ulcers and fibrosis

Incompetent flow in legs

Healthy valves in legs

Incompetent valves in legs

ABC of Dermatology

Who gets ulcers?

Mainly women get ulcers—2% of those over 80 have venous ulcers as a long term consequence of the factors listed above. Leg ulcers are more likely to occur and are more severe in obese people.

Clinical changes

Oedema and fibrinous exudate often lead to fibrosis of the subcutaneous tissues, which may be associated with localised loss of pigment and dilated capillary loops, an appearance known as “atrophic blanche”. This occurs around the ankle with oedema and dilated tortuous superficial veins proximally and can lead to “champagne bottle legs”, the bottle, of course, being inverted. Ulceration often occurs for the first time after a trivial injury.

Lymphoedema results from obliteration of the superficial lymphatics, with associated fibrosis. There is often hypertrophy of the overlying epidermis with a “polypoid” appearance, also known as lipodermatosclerosis.

Venous ulcers occur around the ankles, commonly over the medial malleolus. The margin is usually well defined with a shelving edge, and a slough may be present. There may also be surrounding eczematous changes. Venous ulcers are not usually painful but arterial ulcers are.

It is important to check the pulses in the leg and foot as compression bandaging of a leg with impaired blood flow can cause ischaemia and necrosis.

Treatment

When new epidermis can grow across an ulcer it will, and the aim is to produce an environment in which this can take place. To this end several measures can be taken:

- (1) Oedema may be reduced by means of: (a) diuretics; (b) keeping the legs elevated when sitting; (c) avoiding standing as far as possible; (d) raising the heels slightly from time to time helps venous return by the “calf muscle pump”; (e) applying compression bandages to create a pressure gradient towards the thigh.
- (2) Exudate and slough should be removed. Lotions can be used to clean the ulcer and as compresses—0.9% saline solution, sodium hypochlorite solution, Eusol, or 5% hydrogen peroxide.

Atrophie blanche

“Champagne bottle legs” with ulceration

“Champagne bottle legs” with ulceration

Bandaging

Cleaning the ulcers

Cleaning with saline solution

Applying antiseptic cream

There is some evidence that antiseptic solutions and chlorinated solutions (such as sodium hypochlorite and Eusol) delay collagen production and cause inflammation. Enzyme preparations may help by “digesting” the slough. To prevent the formation of granulation tissue use silver nitrate 0.25% compresses, a silver nitrate “stick” for more exuberant tissue, and curettage, if necessary.

- (3) The dressings applied to the ulcer can consist of:
 - (a) simple non-stick, paraffin gauze dressings—an allergy may develop to those with an antibiotic; (b) wet compresses with saline or silver nitrate solutions for exudative lesions; (c) silver sulfadiazine (Flamazine) or hydrogen peroxide creams (Hioxyl); and (d) absorbent dressings, consisting of hydrocolloid patches or powder, which are helpful for smaller ulcers.
- (4) Paste bandages, impregnated with zinc oxide and antiseptics or ichthammol, help to keep dressings in place and provide protection. They may, however, traumatise the skin, and allergic reactions to their constituents are not uncommon.
- (5) Treatment of infection is less often necessary than is commonly supposed. All ulcers are colonised by bacteria to some extent, usually coincidental staphylococci. A purulent exudate is an indication for a broad spectrum antibiotic and a swab for bacteriology. Erythema, oedema, and tenderness around the ulcers suggest a β haemolytic streptococcal infection, which will require long term antibiotic treatment. Dyes can be painted on the edge of the ulcer, where they fix to the bacterial wall as well as the patient’s skin. In Scotland bright red eosin is traditionally used, while in the south a blue dye, gentian violet, is favoured. Systemic antibiotics have little effect on ulcers but are indicated if there is surrounding cellulitis. A swab for culture and sensitivity helps to keep track of organisms colonising the area.
- (6) Surrounding eczematous changes should be treated. Use topical steroids, not more than medium strength, avoiding the ulcer itself. Ichthammol 1% in 15% zinc oxide and white soft paraffin or Ichthopaste bandages can be used as a protective layer, and topical antibiotics can be used if necessary. It is important to remember that any of the commonly used topical preparations can cause an allergic reaction: neomycin, lanolin, formaldehyde, tars, Chinaform (the “C” of many proprietary steroids).
- (7) Skin grafting can be very effective. There must be a healthy viable base for the graft, with an adequate blood supply; natural re-epithelialisation from the edges of the ulcer is a good indication that a graft will be supported. Pinch grafts or partial thickness grafts can be used. Any clinical infection, particularly with pseudomonas organisms, should be treated.
- (8) Maintaining general health, with adequate nutrition and weight reduction, is important.
- (9) Corrective surgery for associated venous abnormalities.

Arterial ulcers

Ulcers on the leg also occur as a result of: (a) atherosclerosis with poor peripheral circulation, particularly in older patients; (b) vasculitis affecting the larger subcutaneous arteries; and (c) arterial obstruction in macroglobulinaemia, cryoglobulinaemia, polycythaemia, and “collagen” disease, particularly rheumatoid arthritis.

Applying ichthopaste bandages as a protective layer

Bandaging ulcers

Treatment of venous leg ulcers

- Take measures to eliminate oedema and reduce weight—make sure the patient understands these
- Never apply steroid preparations to the ulcer itself or it will not heal. Make sure that both nurses and patients are aware of this
- Beware of allergy developing to topical agents—especially to antibiotics
- There is no need to submit the patient to a variety of antibiotics according to the differing bacteria isolated from leg ulcer slough, unless there is definite evidence of infection of adjacent tissue clinically
- A vascular “flare” around the ankle and heel with varicose veins, sclerosis, or oedema indicates a high risk of ulceration developing
- Make sure arterial pulses are present. A Doppler apparatus can be used

Arterial ulcer

ABC of Dermatology

Arterial ulcers are sharply defined and accompanied by pain, which may be very severe, especially at night. The leg, especially the pretibial area, is affected rather than the ankle. In patients with hypertension a very tender ulcer can develop posteriorly (Martorelli's ulcer).

As mentioned above, compression bandaging will make arterial ulcers worse and may lead to ischaemia of the leg.

Diagnosis

The differing presentation of arterial and venous ulcers helps in distinguishing between them, but some degree of arterial insufficiency often complicates venous ulcers.

Phlebography and Doppler ultrasound may help in detecting venous incompetence and arterial obstruction, which can sometimes be treated surgically.

Ulcers on the leg may also occur secondary to other diseases, because of infection, in malignant disease, and after trauma.

Secondary ulcers

Ulcers occur in diabetes, in periarteritis nodosa, and in vasculitis. Pyoderma gangrenosum, a chronic necrotic ulcer with surrounding induration, may occur in association with ulcerative colitis or rheumatoid vasculitis.

Infections

Infections that cause ulcers include staphylococcal or streptococcal infections, tuberculosis (which is rare in the United Kingdom but may be seen in recent immigrants), and anthrax.

Malignant diseases

Squamous cell carcinoma may present as an ulcer or, rarely, develop in a pre-existing ulcer. Basal cell carcinoma and melanoma may develop into ulcers, as may Kaposi's sarcoma.

Trauma

Patients with diabetic or other types of neuropathy are at risk of developing trophic ulcers. Rarely they may be self induced—"dermatitis artefacta".

Ulcer in diabetic foot

Tuberculous ulceration

Squamous cell carcinoma in venous ulcer

Dermatitis artefacta

10 Acne and rosacea

Acne goes with adolescence, a term derived from the Greek “acme” or prime of life. The young girl who is desperately aware of the smallest comedo and the young man, with his face or back a battlefield of acne cysts and scars, are familiar to us all. Both need treatment and help in coming to terms with their condition.

What is acne?

Acne lesions develop from the sebaceous glands associated with hair follicles—on the face, external auditory meatus, back, chest, and anogenital area. (Sebaceous glands are also found on the eyelids and mucosa, prepuce and cervix, where they are not associated with hair follicles.) The sebaceous gland contains holocrine cells that secrete triglycerides, fatty acids, wax esters, and sterols as “sebum”. The main changes in acne are:

- (1) an increase in sebum secretion;
- (2) thickening of the keratin lining of the sebaceous duct, to produce blackheads or comedones—the colour of blackheads is due to melanin, not dirt;
- (3) an increase in *Propionibacterium acnes* bacteria in the duct;
- (4) an increase in free fatty acids;
- (5) inflammation around the sebaceous gland, probably as a result of the release of bacterial enzymes.

Underlying causes

There are various underlying causes of these changes.

Hormones

Androgenic hormones increase the size of sebaceous glands and the amount of sebum in both male and female adolescents. Oestrogens have the opposite effect in prepubertal boys and eunuchs. In some women with acne there is lowering of the concentration of sex hormone binding globulin and a consequent increase in free testosterone concentrations. There is probably also a variable increase in androgen sensitivity. Oral contraceptives containing more than 50 micrograms ethinyloestradiol can make acne worse and the combined type may lower sex hormone binding globulin concentrations, leading to increased free testosterone. Infantile acne occurs in the first few months of life and may last some years. Apart from rare causes, such as adrenal hyperplasia or virilising tumours, transplacental stimulation of the adrenal gland is thought to result in the release of adrenal androgens—but this does not explain why the lesions persist. It is more common in boys.

Fluid retention

The premenstrual exacerbation of acne is thought to be due to fluid retention leading to increased hydration of and swelling of the duct. Sweating also makes acne worse, possibly by the same mechanism.

Diet

In some patients acne is made worse by chocolate, nuts, and coffee or fizzy drinks.

Acne cysts and scars

Sebaceous gland—histology of acne

Sebaceous gland—pathology in acne

Hormones—the cause of all the trouble

- Androgens
 - increase the size of sebaceous glands
 - increase sebum secretion
- Androgenic adrenocorticosteroids—have the same effect
- Oestrogens—have the opposite effect

ABC of Dermatology

Seasons

Acne often improves with natural sunlight and is worse in winter. The effect of artificial ultraviolet light is unpredictable.

External factors

Oils, whether vegetable oils in the case of cooks in hot kitchens or mineral oils in engineering, can cause "oil folliculitis", leading to acne-like lesions. Other acnegenic substances include coal tar, dicophane (DDT), cutting oils, and halogenated hydrocarbons (polychlorinated biphenols and related chemicals). Cosmetic acne is seen in adult women who have used cosmetics containing comedogenic oils over many years.

Iatrogenic factors

Corticosteroids, both topical and systemic, can cause increased keratinisation of the pilosebaceous duct. Androgens, gonadotrophins, and corticotrophin can induce acne in adolescence. Oral contraceptives of the combined type can induce acne, and antiepileptic drugs are reputed to cause acne.

Types of acne

Acne vulgaris

Acne vulgaris, the common type of acne, occurs during puberty and affects the comedogenic areas of the face, back, and chest. There may be a familial tendency to acne. Acne vulgaris is slightly more common in boys, 30–40% of whom have acne between the ages of 18 and 19. In girls the peak incidence is between 16 and 18 years. Adult acne is a variant affecting 1% of men and 5% of women aged 40. Acne keloidalis is a type of scarring acne seen on the neck in men.

Patients with acne often complain of excessive greasiness of the skin, with "blackheads", "pimples", or "plukes" developing. These may be associated with inflammatory papules and pustules developing into larger cysts and nodules. Resolving lesions leave inflammatory macules and scarring. Scars may be atrophic, sometimes with "ice pick" lesions or keloid formation. Keloids consist of hypertrophic scar tissue and occur predominantly on the neck, upper back, and shoulders and over the sternum.

Acne excorée

The changes of acne are often minimal but the patient, often a young girl, picks at the skin producing disfiguring erosions. It is often very difficult to help the patient break this habit.

Infantile acne

Localised acne lesions occur on the face in the first few months of life. They clear spontaneously but may last for some years. There is said to be an associated increased tendency to severe adolescent acne.

Acne conglobata

This is a severe form of acne, more common in boys and in tropical climates. It is extensive, affecting the trunk, face, and limbs. In "acne fulminans" there is associated systemic illness with malaise, fever, and joint pains. It appears to be associated with a hypersensitivity to *P. acnes*. Another variant is pyoderma faciale, which produces erythematous and necrotic lesions and occurs mainly in adult women.

Gram negative folliculitis occurs with a proliferation of organisms such as klebsiella, proteus, pseudomonas, and *Escherichia coli*.

Types of acne

Acne vulgaris

- Affects comedogenic areas
- Occurs mainly in puberty, in boys more than girls
- Familial tendency

Infantile acne

- Face only
- Clears spontaneously

Severe acne

- Acne conglobata
- Pyoderma faciale
- Gram negative folliculitis

Occupational acne

- Oils
- Coal and tar
- Chlorinated phenols
- DDT and weedkillers

Steroids

- Systemic or topical

Hormones

- Combined type of oral contraceptives and androgenic hormones

Acne keloidalis

Acne with comedones

"Ice-pick" scars

Acne vulgaris

Acne fulminans

Pyoderma faciale

Acne conglobata

Gram negative folliculitis

Occupational

Acne-like lesions occur as a result of long term contact with oils or tar as mentioned above. This usually results from lubricating, cutting, or crude oil soaking through clothing. In chloracne there are prominent comedones on the face and neck. It is caused by exposure to polychlorotriphenyl and related compounds and also to weedkiller and dicophane.

Treatment of acne

In most adolescents acne clears spontaneously with minimal scarring. Reassurance and explanation along the following lines helps greatly:

- (1) The lesions can be expected to clear in time.
- (2) It is not infectious.
- (3) The less patients are self conscious and worry about their appearance the less other people will take any notice of their acne.

It helps to give a simple regimen to follow, enabling patients to take some positive steps to clear their skin and also an alternative to picking their spots.

Patients with acne should be advised to hold a hot wet flannel on the face (a much simpler alternative to the commercial "Facial saunas"), followed by gentle rubbing in of a plain soap. Savlon solution, diluted 10 times with water, is an excellent alternative for controlling greasy skin. There are many proprietary preparations, most of which act as keratolytics, dissolving the keratin plug of the comedone. They can also cause considerable dryness and scaling of the skin.

Benzoyl peroxide in concentrations of 1–10% is available as lotions, creams, gels, and washes. Resorcinol, sulphur, and salicylic acid preparations are also available.

Vitamin A acid as a cream or gel is helpful in some patients. A topical tretinoin gel has recently been introduced.

Ultraviolet light therapy is less effective than natural sunlight but is helpful for extensive acne. It is a helpful additional treatment in the winter months.

Oral treatment. The mainstay of treatment is oxytetracycline, which should be given for a week at 1 g daily then 500 mg (250 mg twice daily) on an empty stomach. Minocycline or doxycycline are alternatives that can be taken with food. Perseverance with treatment is important, and it may take some months to produce an appreciable improvement. Erythromycin is an alternative to tetracycline, and co-trimoxazole can be used for Gram negative folliculitis. Tetracycline might theoretically interfere with the absorption of progesterone types of birth control pill and should not be given in pregnancy.

Topical antibiotics. Erythromycin, the tetracyclines, and clindamycin have been used topically. There is the risk of producing colonies of resistant organisms.

Antiandrogens. Cyproterone acetate combined with ethinylestradiol is effective in some women; it is also a contraceptive.

Synthetic retinoids. For severe cases resistant to other treatments these drugs, which can be prescribed only in hospital, are very effective and clear most cases in a few months. 13-cis-Retinoic acid (isotretinoin) is usually used for acne. They are teratogenic, so there must be no question of pregnancy, and can cause liver changes with raised serum lipid values. Regular blood tests are therefore essential. A three month course of treatment usually gives a long remission. Recently topical isotretinoin gel has been introduced.

Residual lesions, keloid scars, cysts, and persistent nodules can be treated by injection with triamcinolone or freezing with

Treatment of acne

First line	Second line	Third line
Encourage positive attitudes	Topical vitamin A acid	Oral retinoids for 3–4 months (hospitals only)
Avoid environmental and occupational factors	Topical antibiotics	
Topical treatment Benzoyl peroxide Salicylic acid	Ultraviolet light	
A tetracycline by mouth for several months	Antiandrogens	

Acne before treatment

Acne after treatment

Severe cystic acne before (left) and after (right) treatment with tetracycline

Keloid scars

Keloid scars on dark skin

liquid nitrogen. For severe scarring dermabrasion can produce good cosmetic results. This is usually carried out in a plastic surgery unit.

Rosacea

Rosacea is a persistent eruption occurring on the forehead and cheeks. It is more common in women than men.

There is erythema with prominent blood vessels. Pustules, papules, and oedema occur. Rhinophyma, with thickened erythematous skin of the nose and enlarged follicles, is a variant. Conjunctivitis and blepharitis may be associated. It is usually made worse by sunlight.

Rosacea should be distinguished from:

- Acne, in which there are blackheads, a wider distribution, and improvement with sunlight. Acne, however, may coexist with rosacea—hence the older term “acne rosacea”.
- Seborrhoeic eczema, in which there are no pustules and eczematous changes are present.
- Lupus erythematosus, which shows light sensitivity, erythema, and scarring but no pustules.
- Perioral dermatitis, which occurs in women with pustules and erythema around the mouth and on the chin. There is usually a premenstrual exacerbation. Treatment is with oral tetracyclines.

Treatment

The treatment of rosacea is with long term courses of oxytetracycline, which may need to be repeated. Topical treatment along the lines of that for acne is also helpful. Topical steroids should not be used as they have minimal effect and cause a severe rebound erythema, which is difficult to clear. Avoiding hot and spicy foods may help.

Recent reports indicate that synthetic retinoids are also effective.

Lupus erythematosus

Remember the following points

- Avoid topical steroids
- Persevere with one antibiotic not short courses of different types
- Do not prescribe a tetracycline for children and pregnant women
- Oxytetracycline must be taken on an empty stomach half an hour before meals

11 The hair and scalp

D Kemmett

Introduction

Hair, which has an essential physiological role in animals, is mainly of psychological importance in man. A good head of hair provides some degree of warmth for the human head and also protection from ultraviolet radiation, but its significance is otherwise in the eye of the beholder. In the form of wool, hair is of economic importance and considerable research has been carried out into the cycles of growth and the structure of wool keratin in sheep.

Too much hair, particularly on the face of women, is an embarrassment and cosmetic problem and loss of hair from the scalp is equally troublesome. Changes in hair growth are not only of cosmetic significance but can also be associated with underlying diseases. Diseases occurring in the skin of the scalp can damage hair follicles leading to loss of hair. This chapter covers: (a) the normal pattern of hair growth; (b) causes of hair loss; (c) skin diseases involving the scalp; (d) causes of excess hair growth; (e) abnormalities of the hair itself; and (f) treatment.

The normal pattern of hair growth

Unlike other epidermal structures which grow continuously, hair has a cyclical pattern of growth. The growing phase or anagen lasts an average of 1000 days on the scalp followed by an involutinal phase known as catagen which is quite short, lasting only a few days. The hair then enters a resting phase, telogen, lasting about 100 days. In man, hair growth is normally asynchronous, with each individual hair following its own cycle independently of the others. The basal layer of the hair bulb from which the hair itself is produced is known as the matrix and contains melanocytes from which melanin pigment is incorporated into the hair. The type of melanin determines the colour and in grey or white hair, pigment production is reduced or absent.

The body surface with the exception of the palms, soles, the lips, and the genitalia, is covered with fine vellus hairs that do not have a medulla and are not pigmented. These hairs develop into longer coarse, medullated, terminal hair on the scalp and eyebrows. At puberty a similar change occurs in the pubic area and the axillae, also on the face and trunk, in the male. These changes are androgen dependent, even in females, but testicular androgen is required to produce beard growth and balding in men.

Racial characteristics and the genetic make-up of the individual determine the type and colour of the hair. Straight black oriental hair is clearly different from the nordic blonde type.

Hair loss

This is known as alopecia, said to be derived from the Latin "alopex", a fox, presumably because of the bald patches of mange seen in wild foxes.

Adult male pattern alopecia is so common as to be considered normal. Circulating levels of testosterone are not

Diagrammatic cross-section of hair at various growth phases

Hair growth cycle

Male pattern baldness

raised in bald men but there is evidence that availability of the hormone to the hair follicle is increased. In postmenopausal women there may be widespread thinning of the hair but loss of hair at the temples often occurs to some degree at an earlier age.

Alopecia may be diffuse or localised. If it is simply due to a physiological derangement of hair growth, the follicles remain intact, whereas inflammation may lead to scarring and loss of the hair follicles. Hence, hair loss can be classified into the categories shown in the illustration on the right.

Adult pattern of alopecia: comparison between men and women

Classification of alopecia

Diffuse hair loss

An interruption of the normal hair cycle leads to generalised hair loss. This may be due to changes in circulating hormones, drugs, inflammatory skin disease, and “stress” of various types.

Telogen effluvium occurs if all the hairs enter into the resting phase together, most commonly after childbirth or severe illness. Two or three months later the new anagen hair displaces the resting telogen hair, resulting in a disconcerting, but temporary, hair loss from the scalp. Stress of any type, such as an acute illness or an operation, causes a similar type of hair loss.

Postfebrile alopecia occurs when a fever exceeds 39°C, particularly with recurrent episodes. It has been reported in a wide range of infectious diseases, including glandular fever, influenza, malaria, and brucellosis. It also occurs in fever associated with inflammatory bowel disease.

Dietary factors such as iron deficiency and hypoproteinaemia may play a role, but are rarely the sole cause of diffuse alopecia.

Severe malnutrition with a protein deficiency results in dystrophic changes with a reduction in the rate of hair growth.

Congenital alopecia may occur in some hereditary syndromes.

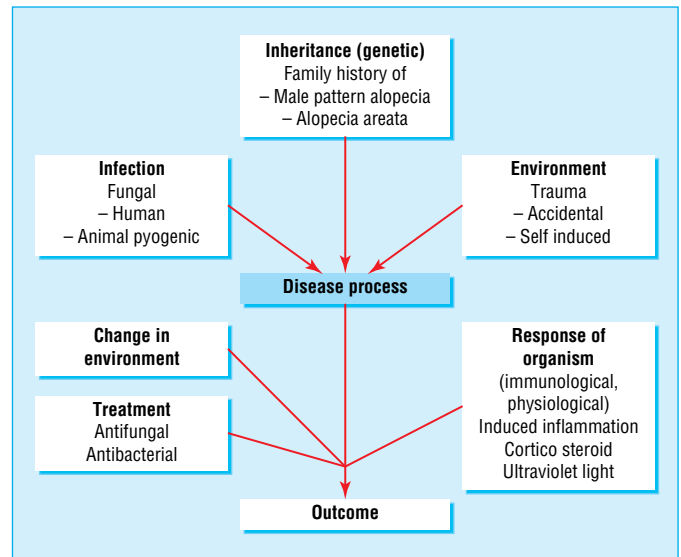

Anagen effluvium occurs when the normal development of hair and follicle is interfered with, resulting in inadequate growth. As a result, hairs are shed earlier than usual, while still in the anagen phase.

Endocrine causes of diffuse alopecia include both hypo- and hyperthyroidism, hypopituitarism, and diabetes mellitus. In hypothyroidism the hair is thinned and brittle, whereas in hypopituitarism the hair is finer and soft but does not grow adequately.

Systemic drugs—cytotoxic agents, anticoagulants, immunosuppressants, and some antithyroid drugs—may cause diffuse hair loss, usually an “anagen effluvium” as mentioned above.

Inflammatory skin disease, when widespread, can be associated with hair loss, for example in erythroderma due to psoriasis or severe eczema.

Deficiency states are a rare cause of alopecia. Patients who suffer from hair loss are often convinced that there is some deficiency in their diet and may sometimes produce the results of an “analysis” of their hairs which show deficiencies in specific trace elements. In fact it is very difficult to cause actual hair loss even in gross malnutrition and in those dying from starvation in refugee camps, the hair growth in the scalp is usually

Factors leading to development of alopecia

Anagen effluvium

Diffuse alopecia caused by ciclosporin

Diffuse alopecia caused by erythrodermic psoriasis

present. In chronic malnutrition or kwashiorkor, the hair assumes a curious red/brown colour which may be due to iron deficiency.

Treatment

Wherever possible, the cause should be treated. This may be a matter of replacement therapy in hormonal deficiency. In alopecia due to stress, once this cause is removed hair growth may revert to normal. Treatment of inflammatory skin disease will result in some improvement of the hair loss.

Androgenic alopecia in men is best accepted, with assurance that it indicates normal virility.

Minoxidil causes hair growth and is commercially available as a lotion. This has to be applied continuously every day as the scalp reverts to a level of loss which would have occurred without treatment as soon as it is stopped. It is effective in about half the patients with male pattern alopecia.

Localised alopecia

Alopecia areata is a common form of hair loss. It is seen in 2% of patients attending the average dermatology clinic in the United Kingdom. There may be small patches of hair loss or the whole scalp may be affected. Resolution occurs in a few months or the condition may persist for years. There may be slight inflammation of the skin in the affected areas—in keeping with the possibility of an underlying immune reaction against the hair follicles. There is also an association with autoimmune disease and atopy.

In the affected areas the follicles are visible and empty. The hairs about to be lost have an “exclamation mark” appearance and in some areas that are resolving, fine vellus hairs are seen. Patches commonly occur on the scalp, face, or eyebrows. In *alopecia totalis*, the whole head is involved, and in *alopecia universalis* hair is lost from the whole of the body.

In many patients, particularly if it is a first episode, regrowth occurs within a few months with fine pale hairs appearing first, being replaced by normal adult hair. In older patients, non-pigmented hair may persist in previous patches of alopecia. Factors associated with a poor prognosis are:

- (1) Repeated episodes of alopecia
- (2) Very extensive or complete hair loss (alopecia totalis)
- (3) Early onset before puberty
- (4) In association with atopy

Differential diagnosis includes trauma from the habit of plucking hair (trichotillomania) in mentally disturbed patients and traction alopecia from tight hair rollers or hair styles that involve tension on the hair. In fungal infections (*tinea capitis*) there is scaling and broken hairs. Fungal spores or hyphae are visible in hair specimens on microscopy.

Inflammation is present with loss of hair follicles in lupus erythematosus and lichen planus.

Treatment

An initial limited area of alopecia areata in adult life can be expected to regrow and treatment is generally not needed. Treatments that are carried out include:

- (1) Injection of triamcinolone diluted with local anaesthetic which usually stimulates localised regrowth of hair. Unfortunately it often falls out again and there is a risk of causing atrophy. Topical steroid lotion can be used but results are variable.

Causes of diffuse non-scarring alopecia

Androgenetic alopecia

Traction alopecia

ABC of Dermatology

- (2) Ultraviolet light or psoralen with ultraviolet A can give good, if transient, results in a few patients but it has little effect in the majority. It may act by suppressing an immune reaction around the hair root.
- (3) Induced contact dermatitis and irritants are occasionally effective. Cantharadin and dithranol have been used for many years as irritants. Primula leaves or chemicals (for example, diphencyprone) can be applied to produce an acute contact dermatitis. The mechanism by which acute inflammation stimulates hair growth is not understood.

Scarring alopecia

The absence of hair follicles is an important physical sign as it indicates:

- (1) The presence of an inflammatory process that requires further investigation.
- (2) That there is unlikely to be any substantial recovery of hair growth.

The presence of inflammation does not necessarily produce marked erythema—in lichen planus and lupus erythematosus, the inflammatory changes are often chronic. Systemic lupus erythematosus produces areas of inflammation that extend, leaving residual scarring. In discoid lupus erythematosus there is more scaling with keratotic plugs in the follicle. Localised scleroderma (morphoea) also causes alopecia, often with a linear atrophic lesion—the *en coup de sabre* pattern.

More acute inflammatory changes are seen as a result of pyogenic infection or kerion in which there is a marked inflammatory reaction to fungal infection from cattle. In “folliculitis decalvans” there is florid folliculitis with deep seated pustules and scarring. Treatment is with prolonged antibiotics.

Tinea capitis can be associated with alopecia.

Trauma can also cause scarring with alopecia.

Skin disease involving the scalp

The scalp can be involved in any skin disease, but most commonly in psoriasis and seborrhoeic eczema. A mild degree of scaling from accumulation in skin scales is so common as to be normal (dandruff). Increased accumulation of scales is seen in seborrhoeic dermatitis in which pityrosporum organisms may play a part. Sometimes masses of thick adherent scales develop in *pityriasis amiantacea*, usually due to psoriasis. Eczema and contact dermatitis can also involve the scalp.

Aetiological factors in alopecia areata

Genetic

- Familial in about 20% of cases
- Associated with Down’s syndrome

Immunological

- T lymphocytic infiltrate around hair follicles
- Associated with autoimmune disease

Stress

- May be associated in individual patients

Causes of scarring alopecia

Trauma

- For example, burns

Inflammation

Acute

- bacterial (pyogenic infection, syphilis)
- viral (herpes simplex, herpes zoster, varicella)
- fungal (kerion caused by animal ringworm)

Chronic

- lupus erythematosus
- lichen planus
- folliculitis decalvans
- morphoea

Rare

- pyoderma gangrenosum
- necrobiosis lipoidica
- sarcoidosis

Scarring in lupus erythematosus

En coup de sabre pattern in alopecia

Folliculitis decalvans

Tinea capitis

Atopic eczema

Pityriasis amiantacea

Contact eczema, hair dye

Treatment

Scaling and inflammatory changes can be improved with the use of sulphur and salicylic ointment. It is effective but messy and best applied at night. Tar preparations, oil of cade, and coconut oil in various formulations are all effective. Topical steroids can also be used to suppress inflammation.

Hair shaft abnormalities

Congenital abnormalities of the hair shaft itself lead to weak, thin and broken hairs. In some cases there is a characteristic appearance, for example “spun glass” appearance of pili torti with a twisted hair. In monilethrix there are regular nodes in the hair shaft.

There are other abnormalities of the hair shaft which are not associated with increased fragility, such as the Willi hair syndrome, progressive kinking of the hair and uncombable hair, in which the hair grows in disorderly profusion, completely resistant to combing and brushing. In pili annulati there may be a spangled appearance due to bright bands in the hair shaft.

Excessive hair

Two types of overgrowth of hair occur:

Hirsuties

This is the growth of coarse terminal hair in a male distribution occurring in a woman. This is not always easy to assess since what is unacceptable and emotionally disturbing to one woman may be quite acceptable to another. The amount of hair growth may appear to be within normal limits in a patient complaining of excessive hair but it should never be dismissed as of no consequence if it is important to the woman concerned. Nevertheless, it is important to limit the number of investigations once it is clear that there is no underlying abnormality. Strong reassurance may then be the most helpful management. It is of course most apparent on the face but is often present on the thighs, abdomen and back as well.

Hirsuties occurs most commonly after the menopause and may be present to some degree in normal women as a result of familial or racial traits. It may arise without any underlying hormonal disorder or as a result of virilising hormones. These causes are listed in the box on the right. In addition to androgens, a number of drugs can cause hirsuties. It is important to remember that hirsuties may be part of a virilising syndrome or polycystic ovaries. It is useful to measure the serum testosterone and oestrogen level, as well as urinary 17 oxosteroid concentrations.

Hypertrichosis

This is an excessive growth of hair which may be generalised or localised. It may be due to metabolic disturbance or drugs, or simply a feature of a localised lesion such as a mole.

Hypertrichosis caused by minoxidil

Cutaneous diseases of the scalp**Common***Inflammatory*

- Psoriasis
- Seborrhoeic eczema
- Contact dermatitis

Infection

- Folliculitis—staphylococcal or streptococcal
- Fungal infection
 - Microsporum, with hair loss
 - Trichophyton, with scaling and inflammation
- Herpes—zoster and simplex

Infestation

- Pediculosis

Less common

- Lupus erythematosus
- Lichen planus
- Pemphigoid and pemphigus

Monilethrix

Monilethrix

Causes of hirsutism

Hereditary, racial with wide variation of normal pattern

Endocrine*Adrenal*

- Virilising tumours
- Cushing's syndrome
- Adrenal hyperplasia

Ovarian

- Virilising tumours
- Polycystic ovary syndrome

Pituitary

- Acromegaly
- Hyperprolactinaemia

Iatrogenic

- Anabolic steroids
- Androgens, corticosteroids
- Danazol, phenytoin
- Psoralens (in psoralen with ultraviolet A)

Hirsuties due to virilising tumour

Treatment

It is clearly important to treat any underlying cause and this will usually improve the condition. Otherwise treatment is symptomatic and includes:

- Removal of hair by shaving or hair removing creams.
- Electrolysis and diathermy, which gives permanent destruction of the hair follicle.
- Antiandrogen drugs such as cyproterone can be used under specialist supervision.

Causes of hypertrichosis

- Naevoid—in pigmented naevi and Becker's naevus
- Congenital (rare)
- Acquired—porphyria, hyperthyroidism, anorexia nervosa some developmental defects, for example, Hurler's syndrome, tumours (hypertrichosis lanuginosa), drugs (diazoxide, minoxidil, ciclosporin)

12 Diseases of the nails

AL Wright

In animals and birds claws are used for digging and grasping as well as for fighting. The human nail may be used as a weapon but its main function is to protect the distal soft tissues of the fingers and toes.

As an ectodermal derivative composed of keratin, the nail plate grows forward from a fold of epidermis over the nail bed which is continuous with the matrix proximally. The keratin composing the nail is derived mainly from the matrix with contributions from the dorsal surface of the nail fold, and the nail bed also adds keratin to the deep surface.

The nail grows slowly for the first day after birth then more rapidly until it slows in old age. The rate of nail growth is greater in the fingers than the toes, particularly on the dominant hand. It is slower in women but increases during pregnancy. Finger nails grow at approximately 0.8 mm per week and toe nails 0.25 mm per week.

Section through finger showing nail structure

Physical signs in the nails

The changes in the nail may be due to a local disease process, a manifestation of a skin disease, or a systemic disorder. Hereditary disorders may also affect the nails. It is therefore important to take both a general history and specifically enquire about skin diseases. It sometimes happens that the nail changes are the only sign of a dermatological disease, although the patient may have a previous history of lichen planus or psoriasis, for example. Localised infection or trauma will affect one or two nails. Skin disease, such as psoriasis, affects many or all nails, usually symmetrically, whereas systemic illness or drugs will affect all the nails.

Effect of trauma

Local nail changes

Trauma

- Acute trauma. This may remove the whole nail.
- Chronic trauma as a result of badly fitting footwear may cause thickening of the nail with deformed growth, onychogryphosis. Chronic trauma due to overenthusiastic manicuring or habitual picking at finger nails can result in deformity and impaired growth.
- Repeated trauma in occupations that involve repetitive action, such as assembling cardboard boxes, may cause detachment of the nail (*onycholysis*) or splitting of the nails.

Paronychia

Infection

- Infection of the tissues around the nail (*paronychia*) is often mixed with pyogenic organisms, including pseudomonas, as well as yeasts such as candida. This condition occurs most frequently in those employed in the food industry and occupations where there is repeated exposure to a moist environment and minor trauma. The index and middle fingers are most frequently involved.
- Infection of the nail plate itself occurs in fungal infections, which are commonly due to *Trichophyton* or *Epidermophyton* species.

Fungal infection

- Those living in the tropics may acquire infection with *Scopulariopsis brevicaulis*, which produces a black discoloration of the nail.

Skin diseases affecting the nails

Since the nail plate consists of specialised keratin produced by basal cells, it is not surprising that it is affected by skin diseases. Some conditions, such as psoriasis, may produce characteristic changes whereas in other conditions, such as eczema, the changes are much less specific.

Psoriasis causes an accumulation of keratin, as in lesions of the skin. This may result in the nail being both thickened and raised from the nail bed (*onycholysis*). There may be the changes of pustular psoriasis in the surrounding tissues, indistinguishable from acrodermatitis pustulosa. Loss of minute plugs of abnormal keratin results in “pitting”.

Lichen planus produces atrophy of the nail plate which may completely disappear. The cuticle may be thickened and grow over the nail plate, known as *pterygium formation*.

Eczema may be associated with brittle nails that tend to split. Thickening and deformity of the nail occurs in eczema or contact dermatitis, sometimes with horizontal ridging.

Darier's disease results in dystrophy of the nail and longitudinal streaks which end in triangular-shaped nicks at the free edge. On the skin there may be the characteristic brownish scaling papules on the central part of the back, chest, and neck. These are made worse by sun exposure.

Alopecia areata is quite often associated with changes in the nails including ridges, leuconychia, and friable nails. It may be associated with “20 nail dystrophy”.

Autoimmune conditions such as pemphigus and pemphigoid may be associated with a variety of changes including ridging, splitting of the nail plate, and atrophy in some or all of the nails.

Discoloration of the nail and friability are associated with *lupus erythematosus*.

Dystrophy due to lupus erythematosus

Pterygium formation due to lichen planus

Nail dystrophy

Beau's line

General diseases affecting the nails

Nail changes in systemic illness

Acute illness results in a transverse line of atrophy known as a Beau's line. Shedding of the nail, *onychomadesis*, may occur in severe illness.

Chronic diseases

Clubbing affects the soft tissues of the terminal phalanx with swelling and an increase in the angle between the nail plate and the nail fold. It is associated with chronic respiratory disease, cyanotic heart disease, and occasionally in chronic gastrointestinal conditions. It is occasionally hereditary and may be unilateral in association with vascular abnormalities.

Colour changes

All the nails may be *white* (leuconychia) due to hypoalbuminaemia in conditions such as cirrhosis of the liver. Brown discoloration is seen in renal failure and the “*yellow nail syndrome*”, may be associated with abnormalities of the lymphatic drainage. The nail may have a yellow colour in jaundice. *Drugs* may cause changes in colour, for example tetracycline may produce yellow nails, antimalarials a blue

Clubbing

Leuconychia

Yellow nail syndrome

discolouration, and chlorpromazine a brown colour. Leuconychia or whiteness of the nails occurs in fungal infections. Small white spots on the nail are quite commonly seen and are thought to be due to trauma of the nail plate.

Longitudinal pigmented streaks result from increased melanin deposition in the nail plate.

Longitudinal brown streaks are frequently seen in individuals with racially pigmented skin, particularly after trauma. This is rare in caucasians but occurs as a result of a benign pigmented naevus at the base of the nail and in associated lentigo. The most important cause to remember is *subungual melanoma*, which may present with a longitudinal deep brown or black streak. Hutchinson's sign with pigmentation extends into the surrounding tissues, particularly the cuticle. Adrenal disease may rarely be associated with longitudinal streaks.

Specific changes in the nail plate

Thickening

This may be due to:

- Hyperkeratosis—psoriasis; fungal infection
- Hypertrophy—chronic trauma (onychogryphosis); pachyonychia congenita
- Atrophy lupus erythematosus—lichen planus; congenital dystrophy.

Thickening of the nail plate may be due to hyperkeratosis in psoriasis, in which case the changes will be symmetrical and there may well also be pitting of the nail and onycholysis. Similar changes are seen in fungal infection of the nail, which may be symmetrical on the toes. Nail clippings should be sent for microscopy and mycological culture.

Hypertrophy of the nail plate occurs as a result of chronic trauma, with only a few nails affected, and is usually seen in the feet.

Pachyonychia congenita is a rare congenital disorder characterised by hypertrophic nails.

Hyperkeratosis, due to the accumulation of keratin under the nail plate, is also seen in psoriasis. It occurs occasionally in association with chronic dermatitis.

Detachment of the nail plate (onycholysis)

- Psoriasis
- Fungal infection
- Trauma
- Thyrotoxicosis.

Onycholysis is due to a detachment of the nail from the nail bed. If it is extensive, there may be complete loss of the nail plate. It is most commonly seen in psoriasis and occasionally in fungal infections of the nail. It may occur as a result of trauma or thyrotoxicosis

Pitting of the surface of the nail plate

- Psoriasis
- Alopecia

Pitting of the nail plate is due to punctate depressions on the surface of the nail plate. They are most often seen in psoriasis but may occur in alopecia areata.

Horizontal ridging

- Beau's lines may be seen after systemic illness and acute episodes of hand dermatitis.

Pigmented streaks

Melanocytic naevus

Psoriasis

Onycholysis due to psoriasis

Onycholysis due to psoriasis

Longitudinal ridging

- Single due to pressure from nail fold tumours
- Multiple due to lichen planus
- Alopecia areata
- Psoriasis
- Darier's disease.

Ridging represents a disturbance of nail growth. Inflammation as seen in acute paronychia or trauma can result in a single nail developing a horizontal ridge. After an acute illness there may be horizontal lines on all the nails. The lines may also occur with eczema.

A single longitudinal ridge can result from pressure due to benign or malignant tumours in the nail fold. A mucoid cyst can produce a longitudinal ridge. Multiple longitudinal lines are characteristic of lichen planus, psoriasis, alopecia areata, and Darier's disease.

Koilonychia is a concave deformity of the nail plate, generally occurring in the finger nails. It may be idiopathic or occur as a result of iron deficiency anaemia.

Lesions adjacent to the nail

Mucoid cysts develop subcutaneously over the distal interphalangeal joint and may be adjacent to the nail, producing abnormalities of growth. These cysts develop as an extension of the synovial membrane and are linked to the joint by a fine tract. Very careful excision is required for a cure.

Naevi may occur adjacent to the nail and a benign melanocytic naevus can produce a pigmented streak. Subungual melanoma may produce considerable pigmentation of the nail and often causes pigmentation of the cuticle, so called Hutchinson's sign. Sometimes subungual melanoma is amelanotic so there is no pigmentary changes and any rapidly growing soft tumour should raise suspicions of this condition.

Subungual exostosis can cause a painful lesion under the nail. It is confirmed by x ray examinations.

Glomus tumours arise as tender nodules.

Periungual fibrokeratomas also develop in patients with tuberous sclerosis.

Treatment of nail conditions

It is clearly not possible to treat congenital abnormalities of the nail, but avoiding exposure to trauma may help. Nail changes associated with dermatological conditions may improve as the skin elsewhere is treated. Systemic treatment of associated dermatoses will of course tend to improve the nail as well, for example methotrexate or retinoids for psoriasis.

Infective lesions respond to antifungal or antibiotic treatment. In chronic paronychia there is often a mixed infection and a systemic antibiotic combined with topical nystatin may be required. It is also important to keep the hands as dry as possible.

The imidazole antifungal drugs are fairly effective but are fungistatic. Terbinafine is fungicidal and a short course is as effective as prolonged treatment with the older drug griseofulvin.

13 Lumps and bumps

The skin is a common site for neoplastic lesions, but most invade only locally and with treatment usually do not pose any threat to the life of the patient. The exception is malignant melanoma, which is dealt with in chapter 15. This is a rare tumour with a high mortality, and recent publicity campaigns have been aimed at preventing the tragedy of fatal metastases from a neglected melanoma.

As a result a large number of patients are being seen with pigmented skin lesions and nodules, only a very few of which are neoplastic. The question is how to distinguish the benign, the malignant, and the possibly malignant. The following guidelines may help in deciding whether the lesion can be safely left or should be treated.

A correlation of the clinical and pathological features is helpful in making a confident diagnosis of the more common tumours.

Seborrhoeic warts

Seborrhoeic warts come in various shapes, sizes, and colours. When deeply pigmented, inflamed, or growing they may appear to have the features of a malignant lesion, but the following features are characteristic:

- Well defined edge.
- Warty, papillary surface—often with keratin plugs.
- Raised above surrounding skin to give a “stuck on” appearance.

Individual lesions vary considerably in size, but are usually 0.5–3.0 cm in diameter. Protuberant and pedunculated lesions occur. Solitary lesions are commonly seen on the face and neck but more numerous, large lesions tend to occur on the trunk. They become more common with increasing age.

Basal cell carcinoma

By contrast, the early basal cell carcinoma—or rodent ulcer—presents as a firm nodule, clearly growing within the skin and below it, rather than on the surface. The colour varies from that of normal skin to dark brown or black, but there is commonly a “pearly” translucent quality. As its name implies, the tumour is composed of masses of dividing basal cells that have lost the capacity to differentiate any further. As a result no epidermis is formed over the tumour and the surface breaks down to form an ulcer, the residual edges of the nodule forming the characteristic “rolled edge”. Once the basal cells have invaded the deeper tissues the rolled edge disappears.

Variants

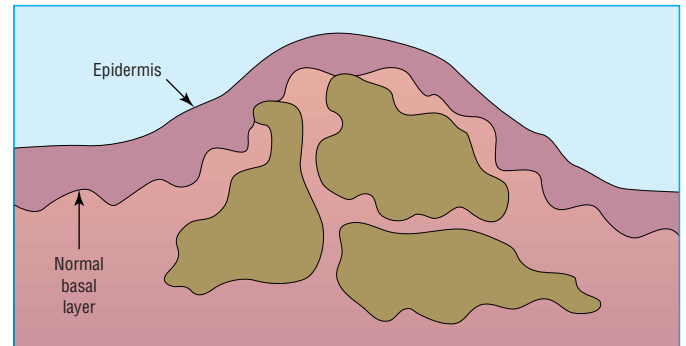

Variants of the usual pattern can cause problems in diagnosis. Cystic basal cell carcinomas occur, and those that show differentiation towards hair follicles or sweat glands may

have a less typical appearance. Pigmented lesions can resemble melanoma. The superficial spreading type may be confused with a patch of eczema. This usually occurs on the trunk, does not itch, and shows a gradual but inexorable increase in size. A firm “whipcord” edge may be present. The sclerosing type has scarring of the epidermis associated with basal cell carcinoma.

Treatment

Various methods of destroying tumour tissue are used and the results are similar for radiotherapy and surgical excision:

- Ulcerated lesions may invade tissue planes, blood vessels, and nerves more extensively than is clinically apparent.
- Although modern techniques of radiotherapy result in minimal scarring and atrophy these may cause problems near the eye.
- Basal cell carcinomas in skin creases, such as the nasolabial fold, tend to ulcerate and are hard to excise adequately.
- Surgical excision has the advantage that should the lesion recur, radiotherapy is available to treat it, whereas it is not desirable to treat recurrences after radiotherapy with further irradiation.

Squamous cell carcinoma

Squamous cell carcinoma represents proliferation of the epidermal keratinocytes in a deranged manner—with a visible degree of differentiation into epidermal cells that may show individual cell keratinisation and “pearls” of keratin. In other tumours bizarre cells with mitoses, cells with clear cytoplasm, or spindle cells may be seen.

This type of cancer often develops from a preceding solar keratosis or an area of Bowen’s disease. They may also complicate a chronic ulcer due to stasis, as in venous ulcer of the ankle, or infection such as leprosy or tuberculosis. In addition to local spread, metastases can occur with involvement of other organs such as the liver, lung or brain, and lymphadenopathy. The first change clinically is a thickening of the skin with scaling or hyperkeratosis of the surfaces. The more differentiated tumours often have a warty, keratotic crust whereas others may be nodular. The edge is poorly defined. There may be associated dilated, telangiectatic blood vessels. The original hard, disc-like lesion becomes nodular and ulcerates with strands of tumour cells invading the deeper tissue. The thick warty crust, often found elsewhere, may be absent from the lesions on the lip, buccal mucosa, and penis.

These histological changes complement the clinical appearance and are clearly different from those of basal cell carcinoma.

Treatment

Small lesions should be excised as a rule, making sure that the palpable edge of the tumour is included, with a 3–5 mm margin. Radiotherapy is effective but fragile scars may be a disadvantage on the hand. Cryotherapy or topical fluorouracil can be used for histologically confirmed, superficial lesions and also for solar keratoses.

Solar keratoses

Solar keratoses occur on sites exposed to the sun and are more common in those who have worked out of doors or sunbathed excessively. The common sites are the face, back of the hands,

Solar keratoses

arms, and legs. They also develop on the scalp in bald men and on the lips, particularly in pipe smokers. They show alterations in keratinisation and have the potential to become dysplastic and eventually develop into squamous cell carcinoma, a change often preceded by inflammation. They can be regarded as squamous cell carcinoma grade 1/2.

The clinical appearance varies from a rough area of skin to a raised keratotic lesion. The edge is irregular and they are usually less than 1 cm in diameter. Inflammation and tenderness may be associated with progression to carcinoma.

Treatment

Treatment with cryotherapy, using liquid nitrogen or carbon dioxide, repeated if necessary, is usually effective.

5-Fluorouracil cream is useful for larger or multiple lesions. It is applied twice daily for two weeks, which produces inflammation and necrosis. Simple dressings are applied for the next two weeks. This process can be repeated if necessary. As it is a cytotoxic drug it should be handled with care and applied sparingly with a cotton bud while wearing gloves.

Other conditions

Bowen's disease is characterised by a well defined, erythematous macule with little induration and slight crusting. It is a condition of the middle aged and elderly, occurring commonly on the trunk and limbs. It is an intraepidermal carcinoma, which has been reported to follow the ingestion of arsenic in "tonics" taken in years gone by or exposure to sheep dip, weedkiller, or industrial processes. After many years florid carcinoma may develop with invasion of deeper tissues. It may be confused with a patch of eczema or superficial basal cell carcinoma. Lesions on covered areas may be associated with underlying malignancy. Erythroplasia of Queyrat is a similar process occurring on the glans penis or prepuce.

Paget's disease of the nipple presents with unilateral non-specific erythematous changes on the aureola and nipple, spreading to the surrounding skin. The cause is an underlying adenocarcinoma of the ducts. It should be considered in any patient with eczematous changes of one breast that fail to respond to simple treatment. Extramammary lesions occur.

Keratoacanthoma is a rapidly growing fleshy nodule that develops a hard keratotic centre. Healing occurs with some scarring. Although benign, it may recur after being removed with curette and cauterly, particularly from the face, and is best excised.

Benign tumours

Dermatofibroma is a simple, discrete firm nodule, arising in the dermis at the site of an insect bite or other trivial injury. Often there is a brown or red vascular lesion initially, which then becomes fibrotic—a sclerosing haemangioma. The histiocytoma is similar but composed of histiocytes.

Skin tags may be pigmented but rarely cause any diagnostic problems unless inflamed. Some are in fact pedunculated seborrhoeic warts and others simple papillomas (fibroepithelial polyps).

Lipomas are slow growing benign subcutaneous tumours.

Other benign tumours

A wide variety of tumours may develop from the hair follicle and sebaceous, exocrine (sweat), and apocrine glands. The more common include *syringomas*—slowly growing, small, multiple nodules on the face of eccrine gland origin.

ABC of Dermatology

Naevus sebaceous is warty, well defined, varying in size from a small nodule to one several centimetres in diameter. Lesions occur in the scalp of children, may be present at birth, and gradually increase in size. They may proliferate or develop into a basal cell carcinoma in adult life and they are therefore best removed.

Verrucous epidermal naevi are probably a variant, found on the trunk and limbs.

Cysts

The familiar *epidermoid cyst*—also known as sebaceous cyst or wen—occurs as a soft, well defined, mobile swelling usually on the face, neck, shoulder, or chest. It is not derived from sebaceous glands but contains keratin produced by the lining wall.

Pilar cysts on the scalp are similar lesions derived from hair follicles.

Milia are small keratin cysts consisting of small white papules found on the cheek and eyelids.

Vascular lesions

The more common vascular naevi are described.

The *port wine stain*, or naevus flammeus, presents at birth as a flat red lesion, usually on the face, neck, or upper trunk.

There is usually a sharp midline border on the more common unilateral lesions. In time the affected area becomes raised and thickened because of proliferation of vascular and connective tissue. If the area supplied by the ophthalmic or maxillary divisions of the trigeminal nerve is affected there may be associated angiomas of the underlying meninges with epilepsy—Sturge–Weber syndrome. Lesions of the limb may be associated with arteriovenous fistulae.

Cavernous angioma—strawberry naevi—appear in the first few weeks of life or at birth. A soft vascular swelling is found, most commonly on the head and neck. The lesions resolve spontaneously in time and do not require treatment unless interfering with visual function.

Spider naevus consist of a central vascular papule with fine lines radiating from it. They are more common in children and women. Large numbers in a man raise the possibility of liver disease.

Campbell de Morgan spots are discrete red papules 1–5 mm in diameter. They are more common on the trunk.

Pyogenic granuloma is a lesion that contains no pus but is in fact vascular and grows rapidly. It may arise at the site of trauma. Distinction from amelanotic melanoma is important.

14 The sun and the skin

R StC Barnetson

People with darkly pigmented skin very rarely get skin cancer. Those of a Celtic constitution, when exposed to strong sunlight in countries such as Australia, get skin cancer very readily. Australia has the highest incidence of skin cancer in the world, with 140 000 new cases per year, and 1200 deaths per year, mainly from melanoma.

It is therefore important to understand that there is a variation in skin sensitivity to sunlight. This is rated from one to six (Fitzpatrick classification). Skin type one subjects have red hair and do not tan, burn very easily in the sun and develop skin cancer readily, whereas skin type six subjects have black skin (with an inbuilt sun protection factor of 10) and very rarely develop skin cancer. This is a useful guide in assessing the risk of sun damage and in determining the dose of ultraviolet B in treatment.

Ultraviolet radiation

There are three types of ultraviolet radiation—the short wavelength ultraviolet C (100–280 nm), ultraviolet B (290–320 nm), and long wavelength ultraviolet A (320–400 nm). Beyond this is visible light then infrared, and radiowaves. ultraviolet C does not penetrate beyond the stratosphere as it is absorbed by the ozone layer. Ultraviolet B is very important in both sunburn and the development of skin cancer. Ultraviolet A is thought to be of increasing importance in the development of skin cancer, and causes tanning but not sunburn. It is also important in people with photosensitivity. The effects of ultraviolet radiation may be classified as short term (sunburn, photosensitivity) or long term (skin cancer, wrinkling, solar elastosis, solar keratoses, seborrhoeic warts).

There is general awareness that the sun causes cancer in the skin, with some people becoming obsessively fearful of any exposure to sun. A sensible approach with emphasis on reasonable precautions is called for. Useful points are:

- Most moles are entirely harmless.
- Detecting the changes in moles or early melanoma enables the diagnosis to be made at an early stage with a good chance of curative treatment.
- The non-melanotic, epidermal cancers—basal cell and squamous cell carcinomas—grow slowly and are generally not life threatening. But squamous cell carcinoma arising at sites of trauma, on the extremities, or in ulcers may metastasise. Exposure to sun has usually occurred many years previously.

Prevention of sun damage and skin cancer

Prevention of sun damage and skin cancer will depend on reducing exposure to ultraviolet radiation. This can be achieved in a number of ways:

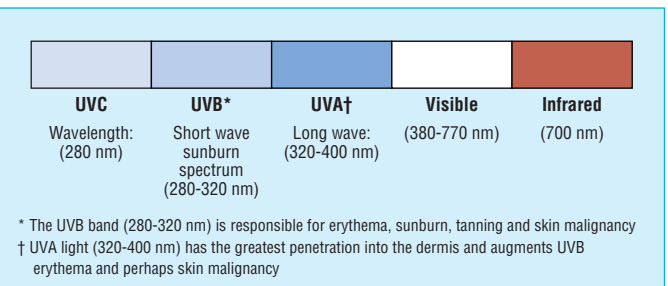

- Covering the skin with clothes. It must be remembered however that light clothes such as shirts or blouses may only have a sun protection factor of four. A wide-brimmed hat is essential to protect the face and neck.
- Sunscreens will greatly reduce sun exposure for exposed parts such as the face and hands. Sunscreens are much more

Skin types and sun

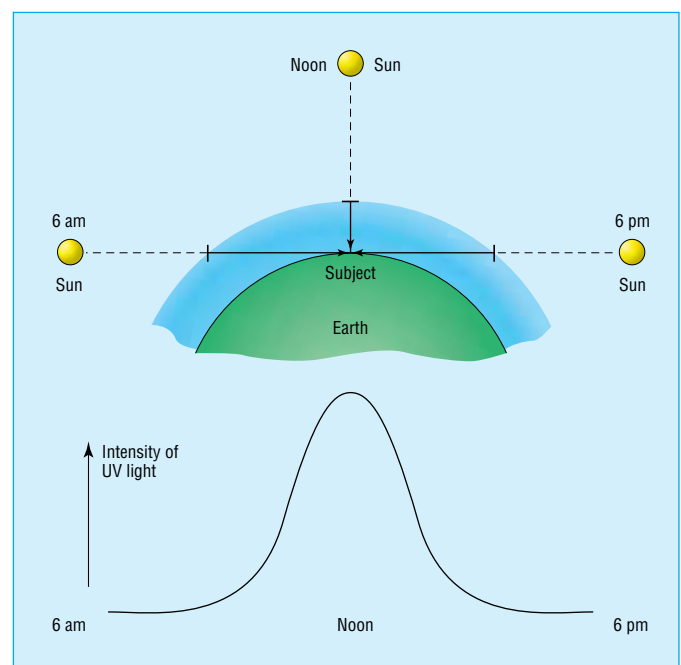

- Type 1—Never tans, freckles, red hair, blue eyes
- Type 2—Tans with difficulty, less freckled
- Type 3—Tans easily, dark hair, brown eyes
- Type 4—Always tans, Mediterranean skin
- Type 5—Brown skin (for example, Indian)
- Type 6—Black skin (for example, African)

Aborigines do not get skin cancer

Light spectrum (UVC=ultraviolet C, UVB=ultraviolet B, UVA=ultraviolet A)

Diurnal variation in UV intensity of light from sun

efficient than previously, particularly those with a sun protection factor greater than 30; they are now water resistant, and most have a broad spectrum, protecting against ultraviolet B and ultraviolet A. This is important because there is now increasing evidence that ultraviolet A is important in the development of skin cancer.

- Exposure to midday sun, particularly in tropical or subtropical latitudes, should be avoided. At this time of the day the sunlight passes vertically through the atmosphere and there is less filtering of dangerous ultraviolet light. So remember the adage: “Between eleven and three, stay under a tree” in the summer months.

Effects of sun

Short term

- Sunburn
- Photosensitivity

Long term

- Skin wrinkling
- Telangiectasia
- Hyper and hypopigmentation
- Solar elastosis
- Actinic keratosis
- Seborrhoeic warts
- Skin cancers

Development of skin cancers

Sun-damaged skin

A number of different features characterise sun-damaged skin, which is often seen in the elderly particularly if they have lived in a sunny climate such as Australia. The skin has many fine wrinkles and often has a sallow yellowish discoloration particularly on the face and other exposed parts of the body. Hyperpigmentation occurs as result of recent sun exposure, which may be diffuse or localised in the form of solar lentigo. In some areas there may be hypopigmentation, particularly where solar keratoses have been treated with liquid nitrogen (cryotherapy). There may be marked telangiectasia and numerous blood vessels are seen. In some, there may be thickening and a yellow hue of the skin, particularly of the neck, due to elastin deposition in the upper dermis; this is known as solar elastosis.

Forms of skin cancer

There are three common forms of skin cancer caused by ultraviolet light: basal cell carcinoma, squamous cell carcinoma, and malignant melanoma. Whereas there seems to be a direct relationship with the amount of ultraviolet exposure and basal cell carcinoma and squamous cell carcinoma, the relationship with ultraviolet exposure and melanoma is more complex and it seems likely that intermittent exposure to ultraviolet light is the main factor (for example, exposure to sunlight on holidays). These different types of neoplastic change that occur in the skin are discussed in chapters 13 and 15.

Photosensitivity

Exposure to sun in non-pigmented races causes inflammation in the skin, depending on the skin type and amount of exposure. In some individuals there is an abnormal sensitivity to sunlight. This may arise because of an idiopathic reaction to sunlight or allergic reaction that is activated by sunlight. Some chemicals seen to induce photosensitivity without causing an allergy. Other causes are metabolic diseases and inflammatory conditions that are made worse by sun exposure.

Polymorphic light eruption

This is the most common of the idiopathic photosensitive rashes and occurs predominantly in women. It is due to both the shorter (ultraviolet B) and longer (ultraviolet A) wavelength types of sunlight. The eruption occurs from hours to days after exposure and varies in severity from a few inflamed papules to extensive inflamed oedematous lesions. There may be only a few trivial lesions initially, but increasingly severe reactions can develop restricting the patients ability to venture outside. A useful measure of severity is to ask the

Sun damaged skin

Solar elastosis

Causes of photosensitivity

- Idiopathic—for example, polymorphic light eruption, actinic prurigo, solar urticaria
- Photoaggravated dermatoses—for example, lupus erythematosus, eczema
- Metabolic—porphyria—for example, erythropoietic, hepatic
- Drug induced—for example, sulphonamides, phenothiazines
- Chemical induced (topical)—for example, tar, anthracene

Photosensitivity caused by drugs

patient if they cross to the shady side of the street to avoid the sun. Treatment includes topical or systemic steroids for the acute rash and prevention by using sunscreens. Desensitisation by narrow waveband phototherapy before exposure is effective.

Solar urticaria

This is a much less common condition and may be induced by longer wavelength (ultraviolet A) and visible radiation as well as ultraviolet B. It is characterised by rapidly developing irritation and in the exposed skin is followed by urticarial wheals. It can occur as part of a photoallergic reaction, in which case avoidance of the relevant allergen will prevent the condition.

Treatment is with antihistamines and sunscreens. In some cases phototherapy with ultraviolet B, narrow waveband or psoralen with ultraviolet A (PUVA), is helpful.

15 Black spots in the skin

There has been a great increase in public awareness of melanoma, and any dark lesions of the skin are sometimes regarded with the same dread as Long John Silver's "black spot" in *Treasure Island*—a sign of imminent demise. However, the vast majority of pigmented lesions are simply moles or harmless pigmented naevi. The most important thing is to know which moles can be safely ignored and which should be removed. Benign moles are described first, then malignant melanoma, followed by a discussion of the differences between these two.

Benign moles

Benign moles are naevi with a proliferation of melanocytes and a variable number of dermal naevus cells. Some moles are congenital and are present from birth, but most develop in early childhood and adolescence. The number of moles remains constant during adult life with a gradual decrease from the sixth decade onwards.

There is often an increase in both the number of moles and the degree of pigmentation during pregnancy.

Acquired melanocytic naevi

Acquired melanocytic naevi are the familiar moles and present in a number of different ways depending on the type of cells and the depth in the skin.

Junctional naevi are flat macules with melanocytes proliferating along the dermo-epidermal border.

Compound naevi have pigmented naevus cells at the dermo-epidermal border and in the dermis, producing a raised brown lesion. The dermal melanocytes may accumulate around the skin appendages and blood vessels and form a band of cells without melanin or more deeply penetrating strands of spindle cells. Proliferating naevus cells may throw the overlying epidermis into folds, giving a papillary appearance.

In a purely *intradermal naevus* the junctional element is lost, with the deeper cells showing characteristics of neural tissue. Other types of acquired pigmented naevi include the following.

Blue naevus is a collection of deeply pigmented melanocytes situated deep in the dermis, which accounts for the deep slate-blue colour.

Spitz naevus presents as a fleshy pink papule in children. It is composed of large spindle cells and epitheloid cells with occasional giant cells, arranged in "nests". It is benign and the old name of juvenile melanoma should be abandoned.

Halo naevus consists of a melanocytic naevus with a surrounding halo of depigmentation associated with the presence of antibodies against melanocytes in some cases. The whole naevus gradually fades in time.

Becker's naevus is an area of increased pigmentation, often associated with increased hair growth, which is usually seen on the upper trunk or shoulders. It is benign.

Freckles or ephelides are small pigmented macules, less than 0.5 cm in diameter, that occur in areas exposed to the sun in fair skinned people. These macules fade during the winter months.

Congenital pigmented naevi

Congenital pigmented naevi are present at birth, generally over 1 cm in diameter, and vary from pale brown to black in colour. They often become hairy and more protuberant, possibly with

Benign moles

Benign mole

Benign pigmented naevus

Blue naevus

Spitz naevus

Halo naevus

Becker's naevus

an increased risk of malignant change. Larger lesions can cover a considerable area of the trunk and buttocks, such as the bathing trunk naevi, and their removal may present a considerable problem.

Dysplastic naevi

These show very early malignant change and may progress to malignant melanoma. They are deeply pigmented often with an irregular margin.

In *dysplastic naevus syndrome* multiple pigmented naevi that occur predominantly on the trunk, becoming numerous during adolescence. They vary in size—many being over 0.5 cm—and tend to develop into malignant melanoma, particularly if there is a family history of this condition.

Congenital hairy naevus

Dysplastic naevus syndrome

Melanoma

Melanoma is an invasive malignant tumour of melanocytes. Most cases occur in white adults over the age of 30, with a predominance in women.

Incidence

The incidence of melanoma has doubled over the past 10 years in Australia (currently 40/100 000 population) and shown a similar increase in other countries. In Europe twice as many women as men develop melanoma—about 12/100 000 women and 6/100 000 men.

Prognosis

The prognosis is related to the thickness of the lesion, measured histologically in millimetres from the granular layer to the deepest level of invasion. Lesions less than 0.76 mm thick have a 100% survival at five years, 0.76–1.5 mm thick an 80% survival at five years, and lesions over 3.5 mm less than 40% survival. These figures are based on patients in whom the original lesion had been completely excised. A recent study in Scotland has shown an overall five year survival of 71.6–77.6% for women and 58.7% for men.

Sun exposure

The highest incidence of melanoma occurs in countries with the most sunshine throughout the year. However, skin type and the regularity of exposure to sun are also important. The incidence is much greater in fair skinned people from higher latitudes who have concentrated exposure to sun during holidays than in those with darker complexions who have more regular exposure throughout the year. Severe sunburn may also predispose to melanoma.

Genetic factors

Since melanin protects the skin from ultraviolet light it is not surprising that melanoma occurs most commonly in fair skinned people who show little tanning on exposure to sun, particularly those of Celtic origin. Members of families with the dysplastic naevus syndrome are more likely to develop melanoma in their moles. These patients have multiple naevi from a young age.

Pre-existing moles

It is rare for ordinary moles to become malignant but congenital naevi and multiple dysplastic naevi are more likely to develop into malignant melanoma.

Melanoma

Melanoma

Nodular melanoma

Superficial melanoma with nodules

Lentigo maligna

Nodule developing in superficial spreading melanoma

Types of melanoma

There are four main types of melanoma.

Superficial spreading melanoma is the more common variety. It is common on the back in men and on the legs in women. As the name implies the melanoma cells spread superficially in the epidermis, becoming invasive after months or years. The margin and the surface are irregular, with pigmentation varying from brown to black. There may be surrounding inflammation and there is often clearing of the central portion. The invasive phase is associated with the appearance of nodules and increased pigmentation. The prognosis is correspondingly poor.

Lentigo maligna melanoma occurs characteristically in areas exposed to sun in elderly people. Initially there is a slowly growing, irregular pigmented macule that is present for many years before a melanoma develops.

Nodular melanoma presents as a dark nodule from the start without a preceding in situ epidermal phase. It is more common in men than women and is usually seen in people in their fifties and sixties. Because it is a vertical invasive growth phase from the beginning there is a poor prognosis.

Acral melanoma occurs on the palm and soles and near or under the nails. Benign pigmented naevi may also occur in these sites and it is important to recognise early dysplastic change by using the criteria set out below. A very important indication that discoloration of the nail is due to melanoma is Hutchinson's sign—pigmentation of the nail fold adjacent to the nail. It is important to distinguish talon noir, in which a black area appears on the sole or heel. It is the result of trauma—for example sustained while playing squash—causing haemorrhage into the dermal papillae. Paring the skin gently with a scalpel will reveal distinct blood filled papillae, to the relief of doctor and patient alike.

Other types of melanoma

As the melanoma cells become more dysplastic and less well differentiated they lose the capacity to produce melanin and form an amelanotic melanoma. Such non-pigmented nodules may be regarded as harmless but are in fact extremely dangerous.

Superficial spreading melanoma

Nodular melanoma in a lentigo

Benign lentigo

Acral melanoma

Talon noir of left heel

Dysplastic melanoma

Amelanotic melanoma

Malignant melanoma in a black person; note the surrounding "halo"

Progressive growth in depth of malignant melanoma

Prognosis

This depends on the depth to which the melanoma has penetrated below the base of the epidermis—lesions confined to the epidermis having better prognosis than those penetrating into the dermis. The Clark classification describes the depth of penetration as follows:

Level I—within the epidermis

Level II—few melanoma cells within the dermal papillae

Level III—many melanoma cells in the papillary dermis

Level IV—invasion of the reticular dermis

Level V—invasion of the subcutaneous tissues

The Breslow classification is based on measurements of tumour thickness from the granular layer overlying epidermis. A depth of less than 1.5 mm is associated with a 90% five year survival, 1.5–3.5 mm with a 75% five year survival, and greater than 3.5 mm with only a 50% five year survival.

In deeper tumours “sentinel lymph node” biopsy may be carried out to assess whether lymphatic spread has occurred.

How to tell the difference

Benign moles show little change and remain static for years. Any change may indicate that a mole is in fact a melanoma or that a mole is becoming active. Size, shape, and colour are the main features and it is change in them that is most important. Patients with moles should have these changes explained to them, in particular that they indicate activity of the cells, not necessarily malignant change.

Criteria for suspecting malignant changes in pigmented lesions

- Growth—Benign pigmented naevi continue to appear in adolescents and young adults. Any mole increasing in size in an adult over the age of 30 may be a melanoma
- Shape—Moles usually have a symmetrical, even outline, any indentations being quite regular; melanomas usually have an irregular edge with one part advancing more than the others
- Colour—Variation in colour of benign moles is even but a melanoma may be intensely black or show irregular coloration varying from white to slate blue, with all shades of black and brown. Inflammation may give a red colour as well. The amelanotic melanoma shows little or no pigmentation
- Size—Apart from congenital pigmentation naevi most benign moles are less than 1 cm in diameter. Any lesion growing to over 0.5 cm should be carefully checked
- Itching—Normally a mole does not itch but a melanoma may. Irritated seborrhoeic warts also itch
- Bleeding and *crusting* occur in an actively growing melanoma

If more than two of these features are present refer the patient for specialist opinion

A simple summary:

A—Asymmetry of the lesion

B—Irregularity of the border

C—Variations in colour

D—Diameter larger than 0.5 cm

16 The skin and systemic disease—Genetics and skin disease (JA Savin)

When a man has on the skin of his body a swelling or an eruption or a spot... and the disease appears to be deeper than the skin it is a leprous disease.

Leviticus 13: 2–3

In ancient times changes in the skin were taken to indicate that the whole body was diseased and although arguments continue about what the Old Testament writers understood by “leprous”, there was clearly an appreciation of the connection between the skin and systemic illness. Clinical signs in the skin may give valuable diagnostic clues to underlying disease. The cutaneous signs of systemic disease is a very large subject; and what follows is only an outline of the more common skin changes that may be associated with systemic illness.

A disease affecting internal organs may produce the same changes in both the skin and other organs—as in the connective tissue diseases. However, underlying conditions may be associated with skin changes brought about by quite different processes, as in acanthosis nigricans or dermatomyositis in which there is an underlying neoplasm with characteristic skin signs. Sometimes severe skin disease itself may be the cause of generalised illness.

The skin is also a common site for allergic reactions to drugs, with a rash being the first clinical sign. The florid skin lesions of AIDS illustrate the results of infections when the immune response is impaired.

Conditions affecting both the skin and the internal organs

Immune reactions

Allergic reactions to drugs such as penicillin can occur. In this case the penicillin molecule attaches to serum protein. This compound acts as an antigen and may form a complex with IgG antibody. It is this complex which attaches to blood vessel walls to produce an inflammatory reaction. This presents as a rash developing a few days to two weeks after treatment on the skin, but if it occurs in the kidneys the resulting tissue damage can have serious consequences. This is an example of Type III allergy with antigen–antibody complexes being deposited in the small blood vessels. Sometimes a much more acute anaphylactic reaction develops. A fixed drug eruption is characterised by a localised patch of erythema that flares up whenever the drug is taken. Erythema multiforme can occur in drug reactions.

Connective tissue diseases involve complex immunological processes that affect both internal organs and the skin. This means that it is particularly important to realise the significance of any associated skin changes.

Lupus erythematosus

This condition has been described as “a disease with a thousand faces” because of the wide range of organs involved

When to suspect an underlying systemic disease

- An unusual rash which does not have the features of one of the common primary inflammatory skin conditions
- Evidence of systemic illness—weight loss, and other symptoms such as breathlessness, altered bowel function or painful joints
- Erythema of the skin due to inflammation around the blood vessels, usually without epidermal changes—reactive erythema. Vasculitis, in which there are palpable erythematous lesions which may be painful or nodular
- Unusual changes in pigmentation or texture of the skin
- Palpable dermal lesions that may be due to granuloma, metastases, lymphoma, or deposits of fat or minerals

Rash from penicillin

Erythema multiforme

and the numerous ways in which it can present. In three quarters of the patients the skin is involved. There are four main types, with numerous variations.

In *systemic lupus erythematosus* (SLE) the commonest skin change is an acute erythematous eruption occurring bilaterally on the malar area of the face in a “butterfly” distribution. There may also be photosensitivity, hair loss, and areas of vasculitis in the skin. There is often intolerance of sunlight. It is more common in females with a female:male ratio of 8:1.

The systemic changes include fever, arthritis and renal involvement, but there may be involvement of a wide range of organs. The criteria for diagnosing the condition include at least four of the features in the box on the right.

Subacute lupus erythematosus is a variant in about 10% of patients with lupus erythematosus that presents with non-scarring erythematous plaques mainly on the face, hands and arms. Papulo squamous lesions also occur. They may be annular. Systemic involvement is less common and severe than in SLE. It is associated with a high incidence of neonatal lupus erythematosus in children born to mothers with the condition. The antinuclear factor test is positive in 60% and anticytoplasmic antibodies are present in 80% of patients.

Discoid lupus erythematosus (DLE) is a condition in which circulating antinuclear antibodies are very rare. There are quite well defined photosensitive inflammatory lesions, with some degree of atrophy and hyperkeratosis of the follicles, giving a “nutmeg grater” feel. It occurs predominantly on the face or areas exposed to the sun, becoming worse in the summer months. Scarring is common causing hair loss in lesions on the scalp.

Treatment of SLE with the threatened or actual involvement of other organs is important. Prednisolone is usually required and sometimes immunosuppressant drugs such as azathioprine as well. Treatment of DLE is generally with topical steroids. Hydroxychloroquine by mouth is also used, generally in a dose of 200 mg daily. This drug can diminish visual acuity in higher doses and this should be checked every few months. A simple chart, the Amsler Chart, is available for patients to use, consisting of a central dot with a grid which becomes blurred when held at arm’s length when there is any impairment of acuity.

Dermatomyositis

This condition is associated in adults with underlying carcinoma—commonly of the breasts, lung, ovary, or gastrointestinal tract. It is characterised by localised erythema with a purple hue (heliotrope), predominantly on the eyelids, cheeks, and forehead. There may be similar changes on the dorsal surface of the fingers, often with dilated nail fold capillaries. These changes may precede the discovery of an underlying tumour and may also fade away once it is removed. There is a variable association with muscle discomfort and weakness, mainly in the upper limb girdle. The finding of muscle weakness together with specific electromyographic changes and an inflammatory infiltrate in the muscle means there is almost certainly an underlying malignancy, so suitable investigation is indicated.

Systemic sclerosis

As the name implies, there is extensive sclerosis of the connective tissue of the lungs, gastrointestinal tract, kidneys, and heart. Endothelial cell damage in the capillaries results in fibrosis and sclerosis of the organs concerned. The skin becomes tethered to the subcutaneous tissues and immobile, leading to fixed claw like hands, constricted mouth with furrowed lips, and beak-like nose. There are vascular changes producing Raynaud’s phenomenon and telangiectasia around

Clinical variants of lupus erythematosus

- Systemic
- Subacute cutaneous
- Discoid (neonatal)
- Systemic sclerosis

Criteria for diagnosing systemic lupus erythematosus

- Malar rash
- Discoid plaques
- Photosensitivity
- Arthritis
- Mouth ulcers
- Renal changes
- Serositis
- Neurological involvement
- Haematological changes
- Immunological changes
- Antinuclear antibodies

Systemic lupus erythematosus

Dermatomyositis

Persistent dermatomyositis

the mouth and on the fingers. There are also flat “mat-like” telangiectasia on the face.

Workers manufacturing polyvinyl chloride can develop skin changes similar to systemic sclerosis with erosions of the bones, hepatic and pulmonary lesions. Pesticides and epoxy resin can also produce scleroderma-like changes.

It is associated with antinuclear antibodies (speckled or nucleolar), and in about 50% of cases, circulating immune complexes may be present.

A variant is the *CREST syndrome*. In this type of scleroderma there is **C**alcinosis with calcium deposits below the skin on the fingers and toes, **R**aynaud’s phenomenon with poor peripheral circulation, immobility of the **E**sophagus, dermal **S**clerosis of the fingers and toes, and **T**elangiectasia of the face and lips and adjacent to the toe and finger nails. It has a better prognosis than systemic sclerosis. Antinuclear antibodies at the centromere are frequently present.

Morphoea is a benign form of localised systemic sclerosis in which there is localised sclerosis with very slight inflammation. There is atrophy of the overlying epidermis. The early changes often consist of a dusky appearance to the skin.

Lichen sclerosus

The full name is lichen sclerosus et atrophicus—or LSA. This is a relatively uncommon condition seen mainly in women in whom well defined patches of superficial atrophy of the epidermis occur with a white colour. There is fibrosis of the underlying tissues. It frequently occurs in the vulva and perineum and may also appear on the penis as balanitis xerotica obliterans. Extragenital lesions may occur anywhere on the skin. It may occur in a more acute form in children where it tends to resolve, but in adults it is a very chronic condition. There is an increased incidence of squamous cell carcinoma. Treatment is with topical steroids and excision of any areas that appear to be developing tumours.

The cause of the hyalinized collagen and epidermal atrophy is unknown, but in early lesions there is an infiltrate of lymphocytes with CD3, CD4, CD8, and CD68 markers. There is also an increase in Langerhans cells, so there may well be an immunological basis for these changes.

Vascular changes

Vascular lesions are associated with a wide range of conditions including infections, neoplasia, and allergic reactions.

Hormones, particularly oestrogen, may affect the small blood vessels of the skin to produce telangiectasia and small angiomas, such as spider naevi.

Vasculitis and purpura, described in chapter 7, may be associated with disease of the kidneys and other organs. “Splinter haemorrhages” under the nails are usually the result of minor trauma but may be associated with a wide range of conditions, including subacute bacterial endocarditis and rheumatoid arthritis.

Livedo reticularis is a cyanotic, net-like discoloration of the skin over the legs. It may be idiopathic or associated with arteritis or changes in blood viscosity.

Erythrocyanosis is a dusky, red, cyanotic change in the skin over the legs and thighs, where there is a deep layer of underlying fat. The condition becomes worse in the winter months. It is most common in young women and usually resolves over the years. Lupus erythematosus, sarcoidosis, and tuberculous infection may localise in affected areas.

Telangiectasia and clubbing may be features of scleroderma in the CREST syndrome described above.

In *carcinoid* and *phaeochromocytoma* vasoactive substances cause episodes of flushing and telangiectasia.

CREST syndrome

- C—Calcinosis cutis
- R—Raynaud’s phenomenon
- E—Esophagus
- S—Scleroderma
- T—Telangiectasia

CREST syndrome

Calcinosis cutis

Vasculitis

Livedo reticularis

In *hereditary haemorrhagic telangiectasia* thin walled ectatic blood vessels develop in the mucous membranes and the skin—generally on the upper half of the body and the nail beds.

Erythemas

Erythema is macular redness of the skin due to congestion in the capillaries. It occurs as part of immunological reactions in the skin as in drug allergies and specific patterns of viral infections, such as measles. There are other types that show a specific pattern but are associated with a wide range of underlying conditions, such as erythema multiforme.

Erythema multiforme is associated with herpes and other viral infections or streptococcal and various bacterial infections, but also with many other conditions, particularly connective tissue disease, sarcoidosis, and reactions to drugs such as sulphonamides.

The lesions consist of erythematous macules becoming raised and typically developing into “target lesions” in which there is a dusky red or purpuric centre with a pale indurated zone surrounded by an outer ring of erythema. The lesions may be few or multiple and diffuse, often involving the hands, feet, elbows, and knees. Blisters may develop.

In the more severe forms there may be dermal changes and blister formation with involvement of the mucous membranes (*Stevens–Johnson syndrome*). There is often pyrexia with gastrointestinal and renal lesions. It can progress to *toxic epidermal necrolysis*, which some consider a form of erythema multiforme.

Erythema annulare is a specific pattern in the skin with a large number of reported associations, ranging from fungal and viral infections to sarcoidosis and carcinoma. It consists of a small erythematous macule that enlarges to form an expanding ring, usually on the trunk.

Erythema chronicum migrans is associated with *Borrelia* infection and Lyme disease—it is described on page 106.

There are many other types of “figurate erythemas”. *Erythema gyratum repens* is associated with underlying carcinoma and *erythema marginatum*, which is now rare, with rheumatic fever.

Erythemas associated with systemic conditions

- Erythema multiforme
- Erythema annulare
- Erythema chronicum migrans
- Erythema gyratum repens
- Erythema marginatum

Figurate erythema

Angiomas

Spider naevi, which show a central blood vessel with radiating branches, are frequently seen in women (especially during pregnancy) and children. If they occur in large numbers, particularly in men, they may indicate liver failure. Palmar erythema and yellow nails may also be present.

Congenital angiomas

Eruptive angiomas may be associated with systemic angiomas of the liver, lung, and brain. Port wine stain due to abnormality of the dermal capillaries commonly develops on the head and neck. It may be associated with congenital vascular abnormalities of the meninges and epilepsy. Vascular abnormalities of the eye, and also glaucoma, occur with lesions on the face.

Erythema of the nailbeds

This may be associated with connective tissue disease, such as lupus erythematosus, scleroderma, and dermatomyositis.

Erythema of nailbeds and clubbing

Changes in pigmentation

Hypopigmentation

Hormonal

A widespread partial loss of melanocyte functions with loss of skin colour is seen in hypopituitarism and is caused by an absence of melanocyte stimulating hormone.

ABC of Dermatology

Genetic

In albinism, an autorecessive condition, there is little or no production of melanin with loss of pigment from the skin, hair, and eyes. Other genetic conditions with loss of skin pigment include piebaldism, phenylketonuria, and tuberous sclerosis.

Localised depigmentation is most commonly seen in vitiligo, in which a family history of the condition is found in one third of the patients. In the sharply demarcated, symmetrical macular lesions there is loss of melanocytes and melanin. There is an increased incidence of organ specific antibodies and their associated diseases.

Other causes of hypopigmented macules include: postinflammatory conditions after psoriasis, eczema, lichen planus, and lupus erythematosus; infections, for example, tinea versicolor and leprosy; chemicals, such as hydroquinones, hydroxychloroquine, and arsenicals, reactions to pigmented naevi, seen in halo naevus; and genetic diseases, such as tuberous sclerosis ("ash leaf" macules).

Hyperpigmentation

There is wide variation in the pattern of normal pigmentation as a result of heredity and exposure to the sun. Darkening of the skin may be due to an increase in the normal pigment melanin or to the deposition of bile salts in liver disease, iron salts (haemochromatosis), drugs, or metallic salts from ingestion. In agyria ingested silver salts are deposited in the skin.

Causes of hyperpigmentation include the following factors.

Hormonal

An increase in circulating hormones that have melanocyte stimulating activity occurs in hyperthyroidism, Addison's disease, and acromegaly. In women who are pregnant or taking oral contraceptives there may be an increase in melanocytic pigmentation of the face. This is known as melasma (or chloasma) and occurs mainly on the forehead and cheeks. It may fade slowly. Sometimes a premenstrual darkening of the face occurs.

Increased deposition of haemosiderin is generalised in haemochromatosis. Localised red-brown discoloration of the legs is seen with longstanding varicose veins. It also occurs in a specific localised pattern in Schamberg's disease, when there is a "cayenne pepper" appearance of the legs and thighs.

Neoplasia

Lymphomas may be associated with increased pigmentation. Acanthosis nigricans, characterised by darkening and thickening of the skin of the axillae, neck, nipples, and umbilicus, occurs with internal cancers, usually adenocarcinoma of the stomach. It is also seen in acromegaly. There is a benign juvenile type. Pseudoacanthosis nigricans is much more common, consisting of simple darkening of the skin in the flexures of obese individuals; it is not associated with malignancy.

Autoimmune associations with vitiligo

- Thyroid disease
- Pernicious anaemia
- Hypoparathyroidism
- Addison's disease
- Diabetes
- Myasthenia gravis
- Alopecia areata
- Halo naevus
- Morphea and lichen sclerosus

Vitiligo

Agyria (silver salts in skin)

Melasma

Acanthosis nigricans

Carcinoma left upper zone

Pseudoacanthosis nigricans

Acanthosis nigricans

Drugs

Chlorpromazine, other phenothiazines, and minocycline may cause an increased pigmentation in areas exposed to the sun. Phenytoin can cause local hyperpigmentation of the face and neck.

Inflammatory reactions

Postinflammatory pigmentation is common, often after acute eczema, fixed drug eruptions, or lichen planus. Areas of lichenification from rubbing the skin are usually darkened.

Malabsorption and deficiency states

In malabsorption syndromes, pellagra, and scurvy there is commonly increased skin pigmentation.

Congenital conditions

There is clearly a marked variation in pigmentation and in the number of freckles in normal individuals. There may be localised well defined pigmented areas in neurofibromatosis with “cafe au lait” patches. Increased pigmentation with a blue tinge occurs over the lumbosacral region in the condition known as Mongolian blue spot.

Peutz-Jeghers syndrome is described under the section “The gut and the skin”, below. There are pigmented macules associated with intestinal polyposis in the oral mucosa, lips, and face.

Neurofibromatosis

Neurofibromatosis

Increased pigmentation in malabsorption syndrome

Peutz-Jeghers syndrome

Malignant lesions

Malignant lesions may cause skin changes such as acanthosis nigricans and dermatomyositis or produce secondary deposits. Lymphomas can arise in or invade the skin. Pruritus may be associated with Hodgkin’s disease.

Mycosis fungoides is a T cell lymphoma of cutaneous origin. Initially well demarcated erythematous plaques develop on covered areas with intense itching. In many cases there is a gradual progression to infiltrated lesions, nodules, and ulceration. In others the tumour may occur de novo or be preceded by generalised erythema.

Poikiloderma, in which there is telangiectasia, reticulate pigmentation, atrophy, and loss of pigment, may precede mycosis fungoides, but it is also seen after radiotherapy and in connective tissue diseases.

Parapsoriasis is a term used for well defined maculopapular erythematous lesions that occur in middle and old age. Some cases undoubtedly develop into mycosis fungoides and a biopsy specimen should be taken of any such fixed plaques that do not clear with topical steroids.

Skin markers of internal malignancy

- Acanthosis nigricans—usually intra-abdominal lesions
- Erythematous rashes, “figurate erythema”
- Pruritus—usually lymphoma
- Dermatomyositis in the middle aged and elderly
- Acquired ichthyosis

Non-specific skin changes associated with malignant disease

- Secondary deposits
- Secondary hormonal effects
 - Acne (adrenal tumours)
 - Flushing (carcinoid)
 - Pigmentation
- Generalised pruritus (particularly lymphoma)
- Figurate erythema
- Superficial thrombophlebitis
- Various eruptive skin lesions seen in Gardner’s and Bazex syndromes

Lymphoma

B cell lymphoma

Poikiloderma

Parapsoriasis

The gut and the skin

Vasculitis of various kinds, periarteritis nodosa, connective tissue diseases such as scleroderma, and many metabolic diseases produce both cutaneous and gastrointestinal lesions. There are, however, some specific associations.

Dry skin, asteatosis, and itching, with superficial eczematous changes and a “crazy paving” pattern, occur in malabsorption and cachectic states. Increased pigmentation, brittle hair and nails may also be associated.

Pyoderma gangrenosum gives rise to an area of non-specific inflammation and pustules break down to form a necrotic ulcer with hypertrophic margins. There is an underlying vasculitis. There is a strong association with ulcerative colitis and also with Crohn’s disease, rheumatoid arthritis, abnormal gamma globulins, and leukaemia.

Dermatitis herpetiformis, which has already been discussed, is an intensely itching, chronic disorder with erythematous and blistering lesions on the trunk and limbs. It is more common in men than women. Most patients have a gluten sensitive enteropathy with some degree of villus atrophy. There is an associated risk of small bowel lymphoma.

Peutz–Jeghers syndrome is inherited as an autosomal dominant characterised by the appearance in infancy of pigmented macules of the oral mucosal membranes, lips, and face. Benign intestinal polyps, mainly in the ileum and jejunum, which rarely become malignant, are associated with the condition.

Other conditions include congenital disorders with connective tissue and vascular abnormalities that affect the gut, such as Ehlers–Danlos syndrome and pseudoxanthoma elasticum (arterial gastrointestinal bleeding), purpuric vasculitis (bleeding from gastrointestinal lesions), and neurofibromatosis (intestinal neurofibromas).

In *Crohn’s disease* (regional ileitis) perianal lesions and sinus formation in the abdominal wall often occur. Glossitis and thickening of the lips and oral mucosa and vasculitis may be associated.

Liver disease may affect the skin, hair, and nails to a variable degree. Obstructive jaundice is often associated with itching which is thought to be due to the deposition of bile salts in the skin. Evidence of this is the fact that drugs which combine with bile salts such as cholestyramine improve pruritus in some patients. Jaundice is the physical manifestation of bile salts in the skin.

Liver failure is characterised by a number of skin signs, particularly vascular changes causing multiple spider naevi and palmar erythema due to diffuse telangiectasia. It is not unusual to see spider naevi on the trunk in women but large numbers in men should raise suspicion of underlying hepatic disease.

Porphyria cutanea tarda as a result of chronic liver disease produces bullae, scarring, and hyperpigmentation in sun exposed areas of the skin. *Xanthomas* may be associated with primary biliary cirrhosis and in chronic liver disease asteatosis, with dry skin producing a “crazy paving” pattern.

Diabetes and the skin

In diabetes the disturbances of carbohydrate–lipid metabolism, small blood vessel lesions, and neural involvement may be associated with skin lesions. The more common of these include the following.

Diseases that pyoderma gangrenosum may occur with

- Ulcerative colitis
- Crohn’s disease
- Rheumatoid arthritis
- Monoclonal gammopathy
- Leukaemia

Early pyoderma gangrenosum

Pyoderma gangrenosum

Dermatitis herpetiformis

Liver disease and the skin

Obstructive

- Jaundice
- Pruritus

Liver failure

- Multiple spider naevi (in men)
- Palmar erythema
- White nails—hypoalbuminaemia
- Porphyria cutanea tarda

Cirrhosis

- Xanthomas (primary biliary cirrhosis)
- Asteatosis

Infection

Diabetic patients have an increased susceptibility to staphylococcal, coliform, and pseudomonal infection. *Candida albicans* infection is also more common in diabetics.

Vascular lesions

“Diabetic dermopathy”, due to a microangiopathy, consists of erythematous papules which slowly resolve to leave a scaling macule on the limbs. Atherosclerosis with impaired peripheral circulation is often associated with diabetes. Ulceration due to neuropathy (trophic ulcers) or impaired blood supply may occur, particularly on the feet.

Specific skin lesions

Necrobiosis lipoidica

Between 40% and 60% of patients with this condition may develop diabetes, but it is not very common in diabetic patients (0.3%). As the name indicates, there is necrosis of the connective tissue with lymphocytic and granulomatous infiltrate. There is replacement of degenerating collagen fibres with lipid material. It usually occurs over the shin but may appear at any site.

Granuloma annulare

This usually presents with localised papular lesions on the hands and feet but may occur elsewhere. The lesions may be partly or wholly annular and may be single or multiple. There is some degree of necrobiosis, with histiocytes forming “palisades” as well as giant cells and lymphocytes. It is seen more commonly in women, usually those aged under 30. There is an association with insulin dependent diabetes. In itself it is a harmless and self limiting condition that slowly clears but may recur.

Other diseases

Porphyrias are due to the accumulation of intermediate metabolites in the metabolic pathway of haem synthesis. There are several types. In hepatic porphyrias there is skin fragility leading to blisters from exposure to the sun or minor trauma. In erythropoietic and erythrohepatic photoporphyrias there is intense photosensitivity. They are sometimes associated with sensitivity to long wavelength ultraviolet light that penetrates window glass.

Porphyria cutanea tarda usually occurs in men, with a genetic predisposition, who have liver damage as a result of an excessive intake of alcohol. There is impaired porphyria metabolism leading to skin fragility and photosensitivity, with blisters and erosions, photosensitivity on the face and the dorsal surface of the hands.

Xanthomas are due to the deposition of fat in connective tissue cells. They are commonly associated with hyperlipidaemia—either primary or secondary to diabetes, the nephrotic syndrome, hypothyroidism, or primary biliary cirrhosis. Four of the primary types are associated with an increased risk of atherosclerosis; type I is not. Diabetes may be associated with the eruptive type.

Necrotising fasciitis is an area of cellulitis that develops vesicles. Necrosis of the skin may indicate much more extensive, life threatening necrosis of the deeper tissues. Urgent surgical debridement is indicated.

Amyloid deposits in the skin occur in primary systemic amyloidosis and myeloma.

Diabetic ulcer

Necrobiosis lipoidica

Granuloma annulare

Porphyria

Xanthomas

Common types of xanthoma

Clinical type	Association with hyperlipidaemia	
	Primary	Secondary
Xanthelasma of the eyelids—yellow plaques	II (may be normal)	
Tuberous nodules on elbows and knees	II, III	+
Eruptive—small yellow papules on buttocks and shoulders	I, III, IV, V	+
Plane—yellow macules, palmar creases involved	I, III	+
Generalised—widespread macules		myeloma
Tendons—swelling on fingers or ankles	II, III	+

Pregnancy

Pregnancy may be associated with pruritus, in which the skin appears normal in 15–20% of women (prunigo gestationis). It is generally more severe in the first trimester.

Polymorphic eruptions also present with pruritus with urticaria papules and plaques (the PUPP syndrome). It usually occurs on the abdomen in the third trimester and then becomes widespread. There may be a postpartum flare up. It can be a distressing condition for the mother but the baby is not affected, and it rarely recurs in subsequent pregnancies. Topical steroids can be used, but systemic steroids should be avoided.

Pemphigoid gestationis is a rare disorder that may resemble PUPP initially but develops pemphigoid-like vesicles, spreading over the abdomen and thighs: autoantibodies to the basement membrane are present.

Polymorphic eruption

Pemphigoid gestationis

Sarcoidosis

Pulmonary and other systemic manifestation of sarcoidosis may occur without involvement of the skin. The most common changes are:

- Erythema nodosum, which is often a feature of early pulmonary disease.
- Papules, nodules, and plaques are associated with acute and subacute forms of the disease.
- Scar sarcoidosis, with papules occurring in scars.
- Lupus pernio is characterised by dusky red infiltrated lesions on the nose and fingers.

Nodule in sarcoidosis

Thyroid disease

Thyroid disease is associated with changes in the skin, which may sometimes be the first clinical signs. There may be evidence of the effect of altered concentrations of thyroxine on the skin, with changes in texture and hair growth. Associated increases in thyroid stimulating hormone concentration may lead to pretibial myxoedema. In autoimmune thyroid disease vitiligo and other autoimmune conditions may be present.

Sarcoid granuloma

Genetics and skin disease by JA Savin

Though many genetic disorders of the skin are inherited in a classically Mendelian way (single gene disorders), others are genetically more complex. As a general rule, the common skin disorders that run in families, such as psoriasis, atopic eczema, and acne, tend to belong to the latter group.

Single gene disorders

Recent advances in genetic technology have been relatively easy to apply to these, usually rather uncommon, disorders, most of which had already been classified accurately on clinical grounds. Several things followed from this:

- (1) The next step has often been an improvement in current clinical classifications, which can now be based logically on the underlying molecular abnormalities of the disorders in question. A good example of this is the modern classification of the inherited mechano-bullous disorders (also known as epidermolysis bullosa).
- (2) New skin constituents were quickly recognized, their function being understood after studying the disorders in which they

Clinical signs of thyroid disease

Hypothyroidism	Hyperthyroidism
Dry skin	Soft, thickened skin
Oedema of eyelids and hands	Pretibial myxoedema
Absence of sweating	Increased sweating (palms and soles)
Coarse, thin hair—loss of pubic, axillary, and eyebrow hair	Thinning of scalp hair
Pale “ivory” skin	Diffuse pigmentation
Brittle poorly growing nails	Rapidly growing nails
Purpura, bruising, and telangiectasia	Palmar erythema Facial flushing

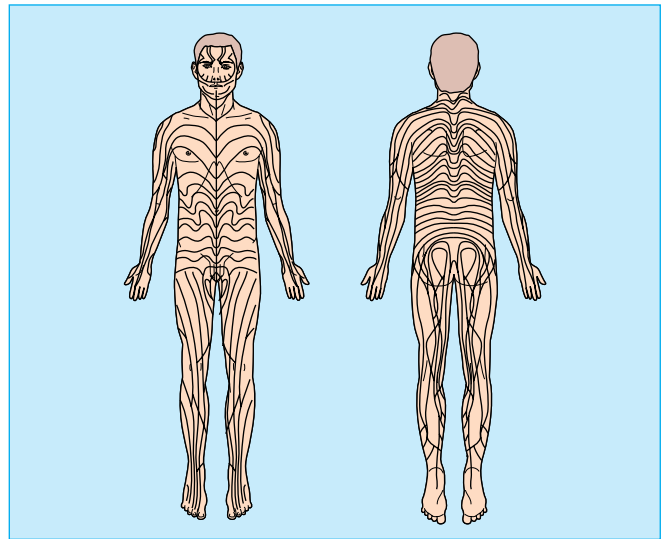

are abnormal. Soon it was realized that the same molecules could be the targets both for genetic abnormalities and for acquired skin diseases. One example of this is the way in which autoantibodies directed against one of the constituents of hemidesmosomes (BP180) cause pemphigoid, whereas mutations in the gene responsible for BP180 are the basis of the junctional type of epidermolysis bullosa.

- (3) Advances have been made too in our understanding of the structure and function of normal skin and its appendages—for example, the finding that melanocortin-1 receptor gene variants are associated with fair skin, red hair, and skin tumours.
- (4) Mosaics were soon recognized. Clinically these are linear abnormalities in the skin, usually present at birth, which often contain cells with the same genetic abnormalities as those of known generalised genodermatoses. A good example of this is the way the same abnormalities in the genes controlling the production of keratins 1 and 10 can be responsible both for a generalised skin condition (epidermolytic hyperkeratosis) and for warty linear naevi. The mosaic areas follow Blaschko's lines, a bizarre pattern of lines and whorls, which are not the same as dermatomes.
- (5) The prenatal diagnosis of severe genodermatoses has become more accurate, though gene therapy has not yet fulfilled its early promise.

Genetically complex disorders

Psoriasis is a good example. It clusters in some families but does not follow a classical Mendelian pattern of inheritance. Environmental triggers are important, as well as genetic factors. Over the last few years, several wide scans of the genome have been undertaken with the aim of identifying the location of the genes that determine susceptibility to psoriasis. Five have been confirmed, all on different chromosomes, and now designated as Psors1 to Psors5. A further six loci may have similar effects, but the evidence for them is less strong. Psors1, on chromosome 6p21.3, is an especially important gene for psoriasis susceptibility in many populations and lies within the area of the major histocompatibility complex (MHC). However it is not itself an HLA class I gene, and may belong to the newly described MHC class I chain-related (MIC) gene family. The possession of one allele (A5.1) of this gene seems to lead to a type of psoriasis that starts especially early, and is more common in familial than in sporadic cases.

In *atopic eczema*, matters are equally complicated. Environmental factors may well be responsible for the recent rise in its prevalence as the gene pool within the population is not likely to have changed greatly, but a genetic component is obvious too, even though affected children can be born to clinically normal parents. Within each family, atopic disorders tend to run true to type, so that, in some, most affected members will have eczema, in others, respiratory allergy predominates. The inheritance of atopic eczema probably involves genes that predispose to the state of atopy, and others that determine whether it is asthma, eczema, or hay fever that develops. One plausible gene for the inheritance of atopy encodes for the β subunit of the high affinity IgE receptor, and lies on chromosome 11q13. However several groups have failed to confirm earlier reports of this linkage, and a gene linked to atopic eczema has recently been found on chromosome 3q21.

Blaschko's lines

The abnormality underlying some inherited skin disorders

Skin disorder	Abnormality in
Ehlers–Danlos syndrome	Collagen and the extracellular matrix
Dystrophic epidermolysis bullosa	Type VII collagen
Pseudoxanthoma elasticum	Elastic tissue
Xeroderma pigmentosum	DNA repair
Simple epidermolysis bullosa	Keratins 5 and 14
Epidermolytic hyperkeratosis	Keratins 1 and 10
Palmoplantar keratoderma	Keratins 9 and 16
Junctional epidermolysis bullosa	Laminins
X-linked recessive ichthyosis	Steroid sulphatase
Darier's disease	Epidermal cell adhesion
Albinism (tyrosinase negative type)	Tyrosinase

17 Cutaneous immunology—Autoimmune disease and the skin (DJ Gawkrödger)

Types of allergic reaction

Allergic and other immune reactions may occur in the skin—the “immunological battleground of the body”—rather than involving internal organs. An acute vasculitis occurring in the skin is unpleasant and requires treatment but the same reaction occurring in the kidneys can be life threatening. The pattern of skin changes can indicate the type of immune process involved and also whether there is likely to be systemic involvement. The immune response of the skin is also used clinically in the tuberculin skin test to detect the level of immunity to tuberculosis. It is also the means of immunisation when an injection of inactivated organisms induces an immune response that protects the entire body.

The different types of immune reaction are all manifested in the skin as part of a normal response to pathogens or as an allergic reaction. The difference is expressed by the word “allergy”, first used by Von Pirquet in 1906, derived from the Greek (αλλοξ εργον), meaning literally “other work”. In other words it is a response that is appropriate for pathogenic organisms such as a tubercle bacillus but is misdirected against a harmless substance such as a rubber glove or the metal of a watch strap buckle.

Immunological reactions are of four types—five if autoimmunity is counted—of responses mediated by antibodies known as the humoral response and one by the lymphocytes known as the cell mediated response.

Immediate hypersensitivity

This type of reaction is caused by “reagin” antibodies, which consist mainly of IgE, that react with allergens such as house dust mite, animal dander, or grass pollens. These reactions may occur in both the skin or the lung to produce asthma. Allergic reactions to insect stings can cause severe systemic effects—“anaphylaxis”, which literally means “without protection”. Food proteins can also cause an immediate type of hypersensitivity reaction. The IgE molecule is attached to specific receptors on the surface of mast cells and when activated by linkage to specific allergen inflammatory mediators are released. This is an acute process, hence the name “immediate hypersensitivity”.

The initial response occurring within five minutes is due to by the release of histamine, heparin, tryptophan. This is followed by inflammatory mediators—released in five to 30 minutes—leukotrien, prostaglandin. The later response, occurring after some hours, is caused by cytokines—predominantly tumour necrosis factor α (TNF- α) and interleukin 4 (IL4).

Severe reactions cause shock that is made worse by stress and exercise, as in the case of a young woman, allergic to wasp stings, who had a wasp sting when picnicking by a lake. She then plunged into the cold water, swimming vigorously, leading to a fatal anaphylactic reaction. Acute anaphylactic reactions to peanuts may be life threatening.

Cytotoxic reactions

In this case cells become the target of attack by circulating antibodies. There are a number of causes, such as drugs or proteins attached to the cell surface that act as haptens so they

Reaction to fish protein

Type I—immediate hypersensitivity

Type II—cytotoxic

become antigenic. This occurs in drug induced haemolysis from drugs. Alternatively, immune complexes are attached to the surface of the cell with the incorporation of complement leading to lysis. In haemolytic anaemia and incompatible blood transfusions antibodies are formed against erythrocytes. They may also be destroyed by killer cells. A typical example is haemolytic anaemia.

This immune response is the means of destroying cells that become antigenic as a result of being infected with virus.

In autoimmune diseases antibodies are directed against specific structures.

Antigen-antibody complex reactions

As a result of antibody production to antigens in the circulation, complexes form in the blood and these may be deposited in capillaries resulting in inflammatory changes. Similar changes may occur in the lung. This involves the activation of complement and the release of mediators of inflammation, producing vasodilatation and the accumulation of polymorphs.

Delayed hypersensitivity

This type of reaction results from lymphocytes known as T cells, because of their derivation from the thymus, which react with antigen in the skin. The reaction is initiated by antigen attached to Langerhan’s cells in the epidermis being transported to the paracortical area of the regional lymph node with the production of lymphocytes sensitised specifically for that antigen. There is also the production of interleukin which has a feedback effect in stimulating the production of more sensitised lymphocytes.

The reaction of the T lymphocytes in the epidermis results in the accumulation of macrophages and the release of inflammatory mediators.

Type III—circulating immune complexes

Type IV—delayed hypersensitivity

Autoimmune disease and the skin by DJ Grawkrodger

There is always the risk that the well developed human immune system may react against the body’s own tissues, with a failure to distinguish between “self” and “non-self”. An immune response develops which may be specific for a particular organ, such as the thyroid gland, or react against a number of different organs, as in connective tissue diseases. The skin can manifest both types of autoimmume response. The results of such reactions can be destruction of the cells concerned and the production of inflammation. There is an inherited tendency to autoimmune disease, marked by specific HLA (human lymphocyte antigen) in some cases.

The most common types of skin disease in which this autoimmune mechanism occurs are the blistering disorders, pemphigoid and pemphigus, as well as dermatitis herpetiformis.

Pemphigoid

In this condition large, tense blisters develop in which there are antibodies attached to the upper layer of the basement membrane at the dermo-epidermal junction, with an underlying inflammatory reaction producing a split above the basement membrane. Lysosomal enzymes are released damaging the basement membrane, resulting in separation of the epidermis and blister formation. The presence of

Reaction to metal

Blistering disorder as a result of an autoimmune response

Split at dermo-epidermal junction

ABC of Dermatology

antibodies, usually IgG, can be shown by an antihuman IgG antibody labelled with fluorescein. When viewed under the microscope with ultraviolet light illumination, the presence of the IgG antibody is shown by fluorescence. The presence of circulating ant basement membrane antibodies in the serum can be shown either by direct immunofluorescence using a specimen of the patient's skin or by incubation by attachment to skin which has been incubated in serum from the patient.

The clinical features are described in chapter 8. The blisters develop, frequently with an erythematous background, on the limbs, trunk, and flexures. It is mainly seen in the elderly and is slightly more common in women.

Direct immunofluorescence

Indirect immunofluorescence

Indirect immunofluorescence

Pemphigus

Pemphigus

In this condition, antibodies are found to have developed against the epidermis above the basement membrane. The main antibody is IgG, but IgM and IgA may also be found. As a result of this reaction, there is separation of the epidermal cells with the formation of a superficial blister. A row of basal cells remains attached to the basement membrane. Direct immunofluorescence of the skin from affected patients shows that antibodies are deposited on the intercellular substance of the epidermis. Circulating antibodies are often present. Oral lesions are much more common than in pemphigoid.

Intraepidermal split

Direct immunofluorescence

Other organ-specific autoimmune diseases of the skin

Vitiligo

In this condition there is a loss of pigment as a result of antibodies developing against melanocytes in the skin in a limited area. However, the areas affected tend to gradually increase. There may be other autoimmune diseases in the same patient, causing, for example, pernicious anaemia, and thyroid disease.

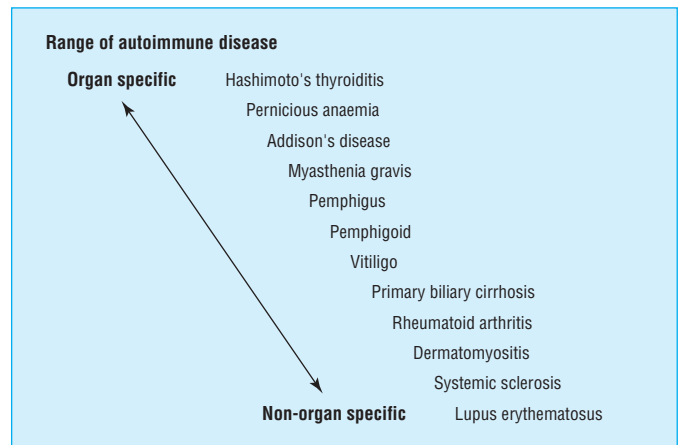

Alopecia areata

There is evidence that this condition may be associated with an immune reaction against the hair follicle. The increased incidence of antibodies to the thyroid gland and gastric parietal cells in patients with alopecia areata provides circumstantial support for an autoimmune aetiology.

Non-organ-specific skin autoimmune disease

Systemic lupus erythematosus (SLE)

The hallmark of this condition is the presence of antibodies against various components of the cell nucleus. Although a wide range of organs may be affected, in three quarters of the patients the skin is involved, generally with an erythematous eruption occurring bilaterally on the face in a "butterfly" distribution. There may also be photosensitivity, hair loss, and areas of vasculitis in the skin. There is often intolerance of

Range of autoimmune disease

Clinical variants of lupus erythematosus

- Systemic
- Subacute cutaneous
- Discoid
- (Neonatal)

sunlight. Subacute lupus erythematosus is a variant that presents with an erythematous eruption in the skin and anticytoplasmic RNA molecules.

Discoid lupus erythematosus (DLE)

This is a condition in which circulating antinuclear antibodies are very rare. There are quite well defined inflammatory lesions, with some degree of atrophy occurring on the face and occasionally on the arms as well.

Treatment of SLE with the threatened or actual involvement of organs is important. Prednisolone is usually required and sometimes immunosuppressant drugs such as azathioprine as well. Treatment of DLE is generally with topical steroids. Hydroxychloroquine by mouth is also used, generally in a dose of 200 mg daily. This drug can diminish visual acuity and this should be checked every few months. A simple chart, the Amsler Chart, is available for patients to use, consisting of a central dot with a grid which becomes blurred when held at arm's length when there is any impairment of acuity.

Systemic sclerosis

This is a condition in which there is extensive sclerosis of the subcutaneous tissues in the fingers and toes as well as around the mouth (scleroderma), with similar changes affecting the internal organs, particularly the lung and kidneys. There are vascular changes producing Raynaud's phenomenon and telangiectasia around the mouth and fingers. It is associated with antinuclear antibodies (speckled or nucleolar), and in about 50% of cases circulating immune complexes may be present. Endothelial cell damage in the capillaries results in fibrosis and sclerosis of the organs concerned. There is considerable tethering of the skin on the fingers and toes, which becomes very tight with a waxy appearance and considerable limitation of movement. A variant is the CREST syndrome.

Morphoea is a benign form of localised systemic sclerosis in which there is localised sclerosis with very slight inflammation. There is atrophy of the overlying epidermis. The early changes often consist of a dusky appearance to the skin.

The clinical features are described in chapter 16.

Dermatomyositis

This condition is described in chapter 16, but the main immunological features are deposition of IgG, IgM, and C3 at the dermo-epidermal junction in about half the cases in the early stages, as well as a lymphocytic infiltrate with CD4+ cells and macrophages. There are reports of autoantibodies in some patients. Dermatomyositis may represent an immune reaction to an underlying mechanism or derangement of the normal immune response.

Lichen sclerosis

This condition is also described in chapter 16 and is characterised by atrophic patches of skin. It occurs mainly in females and predominantly involves the genitals and perineum. The cause is unknown but in early lesions there is a band of lymphocytes, mainly CD3, CD4, and CD8. Immunoglobulins and complement accumulate in the affected areas. There is an association with vitiligo, morphoea, alopecia, and pernicious anaemia, suggesting an autoimmune association.

ABC of Dermatology

Graft versus host disease

This reaction occurs following bone marrow transplantation in immunosuppressed patients. T lymphocytes produced by the graft react against the body's own tissues, producing a skin eruption which may resemble measles. There is lysis of the basement membrane with shedding of the skin and sometimes lichen planus-like eruption. In the more chronic form, localised lesions develop, with immunoglobulins deposited in the walls of blood vessels with the activation of complement.

18 Bacterial infection

RJ Hay

The process of infection involves the interaction between two organisms—the host and the invader. The clinical changes result from mechanisms involved in this process, notably the micro-organism, its virulence, and the patient's immune defenses. The lesions produced often have a well defined appearance, such as impetigo or tinea cruris, but the changes may be less specific.

Several features enable us to recognise that infection is a possible cause of the patient's condition. Acute bacterial infections generally produce some or all of the classical characteristics of acute inflammation.

Cardinal signs of infection

- Erythema
- Swelling and oedema
- Heat or warmth
- Pain and discomfort

Clinical presentation

The woman shown in the photographs had acute *erysipelas* due to streptococcal infection, and all four features of inflammation were present. She was referred to the clinic with a diagnosis of an acute allergic response, which, from the appearance alone, was understandable. However, malaise and fever were also present and the lesions were warm and tender. The condition responded well to antibiotic treatment. The point of entry in such cases is thought to be a small erosion on the face. Erysipelas of the leg or foot may follow the development of a small fissure between the toes, but often there is no discernible portal of entry.

Erysipelas is the local manifestation of a Group A streptococcal infection, in the case illustrated the infection is confined to deep dermis as a form of cellulitis. However the same organism at distal sites, through the production of toxins or superantigens, can cause other skin lesions such as: (a) the rash of scarlet fever; (b) erythema nodosum; (c) guttate psoriasis; and (d) an acute generalised vasculitis.

Other forms of local bacterial infection include *impetigo*, *folliculitis*, and *furuncles* (boils). These conditions are caused by *Staphylococcus aureus* and in the case of folliculitis or boils the infection is associated with a local abscess. *Staph. aureus* colonises the anterior nares or perineum of normal people; it also commonly colonises eczema and may cause an acute exacerbation of atopic dermatitis.

Impetigo is a superficial infection of the skin of which there are two forms. In the non-bullous form the affected skin is covered with crusts. Both staphylococci and streptococci are responsible. However the bullous form which presents with blisters is due to staphylococci. Folliculitis, an inflammation of the hair follicle, is commonly caused by *Staph. aureus*. Infection of the scalp or beard hair (*syccosis barbae*) is uncommon but may become chronic. Abscess formation around the hair follicles may result in furuncles or boils; where several furuncles coalesce the lesion is known as a carbuncle.

Ecthyma, which is most common on the leg, is due to bacterial infection penetrating through the epidermis to the dermis causing a necrotic lesion with a superficial crust and surrounding inflammation. Both streptococci and staphylococci are responsible.

Mycobacterial disease

The clinical presentation of infections due to mycobacteria, a specific group of organisms that includes the causes of tuberculosis and leprosy, reflects the success of the host's response in eradicating organisms. There are clear differences, for instance, between disseminated miliary tuberculosis and lupus vulgaris or, for example, tuberculoid and lepromatous leprosy. These are discussed in chapter 23. As these infections are not common only lupus vulgaris and non-tuberculous or "atypical" mycobacterial infection are described.

Tuberculous mycobacterial infections

Lupus vulgaris presents as a very slowly growing indolent plaque. It usually represents a localised skin infection disseminated from a deep focus of infection. Squamous carcinomas may develop in long standing cases.

Acute erysipelas: presentation

Acute erysipelas: patient shown in same patient two weeks later

Clinical presentation—points to note

- In any patient with a localised area of acute erythema, swelling, and fever—consider infection
- Remember that a generalised erythematous rash may be the manifestation of a localised infection. Scarlet fever arises from streptococcal sore throat, and herpes simplex of the lip may be associated with erythema multiforme
- The common pathogens are also commensals—recent studies showed that 69% of individuals are nasal carriers of *Staphylococcus aureus* and some may carry Group A streptococci in the throat

Lupus vulgaris

Mycobacterial disease—histology

Non-tuberculous mycobacterial infections

The most common is “fishtank” or “swimming pool” granuloma, acquired from tropical fish or rarely swimming pools, respectively, and caused by *Mycobacterium marinum*. Nodular lesions develop slowly with ulceration and may spread along local lymphatics to give a chain of nodules (sporotrichoid spread). Injection abscesses may be caused by mycobacteria such as *M. chelonae*. Buruli ulcer, an extensive ulcerating condition due to *M. ulcerans*, is confined to the tropics.

Swimming pool granuloma

Other infections

Rochalimea infections include bacillary angiomatosis, which presents in AIDS patients with small haemangioma-like papules, and cat scratch disease where crusted nodules appear at the site of the scratch associated with the development of regional lymphadenopathy one or two months later. A maculopapular eruption on the face and limbs or erythema multiforme may occur.

Psittacosis and ornithosis may be associated with a rash.

Rickettsial infections, including typhus, Rocky Mountain spotted fever, and rickettsial pox, are all associated with rashes, often purpuric.

Syphilis

There is a disseminated erythematous rash in secondary syphilis that is followed by a papulosquamous eruption, which affects the trunk, limbs, and mucous membranes. The palms and soles may be involved. There are also small clustered mouth ulcers. In patients with AIDS the rash of secondary syphilis is florid and often crusted or scaly.

Secondary syphilis

Common patterns of cutaneous bacterial infection

	Infected eczema	Impetigo (nonbullous)	Impetigo (bullous)
<i>Appearance</i>	 <p>Exudate Crusts Inflammation</p>	 <p>Transient vesicles Exuding lesions with yellow crusts Erythema Affects mainly face and limbs, commonly in children</p>	 <p>Erythema and bullae which rupture leaving superficial crusts Affects mainly face and limbs in children and adults</p>
<i>Cause</i>	Persistent scratching Topical steroids	Toxic reaction between organisms and epidermis resulting in superficial epidermal split in bullous lesions	
<i>Organisms</i>	<i>Staphylococcus aureus</i> <i>Streptococcus pyogenes</i>	<i>Staphylococcus aureus</i> <i>Streptococcus pyogenes</i> in some outbreaks	<i>Staphylococcus aureus</i>
<i>Treatment</i>	(1) Weaker topical steroids (for the eczema) with topical antibiotics (2) Systemic antibiotics if necessary (3) Soaks with potassium permanganate	Topical antibiotics Systemic antibiotics against both streptococcal and staphylococcal infection	Topical and systemic antibiotics
<i>Notes</i>	<ul style="list-style-type: none"> • Avoid prolonged use of topical antibiotics • Return to using weaker steroid • It is wise to send a specimen for bacteriology: when infection has healed • Even without clinical evidence of infection most lesions of atopic eczema are colonised by <i>Staphylococcus aureus</i> 	<ul style="list-style-type: none"> • Staphylococcal infection can cause generalised superficial shedding of the epidermis—"scalded skin syndrome" (Lyell's disease) • It is wise to send specimens for culture in an outbreak to identify presence of Group A streptococci potentially implicated in glomerulonephritis 	

Boils (furuncles)

Inflammatory nodule affecting the hair follicles develops into a pustule
Tender induration with severe inflammation, followed by necrosis
Heals with scarring
Affects all ages
Several boils may coalesce to form a carbuncle

Underlying disease—for example, atopy
Mechanical damage from clothing, occlusion

Staphylococcus aureus, usually of same strain as in nose and perineum

- (1) Antibiotic (penicillinase resistant) systemically
- (2) Cleaning of skin with weak chlorhexidine solution or a similar preparation

- Nasal and perineal swabs should be taken to identify carriers
- Remember unusual causes—a bricklayer presented with a boil on the arm with necrosis due to anthrax (malignant pustule) acquired from the packing straw used for the bricks

Folliculitis

Various forms:
(1) *Scalp*
Children—"Follicular impetigo"
Adults—
(a) Keloidal folliculitis
Back of neck
(b) Acne necrotica
Forehead/hairline
(2) *Face*—"Sycosis barbae"
(3) *Legs*—Chronic folliculitis

- (1) Underlying disease—for example, eczema
- (2) Infection may be by mechanical precipitated injury, greasy emollients, and occlusive dressings

Staphylococcus aureus
Propionibacterium acnes
Malassezia spp.
Pseudomonas spp. and other Gram negative organisms

Topical and long term systemic antibiotics—for example, erythromycin
Topical antifungal for *Malassezia* infection

- Gram negative folliculitis occurs on the face—a complication of long term treatment for acne
- Gram negative folliculitis on the body is associated with exposure to contaminated baths or whirlpools

Ecthyma

Small bullae may be present initially
An adherent crust is followed by a purulent ulcerated lesion with surrounding erythema and induration, which slowly heals
Usually on legs

Hot climate, occlusion
More common in debilitated individuals
May follow secondary infection of chicken pox

Both *Streptococci* and *Staph. aureus*

Improve nutrition
Use antibiotic effective against both staphylococci and streptococci

- Check for debilitating diseases, reticuloses, diabetes

Erysipelas

Well defined areas of erythema—very tender, not oedematous
Vesicles may form
Common sites—abdominal wall in infants; in adults the lower leg and face
An area of broken skin, forming a portal of entry, may be found

Lymphoedema and severe inflammation due to bacterial toxins

Strep. pyogenes (group A, but may be B, C, or G)
Staphylococcus aureus
Klebsiella pneumoniae
Haemophilus influenzae

Penicillin or erythromycin

- Cellulitis affects the deeper tissues and has more diverse causes, being essentially inflammation of the connective tissue
- *Streptococcus*, *Staphylococcus*, *Haemophilus*, and other organisms may be found
- One of the complications of erysipelas of the face is thrombosis of the cavernous sinus

19 Viral infections

Like the pyogenic bacteria, viruses produce local lesions and may also cause a widespread reaction to the infection such as erythema multiforme. However, the clinical manifestations of common viral infections of the skin are easily recognised.

Local infective lesions caused by DNA viruses which can be isolated from the lesions themselves include the herpes and pox virus groups. In patients with AIDS chronic and widespread viral infections of the skin occur.

Herpes

Herpes simplex

The herpes simplex virus consists of two viral subtypes. Type I is associated with lesions on the face and fingers and sometimes genital lesions. Type II is associated almost entirely with genital infections. Recurrent episodes of infection are common, with both due to latent infection of sensory nerve ganglia.

Primary herpes simplex (type I) infection usually occurs in or around the mouth, with variable involvement of the face. Lesions are small vesicles which crust over and heal but there may be considerable malaise. Type II infection affects the external genitalia and waist area.

Recurrent infections are shorter lived (three to five days), occur in the distribution of a sensory nerve on the face or genitalia, and may be triggered by a variety of stimuli from sunlight to febrile illness.

Herpes simplex—points to note

- The initial vesicular stage may not be seen in genital lesions, which present as painful ulcers or erosions
- There is usually a history of preceding itching and tenderness
- The most rapid methods of detecting virus from scrapings from the base of the ulcer are electronmicroscopy, immunofluorescence, or PCR
- Genital herpes in a pregnant woman carries a great risk of ophthalmic infection of the infant. Caesarean section may be indicated
- “Eczema herpeticum” or “Kaposi’s varicelliform eruption” are terms applied to severe cutaneous and, less commonly, systemic, infection with herpes virus in patients with atopic eczema and some other skin conditions. Treatment is with oral or parenteral aciclovir

Herpes zoster

Varicella zoster virus (VZV) causes both chickenpox, the primary illness, and herpes zoster, which follows reactivation of the virus in the nerve ganglia. In zoster, pain, fever, and malaise may occur before erythematous papules develop in the area of the affected dermatome—most commonly in the thoracic area. Vesicles develop over several days, crusting over as they resolve. Secondary bacterial infection is common. Some patients develop episodes of pain in the affected area—postherpetic neuralgia after clearance of the rash. Skin lesions and nasopharyngeal secretions can transmit chickenpox.

Molluscum inclusion bodies (a pox virus)

Herpes of lips

Inoculation herpes

Herpes simplex

Eczema herpeticum

Herpes zoster

Herpes zoster

Herpes zoster—points to note

- Trigeminal zoster may affect:
 - the ophthalmic nerve (causing severe conjunctivitis)
 - the maxillary nerve (causing vesicles on the uvula or tonsils)
 - the mandibular nerve (causing vesicles on the floor of the mouth and on the tongue)
- Disseminated zoster is a severe illness presenting with widespread lesions. Visceral lesions may present with pleuritic or abdominal pain
- Extensive and haemorrhagic vesicles may develop in patients with AIDS

Mandibular zoster

Treatment

Localised lesions of herpes simplex have been treated with a variety of medications from zinc sulphate to idoxuridine. Topical acyclovir—a drug that inhibits herpes virus DNA polymerase—is effective but only shortens the duration of illness by a day or so. It is useful in primary infection but should be used as soon as the patient is aware of symptoms.

Severe, recurrent, herpes simplex, or herpes zoster can be treated with oral or intravenous aciclovir as early in the course of the illness as possible. Ganciclovir is an alternative.

Secondary infection may require antiseptic soaks, such as 1/1000 potassium permanganate, or topical or systemic antibiotics.

Steroids (prednisolone 40–60 mg/day) given during the acute stage of herpes zoster may diminish pain and postherpetic neuralgia.

Rest and analgesics are recommended treatment for extensive herpes simplex or herpes zoster infections.

Ophthalmic zoster

Pox viruses

The pox viruses are large DNA viruses, with a predilection for the epidermis. Variola (smallpox), once a disease with high mortality, has been eliminated by vaccination with modified vaccinia (cowpox) virus.

Molluscum contagiosum

The commonest skin infection due to a pox virus is molluscum contagiosum, a skin infection seen particularly in children. Despite its name it is not very contagious, but can occur in families.

In adults florid molluscum contagiosum may be an indication of underlying immunodeficiency, as in AIDS patients.

Clinical features

The white, umbilicated papules of molluscum contagiosum are characteristic. Large solitary lesions may cause confusion as can secondarily infected, excoriated lesions. These lesions often itch, particularly in patients with atopy. Resolving lesions may be surrounded by a small patch of eczema.

Diagnosis

Diagnosis is usually based on clinical appearances or microscopy of the contents of papules. Sometimes there is confusion with viral warts.

Treatment

Most treatments result in discomfort and may not be tolerated by young children. An antibiotic–hydrocortisone ointment can be used for excoriated lesions. Treatment with liquid

Steroids may cause disseminated infection in immunodeficient patients

Molluscum contagiosum

ABC of Dermatology

nitrogen is probably the simplest treatment. Other methods include superficial curettage and carefully rotating a sharpened orange stick moistened with phenol in the centre of each lesion.

Other pox virus infections

The other pox infections are of incidental interest.

Cowpox only sporadically infects cows from its natural reservoir, probably small mammals, and may affect humans. Papules on the hands enlarge and develop necrosis and crusting.

Milkers' nodules are due to a virus that causes superficial ulcers in cows' udders and calves' mouths. In humans papules form on the hands and develop into grey nodules with a necrotic centre, surrounding inflammation, and lymphangitis. A more generalised papular eruption can occur.

Orf is often recognised in rural areas. It is seen mainly in early spring as a result of contact with lambs. A single papule or group of lesions develops on the fingers or hands with purple papules developing into bulla. This ruptures to leave an annular lesion 1–3 cm in diameter with a necrotic centre. There is surrounding inflammation. The incubation period is a few days and the lesions last two to three weeks with spontaneous healing. Associated erythema multiforme and widespread rashes are occasionally seen.

Cowpox, early stage

Milker's nodule

Wart viruses

A growing recognition that there is an association between human papilloma viruses (HPV), which cause warts, and cancer has led to a renewed interest in these infections. The wart is one of the few tumours in which a virus can be seen to proliferate in the cell nucleus. The different clinical forms of wart are caused by range of HPV, currently divided into over 80 major types. These viruses are also responsible for cervical cancer and have been associated with squamous carcinomas in the immunosuppressed. Warts are classed as cutaneous or mucocutaneous. Epidermodysplasia verruciformis is a rare condition associated with a defect of specific immunity to wart virus. The following aspects should be remembered:

- Genital warts (due to HPV) very rarely undergo malignant change but HPV infection of the cervix, caused by type 16, frequently leads to dysplasia or in some cases malignant changes. Cervical smears must be taken.
- Very extensive proliferation of warts occurs in patients receiving immunosuppressive therapy, such as renal transplant recipients—in whom wart-like lesions can develop into squamous carcinomas—and in patients with AIDS.
- There is an association between HPV infections of the skin in immunosuppressed patients and the subsequent development of atypical-looking squamous carcinomas.
- Epidermodysplasia verruciformis, an unusual widespread eruption of flat erythematous warty plaques, can also develop into carcinoma.

Orf

Common warts

Treatment

Warts commonly occur in children and resolve spontaneously without treatment or with very simple measures. These include paints or lotions containing salicylic and lactic acids in various proportions, which should be applied daily. Salicylic acid (40%) plasters are useful for plantar warts; they are cut to shape and held in place with sticking plaster for two or three days. Glutaraldehyde solution is also used.

For large or painful warts other measures can be used:

- Liquid nitrogen is effective but has to be stored in special containers and replaced frequently. It can be applied with cotton wool or discharged from a special spray with a focused nozzle. Freezing is continued until there is a rim of frozen tissue around the wart but not for more than 30 seconds. Subsequent blistering may occur. Scarring is unusual. Carbon dioxide is more readily available and can be transported in cylinders that produce solid carbon dioxide “snow”. The temperature (about -64°C) is not as low as liquid N_2 (-196°C)
- Heat cauterization causes more scarring and requires local anaesthesia. The diathermy loop is effective for perianal warts.
- Curettage and cauterization together are effective but leave scars and the warts may recur.
- Podophyllin, 15–25% in tincture of benzoin compound or alcoholic solution, is effective for genital warts when applied each week. It is, however, toxic when ingested or absorbed, may cause burns, and must never be used in pregnancy.

Other treatments include laser therapy, immune enhancement (for example interferon β), and bleomycin injections. However, relapse is common whatever the remedy.

Treatment of warts with liquid nitrogen

Virus diseases with rashes

Measles and rubella are much less common than previously as a result of widespread immunisation. However, measles is probably the best known example of an exanthem (a fever characterised by a skin eruption. In an exanthem the mucous surfaces are affected.) Other common clinical patterns can then be compared with it. All exanthems, except fifth disease (erythema infectiosum), due to RNA viruses.

Virus diseases with rashes

- Measles
- Rubella
- Infectious mononucleosis
- Erythema infectiosum
- Roseola infantum
- Gianotti–Crosti syndrome
- Hand, foot, and mouth disease
- Primary HIV infection

Measles

- *Age.* Measles usually affects children, particularly those aged over five years.
- *Incubation* lasts seven to 14 days. Prodromal symptoms include: fever, malaise, upper respiratory symptoms; conjunctivitis; and photophobia.
- *Initial rash.* Early on Koplik's spots (white spots with surrounding erythema) appear on the oral mucosa. After two days a macular rash appears on the face, trunk, and limbs. Look behind the ears for early lesions.
- *Development and resolution.* The rash becomes papular, with coalescence. There may be haemorrhagic lesions and bullae which fade to leave brown patches.
- *Complications* are encephalitis, otitis media, and bronchopneumonia.
- *Diagnosis.* Specific antibodies may be detected; they are at their maximum at two to four weeks.

Measles

Rubella

- *Age.* Rubella affects children and young adults.
- *Incubation* lasts 14–21 days.
- *Prodromal symptoms.* There are none in young children. Otherwise fever, malaise, and upper respiratory symptoms occur.
- *Initial rash.* Initially some patients develop erythema of the soft palate and lymphadenopathy. Later pink macules appear on the face, spreading to trunk and limbs over one to two days.

Rubella

ABC of Dermatology

- *Development and resolution.* The rash then clears over the next two days, and sometimes no rash develops at all.
- *Complications.* The most important complications are congenital defects in babies of women infected during pregnancy. The risk is greatest in the first month of pregnancy.
- *Diagnosis.* The diagnosis is made from the clinical signs above. Serum should be taken for antibodies and the test repeated at seven to 10 days.
- *Prophylaxis.* Active immunisation is routinely available for all schoolgirls.

Erythema infectiosum (fifth disease)

- *Age.* Erythema infectiosum affects children aged two to 10 years, mainly girls.
- *Incubation* lasts five to 20 days.
- *Prodromal symptoms.* There are usually none, but there may be a slight fever with initial rash.
- *Initial rash.* The initial rash is a hot, erythematous eruption on the cheeks—hence the “slapped cheek syndrome”. Over two to four days a maculopapular eruption develops on the arms, legs, and trunk.
- *Development and resolution.* The rash extends to affect hands, feet, and mucous membranes, then fades over one to two weeks.
- *Diagnosis* is made by finding a specific IgM antibody to parvovirus B19.
- *Complications.* There are no reported dermatological complications but haematological disorders such as thrombocytopenia, arthropathy, and fetal abnormalities may be associated.

Erythema infectiosum

Roseola infantum

- *Age.* Roseola infantum affects infants aged under two years.
- *Incubation* lasts 10–15 days.
- *Prodromal symptoms.* There is fever for a few days.
- *Initial rash.* A rose pink maculopapular eruption appears on the neck and trunk.
- *Development and resolution.* The rash may affect the face and limbs before clearing over one to two days.
- *Diagnosis.* The condition is diagnosed from its clinical features.
- *Complications* include febrile convulsions.

Gianotti–Crosti syndrome

Gianotti–Crosti syndrome

- *Age.* The Gianotti–Crosti syndrome affects children, usually those aged under 14 years.
- *Incubation* period is unknown.
- *Prodromal symptoms.* Lymphadenopathy and malaise accompany the eruption.
- *Initial rash.* Red papules rapidly develop on the face, neck, limbs, buttocks, palms, and soles.
- *Development and resolution.* Over two to three weeks the lesions become purpuric then slowly fade.
- *Diagnosis.* The syndrome may be due to a number of virus infections such as hepatitis B.
- *Complications.* Lymphadenopathy and hepatomegaly always occur and may persist for many months.

Hand, foot, and mouth disease

Hand, foot, and mouth disease

- *Age.* Hand, foot, and mouth disease (Coxsackie virus A) affects both children and adults.
- *Incubation* period is unknown.
- *Prodromal symptoms.* Fever, headache, and malaise may accompany the rash.

- *Initial rash.* Initially there may be intense erythema surrounding yellow-grey vesicles 1–1.5 mm in diameter. These are mainly distributed on the palms and soles and in the mouth. Sometimes a more generalised eruption may develop.
- *Development and resolution.* Over three to five days the rash fades.
- *Diagnosis.* Coxsackie A (usually A16) virus is isolated from lesions and stools. A specific antibody may be found in the serum.
- *Complications* are rare but include widespread vesicular rashes and erythema multiforme.

Other infections

Infectious mononucleosis

As well as the erythematous lesions on the palate a maculopapular rash affecting the face and limbs can occur.

20 AIDS and the skin

MA Waugh

AIDS was first described in 1981 and since then 22 million people have died of the disease. The World Health Organisation estimates that in December 2000, 36 million people were infected with HIV. Of these, 1.5 million were children under the age of fifteen. It is estimated that 5.3 million people were newly infected with HIV in the year 2000 and 3 million have died in the same year. A total of nearly 22 million people have died of AIDS since the start of the epidemic. In the United Kingdom the prevalence of HIV infection is about 30 000. Over 65 000 in Europe are infected.

The human immunodeficiency virus (HIV) is the cause of the acquired immunodeficiency syndrome (AIDS). This virus was first isolated in 1983 in Paris and a second retrovirus, HIV2, was isolated from West Africa in 1986. The virus contains an enzyme that copies viral RNA into the DNA of the host cell in which the HIV virus then persists in the host cells, particularly monocytes, macrophages, and dendritic cells.

Stages of AIDS

Primary HIV infection

In 80% of cases there are initial symptoms and signs—“seroconversion illness”. There are a variety of symptoms including fever, malaise, headache, nausea, vomiting, and diarrhoea. There is often lymphadenopathy. The skin signs consist of a transient maculopapular eruption associated with erythema and erosions in the mouth in some patients.

Early stages

In the early stages 50% of patients have antibodies to HIV and the p24 antigen can be detected. The proportion of CD4 lymphocytes decreases, and this is associated with the development of secondary changes in the skin. There is also an increase in HIV antibodies so a test for this should be repeated six to eight weeks after the initial illness. Counselling should take place before testing is carried out.

Late stage HIV disease

The skin changes are many and variable. Common inflammatory skin diseases such as psoriasis and seborrhoeic dermatitis will be much more florid. Cutaneous infections are more severe due to the impaired immune response and opportunistic infections also develop. In addition, Kaposi's sarcoma occurs in 34% of homosexual men and in 5% of other cases.

AIDS should therefore be considered in any patient with a florid inflammatory skin disease that is resistant to treatment or severe and extensive infection of the skin.

Skin lesions in patients with AIDS

- Skin lesions can develop as a manifestation of primary HIV infection
- Skin lesions can develop as a consequence of immunosuppression (AIDS)

Between these two events there is a latent period that can last from a few months to several years

Flexural candidiasis

Kaposi's sarcoma

Skin changes in AIDS

Seborrhoeic eczema

This is common and may be the only evidence of HIV infection initially. It is more extensive and inflamed than usual. The role of *Pityrosporum* organisms is indicated by the response to imidazole antifungal drugs.

Seborrhoeic dermatitis

Psoriasis

Psoriasis is more widespread, severe, and resistant to treatment in patients with late HIV disease. The use of ultraviolet light may lead to an increased risk of Kaposi's sarcoma.

Infections

Any type of opportunistic infection is more likely in patients with AIDS and will generally be more severe. An itching, inflammatory folliculitis occurs in many cases. The cause is unknown, but it is possible that *Demodex* spp. play a part.

Fungal infections

Superficial fungal infections are often much more extensive and invade more deeply into the dermis than usual. There may also be granuloma formation.

Deep fungal infections that are not normally seen in healthy individuals occur in AIDS patients as opportunistic infections. *Cryptococcus neoformans* and *Histoplasma capsulatum* may cause inflammatory papular and necrotic lesions, particularly in the later stages of the disease.

Candidiasis is common and often associated with bacterial infections. It occurs particularly in and around the mouth, on the palate, and in the pharynx. It commonly causes severe vulvovaginitis in infected women.

Pityrosporum organisms occur more frequently and may produce widespread pityriasis versicolor on the trunk or extensive folliculitis.

Bacterial infections

Impetigo may be severe, with particularly large bullous lesions occurring.

Mycobacteria may produce widespread cutaneous and systemic lesions. Varieties of mycobacteria that do not normally infect the skin may cause persistent necrotic papules or ulcers.

Viral infections

Both herpes simplex and herpes zoster infections may be unusually extensive, with large individual lesions. In the case of herpes zoster the affected area may extend beyond individual dermatomes. Sometimes persisting ulcerated lesions occur.

Molluscum contagiosum lesions are frequently seen. They are much larger than usual and develop over quite large areas of skin. They are readily identified as small, firm papules with an umbilicated centre. When very large individual molluscum lesions occur they may be due to localised fungal infection, particularly *cryptococcus* and *histoplasmosis*.

Viral warts may be large and extensive. Perianal and genital warts due to the human papilloma virus (HPV) are common and may be associated with intraepithelial neoplasia of the cervix and sometimes invasive perianal squamous cell carcinoma. The warts tend to become smaller as the immune status of the patient improves with the treatment. It is not unusual for florid viral warts to develop in the mouth.

Skin changes in AIDS

- Seborrhoeic eczema
- Psoriasis
- Fungal infections
- Bacterial infections
- Viral infections
- Kaposi's sarcoma
- Drug rashes
- Oral hairy leukoplakia

Pseudomembranous candida

Aciclovir-resistant perianal herpes simplex infection

Other manifestations

Oral hairy leukoplakia occurs in 30–50% of patients with AIDS. It is characterised by an overgrowth of epithelial plaques on the sides of the tongue with a verrucous surface and a grey/white colour. It is believed to be due to a proliferation of the Epstein–Barr virus.

Infestations with various organisms is not uncommon and the severe widespread crusted lesions of Norwegian scabies may occur.

Kaposi's sarcoma

Kaposi's sarcoma is associated with the later stages of AIDS but can occur earlier. It is associated with herpes virus type 8. It often presents with small polychromic macules on the face, palate, trunk or groin which vary from red and purple to brown. They then develop into larger livid plaques, involving the trunk, limbs, and face, and also the oral mucosa. They are most common on the palate and nose. Sometimes the lesions are very aggressive.

B cell lymphoma may occur in the skin in 10% of AIDS patients. There is also an increased incidence of basal cell and squamous carcinomas.

Drug rashes

Reactions to sulphonamides and antibiotics are not uncommon, usually presenting as a maculopapular eruption. Occasionally this can be severe and associated with Stevens–Johnson syndrome. Myopathy may occur as a reaction to zidovudine.

All the above manifestations of AIDS become less marked as the CD4 count improves with treatment.

AIDS may thus present with a wide variety of skin conditions, commonly with several present at the same time. Any unusually florid skin condition that is resistant to treatment should raise the suspicion that HIV infection may be present.

Oral hairy leukoplakia

Kaposi's sarcoma of the hard palate

21 Fungal and yeast infections

RJ Hay

Fungal infections

The common fungal infections of the skin are dermatophytosis or “ringworm”, superficial candidiasis, and *Malassezia* infections. There are two growth forms of fungi, moulds, and yeasts. Mould fungi produce thread-like hyphae that comprise chains of cells. In dermatophyte fungal infection of the skin, hair, and nails these hyphae invade keratin and are seen on microscopic examination of skin, hair, or nails from infected tissues. Vegetative spores (conidia) develop in culture, and their distinctive shape helps to identify the different species. Skin scrapings or clippings from infected nails can be easily taken and should always be sent to the laboratory for mycological examination and culture in any patient suspected of having a fungal infection.

In yeast infections such as those due to candida, the fungal cells are individual and separate after cell division by a process called budding. In systemic, or deep, fungal infections subcutaneous or deep visceral structures are attacked. However skin involvement can also occur following blood stream dissemination and such lesions may provide a clue to the diagnosis.

Why should one suspect a lesion to be due to a fungus?

Clinical presentation

Fungal infections usually itch. Those due to zoophilic (animal) fungi generally produce a more intense inflammatory response with deeper indurated lesions than fungal infections due to anthropophilic (human) species. Some lesions, usually those on the trunk, have a prominent scaling margin with apparent clearing in the centre. Hence the name “ringworm”.

Children below the age of puberty are susceptible to scalp ringworm and anthropophilic fungi (from humans) have become common in some inner city areas. They can also be infected with zoophilic fungi (from animals), particularly cattle, dogs, and cats. Cattle ringworm can cause an intense inflammatory response in children, producing a “kerion” described below. They rarely develop anthropophilic fungal infection.

Adults. From adolescence onwards infection of the feet is a common occurrence. Tinea cruris in the groin is seen mainly in men and fungal nail infections (onychomycosis) have become particularly common.

Infection from dogs and cats with a zoophilic fungus (*Microsporum canis*) to which humans have little immunity can occur at any age. A patient returned from a skiing holiday with intensely itchy “eczema”, which refused to clear. A stray kitten, mewing outside in the dark, had been taken indoors, warmed in their sleeping bags, and infected the whole party with *M. canis*.

Nail infections

These occur mainly in adults, usually in their toenails, especially when traumatised—for example the big toes of

Tricophyton rubrum infection of the neck

Animal ringworm

Tinea cruris

Microsporum canis

Fungal infection of nail

ABC of Dermatology

footballers. The nails become thickened and yellow and crumble, usually asymmetrically. The changes occur *distally* and move back to the nailfold. In psoriasis of the nail the changes occur *proximally* and tend to be symmetrical and are associated with pitting and other evidence of psoriasis elsewhere.

Chronic paronychia occurs in the fingers of individuals whose work demands repeated wetting of the hands: housewives, barmen, dentists, nurses, and mushroom growers, for example. Other predisposing factors include diabetes, poor peripheral circulation, and removal of the cuticle. There is erythema and swelling of the nail fold, often on one side with brownish discoloration of the nail. Pus may be exuded. The cause is *Candida albicans* (a yeast) together with secondary bacterial infection.

Pushing back the cuticles should be avoided—this is commonly a long term condition, lasting for years. The hands should be kept as dry as possible, an azole lotion applied regularly around the nail fold, and in acute flares a course of erythromycin prescribed.

Feet

Tinea pedis, or athlete's foot, is a common disease and its prevalence increases with age. It is easily acquired in public swimming pools or showers and industrial workers appear to be particularly predisposed to this infection. The hands may be affected.

In interdigital tinea pedis the itching, macerated skin beneath the toes is familiar, but when a dry, scaling rash extends across the sole and dorsal surface of the foot (dry type tinea pedis) the diagnosis may be missed. The condition needs to be differentiated from psoriasis and eczema.

Hands

Dermatophyte infections often produce a dry rash on one palm. There may be a well defined lesion with a scaling edge.

Trunk

Tinea corporis presents with erythema and itching and a well defined scaling edge. In the groin, tinea cruris, the infection may spread to the adjacent skin on the thighs and abdomen. Intense erythema and satellite lesions suggest a candida infection. In the axillae erythrasma due to *Corynebacterium minutissimum* is more likely. It does not respond to antifungal treatment but clears with tetracycline by mouth.

Tinea versicolor affects the trunk, usually of fair skinned individuals exposed to the sun. It affects mainly the upper back, chest, and arms. Well defined macular lesions with fine scales develop, which tend to be white in suntanned areas and brown on pale skin. It may be confused with seborrhoeic dermatitis, pityriasis rosea, and vitiligo. In skin scrapings the causative

Chronic paronychia

Tinea pedis

Tinea corporis

Erythrasma

Tinea versicolor

Pityrosporum organisms

organisms, *Malassezia* spp., normally found in hair follicles, can be readily seen.

Scalp and face

Scalp ringworm in children may be caused by anthropophilic fungi such as *Trichophyton tonsurans*, which is spreading in cities in the United Kingdom, or *Microsporum audouinii*. Sporadic cases are caused by *M.canis* which is acquired from cats or dogs. In all cases there is itching, hair loss, and some degree of inflammation which is worse with *M. canis* infections.

Kerion, an inflamed, boggy, pustular lesion, is often due to cattle ringworm and is fairly common in rural areas. It is often seen in children in the autumn when the cows are brought inside for the winter.

Tinea incognito is the term used for unrecognised fungal infection in patients treated with steroids (topical or systemic). The normal response to infection (leading to erythema, scaling, a raised margin, and itching) is diminished, particularly with local steroid creams or ointments. The infecting organism flourishes, however, because of the host's impaired immune response—shown by the enlarging, persistent skin lesions. The groins, hands, and face are sites where this is most likely to occur.

Seborrhoeic dermatitis of adults may also be caused by *Malassezia*.

Microsporum ringworm

Yeast infections

Candida infection may occur in the flexures of infants and elderly or immobilised patients, especially below the breasts and folds of abdominal skin. It needs to be differentiated from: (a) psoriasis, which does not itch; (b) seborrhoeic dermatitis, a common cause of a flexural rash in infants; and (c) contact dermatitis and discoid eczema, which do not have the scaling margin. *Candida* intertrigo is symmetrical and "satellite" pustules or papules outside the outer rim of the rash are typical. Yeasts, including *Candida albicans*, may be found in the mouth and vagina of healthy individuals. Clinical lesions in the mouth—white buccal plaques or erythema—may develop. Predisposing factors include: general debility, impaired immunity (including AIDS), diabetes mellitus, endocrine disorders, such as Cushing's syndrome, and corticosteroid treatment. Vaginal candidosis or thrush is a common infection of healthy young women; an underlying predisposition is rarely found. The infection presents with itching, soreness, and a mild discharge.

Deep fungal infection

Fungal infections of the deeper tissues are only rarely associated with skin lesions in the United Kingdom, except in patients with AIDS. Some infections that involve deep tissue, histoplasmosis, cryptococcosis, and infections due to *Penicillium marneffei*, can present with skin lesions. In an HIV positive patient lesions resembling molluscum contagiosum may be the earliest feature of deep fungal infections.

In tropical countries deep fungal infections are more common. These are described in chapter 23. They should be considered in any patient from a tropical country with chronic indurated and ulcerating lesions.

Treatment

Topical treatment

The most commonly used treatments are the imidazole preparations, such as clotrimazole and miconazole (two to

Microsporum—Wood's light

Tinea incognito

Candida albicans

Candida organisms

four weeks) and also topical terbinafine (one to two weeks). The polyenes, nystatin, and amphotericin B are also effective against yeast infection. For damp macerated skin dusting powders may be helpful. In toe web infections a mixture of micro-organisms including dermatophytes and Gram negative bacteria may be present and both require treatment.

Systemic treatment

It is important to confirm the diagnosis from skin scrapings before starting treatment. Terbinafine is a very effective fungicidal drug. It is taken in a dosage of 250 mg once daily for two to six weeks for skin infections, six weeks for finger nail or three months for toenail infections. It is only approved for use in children in some countries. Blood monitoring is only advised in patients with liver disease or impaired renal function. Pregnancy and lactation are relative contraindications. There have been reports of headaches, taste disturbances and, very rarely, liver dysfunction.

Triazole preparations such as itraconazole are effective in both dermatophyte and yeast infections. Cases of liver damage have rarely been reported. Fluconazole is effective in yeast infections. Some drugs interact withazole drugs, the main ones being terfenadine, astemizole, digoxin, midazolam, cyclosporin, tacrolimus, and anticoagulants.

Griseofulvin is mainly used for tinea capitis. The duration of treatment is six to eight weeks for infections of the scalp. The dose is 10–20 mg/kg for children, taken with food. Contraindications to griseofulvin are severe liver disease and porphyrias. The drug interacts with the coumarin anticoagulants.

In countries without access to these drugs simple measures such as antiseptic paints—Neutral Red or Castellán's paint—can be used. Whitfield's ointment (benzoic acid ointment) is easily prepared and is reasonably effective for fungal infections.

Principles of diagnosis and treatment

- Consider a fungal infection in any patient where isolated, itching, dry, and scaling lesions occur without any apparent reason—for example, if there is no previous history of eczema. Lesions due to fungal infection are often asymmetrical
- Skin scrapings or clippings should be sent to the laboratory from lesions, nails, or hair. The skin scales should be removed by scraping the edge of the lesion with a scalpel held at right angles to the skin on to a piece of dark paper—transport packs are available commercially. Clippings can be taken from the nails and as much material as possible should be taken from the nail including subungual debris. Laboratories will report first on the direct microscopy of the material examined after treatment with 10% potassium hydroxide but culture results take at least two weeks
- Lesions to which steroids have been applied are often quite atypical because the normal inflammatory response is suppressed—*tinea incognita*. The patient often states that the treatment controls the itch but the rash persists and may change into a tender form of folliculitis. In such cases microscopy of lesions is usually strongly positive
- Wood's light (ultraviolet light filtered through special glass) can be used to show *Microsporum* infections of hair, as they produce a green-blue fluorescence

22 Insect bites and infestations

*So, naturalists observe, a flea
Hath smaller fleas that on him prey;
And these have smaller fleas to bite 'em.
And so proceeds "Ad infinitum"*

Jonathan Swift

It is, of course, the internal parasites of biting insects that cause trouble for humans, rather than "smaller fleas" on their surface.

An ornithologist went bird watching in Guyana, where he sustained widespread "midge bites" on the arms. He was referred on account of nodules that developed a few weeks later, then enlarged and ulcerated. Other lesions occurred further up the arms with regional lymphadenopathy. A biopsy specimen showed histiocytic inflammatory changes, and *Leishmania braziliensis* was isolated from smears; the midges (phlebotomus or sand fly) had acquired the protozoon while feeding on local rodents and transferred it into the ornithologist's skin.

Serious disease from insect vectors is rare in residents of most Western countries but, as in the patient described above, must be considered in those returning from tropical and subtropical countries.

Body louse

Sand fly

Leishmaniasis

Some diseases with skin lesions resulting from insect bites

Condition	Appearance	Organism	Vector
Cutaneous leishmaniasis	Chronic enlarging nodules with ulceration	Leishmania protozoon (<i>L. braziliensis</i>)	Sand fly
Oriental sore	Ulcerating nodules	Leishmania (<i>L. tropica</i>)	Sand fly
Kala-azar	Hypopigmented, erythematous, and nodular lesions	Leishmania (<i>L. donovani</i>)	Insect vectors
Onchocerciasis	Pruritic nodules	Filaria (<i>Onchocerca volvulus</i>)	Black fly (Simuliidae)
Typhus, human	Erythematous rash and systemic illness	Rickettsia (<i>R. prowazekii</i>)	Human louse
Typhus, murine		(<i>R. mooseri</i>)	Rat flea
Rocky Mountain spotted fever	Maculopapular rash and fever	Rickettsia (<i>R. rickettsii</i>)	Ticks
Rickettsial pox	Vesicular eruption like chickenpox	Rickettsia (<i>R. akari</i>)	House mouse, louse
Tick typhus	Necrotic lesions, maculopapular rash, and fever	Various rickettsias	Ticks
Scrub typhus	Fever, lymphadenopathy, maculopapular rash	Rickettsia (<i>R. tsutsugamushi</i>)	Mites
Relapsing fever	Widespread maculopapular lesions	<i>Borrelia recurrentis</i>	Lice, ticks
Lyme disease	May be annular	<i>Borrelia burgdorferi</i>	Ticks, black fly
Yellow fever and dengue	Flushing of face, scarlatiniform rash	Arbovirus	Aedes mosquito

ABC of Dermatology

Most cases of bites from fleas, midges, and mosquitoes are readily recognised and cause few symptoms apart from discomfort. Occasionally an allergic reaction confuses the picture, particularly the large bullae that can occur from bites on the arms and legs. It may be difficult to persuade patients that their recurrent itching spots are simply due to flea bites and the suggestion may be angrily rejected.

Nevertheless, some patients are convinced that they have an infestation when they do not. Often they will bring small packets containing “insects”. Examination shows these to be small screws of wool, pickings of keratin, thread, and so on. Sympathy and tact will win patients’ confidence; derision and disbelief will merely send them elsewhere for a further medical opinion. Antipsychotic drugs may help to dispel the delusion of parasitic infestation (delusional parasitosis) and should be used in conjunction with advice from a psychiatrist if possible. These drugs should be used with care and with full awareness of their side effects, particularly in patients with cardiovascular disease and a history of epilepsy. Pimozide has been used in the past but because of its side effects risperidone is preferred.

- Flea bites, including those from *Cheyletiella* mites in dogs and cats, occur in clusters, often in areas of close contact with clothing, for example, around the waist.
- Grain mites (*Pyemotes*) and harvest mites (*Trombiculidae*) can cause severe reactions.
- Tick, and possibly mosquito, bites can produce infection with *Borrelia burgdorferi*, causing arthropathy, fever, and a distinctive rash (erythema chronicum migrans)—Lyme disease. The condition responds rapidly to treatment with penicillin. Increasing numbers of cases are being reported in the United Kingdom.

Papular urticaria

Persistent pruritic (itching) papules in groups on the trunk and legs may be due to bites from fleas, bed bugs, or mites.

A seasonal incidence suggests bites from outdoor insects, while recurrence of the papules in a particular house or room suggests infestations with fleas. The term is sometimes used for other causes of itchy skin.

Spider bites

In Europe spider bites rarely cause problems, but sometimes noxious species arrive in consignments of tropical fruit. The patient shown had been bitten by a spider the day before leaving Nigeria and developed a painful necrotic lesion.

Bites from the European tarantula are painful but otherwise harmless.

In tropical and subtropical countries venomous spiders inject neurotoxins that can be fatal. The “black widow” (*Latrodectus mactans*), “fiddleback” (*Loxosceles veclusa*), and *Atrax* species of Australia are better known examples. Scorpions cause severe local and systemic symptoms as a result of stings (not bites).

Infestations

Scabies

The commonest infestation encountered is scabies, and it is easily missed or misdiagnosed. Scabies is due to a small mite, *Sarcoptes scabiei*. The female mite burrows into the stratum corneum to lay

Bullae caused by insect bites

Parasitophobia specimens

Bites on ankles

Erythema chronicum migrans

Harvest mites

Papular urticaria

Spider bite (Nigeria)

Persistent papules in scabies

her eggs; the male dies after completing his role of fertilisation, and the developing eggs hatch into larvae within a few days. Intense itching occurs some two weeks later, during which time extensive colonisation may have occurred. The infestation is acquired only by close contact with infected people.

Diagnosis

Finding a burrow—the small (5–10 mm long) ridge, often S shaped—can be difficult as it is often obscured by excoriation from scratching. Without finding a burrow, however, the diagnosis remains uncertain. Isolation of an acarus with a needle or scalpel blade and its demonstration under the microscope convinces the most sceptical patient. Always ask whether there are others in the patient’s household and if any of them are itching.

Treatment

10% sulphur in yellow soft paraffin is traditional, effective, and safe. There are several more modern treatments, including 25% benzyl benzoate emulsion, 0.5% malathion cream, 1% gamma benzene hexachloride (lindane) lotion, and 1% permethrin. In children benzyl benzoate should be diluted to 10% and used with care as toxicity results from absorption. In infants over two months old permethrin or 2.5% sulphur ointment can be used. Gamma benzene hexachloride should not be given to children under 10 years or pregnant women in the first trimester. Important points are:

- (1) The patient should wash well: a hot bath was formerly advocated but it is now known that this may increase absorption through the skin.
- (2) The lotion should be applied from the neck down, concentrating on affected areas and making sure that the axillae, wrists, ankles, and pubic areas are included. If there is any doubt about the thoroughness of application the process should be repeated in a few days.
- (3) All contacts and members of the patient’s household should be treated at the same time.
- (4) Residual papules may persist for many weeks. Topical steroids can be used to relieve the itching.
- (5) Secondary infection as a result of scratching may need to be treated.

Demodex

Demodex folliculorum is a small mite that inhabits the human hair follicle, the eggs being deposited in the sebaceous gland. It is found on the central area of the face, chest, and neck of adults. It may have a role in the pathogenesis of rosacea, in which it may be found in large numbers. It may be associated with a pustular eruption round the mouth and blepharitis.

Larva migrans

The patient in the illustration had been on holiday at a tropical coastal town and regularly visited a beach frequented by dogs. Two weeks after returning to Britain he started itching on the buttocks and subsequently noticed a linear, raised area—a condition known as larva migrans, due to the larvae of the hookworm of dogs and cats, *Ancylostoma caninum*. The ova are shed in the faeces and in a warm moist environment hatch into larvae that invade “dead end” hosts. They do not develop any further, so systemic disease does not occur.

Burrows of scabies

Scabies—points to note

- There may be very few burrows, though the patient has widespread itching
- The distribution of the infestation is characteristically the fingers, wrists, nipples, abdomen, genitalia, buttocks, and ankles
- Close personal contact is required for infestation to occur; for example, within a family, through infants in playgroups, and through regular nursing of elderly patients
- Itching may persist even after all mites have been eliminated; itching papules on the scrotum and penis are particularly persistent

Larva migrans

ABC of Dermatology

Treatment

This is either by freezing the advancing end of the lesion with liquid nitrogen or by applying thiabendazole (10%) suspension. Similar lesions in patients returning from tropical countries raise the possibility of larva migrans from strongyloides infestation, myiasis from the larvae of flies, or gnathostomiasis.

Visceral larva migrans caused by *Toxocara canis* and *Ascaris lumbricoides* may produce a transient rash.

Pediculosis (lice)

Infestation with lice became less common in the postwar years, but the incidence has recently increased.

There are three areas of the body usually affected by two species of wingless insects—*Pediculus humanus*, infecting the head and body, and *Phthirus pubis*, the pubic louse. The wingless insects feed on blood aspirated at the site of the bite, and each female lays 60–80 encapsulated eggs attached to hairs—"nits" in common parlance.

Head lice are transmitted via combs, brushes, and hats, being more common in girls than boys. The infestation is heaviest behind the ears and over the occiput. If the eyelashes of children are affected this is with "crab lice" (*Phthirus pubis*); it is not pediculosis.

Body lice are less common in western Europe. Transmission is by clothing and bedding, on which both lice and their eggs may be found in the seams. Poor hygiene favours infestation.

Pubic lice infestation occurs worldwide and is generally transmitted by sexual contact. Infestation of eyelashes may occur with poor hygiene.

As a result of scratching there may be marked secondary infection that obscures the underlying infestation.

Treatment

Gamma benzene hexachloride 1% is usually effective as a single application. Permethrin can also be used.

Pediculosis capitis

Head lice and nits

Phthirus pubis on eyelashes

23 Tropical dermatology

B Leppard

The purpose of this chapter is to provide an overview of tropical diseases that most commonly affect the skin. This will be useful for health workers who may not be familiar with tropical diseases and also as a guide to help those who are already working in the tropics and who see them all the time.

Skin disease is extremely common in the tropics, affecting up to 50% of the population. Most are infections or infestations such as impetigo, ringworm, and scabies. These can easily be treated but continue to be common because of overcrowding, poverty, and the lack of resources given to health care (training of health personnel and lack of basic medicines). To a large extent such diseases can be controlled with very simple measures suitable for use by those with minimal training. Atopic eczema is just as common in urban areas in the tropics as in the west. Skin cancers are uncommon in those with a black skin because of the protective effect of melanin, but are common in albinos.

Albino with squamous cell carcinoma

The spectrum of tropical dermatology

All the common inflammatory dermatoses occur in the tropics but may have a different appearance in pigmented skin. Erythema, readily visible in Caucasians, will not be so apparent in black skin.

Infections and infestations occurring in the tropics produce distinctive skin changes. These may be due to the presence of the organism, ova, or larvae in the skin. In other diseases a reaction to the organism produces a rash.

Bacterial infections

Impetigo is particularly prone to occur in the tropics and may complicate any area of minor trauma to the skin. It is characterised by erythema, and exudative lesions forming crusts.

Bullae may develop. If possible swabs should be taken for bacteriology and the appropriate antibiotics given.

Erysipelas is a localised streptococcal infection with erythema and tenderness accompanied by fever and malaise. Treatment is with penicillin.

Leprosy

Leprosy is a chronic infection of the skin and nerves by *Mycobacterium leprae*. It is spread by droplet infection and has a long incubation period (anything from two months to 40 years). There is a spectrum of clinical disease depending on the patient's cell mediated immunity to the organism.

Diagnosis

- **Typical clinical findings:**
 - (a) In tuberculoid leprosy (TT) there is a single anaesthetic patch or plaque with a raised border.

Spectrum of clinical disease in leprosy. (BB = borderline leprosy, BL = borderline lepromatous leprosy, BT = borderline tuberculoid leprosy, LL = lepromatous leprosy, TT = tuberculoid leprosy)

Tuberculoid leprosy

Tuberculoid leprosy

ABC of Dermatology

- (b) In lepromatous leprosy (LL) there are widespread symmetrical shiny papules, nodules, and plaques which are not anaesthetic.
 - (c) In borderline leprosy (BT, BB, BL) there are varying numbers of lesions, few in BT and numerous in BL. They may be widespread but are asymmetrical.
 - (d) Palpably enlarged cutaneous nerves (great auricular nerve in the neck, the superficial branch of the radial nerve at the wrist, the ulnar nerve at the elbow, the lateral popliteal nerve at the knee, and the sural nerve on the lower leg).
 - (e) Glove and stocking sensory loss causing blisters, ulcers or both on anaesthetic fingers or toes.
 - (f) Deformity due to invasion of the peripheral nerves with leprosy bacilli, a leprosy reaction or recurrent trauma to anaesthetic limbs.
- *Slit skin smears* measure the numbers of bacilli in the skin (Bacterial Index (BI)) and the % of these that are living (Morphological Index (MI)).

Lepromatous leprosy

Borderline leprosy

Borderline tuberculoid leprosy

Treatment

Paucibacillary leprosy (BI of 0 or 1+):

Rifampicin 600 mg once a month (supervised)
Dapsone 100 mg daily

} for six months

Multibacillary leprosy (BI of 2+ or more):

Rifampicin 600 mg once a month (supervised)
Clofazamine 300 mg once a month (supervised)
Clofazamine 50 mg/day
Dapsone 100 mg/day

} for two years

Cutaneous leishmaniasis

Cutaneous leishmaniasis is due to the protozoa *Leishmania tropica*, and is transmitted by the bite of a sandfly. There is a spectrum of disease depending on the patient's immunity.

Acute leishmaniasis

A red nodule like a boil occurs at the site of the bite. It enlarges, may or may not ulcerate, and heals spontaneously after about one year leaving a cribriform scar.

Acute leishmaniasis

Chronic leishmaniasis

Chronic leishmaniasis

In a patient with good cell mediated immunity, after the acute leishmaniasis has healed, new granulomata appear at the edge of the scar; these do not heal spontaneously.

Diffuse cutaneous leishmaniasis

This is leishmaniasis in a patient with no immunity to the organism (equivalent to lepromatous leprosy). Extensive skin nodules occur that are full of organisms.

Diffuse cutaneous leishmaniasis

Treatment

Intramuscular injections of sodium stibogluconate 10 mg/kg body weight daily until healing occurs.

Superficial fungal infections

The same fungal infections of the epidermis occur in the tropics as in temperate climates only more so—heat and occlusion of clothing leading to maceration of the skin in which fungi thrive, so expect to see more florid lesions. There are also many fungal infections that are specifically found in the tropics. These include tinea imbricata, tinea nigra, piedra, and favus.

Bacterial Index (BI)

0 = No bacilli seen
1+ = 1–10 bacilli in 100 oil immersion fields
2+ = 1–10 bacilli in 10 oil immersion fields
3+ = 1–10 bacilli in 1 oil immersion field
4+ = 10–100 bacilli in an average oil immersion field
5+ = 100–1000 bacilli in an average oil immersion field
6+ = >1000 bacilli in an average oil immersion field

Suspect a dermatophyte fungal infection in any chronic, itching, scaling, slowly developing lesion with epidermal changes.

Tinea imbricata due to *Trichophyton concentricum* is characterised by superficial concentric scaling rings spreading across the trunk. It occurs mainly in Asia but also in other tropical areas.

Tinea nigra occurs in the tropical areas of America, Asia, and Australia. Brown or black macules are seen on the palms and soles. It is due to *Cladosporium werneckii*.

Piedra is a fungal infection of the hair producing hard nodular lesions on the hair shaft. The lesions may be black (due to *Piedra hortai*) or white piedra (due to *Trichosporum beigeli*).

Favus is widespread throughout the Mediterranean, the Middle East, and tropics, but is rare in Africa. It is due to an endothrix fungus—*Trichophyton schoenleinii*—which causes a thick yellow crust with an unpleasant odour. Erythematous areas of scarring occur that must be differentiated from lichen planus and other causes of scarring alopecia.

Superficial fungal infection

Deep fungal infections

In these conditions there is chronic inflammation in the subcutaneous tissues leading to granulomatous and necrotic nodules.

Mycetoma (Madura foot)

This is a chronic infection of the dermis and subcutaneous fat caused by various species of fungus (*eumycetoma*) or bacteria (*actinomycetoma*). Both types look the same with a swollen foot and multiple discharging sinuses, but it is important to differentiate between them because the treatment is different.

Diagnosis

- Examination of the discharging grains (colour will give a clue as to the cause).
- Culture of the grains to identify the causative fungus or bacteria.
- If no grains can be found a skin biopsy will show them.

Treatment

Eumycetoma:

- Itraconazole 200 mg twice daily for at least 12 months if it is affordable.

If not

- Surgical excision of affected tissue if disease is limited.
- Amputation if extensive.

Actinomycetoma:

- Sulfamethoxazole-trimethoprim mixture 960 mg twice daily for up to two years.

Blastomycosis

This condition is caused by the invasion of lymphatic system, lungs, and skin by *Paracoccidioides brasiliensis*. The widespread cutaneous lesions, which vary in appearance and distribution, must be differentiated from tuberculosis and other mycoses such as sporotrichosis, chromomycosis, and coccidiomycosis. It occurs in central and south America.

Tinea imbricata

Madura foot

ABC of Dermatology

Chromomycosis

This chronic granulomatous condition mainly affects the legs and results from infestation by a variety of parasitic fungi. Large verrucous plaques may require surgical removal.

Histoplasmosis

This occurs in West Africa with nodules, ulcers, and bone lesions developing due to infection with *Histoplasma duboisii*. Treatment is with amphotericin B.

Chromomycosis

Infestations

Tungiasis

Invasion of the skin by sand fleas (*Tunga penetrans*) causes tungiasis in tropical areas of Africa, America, and India. It is most common on the feet, especially under the toes and toenails. The condition looks a bit like plantar warts, but if you watch for a while you will see the eggs being squirted out.

Prevention

Wear shoes.

Treatment

- Carefully wrinkle the fleas out with a pin (most patients know how to do this themselves).
- If the fleas are very extensive, soak the feet in kerosene or treat with a single dose of ivermectin 200 micrograms/kg body weight.

Histoplasmosis in HIV infection

Subcutaneous myiasis

Invasion of the skin by the larvae of the tumbu (mango) fly (*Cordylobia anthropophaga*) in central and southern Africa causes this condition. The fly lays her eggs on clothes layed out to dry on the ground. The eggs hatch out two days later on contact with the warm skin when the clothes are put on. The larvae burrow into the skin causing a red painful or itchy papule or nodule, predominantly on the trunk, buttocks, and thighs.

Other flies that cause myiasis are:

- *Dermatobia hominis*—tropical bot fly, in Mexico, central, and south America with tender nodules developing on the scalp, legs, forearms, and face.
- *Aucheronia* sp.—Congo floor maggot, in central and southern Africa. Bites of the larvae cause intense irritation.
- *Callitroga* sp. in central America causing inflamed lesions with necrosis.

Prevention

Iron the clothes before wearing them.

Treatment

Cover the nodule with petroleum jelly or other grease; the larva will be unable to breathe and will crawl out.

Filariasis

This is an infestation with thread-like helminths (Latin "Filum"—a thread). They are widely distributed in many species and live in the lymphatics and connective tissue. Fertilised eggs develop into embryonic worms—microfilariae. These are taken up by insect vectors that act as intermediate hosts in which further development occurs. They are then inoculated into a human host when next bitten by the insect.

Tungiasis

Myiasis—larvae

Myiasis—papule

Three diseases are caused by filarial worms:

- Lymphatic filariasis due to *Wuchereria bancrofti*, which liberate microfilariae into the blood stream.
- Onchocerciasis due to *Onchocera volvulus*. The microfilariae are liberated into the skin and subcutaneous tissues.
- Loiasis due to *Loa loa*, in which microfilariae are found in the blood.

Lymphatic filariasis affects 120 million people in 73 countries (34% in sub-Saharan Africa). It causes lymphoedema of the legs, genitalia, and breasts. It may be asymptomatic for a long period and the adult worms live for four to six years in the lymphatic vessels and lymph nodes producing thousands of microfilaria each day. These are picked up by mosquitoes when they take a blood meal and are passed on to the next victim when they feed again.

Lymphoema of the legs in filariasis

Treatment

- In endemic areas the whole community should be treated with a single dose of two of the following three drugs once a year for four to six years:
 - (a) Ivermectin 400 micrograms/kg body weight
 - (b) Diethylcarbamazine (DEC) 6 mg/kg body weight
 - (c) Albendazole 600 mg.
- The chronic lymphoedema can be improved by keeping the legs moving, raising the legs when sitting, and prevention of secondary bacterial infection by regular washing and moisturising of the skin.

Onchocerciasis

Onchocerciasis (river blindness) occurs in Africa south of the Sahara and in Central America. It is due to *Onchocera volvulus* transmitted by the bite of black flies Simuliidae which breed by fast flowing rivers. The inoculation of microfilariae by the bite of a black fly causes intense local inflammation and is followed by an incubation period of many months. The adult worms live in nodules around the hips and cause no harm in themselves. They produce thousands of microfilaria each day which travel to the skin and eyes. In the skin they produce a very itchy rash which looks like lichenified eczema. On the lower legs there is often spotty depigmentation. Involvement of the eyes causes blindness.

Risk factors for being infected

- Living, working, or playing near fast flowing rivers.
- Not wearing enough clothes so that the skin is exposed to insect bites.
- The construction of dams leads to less breeding of black flies in the dam itself but increased breeding in the dam spillways.

Diagnosis

- Demonstrate the microfilaria in the skin by skin snips.
- Remove a skin nodule and see the adult worms inside it.
- Polymerase chain reaction to show parasite DNA—not much use in the field.

Treatment

- Spray the breeding areas with insecticides.
- Annual dose of ivermectin 400 micrograms/kg body weight for four to six years. This stops the release of microfilaria from the adult worms.

Diagnosis

- Find the microfilaria on a thick blood smear taken at midnight. This is not a very convenient method of diagnosis.
- Immuno-chromatographic filariasis card test using finger prick blood, which takes less than five minutes to complete. It detects circulating *W. bancrofti* antigens so it can be done at any time of the day or night.
- Polymerase chain reaction to detect parasitic DNA. This is very sensitive and can detect as little as one microfilaria in 1 ml blood.

Onchocerciasis

"Leopard skin" in onchocerciasis

ABC of Dermatology

Loiasis

Loiasis occurs in the rain forests of central and west Africa. It is transmitted by mango flies (*Chrysops*). The adult worms live in the subcutaneous tissues where they can be seen in the skin and under the conjunctiva. The microfilaria are only found in the blood. A hypersensitivity to the worms shows itself as swelling of the skin, particularly of the wrists and ankles (calabar swellings).

Dracontiasis

This condition is due to infestation by *Draculus medinensis* in the connective tissue. It is acquired from drinking water containing the intermediate host, a crustacean, *Cyclops*. Localised papules develop on the lower legs containing the female worm and numerous microfilariae. Treatment consists of very carefully extracting the worm by winding it onto a stick over several weeks. Symptomatic treatment of secondary infection and allergic reactions is also required.

Diagnosis of loiasis

- Find the microfilaria in the peripheral blood between 10 am and 2 pm
- Find the adult worms by ultrasound examination
- High blood eosinophilia

Treatment of loiasis

- A single dose of ivermectin 400 micrograms/kg body weight or a three week course of albendazole 400 mg/kg body weight/bd
- Do not use diethylcarbamazine citrate (DEC) as this can cause death as a result of a reaction to toxins from the rapid destruction of the microfilaria.

24 Practical procedures and where to use them

DWS Harris

Skin lesions are easily accessible for removal or biopsy. The procedure used needs to be appropriate to the site and type of lesion involved. It is important also to keep scarring to a minimum.

Destruction of skin lesions is carried out with:

- Electrocautery
- Cryotherapy
- Laser treatment

This is suitable for lesions where the diagnosis is certain, as no specimen is available or histology.

Removal of skin lesions results in a specimen for the pathologist to examine. The techniques used are:

- Curettage and cautery
- Surgical excision
- Incisional biopsy which provides a specimen for histology to supplement the clinical diagnosis.

Cryotherapy

This involves the destruction of tissues by extreme cold. Current methods used are:

Carbon dioxide

Solid carbon dioxide (temperature -64°C) is produced by allowing rapid expansion of the compressed gas from a cylinder. This can be mixed with acetone to form a slush that can be applied with a cotton wool bud. A solid carbon dioxide stick, for direct application to lesions, is produced by an apparatus using "sparklet" bulbs.

The lesion must be frozen solid with a 1–2 mm margin of surrounding tissue. After thawing the freezing cycle should be repeated.

Liquid nitrogen (-196°C)

This can be simply applied using a cotton wool bud dipped in the vacuum flask of liquid nitrogen. Freezing takes a little longer than using spray apparatus. Various types of such apparatus are available with different sizes of nozzle. The larger ones are used for seborrheic keratoses on the back, for example, and the smaller sizes for small lesions on the face. Freezing takes a few seconds and after thawing a further application can be made if necessary.

Ethyl chloride

This is sprayed directly on the skin, producing lowering of the temperature and temporary analgesia. It is not generally used for treatment.

Nitrous oxide

A cylinder of compressed gas is used to cool a probe to approximately -80°C . It is usually used for the treatment of warts and requires a 30 second freezing cycle.

Precautions

- Cryotherapy produces pain and inflammation. Blistering and haematoma may occur. This can be diminished by the

Cryotherapy—applying the liquid nitrogen

Cryotherapy—the frozen wart

Cryotherapy—subsequent slight blistering

Cryotherapy—liquid nitrogen containers

ABC of Dermatology

application of a strong steroid cream immediately after freezing, except when treating viral warts as it tends to encourage proliferation of the warts.

- Damage to deeper structures is rare but may occur when freezing the deeper tissues—for example, treating basal cell carcinoma.
- It is possible for adjacent structures to be damaged accidentally, especially with the liquid nitrogen spray. This applies particularly when treating lesions on the face, when it is essential to screen the eyes adequately.

Skin lesions suitable for freezing

Viral warts

These may require several treatments at two to three week intervals. Freezing very small plane warts can result in small depigmented areas, so they may be better treated with wart paint.

Seborrhoeic keratoses

These respond well to cryotherapy, but as they are superficial lesions care must be taken to avoid excessive freezing with resultant scars.

Papillomata and skin tags

These can be easily and permanently treated by compression with artery forceps dipped in liquid nitrogen. Surprisingly, this is generally a painless procedure.

Dysplastic lesions

Early lesions, which are potentially neoplastic or of low grade malignancy, can be effectively treated. This includes solar keratoses, if early and superficial, but follow up is essential. The lesions can progress to squamous carcinoma, and if not responding to cryotherapy they should be excised or removed with curettage and cautery for histological examination.

Bowen's disease

An intraepidermal carcinoma, if confirmed by incisional biopsy, can respond to repeated cryotherapy. Follow up is essential since progression to an invasive squamous carcinoma can occur.

Basal cell carcinoma

The superficial spreading type can be treated with liquid nitrogen, but repeated and often prolonged freezing is required. To be certain of effective treatment a thermocouple probe to record the temperature at the base of the tumour is used. This is not usually a routine procedure in general practice or hospital outpatients. Excision or radiotherapy are more effective methods of treatment.

Cryotherapy—practical points

- Be sure of the diagnosis before cryotherapy, taking a biopsy if necessary
- Explain to the patient that inflammation, blistering, or haematoma formation may occur
- Use freezing with care in children and on areas where the skin is thin, such as below the eyelids. In pigmented skin postinflammatory hyperpigmentation can occur

Cryotherapy—freezing a lesion

Electrocautery—pinpoint cautery attachment

Electrocautery—pinpoint cautery attachment

Electrocautery—hyfrecator

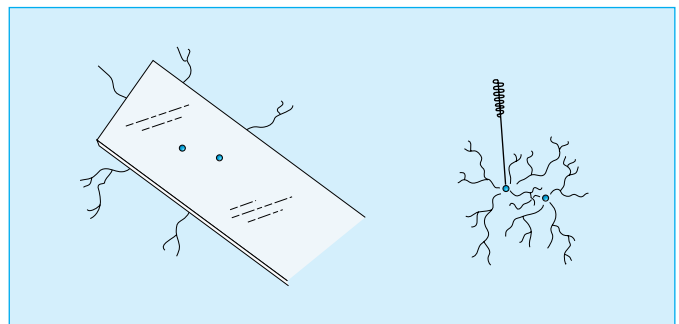

Electrocautery—spider naevus

Electrocautery

There are two forms of treatment:

- (1) Heat from an electrically heated element, which is used for removal of skin tags and for treatment of the surface after curettage of warts, also seborrhoeic keratoses.
- (2) High energy, low current “electrodesiccation” equipment which produces a high energy spark that can coagulate blood vessels or destroy some more papillomata. A fine needle point should be used for small telangiectatic naevi or milia. A larger needle is used for larger surfaces, for example after curettage.

Electrocautery—blanch the lesion to identify feeding vessels, then insert the needle into feeding vessels in the cold state

Laser treatment

Laser—Light Amplification by Stimulated Emission of Radiation—produces high energy radiation. The first laser apparatus was developed from microwave technology in 1960 by the nobel prize winner TH Maiman. It was initially used as a destructive tool to ablate tumours, but now different wavelengths can be directed at specific targets. Blood vessels, for example, take up the blue/green light of the argon laser and the red light of a ruby laser is well absorbed by the green dye of tattoos. Modern developments have resulted in laser equipment that produces minimal scarring and maximum specificity.

Although smaller portable units are available, laser treatment should still only be undertaken by those with appropriate training. The skin lesions most commonly treated by laser are described below.

Tattoos

Tattoos contain a variety of pigments so that more than one type of laser may be necessary for complete removal. The same pigment may vary in response in different patients. Superficial dark pigment usually responds to the Q switch ruby laser, but deeper pigment may require the Nd:YAG laser or Alexandrite laser. Green pigment is usually removed with a Q switch ruby laser and red pigment with a green light laser such as the Q switched Nd:YAG. It is found that professional tattoos are usually more easily removed than the amateur type.

Pigmented lesions

Melanin absorbs light over a wide range of wavelengths, which can result in undesirable loss of skin colour following laser treatment. This can be put to good use in the treatment of benign lentigines and café au lait patches or deeply seated pigmented naevi. A wide range of laser types can be used, including Q switch ruby and Nd:YAG lasers. Congenital pigmented naevi should not be treated unless the biopsy has confirmed that they are benign.

Hair follicles

Laser equipment is available for removing excess hair and is a very effective cosmetic tool.

Laser surgery

Lasers can be used as a cutting tool and recent studies have shown them to be a very effective means of producing incisions in the skin.

Curettage

This is a simple way of removing epidermal lesions. A curette has a metal spoon shaped end with a sharp cutting edge. There are a variety of shapes and sizes suitable for different lesions, from large seborrhoeic keratoses or papillomata to smaller ones for minute keratin cysts. A specimen is provided for histology but completeness of removal cannot be accurately assessed.

Treatment of vascular lesions

- **Port wine stains**
Argon and carbon dioxide lasers cause scarring, so yellow light emitting types such as Krypton, Flashlamp Powered Dye Laser (FIPDL), or Copper Laser are used
- **Telangiectasia**
This is also treated with the FIPDL, although this can cause transient purpura, or Copper Laser
- **Cavernous haemangioma**
These can be treated by yellow dye laser followed by surgical excision

Curettage—seborrhoeic keratosis

Curettage—actinic keratosis

Curettage

Lesions suitable for curetting

- Seborrhoeic keratoses
- Solitary viral warts
- Solar keratoses
- Cutaneous horns
- Small basal cell carcinomas

ABC of Dermatology

Local anaesthetic is used and, with the skin stretched, the curette is applied at the edge of the lesion which is then scooped off. It is advisable to work around the edges of larger or more firmly attached lesions. The dermis normally feels firm but when curetting off a keratotic horn or solar keratoses; a soft consistency may indicate dysplastic change. The base can be lightly cauterised to control bleeding, sterilise the site, and prevent recurrence.

Various types of disposable curettes are available and are easy to use.

Curettage and cautery

- Use a sharp curette of appropriate size
- Very firm control of the curette prevents it from suddenly skidding onto normal skin
- Repeat curettage and cautery for neoplastic lesions such as basal cell carcinoma and solar keratoses
- Send the specimen for pathological examination

Biopsy—equipment needed

Incisional biopsy and punch biopsy

It is essential to have a working clinical diagnosis, but wherever there is doubt the pathologists can provide much more precise information regarding the nature and extent of the lesion. For example, a patch of Bowen's disease (intraepidermal carcinoma) may resemble sclerosing superficial basal cell carcinoma and a biopsy will usually distinguish them. Similarly, what seems to be a dysplastic pigmented naevus clinically may, on the one hand, prove to be benign or, on the other hand, turn out to be a malignant melanoma requiring wide excision.

Immunofluorescent staining of a blistering lesion differentiates dermatitis herpetiformis, which is treated with a gluten free diet, from pemphigoid, which requires corticosteroids and often immunosuppressant drugs.

Incisional biopsy

This is suitable for larger lesions and is taken across the margin of the lesion in the form of an ellipse. It is essential to include deeper dermis, as the significant changes in, for example, granuloma or lymphoid infiltrate may not be near the surface. An adequate amount of normal tissue should be included, so this could be compared with the pathological area and this also means there is enough normal skin to suture the incision together.

Punch biopsy

The biopsy tool consists of a small cylinder with a cutting rim which is used to penetrate the epidermis by rotation between the operator's finger and thumb. There is minimal danger of damaging deeper structures as the elastic subcutaneous tissues merely rotate with the tool without being cut. The resulting plug of skin is lifted out with forceps and cut off as deeply as possible.

Incisional biopsy—marking lesion

Incisional biopsy—histology

Incisional biopsy—amount of tissue that should be taken

Punch biopsy—injecting local anaesthetic

Punch biopsy—examples of punches

Practical procedures and where to use them

With the smaller sized punches the resulting defect can be treated with electrocautery or left to heal spontaneously. With a punch larger than 3 or 4 mm a single suture can be used. The main disadvantage of a punch biopsy is that it only provides a single small piece of tissue. It may not be representative or may miss an area of substantial change. It tends to leave a more prominent scar than the incisional biopsy.

Punch biopsy—tool inserted

Punch biopsy—plug of skin

Punch biopsy—raising plug of skin to cut

Punch biopsy—treating defect with electrocautery

Punch biopsy—specimen taken

Excision of skin lesions is both curative and diagnostic. It may be the best way of making a diagnosis if there are multiple small papules or vesicles, one of which can be excised intact. Incisions should follow tension or wrinkle lines.

In the case of malignant lesions it is particularly important that the whole lesion is adequately excised. The pathologist can report on the adequacy of excision, but not in multifocal basal cell carcinoma where this cannot be assessed. If there is likely to be any doubt about the excision being complete it is helpful to attach a suture to one end of the excised specimen so the pathologist can describe which border, if any, extends over the excision margin.

Surgical excision—“wrinkle lines” of skin

Surgical excision—“wrinkle lines” of skin

Surgical excision—“wrinkle lines” of skin

Technique

The basic technique consists of making an elliptical incision with the length three times the width. This enables suturing without the formation of “dog ears” at the end. The long axis of the excision should follow the “wrinkle lines” of the skin, which are parallel to the collagen bundle in the dermis. This produces stronger, narrower scars. They are not the same as the deeper lines or fascial attachment or “Lange lines”. Lesions on the sternal area, upper chest, and shoulders, where keloid scars often form, should only be excised when it is essential and may be best referred to a plastic surgeon.

Local anaesthetic is injected subcutaneously but close to the skin. The incision should be vertical rather than wedge shaped. Monofilament sutures cause less inflammation and trapping of serum than the braided variety, but are harder to tie securely.

Methods of suturing and the more specialised techniques of flaps and grafts are outside the scope of this book. It is an asset for the dermatologist to be able to carry out surgical procedures on the skin and suitable courses are generally available.

Surgical excision—elliptical incision

Surgical excision—raising skin

Surgical excision—appearance of lesions under skin

Surgical excision—guidance for making elliptical incision

Surgical excision

- After initially inserting the needle, withdraw the plunger of the syringe to check the needle has not entered the blood vessels. Raising a small “bleb” of local anaesthetic ahead of the needle point helps to prevent this
- It is important to learn appropriate suturing techniques for different sites of the body and size of lesion
- Warn the patient that a scar will result and make sure that this is minimal and does not produce any deformity such as displacement of the eyelid
- Always send an excised lesion for histology. A significant number of lesions diagnosed as being benign clinically have been shown to be malignant. This would of course be missed if they had not been sent to a laboratory

25 Dermatology in general practice

R Balfour, E Crawford

In common with other aspects of general practice the management of dermatological problems has changed considerably in recent years. In particular:

- There is an increased expectation from patients, who want an accurate diagnosis and prompt treatment but also expect treatment for even the smallest lesion.
- The management of inflammatory skin conditions no longer requires many weeks of inpatient treatment. "Daily dressing clinics" in hospital dermatology departments enable patients to continue their daily lives while being treated, but still require visits to hospital. In many practices facilities for carrying out dressings by the practice nurse have been developed.
- The demand for specialist services far outstrips supply. Consequently the majority of patients with skin conditions have to be treated by general practitioners. One positive outcome is that there is a greater emphasis on shared care between general practice and hospital specialist departments. This is facilitated by the appointment of dermatology liaison nurses who are able to supervise patient's treatment in the community and, as the name suggests, liaise with both general practice and hospital departments using the resources of each as appropriate.
- General practitioners are increasingly developing special interests and many have part-time posts in specialist departments. In the case of dermatology this enhances their clinical knowledge, which they can bring to bear on the problems in general practice.

Between 10% and 15% of consultations in general practice are for skin related problems, although the actual number of skin conditions seen is probably much higher than this. In one general practice an analysis of 100 consecutive consultations showed that 38 involved some aspect of dermatology.

Increasing knowledge of dermatology enables conditions to be diagnosed and treated. Even if the diagnosis is not known it is important to be able to assess the probable importance of dermatological conditions and differentiate those for whom an urgent referral to hospital is required from those needing a specialist opinion to confirm the diagnosis and treatment but for whom there is no great urgency. This is important with the large demands being made on hospital departments with diminished funding and increasing waiting times. In this respect a good working relationship with the local hospital department is a great asset.

Diagnosis of skin conditions in general practice

As in all aspects of medicine, knowing how the more common conditions present will provide a basis for recognising the unusual variants or less common lesions. Psoriasis, eczema, and other forms of dermatitis usually present no problems. Where they do a review of the history often gives valuable clues. Atopic eczema in childhood may explain the development of a widespread itching rash in a young adult and an otherwise unexplained rash may well be accounted for after a review of

Dermatology in general practice

- In a study of one area of London 55% of adults examined had some form of skin disease*
- Of those with moderate or severe conditions only 24% had made use of medical facilities in the previous six months
- In the same study 30% of patients with skin conditions medicated themselves
- Eight per cent of patients attending a general practitioner for a skin condition are referred to a dermatologist†
- A large reservoir of people in the community with skin conditions do not seek medical attention but can be expected to do so as awareness of skin conditions increases‡
- General practitioners with postgraduate training in dermatology and dermatology liaison nurses linked to specialist centres are needed so that the increasing demand for dermatology services can be met
- In countries with specialist care, basic training in the essentials of diagnosis and treatment of skin conditions enables health officers to make a considerable impact on these conditions in the community

Hospital consultation

ABC of Dermatology

current drugs the patient is taking. Knowledge of the dermatological conditions associated with systemic disease, and conditions that may mimic them, is clearly important. A bilateral malar rash with photosensitivity in a woman should suggest the possibility of lupus erythematosus and appropriate investigations instituted. However, a completely typical case of rosacea does not require extensive investigation. The most useful diagnostic aids in general practice are:

- Skin scrapings and a sellotape strip should be sent for mycology whenever there is an area of itching inflammatory change, particularly in the flexures, that is not responding to treatment.
- A swab for bacteriology should be sent from any area of dermatitis that develops crusting and exudate.
- An incisional biopsy can be carried out to confirm a significant diagnosis, for example in a patch of Bowen's disease. This is not usually needed to make a diagnosis of granuloma annulare, which has a very characteristic presentation. All lesions removed by excision or curettage or cautery should be sent for histology.
- Patch testing is not practicable in general practice as a rule because of the large number of reagents and specialised nursing skills required. Patients suspected of having contact dermatitis should be referred to the appropriate unit.

The management of skin conditions in general practice

One great advantage of general practice is that there is continuity of care and the family doctor has a much more complete overall picture of the patient, their family and social circumstances than can be acquired in a hospital consultation. Increasingly dressings and other treatments are being used by practice nurses in conjunction with the dermatology liaison nurse when necessary. This applies to inflammatory skin conditions such as psoriasis and eczema as well as leg ulcers, but also to conditions such as Darier's disease, dermatitis herpetiformis, and lupus erythematosus where regular supervision and blood tests may be required. There is no reason why continuing treatment with drugs such as ciclosporin and methotrexate cannot be carried out in general practice once the diagnosis and treatment regime have been established. Regular blood tests are mandatory when these drugs are being used.

Procedures in general practice

The details of techniques described in chapter 24.

- *Excisions* and other forms of minor surgery are probably best undertaken by a member of the practice who has developed expertise in this area, and received some level of training. It is particularly important to be aware of which lesions and anatomical sites are the most difficult for minor surgery. It is probably wise not to attempt excisions over the sternum and shoulders, particularly in young people, where keloid scars will probably result. In general it is best to refer any malignant lesion to a hospital department for excision.
- *Curettage and cautery* is a straightforward procedure for the removal of superficial and well defined lesions such as seborrhoeic keratoses and viral warts. It is as well to send all specimens for histology—to confirm the diagnosis and make sure that an unsuspected malignancy is not missed. It is important that a clinical probable diagnosis is made so as to

Demonstration of dressings by liaison nurse

Dressings being applied at home by mother

Mother, liaison nurse, and health visitor discuss treatment

avoid excising lesions where such treatment is not required or when it is inappropriate.

- *Cryotherapy* is suitable for the treatment of warts, seborrheic keratoses, solar keratoses, and conditions such as Bowen's disease. If there is doubt as to the diagnosis or the condition fails to respond to treatment a specialist opinion should be sought. It usually most satisfactory to have a cryotherapy clinic for which liquid nitrogen is regularly supplied and a suitably trained nurse is available to carry out the treatment. It is important that all patients are seen by a doctor before treatment is started so that the diagnosis and suitability for treatment can be confirmed.

Self-help groups

There are now groups that provide an invaluable source of information and advice for a wide range of conditions. A number of these are listed in the appendix.

26 Formulary

The zinc topped tables used for many years to prepare tar “spreads” in a teaching hospital dermatology department were recently thrown out—a sign of the times and an indication of both the increasing use of systemic treatment and much more effective forms of phototherapy. There is still an important place for topical treatment and “dressing clinics” to play a vital role in the treatment of skin diseases and enabling affected individuals to continue their daily lives as far as possible.

The link between hospital departments and community services has been greatly increased by the development of the role of “liaison nurses”. These nurses, with experience and training in the treatment of skin disease, visit patients in their homes to supervise treatment in conjunction with the general practitioner and the practice nurse. As they are based in the hospital they can call on any specialist opinion or treatment needed.

A great variety of preparations is available for the treatment of skin conditions, and those most commonly used are described. There are numerous effective alternatives.

The techniques for the treatment of specific conditions are described in the appropriate chapters.

Topical treatment

General treatments

The epidermis is capable of absorbing both greasy and aqueous preparations or a mixture of the two. The type of lesion influences which type is used.

- Dry, scaling skin—greasy ointments.
- Crusted, weeping lesions—creams which are an emulsion of greases in water.
- For occlusion or long action—pastes which are powder (for example, zinc oxide) in an ointment.
- For the face and scalp—gels

Composition of bases

The consistency and properties of ointment and cream depend on the ratio of oil or grease to water (that is, whether they are oil in water or water in oil) and the emulsifying agents used. For example, emulsifying ointment contains soft white paraffin, emulsifying ointment, and liquid paraffin.

The oils and greases range from mineral oil through soft paraffin to solid waxes. Some are naturally occurring, such as lanolin and beeswax. Creams or ointments may be used on their own as emollients or as vehicles for active ingredients.

Composition of bases

Emollients

There are numerous preparations for softening dry scaling skin and it is largely a matter of personal preference as to which one is used.

Official preparations

- Soft white paraffin—greasy; protects skin and is long lasting.
- Emulsifying ointment—less greasy; mixes with water and can be used for washing.
- Aqueous cream—oil in water emulsion; useful as a vehicle, as an emollient, and for washing.
- Liquid paraffin: white soft paraffin, equal parts—spreads easily and is less greasy than white soft paraffin.
- Hydrophilic ointment—contains propylene glycol; mixes with water and spreads easily.
- Lanolin (hydrous wool fat)—the natural emollient from sheep; mixes with water and greases, softens the epidermis, but can also cause allergic reactions.

Proprietary preparations

Proprietary preparations are numerous, varied, and more expensive than the standard preparations. They may also contain sensitisers—lanolin and preservatives (hydroxybenzoate, chlorocresol, sorbic acid)—and can cause allergies. Some examples are E45 cream (Crookes), Oilatum cream (Stiefel), and Lacticare (Stiefel), Unguentum Merck (Merck), Aquadrone (Norwich Eaton), and Diprobase (Schering-Plough).

Bath additives

Bath additives comprise dispersible oils such as Oilatum (Westwood, United States), Aveeno (Bioglan), Balneum (Merck), Alpha Keri (Westwood, United States), Emulsiderm, and Dermol (Dermal).

Topical steroids

Topical steroids provide effective anti-inflammatory treatment but have the disadvantage of causing atrophy (due to decreased fibrin formation) and telangiectasis. They are readily absorbed by thin skin around the eyes and in flexures. On the face the halogenated steroids produce considerable telangiectasia, so nothing stronger than hydrocortisone should be used (except in lupus erythematosus). They can cause hirsutism and folliculitis or acne. Infection of the skin may be concealed (tinea incognita, for example) or made worse.

Side effects can be avoided by observing the following guidelines:

- Avoid long term use of strong steroids.
- Potent or very potent steroids should be applied sparingly and often for a short time, then a less potent preparation less often as the condition improves.
- Use only mildly potent steroids (that is, hydrocortisone) on the face.
- Use preparations combined with antibiotics or antifungals for the flexures.

Topical steroids come in various strengths and a wide variety of bases—ointments, creams, oily creams, lotions, and gels—which can be used according to the type of lesion being treated.

Their pharmacological activity varies and they are classified according to their potency, the synthetic halogenated steroids being much stronger than hydrocortisone:

- Mildly potent—hydrocortisone 0.5%, 1%, and 2.5%
- Moderately potent—Eumovate (GSK), Stiedex LP (Stiefel)
- Potent—Betnovate (GSK), Cutivate (GSK), Locoid (Brocades), Synalar (Zeneca)
- Very potent—Dermovate (GSK).

In Britain a full list showing relative potencies appears in MIMS. Combinations with antiseptics and antifungals, are listed below:

Mildly potent

- Vioform HC (Zyma)
- Terra-Cortril ointment (Pfizer), containing oxytetracycline and hydrocortisone
- Fucidin H cream or ointment (Leo), containing fucidic acid and hydrocortisone
- Canesten HC (Baypharm)
- Daktacort cream (Janssen)

Moderately potent

- Betnovate N (betamethasone and neomycin) (GSK)
- Synalar N (neomycin; Zeneca)
- Trimovate cream (clobetasone butyrate, nystatin, and oxytetracycline; GSK)
- Fucibet (betamethasone, fucidic acid; Leo)

Very potent

- Dermovate-NN (clobetasone, with neomycin and nystatin; GSK).

Antiseptics and cleaning lotions

Simple antiseptics are very useful for cleaning infected, weeping lesions and leg ulcers.

Potassium permanganate can be used by dropping four or five crystals in a litre of water or in an 0.1% solution that is diluted to 0.01% for use as a soak. It will stain the skin temporarily and plastic containers permanently.

Silver nitrate 0.25% is a simple, safe antiseptic solution that, applied as a wet compress, is useful for cleaning ulcers.

Flamazine (Smith and Nephew) is silver sulfadiazine cream, used for leg ulcers, pressure sores, and burns.

Hydrogen peroxide (6%) helps remove slough but tends to be painful. Hioxyl (Quinoderm) is a proprietary cream for desloughing.

Iodine (2.5%) is an old fashioned, effective preparation as a tincture in alcohol and Betadine (Napp) is a proprietary equivalent.

Shampoos. Ceanel concentrate (Quinoderm) contains cetrimide 10%. Ionil T (Galderma) has benzalkonium chloride and coal tar solution, and Betadine (SSL) contains povidone iodine. Shampoos containing selenium sulphide (Selsun, Abbot) and ketokonazole (Nizoral, Janssen) can be used for seborrhoeic dermatitis and also for pityriasis versicolor of the skin.

There are numerous other antiseptic, cleansing, and desloughing agents such as cetrimide, chlorhexidine, benzalkonium chloride, benzoic acid, and enzyme preparations such as Varidase (Lederle), a streptokinase and streptodornase preparation.

Tar preparations

These are mainly used for treating psoriasis as described in chapter 3.

Tar has an anti-inflammatory effect and seems to suppress the epidermal turnover in lesions of psoriasis. The various tar pastes are generally too messy to use at home and are most suitable for dermatology treatment centres. Standard tar paste contains a strong solution of coal tar 7.5% in 25 g of zinc oxide, 25 g of starch, and 50 g of white soft paraffin.

There are numerous proprietary preparations that are less messy and do not stain but are not so effective. They are useful for treating less severe psoriasis at home. Examples are: Alphosyl cream (Stafford-Miller), Pragmatar (Bioglan), Psoriderm (Dermal); alphosyl HC (Stafford-Miller) and Carbo-Cort (Lagap) contain hydrocortisone as well.

Dithranol can be used in a paste containing salicylic acid, zinc oxide starch, and soft white paraffin. It has to be applied carefully avoiding contact with the surrounding skin, as it can cause severe irritation. It is best to start with a low concentration.

For short contact treatment relatively clean preparations in a range of concentrations are available, such as Dithrocream (Dermal), Anthranol (Stiefel), and Psoradrate cream (Stafford-Miller).

Ichthammol is a useful soothing extract of shale tar. It can be made up as a 1% paste in yellow soft paraffin with 15% zinc oxide.

Bath preparations are useful for dry skin and widespread psoriasis. Coal tar solution (20%) can be used or Polytar Emollient (Stiefel) or Psoriderm.

Tar shampoos are useful for treating psoriasis of the scalp. Polytar (Stiefel), T-Gel (Neutrogena), Capasal (Dermal), and Alphosyl (Stafford-Miller) are some examples.

Keratolytics

These can be used for hyperkeratotic lesions. They soften and help remove excess keratin. If used for extensive areas or in infants systemic absorption can occur. A useful preparation is salicylic acid 2–4% in aqueous cream. Salicylic acid with betamethasone ointment (Diprosalic ointment, Schering-Plough) can be used for hyperkeratotic lesions where inflammation is present.

Antipruritics

Useful anti-pruritics for persistent itching include menthol (0.5%) or phenol 1% in aqueous cream, and calamine lotion, which contains arachis oil.

Barrier and protective preparations

These preparations protect against softening and maceration from moisture in flexures, for example the groins. They also have an occlusive effect. They are essentially bases with zinc oxide or silicone (as dimethicone). There are many preparations; some of the most commonly used are:

- Zinc cream BP, contains zinc oxide, arachis oil, and lanolin
- Zinc and castor oil ointment BP
- Conotrane (Yamanouchi) and Siopel (Bioglan), contain dimethicone (dimethicone)
- Metanium (Roche), contains titanium dioxide
- Sudocrem (Forest) and Drapolene (Pfizer), contain lanolin.

Treatment for specific situations

Sunscreens

These give a degree of protection—mainly to ultraviolet B but also to ultraviolet A. They depend on their effect on a physical barrier (usually titanium dioxide) and chemicals that combine with epidermal cells, usually esters of PABA or oxybenzone.

Camouflage

Scars, congenital naevi and other blemishes that cannot be removed can be covered with suitable creams. Proprietary preparations are available.

Antiperspirants

Aluminium chloride for hyperhidrosis: aluminium chloride 20% (Driclor, Stiefel, or Anhydrol, Dermal Laboratories).

Depigmenting agents

2% hydroquinone cream is available without prescription as "fade-out". Preparations containing corticosteroids are also prescribed but not available as proprietary preparations.

Antimitotic agents

5-Fluorouracil cream is useful for treating incipient malignancies—that is, solar keratoses, but not actual carcinomas. It is available as Efudix cream (Roche), which is applied daily for one to two weeks. It produces a variable degree of inflammation that is allowed to subside before the treatment is repeated.

Infestations

- (1) *Scabies*. The correct procedure for treatment is more important than the preparation used. Benzyl benzoate 25% application BP is still available and is cheap but tends to irritate the skin. Malathion is available as Derbac (SSL), Prioderm (SSL), and Quellada M (Stafford-Miller), and Permethrin as Lyclear cream (Kestrel) preparations are more effective and less likely to irritate. 6% sulphur in white soft paraffin or permethrin are recommended for young children and pregnant or lactating women. The procedures for treatment set out on page 107 should be followed and clearly explained to the patient. For resistant cases ivermectin (Mectizan, MSD) by mouth is available on a named patient basis.
- (2) *Pediculosis*. Preparations containing malathion, carbaryl, and permethrin are used either as shampoos or lotions. Lotions are most effective and should be left on the skin for 12 hours before washing off. The same preparations are available as for treating scabies, with the addition of 0.5% malathion lotion as Suleo-M (SSL). Recently a lotion of phenothrin (Full Marks, SSL) has become available for treating head and pubic lice.

Preparations for the mouth

Steroids—Adcortyl in Orabase (Squibb) or Corlan pellets (Evans). Both these preparations contain corticosteroids.

Antifungals—Daktarin (Janssen) or Fungilin lozenges (Squibb); Nystan (nystatin suspension, Squibb). Corsoidyl (chlorhexidine, GSK), and Difflam (3m Riker) are useful mouthwashes.

Topical immunosuppressants

Tacrolimus (Protopic, Fujisawa) has recently become available as an ointment in two strengths, 0.03% and 0.1%. It has not been evaluated in children under the age of two or in pregnant women. It is recommended that it is only used by dermatologists or those with considerable experience in treating eczema. Although the exact mode of action is unknown it does diminish T cell stimulation by Langerhan cells and diminishes the production of inflammatory mediators from mast cells. It should be used in moderate to severe atopic eczema that has not responded to either treatment. Skin irritation with burning, erythema, and pruritis are the most common side effects. In view of its immunosuppressive activity

any infection should be treated first and it should be used with caution if there is a risk of viral infection or if inoculations using attenuated or live organisms are being used.

Pimecrolimus (Elidel, Steeple Novartis) is a similar preparation recommended for intermittent treatment of eczema can also be used as an initial treatment for any flare up of eczema. It diminishes cytokine activity long term relieving both the erythema and pruritis of eczema.

In common with topical steroids any immunosuppressive drug should be used with caution as viral infections are likely to be present or the patient is undergoing inoculation with live or attenuated organisms.

Systemic treatment

Antibiotics are probably the most commonly used systemic treatment. Long term antibiotics are needed for acne and cellulitis. Antifungal and antiviral drugs are indicated if topical treatment is ineffective, particularly in the immunosuppressed, and when the infection has been confirmed by laboratory tests.

Immunosuppressant drugs have had a considerable impact on the treatment of autoimmune and connective tissue diseases and diminished the need for systemic steroids—previously the only treatment available. They are increasingly used for extensive and persistently inflamed dermatoses, particularly psoriasis and eczema.

Antibacterial drugs

All penicillins may cause allergic rashes, which may be severe, and the broad spectrum penicillins, amoxicillin, ampicillin, and co-amoxiclav, are particularly likely to cause an intense rash in patients with glandular fever. They tend to accumulate in patients with renal failure and may reduce the excretion of methotrexate which is used in the treatment of psoriasis.

Phenoxymethylpenicillin (penicillin V) is useful in Gram positive infections and erysipelas.

Flucloxacillin is used to treat infections due to penicillinase producing organisms. It is used in impetigo and cellulitis.

Amoxicillin and ampicillin are broad spectrum antibiotics but are destroyed by penicillinase. Co-amoxiclav is a combination of amoxicillin and clavulanic acid. It is effective against a wide range of organisms and beta lactamase producing staphylococci as well.

Cephalosporins are not affected by penicillinase and are effective against both Gram positive and Gram negative infections.

Ciprofloxacin is used for infections with both Gram positive and Gram negative organisms such as pseudomonas.

Erythromycin is used for the treatment of acne and is useful in Gram positive infections. Resistant strains of staphylococcus are appearing.

Metronidazole is useful for treating anaerobic infections and trichomonas infections. It is useful for rosacea that is not responding to conventional treatment.

Antifungal drugs

Topical treatment is usually effective but for fungal infection of the nails and intractable infections of the skin systemic treatment may be required.

Griseofulvin (500 mg daily) is a well established treatment for fungal infections of the skin, hair, and nails. Although it should not be used in pregnancy, it can be used in children. It can cause lupus erythematosus to flare up.

Terbinafine (250 mg daily) is an effective systemic antifungal drug that does not affect the liver. It is used for both nail and skin infections.

Imidazole and triazole drugs include itraconazole and ketoconazole, which are effective for dermatophyte infections of the skin and pityriasis versicolor.

Antiviral drugs

Discovery of drugs that inhibit viral DNA polymerase and inhibit their proliferation *in vivo* means that effective treatment for herpes simplex and zoster is now possible. They are effective at the early stages of infection and should be started as soon as symptoms appear. Aciclovir (Zovirax, GSK) is available as a cream.

Aciclovir is effective against both herpes simplex and zoster. The standard dose is 200 mg five times daily for five days. In varicella infections and herpes zoster 800 mg is given five times daily for seven days. It can also be given by intravenous infusion, and should be applied as soon as symptoms appear. In addition, it can be used for prophylaxis, particularly in the immunocompromised patients and atopics who are liable to fulminating infection.

Famciclovir and valaciclovir are similar and are recommended for treating herpes zoster.

Antihistamines

These drugs are used in urticaria and acute allergic (type I immediate hypersensitivity) reactions. The newer long acting and non-sedating antihistamines are useful for treatment during the day and can be combined with one of the sedating type at night if pruritus is preventing sleep.

Non-sedating antihistamines only cross the blood–brain barrier to a slight extent. They may cause arrhythmias, particularly terfenadine.

- Acrivastine (Semprex, GSK) 8 mg three times daily
- Cetirizine (Zirtek, UCB Pharma) 10 mg once daily
- Fexofenadine (Telfast, Hoechst) 120 or 180 mg once daily
- Loratadine (Claritin, Schering-Plough) 10 mg once daily.

Sedating antihistamines

There are many available and which is used is largely a matter of personal preference. The sedating effect, which is enhanced by alcohol, means that they are best taken at night. They also potentiate CNS depressants and anticholinergic drugs. They tend to have anticholinergic effects, causing dry mouth, blurred vision, tachycardia, and urinary retention. Those commonly used are:

- Chlorphenamine (Piriton Stafford-Miller 4 mg daily)
- Cyproheptadine (Periactin (MSD) 4 mg up to four times daily)
- Hydroxyzine (Atarax (Pfizer) 10–25 mg at night; can be used during the day if drowsiness is not a problem)
- Promethazine (10 or 25 mg at night or twice daily)
- Trimeprazine (Vallergan (Castlemead) 10 mg two to three times daily).

Corticosteroids

In addition to topical preparations, systemic steroids may be required for the treatment of severe inflammatory skin conditions such as erythroderma developing from psoriasis or eczema. They are also used in vasculitis and erythema multiforme as well as connective tissue diseases. They are often required for the treatment of pemphigoid and pemphigus together with immunosuppressant drugs.

The side effects must be borne in mind, particularly for any long term treatment. Most important are given below.

Water and electrolytes

Sodium and water retention with loss of potassium.

Musculoskeletal

Osteoporosis, aseptic necrosis of the femoral head, growth retardation in children, and muscle wasting.

Ophthalmic effect

Cataract formation and increased tendency to glaucoma.

Other effects

Increase in blood pressure, peptic ulceration and fat redistribution, and impaired glucose intolerance.

Retinoids

These vitamin A derivatives have proved very effective in the treatment of psoriasis and acne but are not without risk of side effects. The most serious is that they are teratogenic and must be discontinued for at least three months after stopping treatment in the case of isotretinoin and five years after taking acitretin.

All patients should be warned of possible side effects and women of childbearing age must be using an effective form of contraception, which must have been used for at least a month before treatment has started as well as having a pregnancy test carried out. Liver function tests and fasting cholesterol and triglycerides should be carried out on all patients. After prolonged treatment in adolescence, radiological tests should be carried out to ensure that there is no extraosseous calcification. The most important side effects are:

- Abnormal liver function tests
- An increase in cholesterol and triglycerides
- Occasional increases in electron spin resonance and lowered white count.

Clinical side effects

Drying and roughening of the skin and mucous membranes, particularly the lips, can occur. There may also be thinning of the hair and nails. Photosensitivity eruptions can develop. Occasionally muscle and joint pains occur.

Acitretin

This drug is used for severe psoriasis including pustulosis of the hands and feet. It has also been used in other forms of keratosis such as Darier's disease and pityriasis rubra pilaris.

Isotretinoin

This drug is used for severe acne vulgaris that has not responded to antibiotics or other treatments. It is therefore often used in adolescence and it is important to be aware of the musculoskeletal effects and possible mood changes.

Immunosuppressants

Methotrexate

This drug is useful in severe psoriasis that is not responding to topical treatment. The main disadvantage is its adverse effect on the liver, which precludes its use in those who have alcoholic liver disease but who are often those most needing systemic treatments. Idiopathic immunosuppression can occur so a test dose must always be given and a full blood count carried out 48 hours later before treatment has started. There may be gastrointestinal upsets and osteometitis as well.

Methotrexate interacts with anti-inflammatory and antiepileptic drugs. A full list of drug interactions should be consulted before treatment is started.

After a 2.5 mg test dose and full blood count 48 hours later, the regular dose is 5–15 mg by mouth once a week. Full blood count and liver function tests should be carried out once a week for the first six weeks and thereafter once a month during treatment. Folinic acid should be given at the same time, as this prevents bone marrow depression. In many centres a liver biopsy is considered mandatory before treatment is started since blood tests will remain normal for some time during the development of hepatic fibrosis.

Azathioprine

This drug is used for systemic lupus erythematosus, pemphigus, and bullous pemphigoid. It enables the dosage of systemic steroids to be reduced. The most serious side effect is bone marrow suppression. This may occur quite rapidly, particularly in those with diminished ability to metabolise the drug. This is carried out by thiopurine methyl transferase (TMT). The level of this enzyme should therefore be determined before treatment is started and those at low levels given a lower dosage. Those who inherit high activity may require higher doses. Other side effects include gastrointestinal upset, liver toxicity, and an increased tendency to infection.

Ciclosporin

This drug has proved helpful in severe psoriasis within inflammatory lesions and, secondly, in the treatment of severe atopic dermatitis. There are a number of drug interactions and it is important to check renal function and monitor both blood urea and serum creatinine.

Other drugs

Dapsone

This drug was originally developed for treating leprosy but was proved very effective in dermatitis pityformis and some other conditions, such as pyoderma gangrenosum. It may cause haemolytic anaemia, and other side effects include bone marrow suppression, hepatitis, and peripheral neuropathy. Regular blood checks are essential.

Hydroxychloroquine

This drug is used in both systemic and discoid lupus erythematosus as well polymorphic light eruption and porphyria cutanea tarda. The most serious side effect is retinopathy but this does not occur if the dose does not exceed 6.5 mg/kg lean body weight.

Psoralens

These drugs are used in conjunction with long wavelength ultraviolet light as psoralen with ultraviolet A (PUVA) therapy described on page 67. It is used for the treatment of severe psoriasis. It has also proved effective in some cases of atopic eczema, T cell lymphoma of the skin, and occasionally in lichen planus. There is a risk of cataract formation, and a full blood count as well as antinuclear factor tests should be carried out.

Preparations for treating acne and varicose ulcers are described in the appropriate sections.

Acknowledgments

Any ideas or inspiration which these pages may contain have inevitably been learnt or borrowed from others. I am indebted to the late Professor JM Malins and Dr MG FitzGerald, through whose enthusiasm I was first introduced to diabetes, and to the late Dr David Pyke through whose energy this interest has been fostered over many years. Close collaboration with colleagues at King's both past and present has made possible many of the joint ventures described here, and I am grateful to them all. Our registrars and research fellows and above all our patients have been a constant source of inspiration.

I am particularly grateful to the many colleagues who have assisted me with the preparation of this book, especially Professor Stephanie Amiel (RD Lawrence Professor of Diabetic Medicine), Dr Michael Edmonds and Dr Stephen Thomas (consultant physicians), Dr Tyrrell Evans (general practitioner), Dr Phin Kon (renal physician), Dr William Marshall (Reader in Clinical Biochemistry), Dr Joanna Raeburn (associate specialist), Ms Helen Reid (Diabetes Specialist Nurse), and Mrs Eileen Turner (Consultant Nurse Specialist). Dr Simon Page (consultant physician in Nottingham) has helped me considerably by his many valuable comments in reading the manuscript. My wife Mrs Val Watkins has throughout provided me with invaluable support and encouragement.

Consultant physicians to the Diabetes Centre at King's from 1938 (from left to right) Dr Wilfred Oakley (1905-1998); Dr David Pyke (1921-2001) and Dr Peter Watkins

Introduction

Advances in clinical science over a single professional lifetime during the second half of the 20th century have led to improvements in understanding the causes and complications of diabetes, together with alleviation of suffering to an extraordinary degree, unimaginable even 25 years ago. Many of the clinical improvements have been initiated at innovative centres across the United Kingdom.

In the 1960s and 1970s physicians had to stand by helplessly watching their patients overwhelmed by complications of the disease. Prevention of blindness by photocoagulation and renal support treatment for those in renal failure became possible in the 1970s, while development of specialist foot clinics during the 1980s succeeded in halving the amputation rate. The sad outcome for pregnancies even 20 years after the discovery of insulin when the fetal mortality rate was more than 25%, has been transformed so that now more than 95% of these pregnancies succeed. And now, the landmark Diabetes Control and Complications Trial (DCCT) of Type 1 diabetes in the United States, and more recently the astonishing achievement of the late Professor Robert Turner in completing the United Kingdom Perspective Diabetes Survey (UKPDS) of Type 2 diabetes have demonstrated how to reduce the incidence and progression of diabetic complications by good treatment.

Yet there is still more. The present technology of managing diabetes was undreamt of until the last quarter of the 20th century. The introduction of home blood glucose monitoring with new non-invasive technologies now in sight, has made possible the achievement of “tight control”, while at the same time advances in understanding and reversing diminished awareness of hypoglycaemia are reducing its hazards. The invention of insulin pens and more recently the development of insulin pumps has contributed in great measure to improving the quality of life of those with the burden of lifelong diabetes. Furthermore after the British discoveries of the chemical (Frederick Sanger, 1955) and physical structure (Dorothy Hodgkin, 1969) of insulin followed by the revolution in molecular science, man-made insulin analogues have been introduced, giving further advantages in achieving good blood glucose control while minimising hypoglycaemia.

The initially controversial “invention” of the diabetes specialist nurse by Dr Joan Walker in Leicester in the 1950s is arguably one of the most important advances in health care, not only for those with diabetes but across the whole of medicine. The tremendous benefits in the delivery of care especially to those with diabetes and other chronic diseases have been accompanied by recognition of community needs and improvements in crossing the primary/secondary care interface. It is now to be hoped that improvements in information technology, more sophisticated audit, and provision of a national eye screening programme may emerge from the National Service Framework of 2002/2003.

RD Lawrence 1892-1968. Founder of the diabetic clinic at King's in the 1920s, founder of the British Diabetic Association in 1934

Rapid clinical advances of this magnitude require substantial support. Diabetes UK, founded as the Diabetic Association by Dr RD Lawrence and his patient HG Wells in 1934 (later the British Diabetic Association), has uniquely supported both patients and their needs as well as clinical and scientific research. More recently the Juvenile Diabetes Foundation has made substantial contributions. Furthermore the pharmaceutical industry has been both innovative in its own laboratories as well as supportive of both patients and clinicians.

It gives particular pleasure to reproduce some parts of the personal account by Mrs B-J (with her permission) of her own diabetes over the last 70 years of attendances at King's College Hospital. She describes vividly aspects of treatment and some of the problems faced by people with diabetes, and one can see clearly how many improvements there have been during her lifetime. Her account should give tremendous encouragement to those now starting on their own life with diabetes.

The ABC is intended as a strictly practical guide to the management of diabetes and its complications and is directed to all those doctors, nurses, and health professionals, other than established specialists, who see diabetic patients, and medical students should find some value in its pages. Many of the innovations of the end of the 20th century are described in this fifth edition of the ABC in the hope that it will help in the delivery of the very best standards of care to those who need it in the 21st century.

1 What is diabetes?

Diabetes once diagnosed is for life. The perseverance and self discipline needed over a lifetime can often tax even the most robust of people to the limit. Those caring for them also require perseverance and an understanding of humanity combined with a cautious optimism, to guide those with diabetes through the peaks and troughs of their lives.

Definition

Diabetes occurs either because of a lack of insulin or because of the presence of factors that oppose the action of insulin. The result of insufficient action of insulin is an increase in blood glucose concentration (hyperglycaemia). Many other metabolic abnormalities occur, notably an increase in ketone bodies in the blood when there is a severe lack of insulin.

Diagnosis

The diagnosis of diabetes must always be established by a blood glucose measurement made in an accredited laboratory.

Glucose tolerance test

The glucose tolerance test is not normally needed in routine clinical practice, and then only if uncertainty exists in younger patients, or to establish an exact diagnosis in pregnancy. For reliable results, glucose tolerance tests should be performed in the morning after an overnight fast, with the patient sitting quietly and not smoking; it is also important that the patient should have normal meals for the previous three days and should not have been dieting. False results may also occur if the patient has been ill recently or has had prolonged bed rest. Blood glucose concentrations are measured fasting and then one and two hours after a drink of 75 g of glucose in 250-350 ml water (in children 1.75 g/kg to a maximum of 75 g), preferably flavoured, for example, with pure lemon juice. Urine tests should be performed before the glucose drink and at one and two hours. Interpretation of blood glucose values according to WHO criteria is shown in the table.

Gestational diabetes

This term embraces the criteria for both diabetes and impaired glucose tolerance when discovered during pregnancy (see page 80).

Glucose tolerance tests may also show:

Renal glycosuria—this occurs when there is glycosuria but normal blood glucose concentrations; this is a benign condition, only rarely indicating unusual forms of renal disease. It is worth issuing these patients with a certificate to prevent them from being subjected to repeated glucose tolerance tests at every medical examination.

Steeple or lag curve—this is described when fasting and two hour concentrations are normal, but those between are high, causing glycosuria; this is also a benign condition, which most commonly occurs after gastrectomy but may occur in healthy people.

Impaired glucose tolerance

This is defined in the table. Patients are managed at the discretion of the physician. In general, no treatment is given to

Ebers papyrus: early clinical description of diabetes (Egyptian, 1500 BC)

WHO criteria for the diagnosis of diabetes

- 1 Symptoms of diabetes plus casual venous *plasma* glucose ≥ 11.1 mmol/l. Casual is defined as any time of day without regard to time since last meal. The classic symptoms of diabetes include polyuria, polydipsia, and unexplained weight loss
- 2 Fasting *plasma* glucose ≥ 7.0 mmol/l or whole blood ≥ 6.1 mmol/l. Fasting is defined as no calorie intake for at least 8 hours
- 3 2 hour *plasma* glucose ≥ 11.1 mmol/l during oral glucose tolerance test using 75 g glucose load

In the absence of symptoms, these criteria should be confirmed by repeat testing on a different day. If the fasting or random values are not diagnostic, the 2 hour value post-glucose load should be used

Note

Fasting plasma glucose < 6.1 mmol/l—normal
 Fasting plasma glucose ≥ 6.1 and < 7.0 mmol/l—impaired fasting blood glucose
 Fasting plasma glucose ≥ 7.0 mmol/l—provisional diagnosis of diabetes; the diagnosis must be confirmed (see above)

Adapted from *Diabetes Care* 1997;20:1183-1195

Glucose tolerance test

	Glucose concentration (mmol/l)		
	Venous whole blood	Capillary whole blood	Venous plasma
<i>Diabetes mellitus*</i>			
Fasting	≥ 6.1	≥ 6.1	≥ 7.0
2 hours after glucose load	≥ 10.0	≥ 11.1	≥ 11.1
<i>Impaired glucose tolerance</i>			
Fasting	< 6.1	< 6.1	< 7.0
2 hours after glucose load	$\geq 6.7 < 10.0$	$\geq 7.8 < 11.1$	$\geq 7.8 < 11.1$

*In the absence of symptoms at least one additional abnormal blood glucose concentration is needed to confirm clinical diagnosis—for example, 1 hour value of 11 mmol/l or more

ABC of Diabetes

elderly people, but diet, exercise and weight reduction are advisable in younger subjects. Over 10 years, approximately half of those with impaired glucose tolerance will develop diabetes, one-quarter will persist with impaired glucose tolerance, and one-quarter will revert to normal. Pregnant women with “impaired glucose tolerance” must be treated as if they were diabetic; for interpretation of the test in pregnancy see page 80.

Types of diabetes

Type 1 diabetes (previously insulin dependent diabetes) is due to B-cell destruction, usually leading to absolute insulin deficiency). It can be immune mediated or idiopathic.

Type 2 diabetes (previously non-insulin dependent diabetes) ranges from those with predominant insulin resistance associated with relative insulin deficiency, to those with a predominantly insulin secretory defect with insulin resistance.

Type 1 and Type 2 diabetes are the commonest forms of primary diabetes mellitus. The division is important both clinically in assessing the need for treatment, and also in understanding the causes of diabetes which are entirely different in the two groups.

Type 1 diabetes

Type 1 diabetes is due to destruction of B-cells in the pancreatic islets of Langerhans with resulting loss of insulin production. A combination of environmental and genetic factors that trigger an autoimmune attack on the B-cells is responsible, occurring in genetically susceptible individuals. Thus, among monozygotic identical twins only about one-third of the pairs are concordant for diabetes in contrast to the situation in Type 2 diabetes where almost all pairs are concordant. The process of islet destruction probably begins very early in life and is known to start several years before the clinical onset of diabetes.

HLA status

The major histocompatibility complex antigens are adjuncts to several types of immunological activity. Ninety percent of Type 1 diabetic patients show either DR3 or DR4, or both together, while DR2 is protective against diabetes.

Autoantibodies and cellular immunity

Islet cell antibodies are present at diagnosis in most Type 1 diabetic patients and gradually decline and disappear during the following years. Antibodies to specific proteins have more recently been identified: these include antibodies to glutamic acid decarboxylase (GAD, a 64-kDa antigen); and even closer association is found in the presence of antibodies to tyrosine phosphatase (37 kDa, IA-2). The presence in a non-diabetic individual of three or more antibodies (islet cell antibodies, anti-GAD antibodies, anti-IA-2 antibodies, anti-insulin autoantibodies) indicates an 88% chance of developing diabetes within 10 years.

The presence of insulinitis at the onset of Type 1 diabetes represents the role of inflammatory cells (for example, cytotoxic T cells and macrophages) in B-cell destruction. Macrophages also produce cytokines leading to activation of lymphocytes known to be present at the onset of Type 1 diabetes.

Attempts have been made to prevent the onset of Type 1 diabetes. Immune suppression can to some extent preserve islet function, but permanent remissions are not normally achieved and the treatment is in any case too dangerous for routine use.

Other specific types of diabetes

- *Genetic defects of β cell function*—chromosome 12 hepatic nuclear factor-1 α (HNF-1 α) (formerly maturity onset diabetes of the young (MODY) 3), chromosome 7 glucokinase defect (formerly MODY 2), chromosome 20 HNF-4 α (formerly MODY 1), mitochondrial DNA mutation
- *Genetic defects in insulin action*—Type A insulin resistance (genetic defects in insulin receptor), lipotrophic diabetes, genetic defects in the PPAR γ receptor
- *Gestational diabetes*
- *Diseases of the exocrine pancreas*—pancreatitis, pancreatectomy, carcinoma of pancreas, cystic fibrosis, fibro-calculeous pancreatopathy, haemochromatosis
- *Endocrinopathies*—acromegaly, Cushing’s disease, Conn’s syndrome, glucagonoma, pheochromocytoma, somatostatinoma
- *Drug induced* (these agents in particular exacerbate hyperglycaemia in patients with established diabetes)—corticosteroids, diazoxide, β adrenergic agonists (for example, intravenous salbutamol), thiazides, α interferon
- *Uncommon forms of immune mediated diabetes*—stiff man syndrome, anti-insulin receptor antibodies (Type B insulin resistance)
- *Infections*—congenital rubella, cytomegalovirus
- *Other genetic syndromes sometimes associated with diabetes*—Wolfram syndrome, Down’s syndrome, Turner’s syndrome, Klinefelter’s syndrome, Prader-Willi syndrome

Comparison of Type 1 and Type 2 diabetes

Type 1 diabetes	Type 2 diabetes
Inflammatory reaction in islets	No insulinitis
Islet B-cells destroyed	B-cells function
Islet cell antibodies	No islet cell antibodies
HLA related	Not HLA related
Not directly inherited	Strong genetic basis (some cases)

An islet with lymphocytic infiltration (insulinitis)

The use of nicotinamide to prevent diabetes by altering macrophage function has not proved to be of benefit. Giving insulin itself may conserve islet function; the results of trials are awaited.

Associated autoimmune disorders

The incidence of coeliac disease, Addison’s disease, hypothyroidism, and pernicious anaemia are increased in Type 1 diabetic patients, and appear to occur especially in those with persisting islet cell antibodies.

Risks of inheriting diabetes

A child of a mother with Type 1 diabetes has an increased risk of developing the same type of diabetes, amounting to 1-2% by 25 years; the risk is about three times greater if the father has this disease. If both parents have the disease the risk is further increased and genetic counselling should be sought by these rare couples.

Type 2 diabetes

There are numerous causes of Type 2 diabetes, which is now known to include a wide range of disorders with differing progression and outlook. The underlying mechanism is due either to diminished insulin secretion—that is, an islet defect, associated with increased peripheral resistance to the action of insulin resulting in decreased peripheral glucose uptake, or increased hepatic glucose output. Probably as many as 98% of Type 2 diabetic patients are “idiopathic”—that is, no specific causative defect has been identified. Whether decreasing insulin secretion or increasing insulin resistance occurs first is still uncertain, but the sequence of events may vary in different individuals. Obesity is the commonest cause of insulin resistance. Other rare insulin resistant states are shown in the table.

Some adults (especially those not overweight) over 25 years of age who appear to present with Type 2 diabetes may have latent autoimmune diabetes of adulthood (LADA) and become insulin dependent. Autoantibodies are often present in this group of patients.

Type 2 diabetes is a slowly progressive disease: insulin secretion declines over several decades, resulting in an insidious deterioration of glycaemic control which becomes increasingly difficult to achieve.

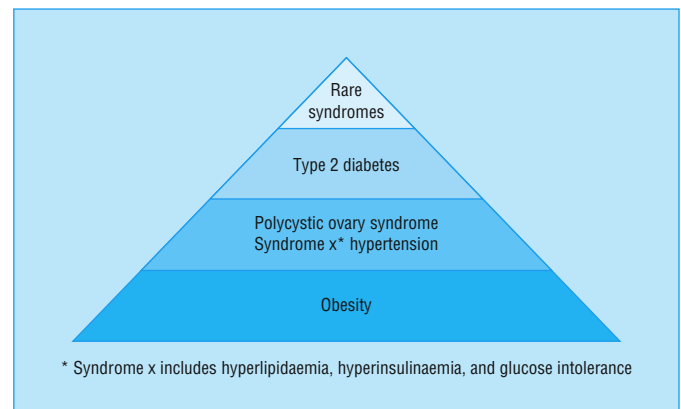

Obesity

Relative insulin resistance occurs in obese subjects, perhaps because of down regulation of insulin receptors due to hyperinsulinaemia. Obese subjects have a considerably increased risk of developing Type 2 diabetes. Fat distribution is relevant to the development of diabetes, so that those who are “apple shaped” (android obesity, waist-hip ratio > 0.9) are more prone to Type 2 diabetes than those who are “pear shaped” (gynoid obesity, waist-hip ratio < 0.7).

The importance of leptin in the evolution of lifestyle related obesity is unclear. Leptin is a single chain peptide produced by adipose tissue and its receptors are expressed widely throughout the brain and peripheral tissues; when injected into leptin deficient rodents it causes profound hypophagia and weight loss. Plasma leptin levels rise in parallel with body fat content. Although very rare cases of morbid obesity due to leptin deficiency have been reported, and are shown to respond to leptin injections, there is in general an absence of measurable biological responses to leptin, which at present has no role in the management of obesity.

Insulin resistance and disease

Increased risk for Type 2 diabetes

- People over 40 years of age
- People of Asian or African-Caribbean ethnic origin
- Overweight people
- Family history of diabetes
- History of gestational diabetes
- History of large baby (birth weight exceeding 4 kg)

Natural history of Type 2 diabetes

ABC of Diabetes

Birthweight and Type 2 diabetes

Recent observations suggest a relationship between low birthweight and the development in middle age of insulin resistance, Type 2 diabetes, and coronary artery disease. Those who are smallest at birth and largest at one year of age are most at risk.

Genetics of Type 2 diabetes

Type 2 diabetes has a strong genetic component, manifest in the high concordance of diabetes in monozygotic twins, familial clustering and differences in prevalence between ethnic groups. An increasing number of specific genetic defects are becoming recognised and some are described below.

Type 2 diabetes in children and young people

Hitherto, childhood diabetes was witnessed in some ethnic minorities and in those with the rare inherited MODY syndromes described below. Growing recognition now exists of a substantial increase of this disease in the prosperous industrialised nations. In the United States, between 8% and 45% of recently diagnosed cases of diabetes among children and adolescents are Type 2, and the problem is increasing. It is most likely to occur at 12 to 14 years of age, more frequently in girls, and is strongly associated with obesity, physical inactivity and a family history of Type 2 diabetes. When young people of lean physique are discovered to have Type 2 diabetes, it is important to attempt to identify whether they may represent those with LADA and thus in need of insulin. There is also evidence that in approximately one-quarter of such patients diabetes is due to a specific genetic defect including those of the MODY group described below or other rare genetic syndromes.

Dominantly inherited Type 2 diabetes (MODY)

Seven genetic syndromes, three of which are shown in the box at the top of page 2, cause MODY—defined as an early onset of dominantly inherited Type 2 diabetes. Two (or at the very least one) members of such families should have been diagnosed before 25 years of age, three generations (usually first-degree) should have diabetes, and they should not normally require insulin until they have had diabetes for more than five years.

Mitochondrial diabetes

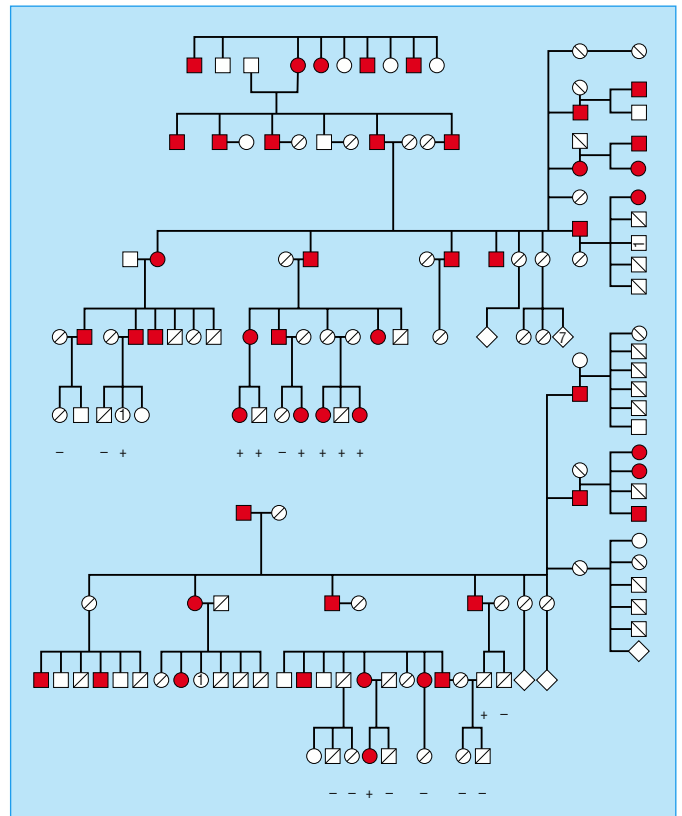

Mitochondrial diabetes and deafness is a rare form of diabetes maternally transmitted, and is related to the A3243G mitochondrial DNA mutation. Diabetes is diagnosed in the fourth to fifth decades, usually in thin patients with symptoms. Patients respond better to sulphonylureas than to diet alone. Diabetic microvascular complications do occur.

Insulin resistant diabetes

Some rare insulin resistant states exist in which hundreds or even thousands of units of insulin may be ineffective. They are often associated with lipodystrophy, hyperlipidaemia, and acanthosis nigricans. Type A insulin resistance is due to genetic defects in the insulin receptor or in the post-receptor pathway. Type B insulin resistance occurs as a result of IgG autoantibodies directed against the insulin receptor; it is often associated with other autoimmune disorders such as systemic lupus erythematosus, and it is much commoner in women of African descent. Management of these conditions can be very difficult and specialist texts should be consulted.

Relative risk of Type 2 diabetes according to body mass index in US women aged 30 to 55 years

A family with dominantly inherited Type 2 diabetes. HNF-1 α defect (chromosome 12), formerly MODY 3. Diabetic patients are shown in black

Prevalence

In the United Kingdom more than three percent of the population have diabetes, and about the same number again can be found on screening in population studies. Among schoolchildren about two in 1000 have diabetes.

Diabetes can occur at any age. Type 2 diabetes is most common after middle age and occurs most often at 50-70 years of age, affecting both sexes equally. The peak incidence of Type 1 diabetes is at 10-12 years with a small male predominance. Nevertheless, elderly people can also have Type 1 diabetes, and some children have Type 2 diabetes.

Worldwide, the incidence of Type 2 diabetes is increasing rapidly: in 1995, it was estimated that there were 135 million people with diabetes, this may rise to about 300 million by 2025, increasing particularly in developing countries.

Ethnic variations

The prevalence of Type 2 diabetes is particularly high in Asian and African-Caribbean people and presents a considerable health burden in some inner urban areas. Thus in the United Kingdom 20% of Asians and 17% of African-Caribbeans over 40 years of age have Type 2 diabetes. Children not infrequently have Type 2 diabetes. Asian people have a particularly high risk of developing diabetic nephropathy and coronary artery disease, and a very low risk of foot ulceration; those among the

Estimated prevalence of diabetes mellitus in selected countries in 2000

Number of people aged ≥ 20 years estimated to have Type 2 diabetes in developed and developing countries

ABC of Diabetes

black races are prone to severe hypertension that can be difficult to treat, and also have a strong tendency to develop gestational diabetes.

Prevention of Type 2 diabetes

Lifestyle changes in those prone to Type 2 diabetes can effectively delay the onset of this disease. Several studies in different countries have demonstrated the feasibility of achieving this by a programme of weight reduction, improved diet (less fat, less saturated fat, and more dietary fibre) and increased physical activity. Recent investigations show that the development of diabetes can be approximately halved if these lifestyle changes are maintained over four years.

Diabetic complications

Patients with long-standing diabetes, both Type 1 and Type 2, may develop complications affecting the eyes, kidneys or nerves (microvascular complications) or major arteries. The major arteries are affected in people with diabetes, causing a substantial increase both in coronary artery disease and strokes as well as peripheral vascular disease. The greatest risk of large vessel disease occurs in those diabetic patients who develop proteinuria or microalbuminuria, which is associated with widespread vascular damage. The distribution of arterial narrowing tends to be more distal than in non-diabetic people, whether in coronary arteries or in the peripheral arteries affecting feet and legs. Medial arterial calcification (Monckeberg's sclerosis) is also substantially increased in patients with neuropathy and in those with renal impairment. The functional effects of vascular calcification are uncertain.

Cumulative incidence of diabetes according to the Diabetes Prevention Programme Research Group. The diagnosis of diabetes was based on the criteria of the American Diabetes Association. The incidence of diabetes differed significantly among the three groups ($P < 0.001$ for each comparison), showing that lifestyle interventions are particularly effective in diminishing the development of Type 2 diabetes

2 Clinical presentation: why is diabetes so often missed?

Thirst, tiredness, pruritus vulvae or balanitis, polyuria, and weight loss are the familiar symptoms of diabetes. Why then is the diagnosis so often missed? Of 15 new patients with diabetes presenting in our diabetic ward for the first time with ketoacidosis, 14 had had no tests for diabetes after a total of 41 visits to their doctors. Almost all these serious cases of ketoacidosis could have been prevented.

Patients do not, of course, always describe their symptoms in the clearest possible terms, or else their complaints may occur only as an indirect consequence of the more common features. Many patients describe dry mouth rather than thirst, and patients have been investigated for dysphagia when dehydration was the cause. Polyuria is often treated blindly with antibiotics; it may cause enuresis in young people and incontinence in elderly people and the true diagnosis is often overlooked. Complex urological investigations and even circumcision are sometimes performed before diabetes is considered.

Confusion in diagnosis

Some diabetic patients present chiefly with weight loss, but even then the diagnosis is sometimes missed, and I have seen two teenagers referred for psychiatric management of anorexia nervosa before admission with ketoacidosis. Perhaps weakness, tiredness, and lethargy, which may be the dominant symptoms, are the most commonly misinterpreted; "tonics" and iron are sometimes given as the symptoms worsen.

Deteriorating vision is not uncommon as a presentation, due either to change of refraction causing myopia (mainly in Type 1 diabetes) or to the early development of retinopathy (mainly in Type 2 diabetes). Foot ulceration or sepsis in older patients brings them to accident and emergency departments and is nearly always due to diabetes. Occasionally painful neuropathy is the presenting symptom, causing extreme pain in the feet, thighs, or trunk.

Glycosuria itself is responsible for the monilial overgrowth which causes pruritus vulvae or balanitis; some older men are first aware of diabetes when they notice white spots on their trousers. In hot climates drops of sugary urine attract an interested population of ants, and at least one patient now attending the clinic at King's College Hospital presented in this way before he came to England.

Patterns of presentation

Symptoms are similar in the two types of diabetes (Type 1 and Type 2), but they vary in their intensity. The presentation is most typical and the symptoms develop most rapidly in patients with Type 1 diabetes; they usually develop over some weeks, but the duration may be a few days to a few months. There is usually considerable weight loss and exhaustion. If the diagnosis is missed, diabetic ketoacidosis occurs. Type 1 diabetes occurs under 40 years of age in approximately 70% of cases but can occur at any age, and even in older people.

Insulin dependent diabetes, 1922

Presence of any retinopathy according to years since clinical diagnosis of Type 2 diabetes among patients in Southern Wisconsin (●) and rural Western Australia (○). Solid lines represent data fitted by weighted regression; lines are extrapolated to indicate the time at which onset of observable retinopathy is estimated to have occurred, demonstrating that diabetes was likely to have been present for several years before the clinical diagnosis was made

Presenting symptoms (%) in 547 consecutive cases of diabetes seen by Professor John Malins

Age	Males	Females	Total	Symptoms							
				None	Thirst	Wasting	Fatigue	Pruritus vulvae	Sepsis	Visual	Other
0-39	28	27	55	9	62	14	4	9	2		
40-59	98	108	206	22	22	9	9	21(2)*	7	6	4
60+	100	186	286	22	22	5	8	22(6)*	6	10	5

*Cases of balanitis in males

Symptoms in patients with Type 2 diabetes are similar but tend to be insidious in their onset; sometimes these patients deny any symptoms, although they often admit to feeling more energetic after treatment has been started. These patients are usually middle aged or elderly, but increasingly children, especially those of ethnic minorities, or those who are inert and overweight, are developing Type 2 diabetes. Microvascular and macrovascular complications are frequently already present when Type 2 diabetes is diagnosed. Type 2 diabetes is commonly detected at routine medical examinations or on admission to hospital with another illness.

Type 2 diabetes—presentations

- Diabetic symptoms 53%
- Incidental 29%
- Infections (for example, candida) 16%
- Diabetic complications 2%

Identifying patients in need of insulin

Patients in need of treatment with insulin must be identified early. This is done by judging the patient’s clinical features; blood glucose concentrations alone offer a relatively poor guide, although most patients with a blood glucose concentration greater than 25 mmol/l are likely to need insulin.

Features suggesting need for insulin are:

- a rapid development of symptoms
- substantial weight loss—patients are usually thin and demonstrate a dry tongue or more severe dehydration
- weakness
- the presence of ketonuria.

If their condition worsens, vomiting can occur and they rapidly become ketoacidotic; these patients are drowsy, dehydrated, overbreathing, and their breath smells of acetone (although many people are unable to detect this smell).

The following groups of patients are likely to need insulin:

- almost all children and most of those under 30-40 years of age
- women who present during pregnancy
- diabetic patients whose tablet treatment has failed
- all patients who have undergone pancreatectomy.

If there is any doubt give insulin. It can never be wrong to do so, and if the decision was mistaken it can easily be reversed.

Identifying patients in need of insulin

<i>Symptoms</i>	<i>Age</i>
• Rapid onset	• Any, more likely under 30 years
• Substantial weight loss	<i>Blood glucose concentration</i>
• Weakness	• Any
• Vomiting	<i>Other indications</i>
<i>Signs</i>	• When tablets have failed during pregnancy
• Usually thin	• When diet has failed during intercurrent illness
• Dry tongue	• In patients who have undergone pancreatectomy
• Weak	• Ill patients need admission
<i>Ketoacidosis</i>	• Others may start insulin at home
• Drowsiness	• If there is any doubt use insulin
• Dehydration	
• Overbreathing	
• Breath smelling of acetone	

Opportunistic screening

The diagnosis of diabetes should no longer be missed. New patients attending their doctor, whether the family doctor, at a hospital outpatient clinic or accident and emergency department, should have a blood glucose measurement as a matter of routine, especially if their symptoms are unexplained. Only a few diabetic patients are wholly without symptoms and their diabetes should be detected by screening at any medical examination. Opportunistic screening for diabetes in this way is a duty.

Della Robbia panel from the Ospedale del Ceppo, Pistoia, 1514

The personal story of Mrs B-J's diabetes

Mrs B-J was born in 1922 and developed Type 1 diabetes at the age of 10 years in 1932. She saw Dr RD Lawrence at diagnosis and in 1989 wrote an account of her own diabetes which will be presented over several chapters in this book.

Presentation and diagnosis

I was always a lively, energetic child so nobody was particularly surprised when I seemed to be growing tall and thin at the end of the summer of 1932. Because of my weight loss, my mother took me to our family doctor who thought I might have TB. He told her to put me to bed for one week, then take me back to him with a urine specimen. Up till then I was perfectly fit and well, but being in bed without exercise, I soon lost my appetite and only wanted oranges and drinks. At night, my mother put water in several quart milk bottles by my bed, but I had drunk it all—about ten pints—before my parents came up to bed. This meant dozens of trips to the toilet each night as a chamber pot could not cope with it.

After about three days, my mother went back to the doctor with a specimen and he said that I had diabetes and must go into hospital the next day. My mother was upset but also relieved, as she had a deep fear of TB.

That night a neighbour called to see how I was. My mother did not realise that I could hear their conversation and told her what was wrong. In a loud, shocked voice this lady asked, "Is she going to die?" I was immediately interested, and hearing my mother say that I wouldn't if I did not eat sweets, cake, biscuits, etc. for the rest of my life, I resolved there and then that I would do just that. I never wanted again to feel as awful as I did just then. I think that eavesdropping probably affected me for the rest of my life, and since then I have had no desire for sweet things except as part of my diet, or for warding off hypos.

The next morning my parents took me by taxi to King's College Hospital.

The first illustration is from Geyelin, HR, Marrop, C. *J Med Res* 1922;2:767-9. The table showing presenting symptoms of diabetes is adapted from Malins J. *Clinical diabetes mellitus*. London: Eyre and Spottiswoode, 1968, and the box showing Type 2 diabetes presentation uses data from UKPDS. *Diabetes Med* 1998;5:154-9.

3 Aims of treatment: a healthy lifestyle

Diabetes is easy to diagnose, but can be managed with negligent ease by those inclined to do so
 RB Tattersall, 1990

The first concerns in treating diabetic patients are to save life, alleviate symptoms, and enhance the quality of an independent life. Thereafter treatment aims to minimise the long-term complications and reduce early mortality.

Aims of treatment

Alleviation of symptoms and improvement in quality of life

This is achieved by reducing hyperglycaemia; patients who need insulin immediately (those with Type 1 diabetes) were described in the previous chapter. All others normally begin on diet alone, moving to diet and oral hypoglycaemic agents, or diet and insulin as indicated. All treatments must be adjusted to ensure that patients are symptom-free. Education of patients plays an important role in enhancing the quality of life, and needs to be maintained over many years.

Maintenance of health by reduction of risk factors and preventing the development of diabetic complications

The needs here are for:

- achievement of optimal blood glucose control
- detection and control of hypertension
- assessment and control of hyperlipidaemia
- assessment of the need for antiplatelet medication
- cessation of smoking
- regular complications screening procedures (described on page 45).

Management of long-term diabetic complications

Management of other medical problems affecting the patient

The aims of controlling diabetes

Once diabetes treatment has been established, there is a need to agree the level of control to be achieved in each individual patient. Once symptoms have been eliminated, targets for optimal control (shown in the table) should be discussed and agreed, but it is not always possible to reach ideal goals and pragmatic decisions have to be made.

The following criteria need consideration:

- ensure that symptoms have been eliminated
- lean patients should gain weight
- obese patients should lose weight
- children should grow normally
- prevention of long-term diabetic complications.

Healthy lifestyle

People with diabetes can help themselves considerably by attention to healthy eating, appropriate exercise levels and weight reduction, and cessation of smoking. These measures

Treatment aims

- Save life
- Alleviate symptoms
- Prevent long-term complications
- Reduce risk factors:
 - smoking
 - hypertension
 - obesity
 - hyperlipidaemia
- Educate patients and encourage self-management
- Achieve goals of St Vincent declaration (see page 82)

Risk reduction for complications in young Type 1 diabetic patients under intensive diabetic control: results from the DCCT

Targets for control of diabetes

	Very good*	Acceptable	Less than ideal
Body mass index (kg/m ²)	< 25	< 27	> 27
HbA _{1c} (%) (normal 4.0-6.0)	< 6.5	6.5-7.5	> 7.5 (> 8.0 poor)
Blood glucose in Type 2 diabetes [†] (mmol/l):			
Fasting	< 5.5	< 8.0	≥ 10.0
Postprandial	< 9.0	< 10.0	≥ 10.0

*This is the ideal and may be difficult, impossible, or unnecessary to achieve in certain patients (for example, elderly people)

Individual targets should be established for each patient

[†]The optimal range in Type 1 diabetes is about 4.0-9.0 mmol/l

are of great benefit, and may also substantially reduce the need for medication. Behaviour change strategies may be needed to help patients to implement them.

Healthy eating

Healthy eating is the cornerstone of diabetic treatment, and control of the diet should always be the first treatment offered to Type 2 diabetic patients before drugs are considered. Eliminating sugar (sucrose and glucose) lowers blood glucose concentrations in both Type 1 and Type 2 diabetic patients, and although recent dietary recommendations suggest that eating small amounts of sugar is of little consequence, this practice is not recommended. Artificial sweeteners can be used. Good dietary advice is essential to the proper care of diabetic patients; ill considered advice can be very damaging or else it is ignored. I recall one patient who kept to the same sample menu for many years before she reported it to be rather boring. The diet needs to be tailored to the patient's age and weight, type of work, race, and religion.

Recommendations for Type 2 diabetic patients

Diets for overweight Type 2 diabetic patients should aim to eliminate all forms of sugar and restrict the total energy intake. Many of the patients are overweight, and their main goal is to lose weight, although this aim is difficult to achieve. It is important to try to ensure that when patients reduce their intake they do not replace it by an increase of fatty foodstuffs, notably a high intake of cheese. The present emphasis is on reducing total calorie intake, with special emphasis on fat reduction and a proportionately more generous allowance of carbohydrate than in previous years. It has been suggested that as much as half the energy content of the diet may be derived from carbohydrate, while the fat intake is drastically reduced, although these diets in practice require rather difficult and radical changes in the types of food normally eaten. The use of polyunsaturated fats is desirable. These diets are of value and help to reduce blood glucose concentrations if enough fibre is taken. Bran, All Bran, wholemeal bread, and beans have a relatively high fibre content, and are therefore recommended, but foodstuffs with a very high fibre content, such as guar gum, are unpalatable.

For some elderly patients it is enough simply to eliminate all forms of sugar from the diet. Their blood glucose concentrations then fall and symptoms may resolve.

Prevalence of obesity in England

Simple dietary guidelines

- Never take any form of sugar
- Do not take too much fat
- There is no need to restrict most meat, fish, or vegetables
- Control your weight

There is no need to buy proprietary diabetic foodstuffs. Most forms of alcohol (other than sweet wines and liqueurs) are suitable for diabetics, with the usual restrictions for the overweight

A diabetic diet: elimination of sugar/glucose/sucrose

Do not eat or drink:

- Sugar or glucose in any form and do not use sugar in your cooking
- Jam, marmalade, honey, syrup, or lemon curd
- Sweets or chocolates
- Cakes and sweet biscuits
- Tinned fruit
- Lucozade, Ribena, Coca-Cola, Pepsi-Cola, lemonade, or other fizzy drinks

You may use artificial sweeteners, such as saccharin, Sweetex, Hermetas, Saxin, but NOT Sucron, and any sugar-free drinks including squashes and Slimline range

Fibre content of diet

The following will increase the fibre content of the diet:

<i>Bread</i>	Wholemeal or stoneground—wholemeal for preference If these are not available use HiBran or wheatmeal or granary loaves
<i>Biscuits and crispbreads</i>	Ryvita, Macvita, and similar varieties. Digestive, oatcakes, coconut, and bran biscuits, etc. Crackawheat
<i>Breakfast cereals</i>	Porridge, Weetabix, Weetaflakes, All Bran, Bran Buds, Shredded Wheat, Oat Krunchies, muesli, Alpen, and similar cereals
<i>Wholemeal flour or 100% rye flour</i>	Should be used with white flour for making bread, scones, cakes, biscuits, puddings, etc
<i>Fresh fruit and vegetables</i>	Should be included at least twice daily. The skin and peel of fruit and vegetables such as apples, pears, plums, tomatoes, and potatoes should be eaten
<i>Dried fruit and nuts</i>	Eat frequently
<i>Brown rice, wholemeal pasta</i>	
<i>Pulse vegetables</i>	Such as peas and all varieties of beans

ABC of Diabetes

Optimal control may not be needed and it is best to interfere as little as possible with the patient's usual way of life.

Diets for Type 1 diabetic patients

Greater finesse is required in managing the diets of Type 1 diabetic patients; if they eat too much, diabetic control deteriorates; if they eat too little they become hypoglycaemic. The important principles are that carbohydrate intake should be steady from day to day and that it should be taken at fairly regular times each day. If this discipline is not followed diabetic control becomes difficult, although new approaches to the management of Type 1 diabetes such as dose adjustment for normal eating (DAFNE) (see page 29) may permit flexibility in which calculation of carbohydrate intake is used to calculate the insulin dose, thus freeing the patient from a rigidly controlled dietary intake. Severe carbohydrate restriction is not necessarily required; indeed, if the diet is fairly generous patients are less likely to resort to a high fat intake, which may be harmful in the long term.

The actual requirement for carbohydrate varies considerably; it is unsatisfactory to recommend less than 100 g daily, and control may become more difficult if more than 250 g daily is allowed. The smaller amounts are more suitable for elderly, sedentary patients while the larger amounts are more appropriate for younger, very active people particularly athletes who may need considerably more. Although it has been observed that not all carbohydrate-containing foodstuffs are equally absorbed and that they do not have the same influence on blood glucose values, it is impracticable to make allowances for such variations other than recommending that sugar (sucrose) should be avoided except for the treatment of hypoglycaemia.

For social convenience it is customary to advise that most of carbohydrate should be taken at the main meals—breakfast, lunch, and dinner—even though these are not necessarily the times when, according to blood glucose profiles, most carbohydrate is needed; for example, less carbohydrate at breakfast and more at mid-morning and lunch often improves the profile. Snacks should be taken between meals—that is, at elevenses, during the afternoon, and at bedtime—to prevent hypoglycaemia. At least the morning and night snacks are essential and should never be missed.

For the convenience of some, and for those adopting the DAFNE method of controlling Type I diabetes and therefore needing to calculate the carbohydrate content of their meals, 10 g of carbohydrate is described as “one portion” so that a 170 g carbohydrate diet is described to patients as one of “17 portions”. Patients sometimes find it valuable to know the carbohydrate values of different foodstuffs.

Foods suitable during intercurrent illness

The presence of malaise, nausea, and anorexia during illness may deter patients from eating, yet food is needed to avoid hypoglycaemia following insulin administration, which should never be stopped (see page 37). Suitable foodstuffs for use at this time are shown in the box.

Weight control: the role of exercise

Weight control towards optimal levels yields considerable health benefits to all, notably in this context to those who have the combined disadvantages of being overweight and having Type 2 diabetes. Exercise has a central role in weight reduction and health improvement. The proven benefits include reduced insulin resistance (hence enhanced insulin sensitivity) leading to better glycaemic control which may even be independent of actual weight reduction. Risk factors for cardiovascular disease,

A sample meal plan for a Type 1 diabetic

	Carbohydrate portions	Recommended food and drink
Breakfast	1	Fruit
	1	Wholemeal cereal
	1	Milk
	1	Wholemeal bread Egg/grilled bacon Tea/coffee
Mid-morning	1	Fruit/plain biscuit Tea/coffee/diet drink
Lunch		Lean meat/fish/ egg/cheese
	2	Potatoes/bread/rice/ pasta
	2	Vegetable salad Fruit/sugar-free pudding
Mid-afternoon	1	Fruit/plain biscuit Tea/coffee/diet drink
Dinner		Lean meat/fish/eggs/ cheese
	2	Potatoes/bread/rice/ pasta
	2	Vegetable salad Fruit/sugar-free pudding
Bed-time	1	Bread/fruit/plain biscuit Tea/coffee/diet drink
Total 15		

Alcohol

- Alcohols containing simple sugar should not be drunk by people with diabetes, especially sweet wines and liqueurs
- Dry wines and spirits are mainly sugar-free and do not present special problems
- Beers and lagers have a relatively high sugar and calorie content and their amount needs to be both limited and counted as part of the controlled carbohydrate intake
- Sugar-free beers are high in calorie and alcohol content and therefore have some limitations to their usefulness, whereas “low alcohol” beers are high in carbohydrate
- Profound hypoglycaemia may be provoked in those who take large amounts of alcohol, and omit their normal diet, especially in those taking sulphonylureas; this can be dangerous
- Normal social drinking is usually free from this hazard but care is still needed
- Reduction in alcohol intake is sometimes an important part of helping weight loss

Foods suitable during intercurrent illness

For patients who are feeling ill but need to maintain their carbohydrate intake, the following are useful (each item contains 10 g of carbohydrate):

- $\frac{1}{3}$ pint (0.15 l) tinned soup
- 1 glass fruit juice
- 1 scoop of ice cream
- 1 glass of milk

The following each contain 20 g of carbohydrate:

- 2 teaspoons Horlicks and milk
- 2 digestive biscuits
- 1 Weetabix and a glass of milk
- 1 ordinary fruit yoghurt
- “Build-up” made with $\frac{1}{2}$ a pint (0.25 l) of milk and $\frac{1}{2}$ a sachet

which include high blood pressure, also diminish. Indeed, the prevention of Type 2 diabetes itself in those at high risk has been amply demonstrated (see page 6). People with osteoarthritis, chronic heart failure, and chronic lung disease all benefit from appropriate exercise programmes and weight reduction, and there are advantages to those recovering from myocardial infarction. A healthier life is also gained by the very old and by the overweight child. For those with Type 2 diabetes it is recommended that exercise of moderate intensity should be undertaken for about 30 minutes each day. This can include walking, as well as both aerobic and resistance exercise.

The effects of exercise in Type 1 diabetes present the hazard of hypoglycaemia and it is not a specific contributor to improvement of diabetes control. Advice is required on the use of insulin and the need for additional food (in particular carbohydrate) before, during, and after periods of exercise especially (since hypoglycaemia may develop after cessation of exercise) for those engaged in major sports and athletics. The challenge for sportsmen can be extreme but nevertheless people with Type 1 diabetes are known for huge achievements. Great credit went to Sir Steven Redgrave for his ingenious food and insulin regimen which enabled him to win a rowing gold medal in the 2000 Olympic Games.

Smoking

The addiction of smoking is now well established. Its harmful effects are numerous, and include a substantial increase in cardiovascular and peripheral vascular disease as well as the best known consequences of lung cancer and chronic obstructive pulmonary disease. In diabetes, higher rates of both nephropathy and retinopathy have been well documented.

Nicotine replacement therapy using proprietary sublingual preparations, chewing gum, self adhesive patches, or alternatively amfebutamone tablets can help, especially if used in conjunction with the counselling which is provided by smoking clinics. Detailed use of these medications is described in the *British National Formulary (BNF)*.

How 10 fat men and 10 lean men fare on the journey through life (Joslin, 1941)

The histogram of risk reduction for complication in young Type 1 diabetic patients under intensive diabetic control is adapted from Watkins PJ, et al. *Diabetes and its management*, 5th ed. Oxford: Blackwell Science, 1996. The histogram showing prevalence of obesity in England is adapted from Nutrition and Obesity Task Force. *Obesity: reversing the increasing problems of obesity in England*. London: Department of Health, 1995. The illustration of how 10 fat men and lean men fare through life is from Joslin EP. *Diabetic manual*, 1941, Lea and Febiger.

The story of Mrs B-J continued: the diet

I was put in a Women's ward and I was given my first dose of insulin. The bed was in the centre of the ward and I soon became the ladies' pet. They threw sweets on to my bed, which I politely refused, no doubt recalling how I had sworn such poison.

I stayed in hospital for three weeks, and each day I was given lessons in diet. I had a red exercise book in which I set out different diets, stating the weight and value of each carbohydrate item. I had a chart with various foods listed. Those printed in black were called "black lines" and had to be limited by weight to equal the "black lines" allowed at each meal. The protein foods were "red lines" and could be taken ad lib.

4 Treatment of Type 2 diabetes mellitus

Type 2 diabetes is a complex disorder generally affecting older people who are often overweight and likely to suffer other medical problems as well. Its management presents considerable challenges to medical and nursing staff, whose care must be directed at the sum of the problems of the individual patient. Management now requires not only attention to blood glucose control, but also to the treatment of hypertension and hyperlipidaemia, as well as introducing the necessary measures for reducing cardiovascular risk factors.

Optimal treatment of Type 2 diabetic patients, especially those who are symptom-free, overweight and have in addition several cardiovascular risk factors, exercises our clinical skills and judgments to the limit. There needs to be a sense of reality within the consultation, bearing in mind the potential dangers of unacceptable polypharmacy accompanied by low adherence to prescribed treatment as well as a sense of guilt experienced by those who fail to achieve ideal targets set by physicians. Awareness of the priorities and intentions of individual patients needs to be given consideration, and patients need to agree on the objectives for treatment. Recommendations for treatment must be clinically relevant for the individual patient, who should be involved in choosing which of the many therapeutic options to select after explanation of advantages and risks. The difficulties of controlling Type 2 diabetes tend to increase with the passage of time as the disease progresses. Management is often difficult and needs to be pragmatic: the late Professor John Malins when asked how this should be done used to quote the advice given by Chekhov to his actors—that it should be “done as well as possible”.

Approaches to management

There are three distinctive aspects in management, each of which requires entirely different approaches

- To alleviate symptoms and improve quality of life, achieved by reducing hyperglycaemia and weight
- To maintain health by reduction of risk factors (especially hypertension, hyperlipidaemia, and smoking) and by screening programmes to diminish the development of diabetic complications
- Management of diabetic complications
- Management of other medical problems

Natural history of Type 2 diabetes

Glycaemic control

Natural history

Type 2 diabetes is an insidiously progressive disease. Gradually decreasing insulin secretion leads to a slow increase in hyperglycaemia and a rise of HbA_{1c} values, often despite vigorous clinical attempts to maintain control. Thus, while control during the early years is often straightforward, it becomes increasingly difficult with the passage of time, so that the appropriate need for tablets and insulin requires continuing consideration.

Non-obese patients

Such patients require different consideration from the obese. They are much more likely to require insulin early in the course of treatment, and indeed apparent presentation as Type 2 diabetes may be deceptive when they progress to Type 1 diabetes as cases of latent autoimmune diabetes of adulthood (LADA). Sulphonylurea treatment is used initially while metformin treatment is inappropriate for these patients. Some of them cling desperately to minute diets with the large doses of sulphonylureas as weight and health decline: these patients regain their health rapidly when insulin treatment is started and indeed it should not be delayed.

Obese patients

These patients require a different approach. The need for healthy eating and exercise in an attempt to reduce weight are paramount yet difficult to achieve. When these measures fail,

Cross sectional and 10-year cohort data for HbA_{1c} in patients receiving intensive or conventional treatment, from UKPDS (Type 2 diabetes; see page 42)

metformin is the first choice, and will to a small extent diminish the weight gain which comes almost inevitably with improved glycaemic control. A sulphonylurea or meglitinide analogue is added when metformin alone fails. The use of thiazolidinediones is described below.

Patients who remain unwell and often symptomatic (thirst and nocturia especially) and who continue to lose weight should be switched to insulin without delay.

Achieving glycaemic control and reducing risk factors

- Healthy lifestyle advice—healthy eating plan, exercise, and weight reduction plan.
- Oral hypoglycaemic agents should be given only when dietary treatment alone has failed after a proper trial period, usually lasting at least three months. They should not normally be given as the initial treatment (this is a common error).
 - **Sulphonylureas** stimulate insulin secretion
 - **Meglitidine analogues** stimulate insulin secretion
 - **Biguanides (metformin)** reduce hepatic gluconeogenesis and enhance glucose uptake
 - **Thiazolidinediones** enhance insulin sensitivity
 - **α glucosidase inhibitors (acarbose)** reduce absorption of complex carbohydrates.
- Pharmacological agents to assist weight reduction:
 - **Orlistat** inhibits pancreatic lipase and reduces fat absorption
 - **Sibutramine** is a monoamine reuptake inhibitor, causing reduced appetite
- Antihypertensive and lipid lowering agents (see chapter 17).

Sulphonylureas

Seven sulphonylureas are available. They are remarkably safe and free from side effects, although rare toxic effects have been reported, including rashes and jaundice. Only one sulphonylurea should be used at a time since there is nothing to be gained from any combination of these drugs and there is no evidence that any one drug is likely to be more successful than another.

Selecting a sulphonylurea is largely a matter of personal choice, though it is now usual to use one of the shorter acting, metabolised drugs such as gliclazide or glipizide, which are suitable for all ages and for those with renal impairment as well. Glibenclamide, which has the advantage of once-daily use, is still suitable for younger patients, but is contraindicated in the elderly. Glimepiride is also given once daily and may cause less hypoglycaemia. Excessive doses can cause hazardous (even fatal) hypoglycaemia, and it is thus usual to start treatment with the smallest useful dose. If hypoglycaemia does occur in a patient taking a sulphonylurea, the drug should be stopped or at the very least the dose substantially reduced.

Chlorpropamide is now obsolete. It has a very long half life, thus increasing the risk of hypoglycaemia, and many patients experience an unpleasant facial flush on drinking very small amounts of alcohol.

Meglitidine analogues

The mode of action of this group of drugs is similar to that of sulphonylureas though acting at a different site. Their advantages are the rapid onset and short half life, efficacy when taken just 15 minutes before meals, and a duration of effect of no more than three hours. They are omitted if no meal is taken. There may be some benefit in reducing postprandial glycaemia and in theory at least there might be less hypoglycaemia.

Daily dose ranges for oral hypoglycaemic agents

Oral hypoglycaemic agents	Dose range (mg)
<i>Sulphonylureas</i>	
Glibenclamide (× 1/day)	2.5-15
Gliclazide	40-320
Glimepiride (× 1/day)	1-4
Glipizide	2.5-20
Gliquidone	15-180
Tolbutamide	500-2000
<i>Meglitidine analogues*</i>	
Nateglinide	180-540
Repaglinide	1.5-16
<i>Biguanide</i>	
Metformin	1000-2000
<i>Thiazolidinediones</i>	
Pioglitazone (× 1/day)	15-30
Rosiglitazone	4-8
<i>α glucosidase inhibitors</i>	
Acarbose	50-600

*Meglitidine analogues are taken three times daily; before meals. Most of the other drugs can be started as single daily doses, but as requirements increase are more effective in divided doses

The hypoglycaemic effect of early sulphonamides was observed in the 1940s, and in the next decade first tolbutamide (1956) and then chlorpropamide (1957) were introduced into clinical practice. They act chiefly by stimulating insulin release from the B-cells of pancreatic islets

Increased patient compliance is associated with once-daily oral hypoglycaemic agents

ABC of Diabetes

Nateglinide is one of a new class of oral hypoglycaemic agents, namely an amino acid derivative. Insulin release after meals is both faster and of shorter duration than that with either sulphonylureas or repaglinide, giving less postprandial hyper-insulinaemia and less reactive hypoglycaemia. It is licensed only for use in combination with metformin, but not for monotherapy or substitution for conventional sulphonylureas.

Biguanides: metformin

Biguanides act chiefly by reducing hepatic glucose production. They also enhance peripheral glucose uptake, and to some extent reduce carbohydrate absorption. Metformin is the only biguanide available in the United Kingdom. It is the drug of choice in the treatment of overweight Type 2 diabetic patients when diet alone has failed. UKPDS found some evidence for a reduction in mortality after the use of metformin.

Lactic acidosis is a serious consequence of the inappropriate use of metformin. It is contraindicated in any patient with renal failure, and serum creatinine should be monitored. A creatinine concentration above 150 $\mu\text{mol/l}$ indicates that the drug should be stopped. Metformin should not be used in any seriously ill or shocked patient, nor in those with heart failure, serious liver disease or a very high alcohol intake. It is not appropriate for the treatment of thin diabetic patients nor for use in frail elderly patients.

α Glucosidase inhibitors

These agents block the enzyme responsible for the breakdown of complex carbohydrates in the gut and can effectively reduce the increase in blood glucose after a meal. Acarbose acts in this way and can be used alone or in combination with other oral hypoglycaemic agents. Its hypoglycaemic effect is relatively small and the severe flatulence which develops (to some extent avoidable by starting with small amounts) deters many patients from using it.

Thiazolidinediones

This newly introduced group of hypoglycaemic agents act by reducing insulin resistance and by activation of the peroxisome proliferator activated receptor γ expressed predominantly in adipose tissue.

These drugs are licensed for use with metformin if this alone has failed to control the diabetes, or with a sulphonylurea if metformin is either not tolerated or contraindicated (for example, in renal failure). In the European Union they are not licensed for use alone or in combination with insulin, and should not be given to patients with a history of heart failure, or during pregnancy. They may cause oedema, a minor reduction of haemoglobin, and a small increase of HDL cholesterol. There are very rare reports of liver dysfunction, and liver function should be monitored before, and every two months after, starting treatment, for the following 12 months.

Drugs for management of obesity

There is a limited place for the use of medication in assisting with weight reduction in the obese diabetic patient. The use of such drugs is restricted to those whose BMI is 28 or more and who are between the ages of 18 and 65 years; they should only be prescribed for individuals who have lost at least 2.5 kg body weight by diet and exercise during the preceding month. Patients should continue to be supported by their advisers and counsellors throughout treatment. Orlistat inhibits fat absorption by inhibition of pancreatic lipase. Weight reduction

Use of metformin

- Drug of first choice for overweight Type 2 diabetes
- May reduce mortality (UKPDS)
- Never use when creatinine is $>150 \mu\text{mol/l}$
- Danger of lactic acidosis if given to:
 - renal failure patients
 - patients with liver disease
 - patients with a high alcohol intake
- Not to be used for thin patients or those in heart failure
- During intravenous contrast procedures:
 - stop metformin for 48 hours beforehand and do not restart until 48 hours after procedure completed

Side effects of metformin

- Nausea
- Diarrhoea
- Metallic taste

These effects can be minimised by starting with a low dose and taking tablets during meals. The effects generally resolve with time

Thiazolidinediones should be used in patients expected to be insulin resistant, namely those who are overweight and likely to be hyperlipidaemic and hypertensive as well

Useful drug combinations

- Sulphonylurea (or metaglitinide analogue) with metformin
- Sulphonylurea (or metaglitinide analogue) with thiazolidinedione (if metformin is contraindicated or not tolerated)
- Metformin with thiazolidinedione
- Nateglinide with metformin
- Metformin with insulin (for overweight patients)
- Acarbose can be used in association with any of the above

indicating a successful response should be greater than 5% after 12 weeks, in which event prescription may be continued for one year to a limit of two years, otherwise treatment should cease. Unpleasant oily leakage and steatorrhoea can occur.

Sibutramine also acts centrally as a serotonin and noradrenaline reuptake inhibitor and enhances the satiety response. It is used as an adjunct to weight maintenance after weight loss. Full details of its use and contraindications are to be found in the *BNF*.

Guar gum

Guar gum preparations, taken in adequate quantity three times daily before meals, can reduce postprandial blood glucose concentrations. Flatulence is common and often unacceptable. Guarem is the only available preparation. It has a very limited role.

Hypoglycaemia

Only sulphonylureas and meglitinide analogues cause hypoglycaemia, but it should not be allowed to occur at all—it almost invariably indicates excessive dosage. Those most at risk are elderly people who may make dosage errors or fail to take their normal meals. Hypoglycaemia in this situation can be fatal. The shorter acting sulphonylureas cause the least hypoglycaemia and are therefore best for older people (see below). Management of hypoglycaemia is described in chapter 8. β Blockers may not only exacerbate hypoglycaemia, but also occasionally inhibit the early warning symptoms.

Indications for insulin in Type 2 diabetes

Approximately 6% of non-obese and 2% of obese Type 2 diabetic patients need to start insulin each year. Predicting the need for insulin is difficult: those of lean body mass, especially in the presence of islet cell antibodies, are at greatest risk.

Whether to give insulin to Type 2 diabetic patients is one of the most important yet difficult decisions to be made in treating these patients. Failure to give insulin to some patients results in protracted and needless malaise if not actual danger. On the other hand, giving insulin inappropriately can cause needless problems, notably from hypoglycaemia and weight gain.

Indications for giving insulin to Type 2 diabetic patients who are inadequately controlled despite adherence to their recommended diet and oral hypoglycaemic agents are as follows:

- Continuing weight loss (even if this is insidious), and persistent symptoms, or both. Insulin treatment in these patients almost always results in a substantial improvement in health.
- A non-obese patient without symptoms whose weight is stable and who is conscientious with existing medication. Diabetic control will usually improve, and about half of the patients will enjoy an improvement in well-being.
- An obese patient without symptoms whose weight is stable presents an even more difficult problem. The correct management is to ensure that they are taking their medication, together with intensification of diet, but sometimes insulin may be needed simply to improve control of diabetes in order to reduce long-term complications during the following decade or more. A reduction of HbA_{1c} of approximately 2% together with weight gain of around 5-7 kg can be expected. Unfortunately improvement in glycaemic control is not always achieved. Patient choice is important here, and some prefer not to take insulin after all explanations have been presented. Reluctant patients can be

Drug interactions

- Alcohol can cause serious hypoglycaemia when used with sulphonylureas and lactic acidosis in those taking metformin
- Aspirin, sulphonamides, and monoamine oxidase inhibitors may enhance the hypoglycaemic action of sulphonylureas, but in practice problems are rarely seen
- Selective serotonin reuptake inhibitors used in the treatment of depression may provoke hypoglycaemia
- Serious hyperglycaemia is provoked by corticosteroids, dopexamine (inotropic support agent) and intravenous β agonists (salbutamol, terbutaline, ritrodrine)
- Thiazide diuretics (other than minimum dosage, for example, bendrofluazide 2.5 mg) can exacerbate hyperglycaemia
- The immunosuppressive drug ciclosporin can also exacerbate hyperglycaemia
- Protease inhibitors used in the treatment of patients with HIV can cause a syndrome of lipodystrophy, hyperlipidaemia, and insulin resistance leading to severe exacerbation of hyperglycaemia or even causing diabetes
- Clozapine may provoke hyperglycaemia
- β blockers may exacerbate hyperglycaemia or hypoglycaemia depending on dose, concomitant medication, nutritional state, severity of illness, and the patient's age
- Other less common drug interactions are described in the *BNF*

Indications for insulin in Type 2 diabetes

- Insulin is usually contraindicated in overweight patients whose weight is increasing—giving insulin will make this worse
- Patients who continue to lose weight usually need insulin
- Achievement of tight control in order to prevent complications is obviously more appropriate in younger than in older patients, so the patient's age needs to be considered in deciding whether or not to start giving insulin
- Many older patients, however, benefit greatly from insulin treatment, with an improvement of well-being, and insulin should not be withheld on grounds of age alone

Indications for insulin in Type 2 diabetes mellitus

ABC of Diabetes

given a three-month trial of insulin and then make their decision, which experience shows to be usually affirmative.

Those with a short life expectancy do not necessarily benefit, and those with other medical disorders will require individual consideration.

- Insulin is often required in patients with intercurrent illness. Many disorders, notably infections, increase insulin resistance, leading to the temporary need for insulin. Withdrawal of insulin after recovering from the illness is important provided adequate control is achieved and maintained.

Corticosteroids always exacerbate hyperglycaemia and often precipitate the need for insulin. This should not deter doctors from prescribing them when they are needed.

Combination treatment with insulin and metformin

Metformin can be given together with insulin to overweight Type 2 diabetic patients: this can to a small extent limit the inevitable weight gain following introduction of insulin. A combination of sulphonylureas with insulin gives little benefit and has the added disadvantage that patients must continue with both modes of treatment.

Insulin regimens suitable for Type 2 diabetic patients are described in chapter 5.

The figure showing the cross sectional and 10-year cohort data for HbA_{1c} in patients receiving intensive or conventional treatment is adapted from UKPDS *Lancet* 1998;352:837-53 with permission from Elsevier Science. The histogram showing increased patient compliance is adapted from Paes AH, Bakker AS, Soe Agnie CJ. Impact of dosage frequency upon patient compliance. *Diabetes Care* 1997;20:1512-17.

5 Insulin treatment

I was like a dried tree, but you have given me new life.
 An Ethiopian villager, after starting insulin.

The astonishing power of insulin to restore health and well-being to rapidly deteriorating newly diagnosed Type 1 diabetic patients is as remarkable now as it was in 1922. After Banting gave insulin to Elizabeth Hughes in that year, she wrote to her mother that “it is simply too wonderful for words this stuff.” Insulin to this day always has this effect; the challenge now is to optimise control in order to maintain health throughout life.

Insulin is also needed to enhance well-being and control in many Type 2 diabetic patients when the natural progression of their disease has led to loss of optimal control. The potential to reduce the development of long-term diabetic complications as demonstrated by the UKPDS (see page 42) has led to a recent explosion in conversions from tablets to insulin. The difficult decisions which surround the need for insulin in this situation, together with benefits, uses and misuses of insulin have been described in the previous chapter.

The use of insulin must be tailored to meet individual requirements. The aim is to achieve the best possible control in the circumstances, avoiding at all costs the disabling hypoglycaemia which can occur if control is excessively tight. In some elderly patients and those who lack motivation, it is therefore wise to aim only at alleviating symptoms and not to attempt very strict control.

An Ethiopian patient carrying his diabetes equipment to the clinic

Types of insulin

Soluble insulins

These were first introduced in 1922. They have a rapid onset of action (within 15-30 minutes) and a relatively short overall duration of action of six to eight hours. They play an important part in both daily maintenance of diabetic patients by subcutaneous injection, and also in managing emergencies, when they can be given intravenously or intramuscularly. Other insulin preparations are not suitable for intravenous or intramuscular use.

New recombinant insulin analogues

These have a very rapid onset and very short action, and have been developed by altering the structure and thus the property of the insulin. The preparations available in the United Kingdom

Elizabeth Evans Hughes (1907-1981). Banting’s prize patient, who found insulin “unspeakably wonderful.” The photograph is from Banting’s scrapbook

Insulins available in the United Kingdom

Insulins are available as human, pork or beef preparations, or as insulin analogues.

Very short acting insulin analogues

- Insulin Aspart (Novo Rapid)
- Insulin Lispro (Humalog)

Short acting neutral soluble insulins

- Human Actrapid
- Human Velosulin
- Humulin S
- Insuman Rapid
- Pork Actrapid
- Pork Neutral
- Beef Neutral

Medium acting isophane insulins

- Human Insulatard
- Humulin I
- Insuman Basal
- Pork Insulatard
- Pork Isophane
- Beef Isophane

Medium acting insulin zinc suspensions

- Human Monotard
- Humulin Lente
- Lentard MC (beef or pork)
- Beef Lente

Long acting insulin zinc suspensions

- Human Ultratard
- Humulin Zinc

Long acting insulin analogue

- Insulin Glargine

ABC of Diabetes

at present are Insulin Lispro (Humalog) and Insulin Aspart (Novo Rapid). They have some advantages because they may be given immediately before meals (or even immediately after meals if necessary). By virtue of their very short action, there is less hypoglycaemia before the next meal, and when they are used before the main evening meal nocturnal hypoglycaemia is effectively reduced.

There is a risk of postprandial hypoglycaemia if they are used before a meal with a very high fat content because of the delayed gastric emptying. Duration of action is short and does not normally exceed three hours, and their use is therefore inappropriate if the gap between meals exceeds about four hours. Preprandial blood glucose levels are slightly higher than with conventional soluble insulins.

They are also ideal for use in continuous subcutaneous insulin infusion pumps (CSII).

Protamine insulins

These are medium duration insulins introduced in Denmark during the 1930s. Isophane insulin is the most frequently used insulin in this group.

Insulin zinc suspensions

These were first introduced during the 1950s; there are several preparations with widely ranging durations of action. There are limited indications for using insulins with a very long duration of action (ultratarad).

Insulin glargine

This is a new prolonged action, soluble insulin analogue (clear solution) forming a microprecipitate after subcutaneous injection. Its onset of action is after about 90 minutes, it has a prolonged plateau rather than a peak, and lasts 24 hours or more. Thus it mimics more closely the basal insulin secretion of healthy people. When taken at bedtime it reduces the incidence of nocturnal hypoglycaemia, and also reduces the prebreakfast hyperglycaemia. It does not appear to reduce symptomatic or severe hypoglycaemia during the day, and there is no significant beneficial effect on overall diabetic control. More extensive clinical experience in using this insulin is still needed.

Insulin mixtures

Some preparations of insulin are presented as proprietary mixtures in either vials or pen cartridges, eliminating the need for patients to mix insulins in the syringe. The most popular mixture contains 30% soluble insulin and 70% isophane, whereas the whole range also includes ratios 10%/90%, 20%/80%, 40%/60%, and 50%/50%. These insulin mixtures represent a considerable advantage for many patients, especially those who find it difficult to mix insulins in the syringe or those whose visual acuity is impaired. Details of the types of insulin available in the United Kingdom are shown in the box.

Selection of insulin

The choice of insulin preparation is based on the duration of action. Although insulins can be broadly classified as having very short, short, medium or long duration of action, their effect varies considerably from one patient to another and can be discovered in the individual patient only by trial and error. There are several preparations of medium acting insulins, but those most often used are either one of the isophane preparations or less frequently Human Monotard zinc insulin preparation (see box on page 19).

Most patients (85%) now use insulin of human sequence, a few prefer porcine preparations, while use of some insulin

Some insulins

Insulin mixtures

These are all mixtures of a short acting soluble insulin (or very short acting insulin analogue) with a medium acting isophane insulin (or insulin analogue). The number after the insulin name indicates the percentage of the short acting insulin, for example, “30” or “M3” indicates 30% soluble insulin mixed with 70% isophane insulin.

- Human Mixtard 10 (pen only)
- Human Mixtard 20 (pen only)
- Humulin M2 (pen only)
- Human Mixtard 30
- Humulin M3
- Human Mixtard 40 (pen only)
- Human Mixtard 50
- Humulin M5
- Insuman Comb 50
- Insuman Comb 15
- Insuman Comb 25
- Pork Mixtard 30
- Pork 30/70 Mix

Insulin analogue mixtures

- Humalog Mix 25 (pen only)
- Humalog Mix 50 (pen only)
- NovoMix 30 (pen only)

Insulins are available in vials for use with syringe and needle; in cartridges for use in insulin pens; or in preloaded pens. The insulins listed above are available in one or more of these preparations.

analogues with specific indications is increasing (see also chapters 6 and 8). Some preparations of bovine insulins are still available for the few patients who prefer them.

Insulin regimens

Starting insulin in patients with Type 1 diabetes

Some patients start treatment with twice-daily insulin injections using either a mixture containing premixed short and medium acting insulins twice daily or medium acting insulin alone; 8 units twice daily, 15 to 30 minutes before meals is a suitable initial dose for most patients; others will start with a three or four times daily regimen. Only those who are seriously weakened or ill need hospital admission and treatment either with intravenous insulin and fluids or multiple insulin injections. Many patients who present with acute diabetes enter partial remission soon after diagnosis, known as the “honeymoon” phase, when a small dose of almost any insulin is enough to maintain control. The practice of withdrawing insulin at this stage is not encouraged because after a few months the need for insulin is almost inevitable.

Maintenance regimens

Most Type 1 diabetic patients who want to achieve very good control will need at least thrice-daily injections. Multiple injections (three or four times daily) may improve control, reduce the risk of serious hypoglycaemia, and to some extent increase flexibility (for example, the timing of the midday meal) and are often needed in pregnancy. Suitable insulin regimens are as follows:

Twice daily: short and medium acting insulins or occasionally medium acting insulin alone are taken twice daily before breakfast and the main evening meal.

Three times daily: the mixture of neutral soluble and medium acting insulins is taken before breakfast; neutral soluble insulin alone before the evening meal; medium acting insulin alone before bedtime. This insulin regimen has the advantage that the noon injection is not required and is thus favoured by many. Fasting blood glucose is also improved using this regimen.

Four times daily: neutral soluble insulin alone or a short acting insulin analogue is taken before each of the three main meals, and medium acting insulin at bedtime. (Occasionally the long acting Human Ultratard insulin is used, though this has not proved to be as advantageous as it should be in theory.) Sometimes there is a further advantage in adding a medium acting insulin to the prebreakfast soluble insulin.

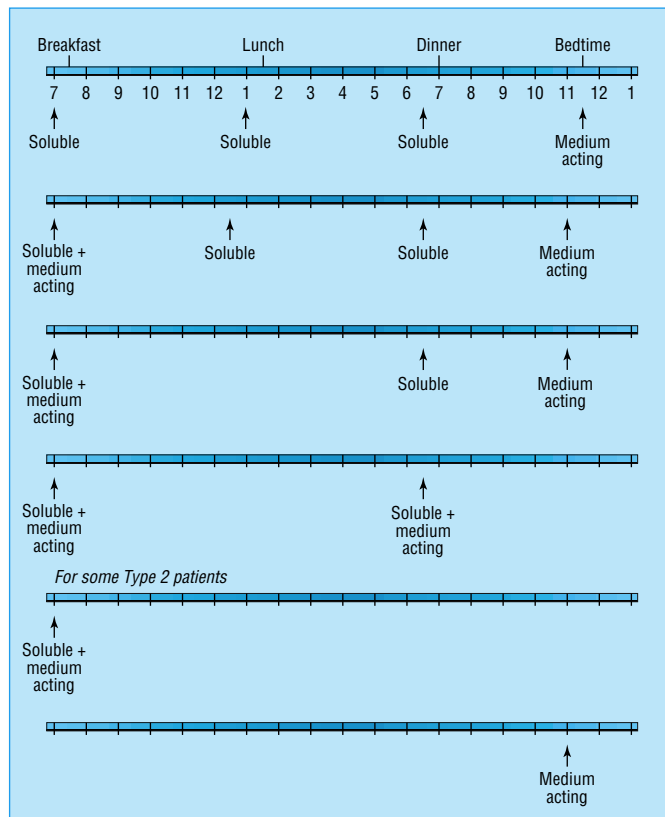

For some Type 2 diabetic patients, when control on oral medication fails, a single daily injection may suffice; the use of medium acting insulin at bedtime alone has gained popularity and by lowering fasting blood glucose may achieve an acceptable profile throughout the day. This regimen can be usefully combined with concurrent use of metformin. If this fails, insulin needs to be delivered on a twice daily basis or more often, as described above. Premixed insulin mixtures are valuable for many Type 2 diabetic patients.

When changing from one insulin regimen to another some trial and error by regular blood glucose monitoring is always needed. In converting a patient to the four times daily regimen the normal dose should be divided by four and a slight adjustment made to give more than one-quarter before breakfast and less than one-quarter before bedtime.

Administration of insulin

Insulin “pens” and syringes

The use of insulin “pen” devices which deliver metered doses of insulin from an insulin cartridge is now favoured by most

Insulin regimens: short acting insulin analogues can replace conventional soluble insulins

Examples of insulin pens

ABC of Diabetes

patients. They are portable and simplify the procedure of measuring the insulin dose. The required dose can be dialled, and some pens feature audible and palpable dose graduations which are of value to those with impaired vision. Some versions of the pen are preloaded and disposable.

Plastic insulin syringes with needle attached are still preferred by some patients, and they are still required by those who prefer to mix individual insulins in the syringe. They can be reused several times and between use can be stored in a refrigerator.

Insulin pumps

Sophisticated insulin pumps infuse insulin subcutaneously over 24 hours, with facilities for preprandial boosts. They are worn on a belt and attached to a subcutaneous cannula. They are expensive and not at present available on the NHS although they should be. They are of value for selected patients with Type 1 diabetes. For more detail regarding their use, see page 29.

Inhaled insulin

While nasal administration of insulin proved unsuccessful, the use of inhaled insulin looks promising. Absorption though inefficient is adequate to reduce hyperglycaemia, and this route of administration may prove to be of value, notably in Type 2 diabetic patients. The practicality of this technique is still under investigation.

Pancreas transplantation

For those needing a kidney transplantation, pancreas transplantation can be performed simultaneously, eliminating the need for insulin injections and rendering glucose tolerance normal or very nearly normal. Five years after transplantation, 60% of patients remain well without needing insulin injections (see page 70).

Islet cell transplantation

The feasibility of islet transplantation has been demonstrated, and with novel immunosuppression techniques islet survival has improved considerably, eliminating the need for injected insulin over increasing periods of time up to three years. Intensive research of this technique is in progress, and at present it is only available for those participating in carefully organised research trials now conducted in several centres including some in the United Kingdom.

Insulin injection sites

Insulin for routine treatment is given subcutaneously by intermittent injections or by continuous infusion. Insulin can be injected subcutaneously almost anywhere if there is enough flesh. The best site is the front of the thigh. The lower abdominal wall, buttocks, and upper arms may also be used. Patients who want to wear sleeveless clothes should normally avoid using the arms in case unsightly marks or fat hypertrophy should appear; some may then prefer to confine injections to the lower abdomen.

It is important to vary the injection sites from day to day, using for example, each thigh alternately over as wide an area as possible. Absorption of insulin varies from one site to another, being most rapid from the abdominal site, and less rapid from the arms and least from the legs. If there are any difficulties with "control" it is advisable to use one area consistently—for example, the thigh.

In diabetic emergencies soluble insulin is given intravenously, or occasionally intramuscularly (see chapter 9).

Insulin pump

Effect of continuous subcutaneous insulin infusion on plasma glucose

Insulin injection sites

Injection of insulin

Drawing up insulin from the vials

- 1 Clean the top of the insulin bottle with industrial methylated spirit.
- 2 Draw air into the syringe to the number of units of insulin required and inject this into the insulin bottle.
- 3 Draw the required dose of insulin into the syringe, and before withdrawing the needle from the insulin bottle, expel the air bubble if one has formed.

If clear and cloudy insulins are to be mixed:

- 1 Inject the correct number of units of air first into the cloudy insulin bottle.
- 2 Withdraw the needle from the cloudy bottle.
- 3 Inject the air into the clear bottle, and withdraw the insulin into the syringe.
- 4 Finally, insert the needle into the cloudy bottle and withdraw the insulin.

Injecting insulin

- 1 The skin needs to be clean, but application of spirit, which hardens the skin, is not necessary.
- 2 Stretching the skin at the injection site is the best way to obtain a painless injection; in thin people it may be necessary to pinch the skin between thumb and forefinger of the hand.
- 3 The needle should be inserted briskly at 90 degrees to the skin, to its whole length.
- 4 Inject the insulin by depressing the plunger.
- 5 Withdraw the needle briskly.

Problems associated with insulin injections

Many patients develop some blurring of vision soon after starting insulin, which makes reading difficult. This is due to a change of lens refraction, and it corrects itself within two to three weeks. Patients should be advised that this may occur, both to avoid extreme anxiety which they may experience, and to stop the needless purchase of new glasses. Transient oedema of the feet is not uncommon during the first few weeks of insulin treatment.

ABC of Diabetes

Fatty lumps at injection sites are common, and occasionally so large as to be unsightly. Their cause is not known but they sometimes develop if injections are repeatedly given over a very limited area of skin. For this reason it is best to vary the site from day to day. They are rarely troublesome, but once present they tend to persist; the occasional very large fatty tumour may even require surgical removal. Furthermore if insulin is repeatedly injected into a fatty lump, the rate of absorption may be delayed and this may have some adverse effect on blood glucose control. Fat atrophy at injection sites is now very rare.

Red itchy marks at injection sites after starting insulin are also rare, and if they do occur usually disappear spontaneously. If they are very troublesome, adding hydrocortisone to the insulin bottle so that each dose contains about 1 mg eliminates the problem. Insulin allergy causing urticaria still occurs from time to time though it is certainly a very infrequent event: investigation by skin testing and desensitisation may be needed. Abscesses at injection sites are also remarkably rare.

The illustration of Elizabeth Evans Hughes is from Bliss M. *The discovery of insulin*. Edinburgh: Paul Harris, 1983. The photographs of insulin pens and insulin pump are published with permission from Eli Lilly, Novo Nordisk, and Medtronic MiniMed Ltd.

Fatty lumps at injection sites

The story of Mrs B-J continued: starting insulin

I was put in a Women's ward where I was given my first dose of insulin. I can remember vividly my parents' first visit and my mother's anxious face as she walked down the ward, with one enormous white chrysanthemum in her hand. She had expected to see me prone and white and half dead, not sitting up and a picture of health.

I had a lesson on how insulin burnt up the sugar and produced energy, so that I could return to my former activities, and before long I was doing my own injections. I stayed in hospital for three weeks. The Sunday before I was discharged, my parents were asked to come to the diabetic kitchen to witness me doing my insulin and explaining what I was eating and how it had to be calculated. My mother did not see the injection, having passed out, and she told Sister Wheeler that she would never understand the diet. Sister replied "Don't worry about it. She knows, so give her what she tells you". Such confidence was well founded, as my mother never got the hang of it, and I used to write out the amount of potato etc. before I went to school, and my mother would weigh it up before serving it.

They bought all the necessary equipment from King's when I was discharged, including a very solid metal syringe case which I used constantly until it became redundant with the advent of U100 insulin, and also a copy of RD Lawrence's book "A Diabetic ABC". I also had a marvellous pair of German-made scales which would weigh up to 2lbs."

6 Blood glucose monitoring: optimising diabetic control

There are two important reasons for optimising diabetes control: the first is to eliminate symptoms, and the second is the longer-term aim of aborting the development of diabetic complications. Before embarking on complex programmes, it is essential to have a clear view of the requirements of each individual patient. The malaise associated with poorly controlled diabetes almost always responds to better treatment with considerable improvement in well-being. Occasionally, those whose control has been persistently poor for very long periods may for a time feel less well when blood glucose levels are reduced and consequently are at first reluctant to make the effort to improve control.

The key to achieving optimal diabetes control is regular blood glucose measurement accompanied by a clear understanding of the diurnal profiles so obtained. The optimal insulin regimen can then be devised

Blood glucose measurement

Equipment

- A spring-loaded finger pricking device.
- A blood glucose meter and test strips.
- For some, a blood ketone meter combined with a blood glucose meter and test strips.

Note: The MiniMed Continuous Glucose Monitoring System measures interstitial glucose levels every 10 seconds using a sensor inserted under the skin of the abdominal wall; and Glucowatch worn on the wrist is a new technique which repeatedly measures subcutaneous glucose levels. They are still expensive, and more experience in ascertaining their reliability is needed before recommending them for routine use.

Purpose

- Spot check to detect hypoglycaemia or impending hypoglycaemia.
- Assess control at times of illness.
- Assess blood glucose profile over 24 hours in order to achieve ideal diabetic control.

Apart from the first two indications, isolated blood glucose readings are of little value for optimising control.

Timing and frequency of testing for blood glucose profiles for Type 1 diabetes

- One or two tests should be performed each day as a routine for stable patients.
- Tests should be done at different time points each day to build up a profile over several weeks (see page 27).
- A 12-hour profile can be measured on a single day from time to time, taking recordings before meals (four times a day), one to two hours after meals (three times a day) and at bedtime. Occasionally it helps to record a reading around 3 am.

Detecting and eliminating hypoglycaemia (see also chapter 8)

Measurement of blood glucose by patients themselves, or by their relatives, when hypoglycaemia is suspected is the only way of establishing whether or not the blood glucose is actually low. This is of particular value in the assessment of children during periods of bad behaviour, unconsciousness or convulsions. Prediction of hypoglycaemia and therefore prevention is also valuable especially at vulnerable times, notably mid-morning, and at bedtime. Methods of reducing the risks of hypoglycaemia are described in chapters 5 and 8.

Some blood glucose meters

Times for taking blood

Blood glucose profiles

Assessment by insulin-treated patients of the daily fluctuations of their blood glucose values gives a much greater understanding by patients and doctors of both diabetic control and the effects of different insulin preparations. Indeed, home blood glucose measurement provides an important educational exercise for all seriously motivated diabetic patients as well as being the essential tool to achieve tight blood glucose control. Reproducible blood glucose profiles are essential for making rational adjustments to treatment. They can show not only the times of the peaks and troughs of blood glucose concentration but also the duration of action of different insulin preparations in an individual patient. Unfortunately, those whose lifestyles are chaotic also produce chaotic blood glucose profiles.

Home blood glucose monitoring by the correct technique, combined with the ability to understand the true significance of the readings, represents on the one hand a very important aspect of diabetes care. On the other hand, obsessive patients who perform tests too often with frequent alterations of insulin dose, cause themselves protracted misery and often disabling hypoglycaemia. While this approach sometimes evolves as a result of the patient's personality, such techniques are all too often encouraged by medical attendants.

The aim is to maintain blood glucose in an acceptable range, usually about 4.5 to 7.7 mmol/l before meals, 6.0-9.0 mmol/l after meals, and >7.0-9.0 mmol/l at bedtime.

Blood glucose monitoring. (A) Inserting the blood glucose strip; (B) loading the finger pricker; (C) pricking the finger; (D) applying the blood to the testing strip; and (E) awaiting result

Chaotic profiles taken by one patient on seven consecutive days

Reproducible profiles taken by one patient on five consecutive days

Occasional excursions outside this range are inevitable, leading to either transient hypoglycaemia or equally transient hyperglycaemia. Thus the occasional high blood glucose readings in an otherwise satisfactory profile can be ignored, although patients are strongly advised to avoid readings below 4.0 mmol/l which if frequent can lead to impaired warning symptoms of hypoglycaemia.

Patients should not respond to isolated high blood glucose readings by taking extra insulin: this causes worsening of blood glucose oscillations rather than an improvement in their blood glucose profile.

Preparing blood glucose profiles

- From patients' record books: visual scanning of records can often detect times of peak and trough readings. Some patients plot their readings graphically which can be very helpful. A few patients present spurious readings which may be difficult to detect.
- Computer-generated profiles: memory records from some blood glucose meters can be downloaded using specially designed computer programs. They can show an excellent visual presentation of readings of any selected time period and may clearly delineate peaks and troughs through 24 hours. Some meters offer this programme on an inbuilt screen.

Blood glucose recording book

Interpretation of blood glucose profiles

Before adjusting insulin treatment, it is essential to understand the causes of fluctuating patterns of the blood glucose profile through 24 hours. The following points are crucial.

- Blood glucose rises as insulin action declines, even when no food is taken, because of hepatic gluconeogenesis. This accounts especially for the rapid increase in blood glucose which occurs in the small hours of the morning *before* breakfast.
- These rapid changes in blood glucose also explain why so many patients record different blood glucose readings each day, since even a half to one hour difference in timing can give a very different result.
- Troughs in the blood glucose profile—that is, representing a tendency to hypoglycaemia—almost always occur around noon and between 3 and 5 am at peak insulin activity, so that measures need to be taken to avoid hypoglycaemia especially preceding these times.

Computer-generated blood glucose profile. Modal day—data points with average line. Patient tends to measure blood glucose at extremes. Target range: high 10.0, low 4.0

ABC of Diabetes

- When patients perform three or four isolated blood glucose readings over 24 hours, it is essential for them and their advisers to understand what happens to the blood glucose profile between the single readings. Thus, readings taken at points A, B, C, and D give a very different impression from those taken at points P, Q, R, and S, yet they belong to the same profile.

Guidelines for adjusting treatment

- Changes in insulin dose should be made only once or twice weekly except in times of illness when more frequent changes may be needed, or in those following dose adjustment for normal eating (DAFNE) (see page 29).
- Changes in insulin dose at any one time should normally be kept within 10% of the existing daily dose—for example, a change of four units may be made in a patient taking a total daily dose of 40 units.

The following issues need consideration:

- type of insulin (considered in detail on page 19)
- frequency of administration of insulin
- dose of insulin in units
- carbohydrate distribution.

The patterns of the blood glucose profile need to be understood and are much more important than single, randomly taken readings. When consistent daily fluctuations of blood glucose have been shown, treatment should be modified, aiming chiefly to eliminate hypoglycaemic episodes, and thereafter to obtain better control by increasing the blood glucose in the troughs and decreasing it at the peaks. There are several ways of achieving fine glucose control.

Self assessment of diabetic control in Type 2 diabetes

Home blood glucose monitoring is of value for many (though not necessarily all) patients with Type 2 diabetes, as it is for those with Type 1 diabetes. Those taking oral hypoglycaemic agents or on diet alone have the option to monitor their control by either self blood glucose measurement or regular urine testing. Measurement of the fasting blood glucose two or three times weekly in those on diet alone provides a valuable guide to control, while the addition of some postprandial readings in those taking oral hypoglycaemic agents also provides important information.

Continuous subcutaneous insulin infusion (CSSI)

CSSI was introduced 25 years ago by workers at Guy's Hospital in London, and now the development of more reliable and more sophisticated pumps brings distinct advantages in specific indications to approximately 2 to 5% of those with Type 1 diabetes. A small improvement in overall diabetic control compared with optimised injection regimens can be achieved without necessarily aggravating or indeed actually reducing problems from hypoglycaemia. CSSI is not suitable for those with psychological or psychiatric problems.

Hazards

Experience has virtually eliminated earlier hazards of excessive problems from hypoglycaemia or, because of the very small insulin depot, higher rates of diabetic ketoacidosis. All patients should have a supply of insulin pens or syringes in case of pump failure.

Adjustments after assessment of blood glucose profiles. Note the apparent different shape of the profile if readings are taken at points ABCD or PQRS

To increase blood glucose in the troughs

- Eat more carbohydrate at or before the times when blood glucose values are at their lowest, usually mid-morning and at bedtime; the exact amount of extra carbohydrate can be determined only by trial and error
- Reduce the dose of insulin before the trough
- Premeal hypoglycaemia can be ameliorated by substituting short acting insulin with a very short acting insulin analogue

To decrease blood glucose in the peaks

- Reduce by a little the amount of carbohydrate taken at the meals which precede the peaks by two or three hours
- Increase the dose of insulin before the peak

Soluble insulin should be altered to change blood glucose concentrations during the following six hours. Medium acting insulin should be altered to change blood glucose during the following six to 12 hours. The duration of insulin action varies considerably however in individual patients

To decrease fasting hyperglycaemia

- Increase predinner medium (or long) acting insulin.
- If that provokes night-time hypoglycaemia, then split the predinner insulin into two parts, retaining the short acting insulin before dinner and taking medium acting insulin at bedtime; or consider changing the medium acting insulin component to insulin glargine

To lessen nocturnal hypoglycaemia

- Reduce the evening medium acting insulin dose
- Check that the patient is taking their bedtime snack
- Check bedtime blood glucose, taking additional carbohydrate if it is less than 5.0 to 6.0 mmol/l
- Split predinner insulin dose, or consider changing to insulin glargine

For a detailed description of the use of individual insulin types, see chapters 6 and 8

Infusion strategy

- Initially reduce total daily insulin dose by 30%.
- Give half the daily insulin dose as the constant basal pump rate (usually around 1 unit/hour).
- Give half the daily insulin dose divided between the three main meals, giving the insulin boost immediately before the meal.
- The patient is taught to count carbohydrate portions (see page 12) and thereafter will give the bolus doses in direct relation to the amount of carbohydrate consumed (for example, 1 unit for every 10 g of carbohydrate).

During the first few days adjustments need to be made as follows:

- basal rate determined by assessment of fasting and 3 am blood glucose readings
- preprandial boosts are adjusted by assessment of postprandial blood glucose readings.

Note: Specific instructions are given for exercise, and basal rates should be reduced during and after exercise.

Dose adjustment for normal eating (DAFNE)

A more liberal dietary pattern for Type 1 diabetic patients has become possible by using the DAFNE approach, ideal for some people who thus regain considerable freedom while at the same time maintaining good control. It is based on:

- a 5-day structured, group education programme delivered by quality assured diabetes educators
- the educational approach is based on adult educational principles to facilitate new learning
- two injections of medium acting insulin each day (see page 21)
- injections of short acting insulin every time meals are taken
- testing blood glucose before each injection.

This programme enables people to eat more or less what they like when they like, and not to eat if they do not wish to do so. It depends on a quantitative understanding of the carbohydrate values of individual foods, and calculating by trial and error the correct amount of soluble insulin needed for a specified quantity of carbohydrate, developing an insulin/carbohydrate ratio for each individual patient.

DAFNE has been used in continental Europe for many years: the approach is popular and gives considerable benefits to some patients. Good diabetic control can be achieved without any increase in hypoglycaemia and at the same time there is improvement in the quality of life.

Indications for CSSI

- Management of patients with frequent unpredictable hypoglycaemic episodes
- For control of the dawn hyperglycaemic phenomenon when conventional, optimised regimens have failed
- For greater flexibility of lifestyle
- In pregnancy when conventional methods fail
- For patients employed on shift rotas who are not able to achieve glycaemic control on multiple injections

Optimal results are achieved using non-associating, monomeric insulin analogues, for example, lispro insulin (Humalog), or Insulin Aspart (Novo Rapid)

Training of patients is undertaken by the nurse educators and a 24-hour duty scheme is needed to deal with emergencies

The photographs of blood glucose meters and the finger pricking devices are reproduced with permission from MediSense and Roche Diagnostics.

The story of Mrs B-J continues: attending the clinic

Then I began my regular visits to the clinic, which I think was every three weeks at first. This was held upstairs in the pathology laboratory, with the doctors in a small room off. I was fascinated by all that was going on there; so many bottles, test tubes, Bunsen burners, etc., as the tests were done there for all the hospital. The waiting room was very small and if a dozen patients attended it was a crowd, for there were only about 200 diabetic patients on the hospital's roll.

I remember Dr RD Lawrence vividly. He always looked very smart in black jacket and striped trousers and a black bow. He took a great interest in the children, and I felt encouraged that such a great man was also diabetic.

Over the years the number of patients attending the clinic increased. We often had long waits and were obliged to listen to very gruesome tales from some of the adults. Shortly afterwards, the children's clinic was arranged, and I attended with quite a few others on Saturday mornings.

There were "elevenses" laid on, and an ice cream could be had as a portion. At first, ice cream was not considered suitable for diabetics even as part of the diet, so I was happy to find this was no longer so, and a Walls twopenny brick was a real treat.

7 The unstable Type 1 diabetic patient

Blood glucose concentrations inevitably oscillate considerably over 24 hours in many Type 1 diabetic patients. If these swings are used as a definition of instability then such patients might be classified as unstable. Indeed the ardent desire of some doctors to “stabilise” these patients sometimes leads the patient to undertake innumerable blood tests, to keep obsessional records, and to make themselves thoroughly miserable. The failure to succeed leads to recriminations, admissions to hospital, and absence from work. This form of physician-induced, unstable diabetes is made worse by the inappropriate use of home blood glucose monitoring. It needs considerable patience to unravel the effects of such advice, but a more relaxed approach, together with fewer tests, can have a remarkably beneficial effect.

Very unstable diabetes (sometimes described as “brittle”) disrupts the lives of a small group of insulin treated diabetic patients, with repeated admissions to hospital due either to hypoglycaemia or ketoacidosis. Homelife, school, and work are totally disrupted. With very few exceptions, this is probably not a special type of diabetes; it most commonly occurs in teenage girls, it is almost always temporary, and problems appear to vanish as life itself stabilises with employment or marriage.

Management of disruptive diabetes demands time and patience; the doctor must identify any technical errors, recommend the best possible diabetic treatment, search for intercurrent illness, and seek social or psychological problems which might cause the patient to manipulate his or her diabetes. Some elderly patients also experience serious problems from violent swings of blood glucose. Loss of support at home following separation or bereavement can be added to the specific problems already described.

Solving technical problems

After all the technical issues have been checked, the dose and type of insulin should be adjusted to the best possible regimen (ideal insulin regimens have been described elsewhere). Some obsessional patients respond well to a reduction of the number of daily injections. A few unstable diabetic patients may benefit from continuous subcutaneous insulin infusion, which may also alleviate unpleasant hypoglycaemic episodes.

If recurrent hypoglycaemic episodes are the chief problem then careful education is needed to eliminate them (see chapter 8); careful attention needs to be given not only to the dose of insulin but also to the timing and amount of food, the effects of exercise, and the judicious use of home measurement of blood glucose. Sometimes excessive amounts of insulin, especially soluble insulin, may cause severe hypoglycaemia. Improvement results either from reducing the dose or changing the insulin regimen.

In a few women menstruation regularly causes severe upset of diabetes; control usually deteriorates in the premenstrual phase, causing ketoacidosis at times, followed by an increase in insulin requirement and sometimes troublesome hypoglycaemia. A carefully planned campaign of insulin adjustment usually overcomes this problem.

Chaotic blood glucose profiles in one patient over seven consecutive days

Disruptive diabetes has several causes, ranging from simple technical errors to gross deceptions of great ingenuity

Identifying technical problems

- The technique of injecting insulin should be meticulously checked
- Injection sites should be inspected
- Equipment needs to be scrutinised
- Sometimes, especially in elderly patients, reduced visual acuity makes measurement of the insulin dose extremely inaccurate
- The brand of insulin itself should be checked
- Techniques of blood glucose testing must be observed and checked with laboratory results
- Adequate understanding of diet should be verified

Above all, patients need encouragement and restoration of self-confidence together with the reassurance that they are neither physically nor mentally abnormal. The telephone number of the doctor or nurse offers added security. If at all possible unstable patients should not be admitted to hospital. If all these measures fail, however, and life is still disrupted by diabetes, then an admission is after all required.

Admission to hospital

In hospital the nursing staff take over the administration of insulin completely—both the procedure of drawing up the insulin and giving the injections. If some measure of stability is then achieved the patient's equipment is returned for self injection: if chaos resumes it seems likely that the patient is either incompetent or cheating.

If diabetes continues to cause disruption even when the nursing staff are giving insulin injections, some form of manipulation should be suspected. Some patients use great ingenuity; insulin may just be concealed in a locker, but it has also been found inside transistor radios, in the false bottoms of jewellery boxes, and taped outside hospital lavatory windows.

Manipulation should be suspected in patients whose lives are totally disrupted by their diabetes. A careful history may reveal slips which give the vital clue. For instance, one teenager developed profound hypoglycaemia two days after apparently "stopping insulin"; another, whose life was spent in and out of hospital with hypoglycaemia or ketoacidosis, claimed to be perfectly stable in-between, presenting a whole volume of negative urine tests. Even constant insulin infusion does not necessarily solve the problem, especially when the patient replaces the insulin in the syringe with water. When there is strong evidence of manipulation, try hinting at the possibility to the patient or their parents but without accusation. The technique is sometimes successful and gratitude considerable.

Emotional, social, or psychiatric causes underlie disruptive diabetes and the desire to manipulate the situation to cause widespread havoc among families. Teenage defiance is a common cause. Quiet support of families at these difficult times helps to overcome what is almost always a temporary phase. Careful enquiry should establish whether there is family strife, and family counselling is often valuable. Psychiatric advice should only be sought if there is evidence of a psychiatric disorder. It is a huge advantage to work closely with a sympathetic liaison psychiatrist who understands the specific problems of diabetes and is unthreatening to patients; otherwise, confrontation with a psychiatrist may provoke even more aggression. Nonetheless, a few patients remain incapable of independent existence, and then community care strategies are essential.

Various disorders, especially infections and some endocrine disorders, may alter the insulin requirements, although they rarely cause the type of instability already described.

At one clinic of yours which I attended, you asked me if I was taking overdoses. I was stupid and did not admit this until December 1981. I am still not as well balanced as I would like, but I am better than I was.

Letter from a patient

Falsified urine chart from a very unstable teenage patient

8 Hypoglycaemia

Hypoglycaemia is the major hazard of insulin treatment, and problems have increased in the drive to achieve “tight control”. Patients may experience the symptoms of hypoglycaemia when the blood concentration is less than 3.0 mmol/l. However, individual susceptibility varies considerably and it is interesting that some patients whose control has been persistently very poor for long periods appear to experience hypoglycaemic symptoms at levels a little above this. The risks of hazard from hypoglycaemia are small in most patients, but because they exist at all, patients taking insulin are barred from certain occupations such as driving trains or buses. All patients taking insulin whose diabetes is reasonably well controlled will experience hypoglycaemia at some stage. At its mildest, it is no more than a slight inconvenience, but at its severest, when unconsciousness can occur, it is both a hazard and an embarrassment. Furthermore, manipulative patients can use hypoglycaemia to threaten family and friends. This sword of Damocles is ever present once insulin treatment has started, and the need to use measures to avoid it requires constant, indeed lifelong, vigilance. Hypoglycaemia occurs infrequently in patients taking oral hypoglycaemics.

Symptoms

Most patients experience the early warning symptoms of hypoglycaemia and can take sugar before more serious symptoms develop. These warning symptoms are well known and are described in the box. Tremulousness and sweating are by far the commonest symptoms, while circumoral paraesthesiae is the most specific. Many patients have highly individual symptoms of hypoglycaemia which range from quite inexplicable sensations to peripheral paraesthesiae. In three patients carpal tunnel compression resulted in tingling fingers when they were hypoglycaemic, representing their sole warning. Neuroglycopenic symptoms and diminished cognitive function follow if corrective action is not taken, with progressive confusion and eventually unconsciousness and occasionally convulsions. There is a prolonged debate as to whether recurrent hypoglycaemia causes long-term intellectual decline; the evidence in general is unconvincing although major and recurrent episodes in childhood may have an adverse effect in this regard.

Patients who become unconscious from hypoglycaemia need urgent treatment. Brain damage and death do not normally occur because the blood glucose concentration tends to increase spontaneously as the effect of the insulin wears off and the normal counter-regulatory responses become effective. Many diabetics, especially children, need reassurance that they will not die in their sleep. Nevertheless, a very small number of otherwise unexplained deaths at night have been reported in Type 1 diabetic patients (described as the “dead in bed” syndrome) and no precise cause has ever been established. Deaths from prolonged hypoglycaemia are most likely to occur after insulin overdoses, as a result either of a suicide or murder attempt, but even in these circumstances most patients recover.

Hypoglycaemia (“hypo” “insulin reaction”)

This is when the blood sugar goes too low in diabetics taking insulin

Symptoms are sweating, shaking, tingling round the mouth, hazy eyesight or seeing double, slow thinking, in children naughtiness

Causes are late meal, too little carbohydrate, extra exercise, too much insulin.

Cure is to take carbohydrate—preferably three dextrosol tablets, glucose, sugar (two large lumps), barley sugar, Lucozade followed by a small snack

Symptoms will soon wear off

If in doubt about an attack, take sugar

Always carry some form of SUGAR with you

Symptoms of hypoglycaemia

- **Early warning**
 - Shaking, trembling
 - Sweating
 - Pins and needles in lips and tongue
 - Hunger
 - Palpitations
 - Headache (occasionally)
- **Neuroglycopenia**
 - **Mild**
 - Double vision
 - Difficulty in concentrating
 - Slurring of speech
 - **More advanced**
 - Confusion
 - Change of behaviour
 - Truculence
 - Naughtiness in children
 - **Unconsciousness**
 - Restlessness with sweating
 - Epileptic fits, especially in children
 - Hemiplegia, especially in older people (but rare)

Observation of a hypoglycaemic attack

“When she is having a hypo she gives the impression of being drunk. The change in her behaviour is sudden and very noticeable. She slurs her words and appears drowsy. There is lots and lots of yawning. If she is still in the state of which she can walk, she will bump in to things and knock things over and be generally clumsy. She will hardly be aware of where she is or who she is talking to. She rambles”

Diminished awareness of hypoglycaemia

This is the problem which all insulin treated patients dread, and at some stage it affects up to one quarter of Type 1 diabetic patients. It occurs when patients do not experience the early warning symptoms and directly develop diminished cognitive function which prevents them from taking the required preventive action. In this situation, help is required from a third party. This commonly occurs in the home when friends and relations observe the person to be slow-witted with a vacant expression and perspiring face. They may be taciturn, truculent or even obstructive, sometimes refusing to take sugar when advised, although many learn to accept this advice. This state of cognitive impairment can persist for some considerable time, long enough for abnormal behaviour to be noticed during driving, even for several miles; shoppers in the High Street may be unaware that they are shoplifting. If corrective action is not taken, the more serious state of unconsciousness already described can occur.

Night-time hypoglycaemia is very common, usually occurring between 3 and 6 am. The blood glucose concentration often falls below the hypoglycaemic threshold; levels as low as 1.0 mmol/l are not rare, and are known to cause electroencephalogram abnormalities even in the absence of symptoms. Many people become very restless when hypoglycaemic; this is recognised most frequently by the spouse who takes the necessary remedial action. Profound sweating is common, sometimes necessitating a change of nightclothes or bedclothes and may be the only manifestation that hypoglycaemia has occurred. Convulsions are not rare, and some patients wake in the morning with a bitten tongue as the only indication that this may have occurred.

Recurrent hypoglycaemia is the principal underlying cause leading to diminished awareness of hypoglycaemia, with dangerous impairment of cognitive function its chief manifestation. It is therefore most likely to occur in those who are most tightly controlled, and was manifest in the famous Diabetes Control and Complications Trial (DCCT) in which severe hypoglycaemia occurred three times more often in the tightly controlled group of patients. This cause outweighs all others, although the use of β adrenergic blockers has the same effect in a small number of patients. Autonomic neuropathy is not normally the cause of diminished warning, and the contentious role of human insulin in this regard has led some patients to change back to animal insulins, though scientific evidence of harm is still lacking. Diminished warning also increases with lengthening duration of diabetes.

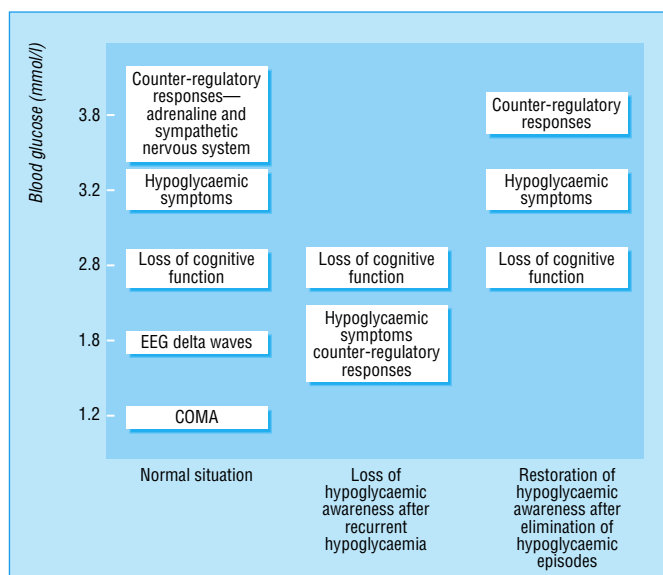

Why does recurrent hypoglycaemia beget loss of warning? The answer probably lies in the readjustment of the threshold of sensitivity of a glucose sensor in the hypothalamic region of the central nervous system. This alters the hierarchy of responses to hypoglycaemia. Thus, the hypoglycaemic symptoms and counter regulatory responses, instead of occurring at a blood glucose just above 3.0 mmol/l, develop at a lower level, rather less than 2.0 mmol/l. Because in either case the loss of cognitive function occurs around 2.8 mmol/l it is clear that, in cases of diminished hypoglycaemic awareness reduced cognitive function develops before hypoglycaemic warning symptoms.

Recent research has also shown that by eliminating recurrent hypoglycaemia it is possible to restore the normal sequence of events when blood glucose falls, thus also restoring adequate warning. It is therefore necessary to eliminate as far as possible all hypoglycaemic episodes, even those occurring

Relationship between glycated haemoglobin and hypoglycaemia rates shown in the DCCT study

Avoiding hypoglycaemia can restore proper warning symptoms. Patients should try to avoid blood glucose levels < 4.0 mmol.

Loss of warning of hypoglycaemia (EEG=electroencephalogram)

ABC of Diabetes

quietly at night. This can often be achieved simply by reducing the insulin dose, ensuring adequate carbohydrate intake and to some extent relaxing overall diabetic control in the interest of safety. It is much more difficult, yet possible, to eliminate hypoglycaemia and retain optimal control of diabetes. The acquired skill of the diabetes team and the co-operation of patients is needed if this is to be done, and the time and resources needed are considerable. The introduction of programmes such as blood glucose awareness training (BGAT), in which patients are taught how to recognise the most subtle symptoms of early hypoglycaemia, can be very effective in reducing serious hypoglycaemia and thus helping to restore adequate warning.

A questionnaire which helps physicians to assess whether a patient has diminished awareness of hypoglycaemia is shown in Appendix 1.

Causes of hypoglycaemia

In every patient taking insulin the blood glucose concentration shows peaks and troughs, which can be most clearly shown by home measurements of blood glucose. Since the lowest blood glucose concentrations occur at different times in each patient, it is a great advantage if individual patients know when their own troughs are likely to occur. The commonest times are before lunch and during the night. Some patients in their constant fear of developing diabetic complications drive their blood glucose levels ever lower with disastrous consequences in terms of hypoglycaemia.

Severe physical activity, such as swimming very long distances, is a powerful stimulus of hypoglycaemia, and as much as 40 to 50 g additional carbohydrate may be needed to prevent it. Hypoglycaemia in these situations is sometimes delayed for several hours. Several well-known sportsmen and women with diabetes show considerable ingenuity and perseverance in the way in which they cope with their diabetes during international competitions, by individual attention to food and insulin intake, carefully timed blood glucose monitoring, and ready availability of sugary fluids such as Lucozade at exactly the right moment.

Hypoglycaemia is particularly likely to occur shortly after stabilisation of new patients, as their insulin requirements may decline considerably; their insulin dose should therefore always be reduced before they leave hospital.

Hypoglycaemia is also troublesome when insulin requirements insidiously decrease during the evolution of such conditions as Addison's disease, hypopituitarism, and malabsorption syndromes.

Treatment and prevention of hypoglycaemia

Much of the skill required to manage insulin treated diabetic patients is therefore devoted to achieving adequate control of diabetes, yet avoiding hypoglycaemia. There are quite straightforward measures which many patients neglect: they must therefore at all times carry a supply of glucose both on their person and in their cars, and take 10 to 20 g at the first warning symptoms, preferably followed by a carbohydrate snack. The late RD Lawrence always demanded that his patients should demonstrate that they were carrying their sugar supply with them. This can take the form of sugar lumps, sweets (non-diabetic), sugar gel or dextrose tablets.

Reproducible blood glucose profiles in one patient during five consecutive days, showing the times of blood glucose "troughs" when hypoglycaemia is most likely to occur

Events likely to provoke hypoglycaemic attacks

- Insufficient carbohydrate in meals
- Delayed meals
- Increased physical activity
- Errors of insulin dosage
- Erratic insulin absorption from areas of fat hypertrophy at injection sites

Items containing 10 g of carbohydrate

- | | |
|-----------------------|-----------------------|
| • Milk | 200 ml (1/3 pint) |
| • Lucozade | 60 ml (4 tablespoons) |
| • Ribena | 15 ml (1 tablespoon) |
| • Coca Cola | 90 ml |
| • Sugar | 2 teaspoons |
| • Sugar lumps (small) | 3 |
| • Dextrosol tablets | 3 |

They should take ample carbohydrate at times when blood glucose troughs occur, notably mid-morning and bedtime, and they must take appropriate amounts of additional carbohydrate before and during vigorous exercise. Careful blood glucose monitoring plays a crucial part in avoiding hypoglycaemic episodes, and helps to restore warning of hypoglycaemia. Patients should try to avoid blood glucose levels below 4.0 mmol/l. Appropriate insulin regimens that need to be devised for individual patients are described in chapters 5 and 6.

Glucagon

Glucagon is a hormone produced by the A-cells of the pancreatic islets. It raises the blood glucose by mobilising the glycogen stores in the liver (and therefore will not work after prolonged starvation). It is given in a 1 mg dose by injection most conveniently intramuscularly. It can also be used subcutaneously or intravenously and is effective in five to 10 minutes. It is of great value for bystanders of severely hypoglycaemic patients who are unable to take oral glucose, and can be injected by family members, nurses or doctors. It is valuable in relieving stress in a home where a diabetic patient, often a child, is prone to recurrent disabling attacks of hypoglycaemia.

Unconsciousness

In cases where the patient has lapsed into severe unconsciousness, treatment in hospital is urgently needed. The unconscious patient should be placed in the recovery position, and the airway maintained. Blood should be taken for blood glucose analysis and the sample should be kept in case the patient fails to respond to treatment since the possibility always exists that the coma has another cause. Intravenous glucose is given using 50 ml of 20% glucose solution. The more concentrated 50% solution is highly irritant and should no longer be used. The response is usually immediate but if not, a further dose should be given after five to 10 minutes followed by an infusion of 10% glucose. Once consciousness is restored and a history can be taken, the patient should be fed with longer acting carbohydrate to prevent recurrence. If recovery does not occur rapidly, blood glucose measurement should be repeated and another cause for the coma must be sought. If hypoglycaemia has been profound, cerebral oedema can occur and may require treatment with dexamethasone or mannitol. After recovery appropriate adjustment must be made to the diabetic treatment in order to avoid further episodes, and the patient should be carefully reviewed in the diabetic clinic.

Hypoglycaemia due to oral hypoglycaemics

This may occur during treatment with sulphonylureas and similar agents (but not with metformin) especially in some confused elderly patients who either inadvertently take additional tablets or omit their meals. It is treated in the same way as described above. These patients usually require admission to hospital for continuous glucose infusion to avoid relapse into hypoglycaemia, which often occurs until the drug has been cleared from the circulation.

Dr Charles Fletcher's account of hypoglycaemia

My main problem has always been hypoglycaemia. At first I was nearly always aware of it by day and woke at night, because of the adrenaline response. But, particularly in the past 20 years, it gradually became more difficult. I may now feel normal and do ordinary tasks quite easily with blood sugar as low as 2.5 mmol/l (45 mg/100 ml). Sometimes diplopia, dysphasia, weariness, or inability to think may lead me to do a blood sugar. But I often become too muddled to know what is wrong, and I have had to thank my wife, my children, and many generations of housemen, registrars, and secretaries for spotting these low levels on many occasions. Before I retired 50% glucose was always available with syringe in a drawer in my desk. I became quite used to a quiet registrar's voice in outpatients (and elsewhere) saying, "I think, sir, a little extravenuous glucose might help". Lucozade has been invaluable. I always have it available in the car, in the office, and at home. It is acceptably free from sugariness, it saves me chewing and choking on dry glucose tablets, and it is rapidly absorbed. My wife finds it much easier to get me to drink this than to take any other form of sugar when I am severely hypoglycaemic and refuse to acknowledge it. I have made it a rule, which I now keep, even when semi-comatose, that if my wife—or anyone else—tells me to take sugar I do so however sure I may be that I'm not hypoglycaemic. They have only been wrong on rare occasions. I am very sensitive to exercise, but for some reason I find it difficult always to suck prophylactic sweets on country walks or when digging or mowing in the garden.

Glucagon injection kit

Conclusions

Any serious hypoglycaemic episodes can to some extent be regarded as a failure of the doctor, the patient or the treatment regimen itself. It should provoke a serious inquiry to establish the cause and to discover if it is likely to recur. The opportunity for the necessary education should be taken, and patients should be encouraged to carry a diabetic identification card. Finally, the professional attending the patient, whether doctor or nurse, has a duty to inform people who have had an episode of severe hypoglycaemia comprising diminished cognitive function resulting from diminished awareness of hypoglycaemia to stop driving and inform the Driver and Vehicle Licensing Agency. They should also avoid any other potentially dangerous activity. The endeavour to avoid hypoglycaemia needs to be maintained, and patients need considerable support to this end at almost every diabetic consultation throughout life.

The figure showing the relationship between glycated haemoglobin and hypoglycaemia rates is adapted from Donnelly R, et al *BMJ* 2000;320:1062-6. The photograph of the glucagon injection kit is with permission from Novo Nordisk. Dr Charles Fletcher's account of hypoglycaemia is from *BMJ* 1980;280:1115-16.

The story of Mrs B-J continued: hypoglycaemia

When I was 12 I was sent to The Old Palace School in Croydon. Never having done any gymnastics, I was surprised at what was expected of me at the new school. Rope climbing, parallel bars, and marching up and down the long hall where kings had been entertained by archbishops, I was soon very hypo and staggering about like a drunk. This disrupted the session so much that finally I was banned from gym and all other sports. My fellow diabetic, Barbara, had also been banned, but it did not worry me too much. But it was a bitter blow when I was told I would not be allowed to take part in the school pageant "in case I was ill"! My mother went up to see Sister and assured her I would have plenty of sugar etc., but to no avail. Gentle nuns can be very obstinate and quite hardhearted at times.

9 Diabetic ketoacidosis and management of diabetes during surgery

Ketoacidosis

Ketoacidosis results from a lack of insulin. In practice it is usually due to:

- stopping insulin or reducing the dose either in error or deliberately
- resistance to insulin during infections or other intercurrent illness
- the unrecognised onset of Type 1 diabetes.

The clinical onset of ketoacidosis occurs over hours or days. Symptoms of uncontrolled diabetes are always present. Vomiting in Type 1 diabetic patients is always serious. Patients usually consult their doctors during the preceding days, but the presence of uncontrolled diabetes is frequently overlooked. Diabetic control should always be assessed if a diabetic patient becomes unwell for any reason. Many cases of ketoacidosis could be prevented.

Preventing ketoacidosis: sick day rules

During any illness or infection the blood glucose concentration tends to increase and diabetic control deteriorates. Most patients then need a larger dose of insulin than usual, and some who normally take tablets may need insulin just during the illness. The increased need for insulin occurs even when the appetite declines or vomiting begins.

Every insulin treated patient should understand that insulin should never be stopped. Stopping or even reducing insulin during the course of an illness often leads to diabetic ketoacidosis.

When a diabetic person is ill the normal insulin dose should be continued, carbohydrate taken in some palatable fluid form, and the blood tested regularly—four times a day if necessary. If blood glucose readings greater than 15 mmol/l are obtained the dose of insulin should be increased. Additional doses of insulin (about 8 units) may also be given at noon or bedtime when control is very poor. It is preferable to make these adjustments with short acting (soluble) insulin if this is available. If vomiting continues without remission for more than a few hours, admission to hospital for treatment with intravenous fluids and insulin is advisable to prevent ketoacidosis.

Assessment of blood or urine ketones during illness is helpful. Using the new blood ketone meters, readings of 1.0-3.0 mmol/l taken in conjunction with the blood glucose reading usually indicate the need for additional insulin; readings should be repeated within two to four hours. If they persist or increase above 3.0 mmol/l, specialist advice is required from the hospital clinic staff. Ketonuria can be detected using Ketostix, which are readily available.

Recognising ketoacidosis

Dehydration is the most obvious clinical feature of patients with ketoacidosis. They are also drowsy, but rarely unconscious—“diabetic coma” is an inappropriate description; they are often overbreathing, but not usually breathless; their breath smells of acetone (though many people cannot smell this); and many also have the gastric splash. In more severe cases patients are

Causes of diabetic ketoacidosis

| • Miscellaneous | 16% |
| • No cause found | 18% |

King's College Hospital 1968

Ketoacidosis

Prevention of ketoacidosis

Insulin should never be stopped

Insulin dose during illness or infection

During illness or infection your blood glucose level may rise, causing you to feel dry, thirsty and pass too much urine. The blood glucose is also likely to increase

You MUST continue to take your normal insulin dose NEVER stop it. You may need an increased dose if your blood tests are bad. If you are vomiting, consult your doctor or the diabetic clinic at once. If you are unable to eat, take your carbohydrate portions in liquid form—for example, milk, Lucozade, Ribena

Test your blood twice a day or even more frequently
If you continue to feel unwell, consult your doctor.

Features of ketoacidosis

- Drowsiness
- Dehydration
- Overbreathing
- Acetone on breath
- Hypotension
- Gastric splash

ABC of Diabetes

hypothermic (even in the presence of infection) and hypotensive. Hyperosmolar non-ketotic (HONK) patients are usually grossly dehydrated but without overbreathing or the smell of acetone. Inexperienced clinicians often have difficulty in recognising patients with this condition, especially when they seem deceptively well.

Diagnosis

The diagnosis of ketoacidosis is confirmed by laboratory tests.

- **Blood glucose** concentrations may range from slightly increased to extreme hyperglycaemia. The blood glucose concentration itself does not usually indicate the severity of the illness, although most patients are seriously unwell when it is greater than 30 mmol/l.
- **Blood acid-base status** pH ranges from 6.9 to normal. The bicarbonate level is depressed.
- **Plasma ketones** are easily detectable with a ketone meter and exceed 3.0 mmol/l.
- **Urine test** shows heavy glycosuria and ketonuria.
- **Electrolytes:** the serum potassium concentration is either normal or raised, and very rarely low. This measurement is vital, and life-saving treatment is needed to maintain potassium values in the normal range. The sodium concentration is normal or reduced, and urea and creatinine concentrations are often raised through dehydration.
- **Blood count:** if a blood count is performed the white cell count is often spuriously raised to $15\text{--}20 \times 10^9/l$ even in the absence of infection.

Serum amylase is sometimes moderately elevated in patients with diabetic ketoacidosis: it is of salivary origin and need not be indicative of pancreatitis

Treatment

Patients should be treated in an area where they can be observed regularly, preferably by staff familiar with managing this condition, in a high dependency area, or if very ill in intensive care.

- Insert a nasogastric tube if consciousness is impaired. Do not allow any fluids by mouth; if patients are thirsty they may suck ice.
- Give intravenous fluids. The regimen needs to be modified according to age, weight, and the presence of cardiac disease. In seriously ill patients and all those with cardiac disease a catheter for measuring central venous pressure is essential. A suitable regimen for most patients is shown in the box; 0.9% saline is used.
- The fluid should be changed to 10% dextrose once the blood glucose concentration has fallen to less than 10 mmol/l. The rate of infusion is determined by individual need but at this stage should probably be about one litre every eight hours.
- Start intravenous soluble insulin immediately. If there is any delay in obtaining intravenous access. Soluble insulin (20 units) can be given immediately intramuscularly.

Insulin treatment

Intravenous insulin: soluble insulin is diluted in 0.9% saline in a syringe, at the concentration of 1 unit/ml. It is given by infusion pump at 6 units/h (0.1 units/kg/h for children) until the blood glucose concentration is less than 10 mmol/l. Blood glucose should fall at a rate of about 5.0 mmol/l/h, and plasma ketones should fall at the same time. When the blood glucose is less than 10 mmol/l, the dose may be reduced to 3 units/h. Higher infusion rates are rarely needed; when they are needed

Tests for ketoacidosis

- Blood glucose
- Serum potassium and sodium
- Acid-base status
- Urea, creatinine
- Plasma or urine ketones
- Blood count
- Blood culture (when indicated)

Blood glucose and ketone meter

Treatment of ketoacidosis

Physiological saline:*	1 l in first half hour	-1/2 h
	1 l over next hour	1/2-1 1/2 h
	1 l over next hour	1 1/2-2 1/2 h
	1 l over next 2 hours	2 1/2-4 1/2 h
	1 l over next 3 hours	4 1/2-7 1/2 h
	1 l over next 4 hours	7 1/2-11 1/2 h
Total:	6 l	11 1/2 h

*Change to 10% dextrose when blood glucose is less than 10 mmol/l

in insulin resistant patients the rate should be doubled or quadrupled, etc. If the patient is not responding, medical staff should check the equipment for pump failure, blockage or leakage. The insulin infusion is continued until the patient is well enough to eat. The changeover to subcutaneous insulin should be made before breakfast. Preprandial subcutaneous soluble insulin is then given and intravenous insulin discontinued after the meal. Intravenous insulin should not be stopped before subcutaneous insulin has been given (see below).

Intramuscular insulin is used only when an infusion pump is not available. Soluble insulin 20 units is given as a loading dose, than 6 units every hour until blood glucose is less than 10 mmol/l, then continued at two hourly intervals. As with intravenous insulin, higher doses are rarely needed.

Potassium and sodium bicarbonate

Potassium chloride administration should usually start at about the second hour, preferably not before the serum potassium concentration is known. It should be withheld in exceptional cases of oliguria or anuria, or if the serum potassium value remains above 5.0 mmol/l. After the second hour, or earlier if the initial serum potassium value is normal or less than 4.0 mmol/l, 20 mmol potassium chloride should be added to each litre of saline. If the serum potassium value falls below 3.5 mmol/l, 40 mmol should be used in each litre. The exact amount should be determined by serial serum potassium measurements—every two hours at first, then every four hours—and serum potassium maintained between 4.0 and 5.0 mmol/l. An electrocardiographic monitor should be set up; however, there is no substitute for serial potassium measurements.

Sodium bicarbonate is not normally beneficial and is not given unless the blood pH value is less than 7.0 or the patient is shocked. If it is needed, aliquots of sodium bicarbonate (500 ml of 1.26%) with added potassium chloride (15 mmol) should be given. This can be repeated if there is no response within one hour and if the patient's condition remains serious.

Note: Never use sodium bicarbonate 8.4% concentration.

Treatment of the underlying condition

Underlying disease should be sought, especially respiratory or urinary infections, which may not be obvious at the onset. Blood culture, culture of the midstream specimen of urine, and chest radiography are performed. There is no need to give antibiotics routinely. Abdominal pain may occur, especially in young patients with severe ketoacidosis. It is vital to discover whether there is indeed an intra-abdominal cause needing attention if the pain does not resolve rapidly.

HONK patients

Blood glucose in these patients can be extremely high without ketosis or acidosis. Management is the same as that for ketoacidosis, except that 0.45% saline is given if the serum sodium value is greater than 150 mmol/l, and a lower rate of insulin infusion (3 units/h) is often sufficient. In shocked and dehydrated patients prophylactic, low dose, subcutaneous heparin is considered.

Lactic acidosis

These patients are profoundly ill and the cause of the acidosis must be sought and rigorously treated. They are often very insulin resistant due to serious intercurrent illness, and need large amounts of sodium bicarbonate. Absence of a raised plasma ketone level excludes ketoacidosis as the cause of the metabolic acidosis. Metformin induced lactic acidosis should be borne in mind.

Intravenous soluble insulin	
Initially	6 U/h
When blood glucose < 10 mmol/l	3 U/h
or	
Intramuscular soluble insulin	
Initially	20 U
Then	6 U/h
When blood glucose < 10 mmol/l	6 U/2h

Giving intravenous insulin

Potassium chloride administration

Serum value (mmol/l)	< 3.5	3.5-4.0	4.0-5.0	> 5.0
Administer	40 mmol/l	30 mmol/l	20 mmol/l	0

Patients who develop HONK are often elderly or West Indian, and they often turn out to have Type 2 diabetes

Management of insulin treated diabetes during surgery

The chief principle of diabetic management through any crisis in which patients cannot eat or drink for any reason is to continue insulin administration. The best method is to give the insulin by continuous intravenous infusion either by infusion pump or directly from the drip bag.

For operations in which a patient is likely to be maintained on a drip for more than 12 hours a regimen is needed which can be continued for an indefinite period. Again there are two methods of administering the insulin: a variable rate infusion using a pump, or if this is not available, a glucose insulin-infusion. **Note:**

- The rate of intravenous infusion must depend on the clinical state of the patient with regard to the volume depletion, cardiac failure, age, etc.
- Potassium replacement is required.
- If the blood glucose is persistently above 10 mmol/l the infusion should be changed to 0.9% saline.
- Blood glucose should be monitored every one to two hours during surgery and regularly postoperatively.
- Try to maintain the blood glucose concentration in a safe range—6.0-12 mmol/l.
- Regular (at least daily) electrolyte measurements are required.

After recovery: changing to subcutaneous insulin

Once the patient starts to eat and drink conversion back to subcutaneous insulin injections is undertaken as follows.

- Always change to subcutaneous insulin before breakfast and never in the evening so that adequate supervision can be assured.
- Stop the insulin pump 30 minutes after the first subcutaneous insulin injection.
- Insulin regimen and dose: if the previous regimen is known then this should be given; if the patient is still in bed or unwell the total dose may need to be 10 to 20% more than usual. If the patient was not previously taking insulin, predicting the requirement is not easy and the amount needs adjustment from day to day. Initially use insulin 30-40 units daily in divided doses given four times daily.

Patients with hyperglycaemia often relapse after conversion back to subcutaneous insulin. When this happens there are three possible approaches.

- Give additional doses of soluble insulin at any of the four injection times (before meals or bedtime).
- Add an intravenous insulin infusion temporarily while continuing the subcutaneous regimen until the blood glucose concentration is satisfactory.
- Revert completely to the intravenous regimen, especially if the patient is unwell.

Surgery in Type 2 diabetes

Management of diabetic patients treated with diet or oral hypoglycaemic agents is more straightforward, so long as the diabetes is well controlled.

If the random blood glucose value is less than 12 mmol/l:

- omit the tablet on the day of surgery
- check the blood glucose concentration before and soon after the operation; if the blood glucose value is more than 12 mmol/l start soluble insulin.

If the diabetes is poorly controlled (random blood glucose greater than 12 mmol/l) the patient should be started on

Dextrose drip and variable rate insulin infusion

- (1) Give normal insulin on the night before the operation
- (2) Early on the day of operation start an infusion of 10% dextrose, add 20 mmol potassium chloride to each litre, and run at a *constant* rate appropriate to the patient's fluid requirement, usually 100 ml/h
- (3) Make up a solution of soluble insulin 1 unit/ml saline in a syringe and infuse intravenously by a line piggybacked to the intravenous drip by using a syringe pump. The infusion rate should normally be as shown in regimen 1, but in resistant cases use regimen 2 or 3

Blood glucose	Soluble insulin infusion rate		
	Regimen 1	Regimen 2	Regimen 3
< 4 mmol/l	0.5 unit/h	1 unit/h	2 unit/h
4-10 mmol/l	2 unit/h	4 unit/h	8 unit/h
10-15 mmol/l	4 unit/h	8 unit/h	16 unit/h
15-20 mmol/l	6 unit/h	12 unit/h	24 unit/h
> 20 mmol/l	Review		

Blood glucose is measured preoperatively and then two hourly until stable, then six hourly

Regimen 1 is satisfactory for most cases; very severely ill patients, shocked patients, and those receiving steroids, salbutamol, or dopexamine infusions may need higher dose infusions, such as regimens 2 or 3, occasionally even more.

Do not stop the insulin infusion since intravenous insulin lasts for only a few minutes

Only if the patient becomes frankly hypoglycaemic (blood glucose < 2.0 mmol/l) should insulin be stopped for up to 30 minutes

Glucose-insulin infusion

- (1) Give normal insulin on the night before the operation
- (2) Begin an infusion of 10% dextrose containing 20 mmol/l potassium chloride and soluble insulin 15 units/l. Run it at a rate appropriate to the patient's fluid requirements, usually 100 ml/h. Adjust insulin dose as follows

Blood glucose	Soluble insulin infusion
< 4 mmol/l	15 unit/l
4-10 mmol/l	30 unit/l
10-15 mmol/l	40 unit/l
15-20 mmol/l	60 unit/l
> 20 mmol/l	Review

Blood glucose is measured two hourly until stable, then six hourly

Surgery in Type 2 diabetes

- Omit usual treatment
- Use insulin if diabetic control deteriorates
- Maintain blood glucose chart

insulin before the operation, using one of the regimens described on the previous page.

Management of insulin treated diabetes during day surgery

Patients with insulin treated diabetes requiring an anaesthetic for relatively minor operations or investigative procedures (for example, barium radiological examinations, cystoscopy, endoscopy, etc.) can be treated as day cases without hospital admission provided that:

- the procedure is undertaken in the morning first on the list (if the procedure is performed first on an afternoon list, a light breakfast is taken after half the normal insulin dose, followed by regular blood glucose monitoring)
- the procedure does not exceed approximately one hour in duration
- the patient will be able to eat and drink within one hour of the procedure
- the patient is able to self-monitor blood glucose and adjust insulin appropriately.

The blood glucose should be rechecked before discharge. If significant problems with diabetes control persist, then hospital admission may be required after all.

Instructions for management of insulin treated diabetes in day surgery

- The procedure should be performed after an overnight fast
- Insulin is taken on the previous evening as usual
- Insulin and breakfast are omitted on the morning of the procedure
- The blood glucose must be measured before leaving home and again before the procedure is commenced.
- If the blood glucose is less than 6.0 mmol/l a 10% dextrose drip is needed
- Within one hour after completion of the procedure, the normal morning insulin dose should be administered followed by appropriate food and fluid giving the equivalent amount of carbohydrate to the usual breakfast

10 Diabetic complications: cause and prevention

Introduction

Patients with long-standing diabetes may develop complications affecting the eyes, kidneys or nerves (microvascular complications) or major arteries. The major arteries are affected in people with diabetes, causing a substantial increase in both in coronary artery disease and strokes as well as peripheral vascular disease. The greatest risk of large vessel disease occurs in those diabetic patients who develop proteinuria or microalbuminuria, which are associated with widespread vascular damage. These complications are often discovered at presentation in Type 2 diabetic patients who must have had diabetes for many years before it has been diagnosed. Issues concerning macrovascular complications are described in chapter 17.

During the last two decades, there has been a considerable increase in understanding the mechanisms underlying the development of the long-term diabetic microvascular complications (retinopathy, nephropathy, and neuropathy) and macrovascular disease, accompanied by major developments in preventing them. The United Kingdom Prospective Diabetes Survey (UKPDS) in particular demonstrated quantitatively the long-term harmful effects of hyperglycaemia and hypertension in the development of both microvascular and macrovascular complications in Type 2 diabetes. Both UKPDS and the Diabetes Complications and Control Trial (DCCT) of Type 1 diabetes demonstrated the benefits of optimal control.

HbA_{1c} values during 9 years in the DCCT study of Type 1 diabetes, showing steady levels in intensively and conventionally controlled groups

Causes and prevention of complications

Major advances in recent years have resulted in an actual decrease of some complications, notably nephropathy. Primary prevention of diabetic complications, together with retardation of their progression, is now possible, chiefly by tight control of the diabetes and of hypertension, together with reduction of other “risk factors” detailed in chapter 17. Even when the complications are established, their progression leading to serious damage can be delayed.

Although many attempts have been made to develop specific pharmacological agents to alter the course of diabetic complications, and although many trials are in progress at the present time, none have proved unequivocally successful and none are licensed. There is at present intense interest in and optimism for the use of protein kinase-C inhibitors.

Two major studies

DCCT: a multicentre study of 1441 Type 1 diabetic patients in the United States examining the effects of tight control on the development of microvascular complications, terminated after nine years because of highly significant benefits reported in 1993. The benefits on the microvascular complications were considerable.

UKPDS: a multicentre study of 5102 Type 2 diabetic patients co-ordinated from Oxford, assessed both the harmful effects of persistent hyperglycaemia and hypertension on the development of microvascular and macrovascular complications, and also demonstrated the

HbA_{1c} values during 15 years of the UKPDS study of Type 2 diabetes showing progressive deterioration of both intensively and conventionally controlled groups

benefits of 10 years of better, compared with less satisfactory, control of both glycaemia and blood pressure reported in 1998. Benefits were achieved regardless of the drugs used to reach the required standards of either blood glucose or blood pressure control.

The long-term effects of treatment in the two studies are shown in the two figures demonstrating the stable control in Type 1 diabetes (DCCT) compared with the deteriorating control in Type 2 diabetes as the disease progresses (UKPDS).

Persistent hyperglycaemia

Over many years this is the principal underlying cause of the microvascular complications of diabetes. It is also an independent risk factor for the development of macrovascular coronary artery disease and cataract formation. The UKPDS showed precisely the increasing hazard in relation to continuously rising HbA_{1c} levels, without any specific threshold point, and then demonstrated the benefits of tight control. Once complications are established additional factors, notably hypertension, may accelerate their progression (for further details see chapters on specific complications).

For every 1% increase in HbA_{1c}:

- microvascular complications increased by 37%
- any end point (micro and macrovascular) related to diabetes increased by 21%
- deaths related to diabetes increased by 21%.

(Microvascular complications are here defined as retinopathy requiring photocoagulation, vitreous haemorrhage, and fatal or non-fatal renal failure.)

The progression of neuropathy assessed in a group of Type 1 diabetic patients in a prospective 14-year study conducted in Dusseldorf has also shown clearly that the decline of numerous measurements of nerve function occurs almost exclusively in those with poor glycaemic control.

The effect of better blood glucose control on the microvascular complications was as follows:

- reduction of microvascular complications (chiefly the need for photocoagulation) by 25%
- reduction of any diabetes end point by 12%
- reduction of any diabetes related death by 10%.

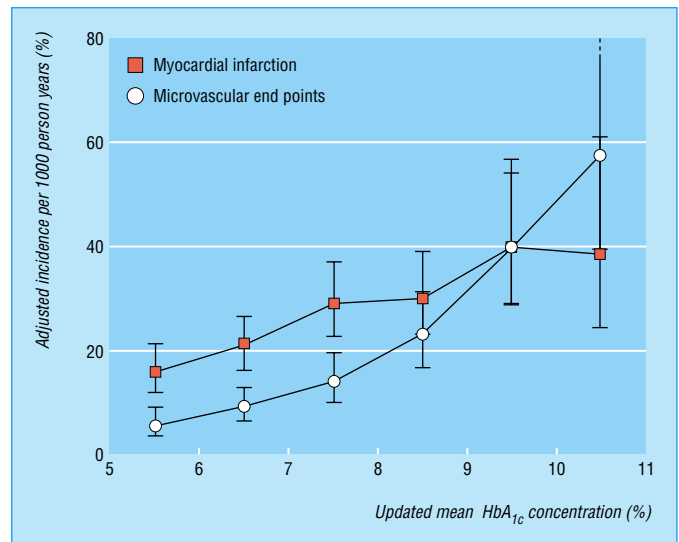

Glycaemic control was also shown to reduce the evolution of microalbuminuria after nine years, and the loss of vibration perception after 15 years of the study. Tight blood glucose control had a non-significant effect on reduction of myocardial infarction, and none on diabetes related mortality.

The DCCT (Type 1 diabetes) demonstrated that primary prevention and retardation of progression of diabetic complications can be achieved over a decade if tight diabetic control is achieved. Retinopathy, nephropathy, and neuropathy were reduced by 35-70% if HbA_{1c} was maintained around 7%. Maintaining tight control requires optimisation of insulin regimen and diet (see chapters 5 and 6), careful blood glucose monitoring, and substantial professional support.

Five years after termination of the DCCT, the EPIC study showed that, despite lapse of the earlier tight blood glucose control, the benefits with regard to amelioration of complications persisted.

Hypertension

This is the principal underlying risk factor for the development of coronary artery disease leading to myocardial infarction, and increases the risk of strokes and heart failure as well.

Incidence rates and 95% confidence intervals for myocardial infarction and microvascular complications by category of updated mean HbA_{1c} values, adjusted for age, sex, and ethnic group, expressed for white men aged 50-54 years at diagnosis and with mean duration of Type 2 diabetes of 10 years (UKPDS)

Kaplan-Meier plot of aggregate microvascular end points resulting from intensive and less intensive blood glucose control in patients with Type 2 diabetes in UKPDS. Microvascular disease here includes renal failure, death from renal failure, retinal photocoagulation, or vitreous haemorrhage

ABC of Diabetes

It also exacerbates the progression of retinopathy, the evolution of proteinuria, and probably the deterioration of nerve function as well.

The UKPDS (Type 2 diabetes) has shown that for every 10 mm Hg increase in systolic blood pressure:

- any complication related to diabetes is increased by 12%
- deaths related to diabetes are increased by 15%
- myocardial infarction is increased by 11%
- microvascular complications are increased by 13%.

By achieving a mean blood pressure of 144/82, representing a reduction of systolic blood pressure of 10 mm Hg compared with the less intensively treated group, microvascular end points (chiefly the need for photocoagulation) were reduced by 37%, and risk of vision declining by three lines on the Snellen chart was reduced by 47%, chiefly by protection from the development of macular disease.

Better control of blood pressure also resulted in a 32% reduction in deaths related to diabetes, and a 44% reduction in strokes; there was a non-significant reduction in myocardial infarction.

Further details on the benefits of good blood pressure control in general and on established nephropathy in particular are described in chapters 16 and 17.

Smoking

This exacerbates all the complications of diabetes, both microvascular and macrovascular.

Dyslipidaemias

These increase the propensity to macrovascular disease; targets for control are described in chapter 17.

The presence of the above factors in combination additively increases the risks of developing complications.

Targets for control and reduction of risk factors

Blood glucose

The facility for patients to measure their own blood glucose empowers them to achieve optimal control by their own interventions. The aims are as follows:

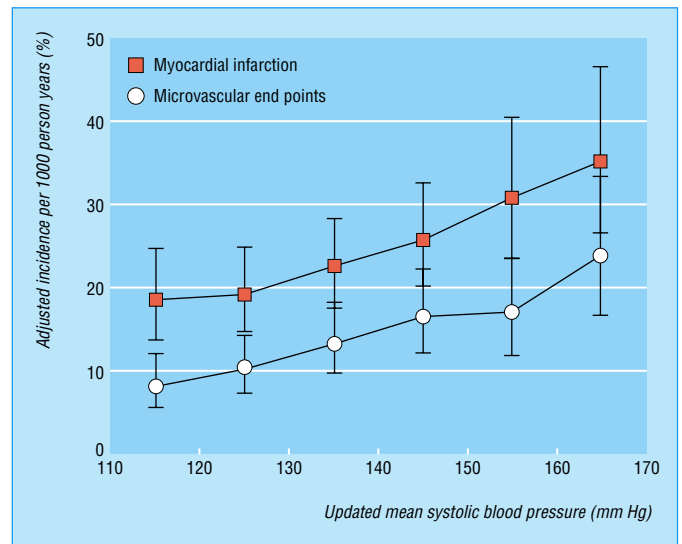

- Type 1 diabetes: achieve preprandial blood glucose readings mainly in the range 4.5-7.7 mmol/l, postprandial readings in the range 6.0-9.0 mmol/l, and 7.0-9.0 mmol/l at bedtime, and preferably never below 4.0 mmol/l to avoid blunting of hypoglycaemic awareness.
- Type 2 diabetes: fasting < 5.5 mmol/l; postprandial < 9.0 mmol/l.

Glycated haemoglobin

Aim for an HbA_{1c} < 6.5% (normal value 4.0-6.0%) as an ideal, since values > 7% are increasingly associated with development of all microvascular and macrovascular complications, and reduction of HbA_{1c} has been shown to diminish microvascular complications substantially (see below). Values up to 8% are acceptable in those who cannot readily achieve the ideal (and there are many). When HbA_{1c} values exceed 9%, additional education and counselling should be attempted although even then patients may not succeed, and some show no inclination to do so.

Blood pressure

Targets for control are described in chapter 17.

Incidence rates (95% confidence interval) of myocardial infarction and microvascular end points by category of updated mean systolic blood pressure, adjusted for age, sex, and ethnic group expressed for white men aged 50-54 years at diagnosis and mean duration of Type 2 diabetes of 10 years (UKPDS)

The benefits of controlling glycaemia required persistently good control over a decade; benefits of successful blood pressure control were witnessed after approximately 4 to 5 years

Targets for glycaemic control suggested by the European Diabetes Policy Group

	Low risk	Arterial risk	Microvascular risk
HbA _{1c} %	≤ 6.5	> 6.5	> 7.5
<i>Venous plasma glucose</i>			
Fasting/preprandial			
mmol/l	≤ 6.0	> 6.0	≥ 7.0
mg/dl	< 110	≥ 110	≥ 126
<i>Self-monitored blood glucose*</i>			
Fasting/preprandial			
mmol/l	≤ 5.5	> 5.5	> 6.0
mg/dl	< 100	≥ 100	≥ 110
Postprandial or peak			
mmol/l	< 7.5	≥ 7.5	> 9.0
mg/dl	< 135	≥ 135	> 160

*Fasting capillary blood glucose is about 1.0 mmol/l (18 mg/dl) lower than venous plasma blood glucose. Postprandial capillary blood glucose is about the same as venous plasma blood glucose

Weight

Body mass index < 25 is ideal; 27 acceptable; greater than 30 represents obesity.

Lipids

Targets for control are described in chapter 17.

Smoking

Aim: to stop smoking.

Complications screening programme

Detection of the earliest signs of diabetic complications is an essential requirement of diabetes care leading to early preventive and treatment strategies which can abort progression of some of the most serious consequences.

Screening is ideally performed as a structured service undertaken by nurses and technicians outside the process of professional consultation, which should be informed by printed results from the screening programme. Screening should be performed at onset and then annually, from the onset of diabetes in all diabetic patients. Complications in Type 1 diabetes, however, are unlikely to develop during the first five years after diagnosis, so that the complete annual screening protocol can be deferred for a short time. The screening programme can be performed wherever appropriate facilities exist. Once complications are present and established, more frequent screening or treatment, or both may be needed.

Eye screening requires specialist equipment and is often undertaken as a community responsibility, and there are strong representations that there should be a national screening programme. Detection and prevention of foot problems linked to delivery of adequate community podiatry services is also crucial and highly effective in preventing serious foot disorders.

The annual complications screening programme

This comprises:

- weight (height): body mass index
- blood pressure
- eye examination (visual acuity, fundoscopy, and photography)
- foot examination:
 - check for deformities, abrasions and ulcers
 - sensation (monofilament tests, and other sensory modalities if available, see pages 52 and 63)
 - palpate foot pulses
- blood tests: HbA_{1c}; lipid profile; creatinine
- urine tests: strip tests for proteinuria or microalbuminuria (if either of these are positive, total 24 hour proteinuria or the albumin creatinine ratio (ACR) should be measured, preferably on an early morning urine sample)
- assessment of smoking status.

Other complications

Necrobiosis lipoidica diabetorum

Necrobiosis is an uncommon and unsightly blemish of the skin which chiefly affects diabetic women. It is unrelated to microvascular complications. The shin is the most common site. The lesions show rather atrophic skin at the centre with obviously dilated capillaries (telangiectasis) and a slightly raised pinkish rim; ulceration sometimes occurs. The lesions are indolent and rarely resolve. There is no effective treatment although steroid applications and even injection have been attempted.

Necrobiosis lipoidica diabetorum

Necrobiosis lipoidica diabetorum (close up)

ABC of Diabetes

Cheiroarthropathy

The development of tight, waxy skin, probably as a result of glucose related alteration of collagen structure, leads to some limitation of joint mobility. A relatively common yet symptomless consequence of these skin changes is the development of some fixed curvature of the fingers which may typically be seen in some patients with long-term diabetes. Those affected are unable to place the palm of the hand on a flat surface. The characteristic appearance is shown in the illustration on the right.

Cheiroarthropathy

11 Retinopathy

Blindness is one of the most feared complications of diabetes, but also one of the most preventable. Diabetes is the commonest cause of blindness in people aged 30 to 69 years. Twenty years after the onset of diabetes almost all patients with Type 1 diabetes and over 60% of patients with Type 2 diabetes will have some degree of retinopathy, and even at the time of diagnosis of Type 2 diabetes, approximately one-quarter of patients already have established background retinopathy. As treatment is now available to prevent blindness in the majority of cases, it is essential to identify patients with retinopathy before their vision is affected.

Classification of retinopathy

Diabetic retinopathy is due to microangiopathy affecting the retinal precapillary arterioles, capillaries, and venules. Damage is caused by both microvascular leakage due to break down of the inner blood-retinal barrier and microvascular occlusion. These two pathological mechanisms can be distinguished from each other by fluorescein angiography, which is the “gold standard” for assessing diabetic retinopathy.

Background retinopathy

Microaneurysms are small saccular pouches possibly caused by local distension of capillary walls. They are often the first clinically detectable sign of retinopathy, and appear as small red dots commonly temporal to the macula.

Haemorrhages may occur within the compact middle layers of the retina, and appear as “dot” or “blot” haemorrhages, or

Frequency of retinopathy (any degree) and proliferative retinopathy by duration of diabetes in people receiving or not receiving insulin, and who were diagnosed to have diabetes at or after 30 years of age

Fluorescein angiogram showing normal eye

Fluorescein angiogram showing capillary closure

Fluorescein angiogram showing capillary leakage with macular oedema

Microaneurysms, haemorrhages, and exudates

ABC of Diabetes

rarely, in the superficial nerve fibre layer where they appear as “flame shaped” haemorrhages (the latter better recognised as related to severe hypertension).

Hard exudates are yellow lipid deposits with relatively discrete margins. They commonly occur at the edges of microvascular leakage, and may form a “circinate” pattern around a leaking microaneurysm. They may coalesce to form extensive sheets of exudate. Vision is affected when hard exudates encroach upon the macula.

Retinal oedema is due to microvascular leakage and indicates breakdown of the inner blood-retinal barrier. It appears clinically as greyish areas of retinal thickening, and may assume a petal-shaped cystoid appearance at the macula, where it may cause marked visual deterioration.

Clinically significant macular oedema (CSMO) requires treatment. It is defined as any one of the following:

- retinal oedema within 500 µm (one-third of a disc diameter) of the fovea
- hard exudates within 500 µm of the fovea, if associated with adjacent retinal thickening
- retinal oedema that is one disc diameter (1500 µm) or larger, any part of which is within one disc diameter of the fovea.

Twenty percent of eyes with untreated CSMO will suffer significant visual loss in two years compared with 8% of treated eyes.

Pre-proliferative retinopathy

Retinal ischaemia due to microvascular occlusion may lead to neovascular proliferation. Signs of ischaemia include:

- cotton wool spots, which appear as white patches with rather feathery margins and represent nerve fibre layer microinfarcts; they become highly significant when there are more than five
- large dark “blot” haemorrhages
- venous beading and looping
- intraretinal microvascular abnormalities (IRMA).

Proliferative retinopathy

New vessel formation may occur at the optic disc (NVD) or elsewhere on the retina (NVE). Disc new vessels are particularly threatening to vision and if allowed to progress commonly lead to vitreous haemorrhage. If untreated, 26% of eyes with “high-risk” and neovascular proliferation on the disc will progress to severe visual loss within two years. With laser treatment this is reduced to 11%.

Advanced eye disease

In advanced proliferative diabetic retinopathy, progressive fibrovascular proliferation leads to blindness due to vitreous haemorrhage and traction retinal detachment. Rubeosis iridis and neovascular glaucoma occur when new vessels form on the

Exudative maculopathy

Disc new vessels (NVD)

New vessels elsewhere (NVE)

Rubeosis iridis

iris and in the anterior chamber drainage angle, leading to a most painful blind eye which occasionally requires enucleation.

Blindness in diabetic patients

Vision-threatening retinopathy is usually due mainly to neovascularisation in Type 1 diabetes and maculopathy in Type 2 diabetes. In North America, 3.6% of patients with Type 1 diabetes and 1.6% of patients with Type 2 diabetes are legally blind. In England and Wales about 1000 diabetic patients are registered as blind or partially sighted each year, with diabetic retinopathy being the commonest cause of blindness in the working population.

Vitreous haemorrhage occurs suddenly and painlessly. The blood usually clears over the following weeks, but the underlying proliferative retinopathy causes repeated haemorrhages and progressive visual loss in most cases if it is not treated. Retinal detachment resulting from contracting fibrous bonds sometimes causes blindness.

Maculopathy: Macular disease has three causes in diabetic patients—exudative maculopathy, retinal oedema, and ischaemia. Deterioration of vision in these situations is often insidious, it can to some extent be prevented by appropriate laser treatment, but once vision has been lost it cannot be restored. Ischaemic maculopathy due to loss of perifoveal capillaries may cause severe visual loss and is very difficult to treat.

Cataract: Lens opacities or cataract develop earlier in diabetic patients and often progress more rapidly.

Primary open-angle glaucoma has an increased prevalence in diabetic patients compared with the general population.

Prevention of blindness

The presence of retinopathy must be actively sought by physicians because, if detected early enough, blindness can be prevented in many cases by treatment with laser photocoagulation. The indications for laser treatment are:

- NVD or NVE; advanced pre-proliferative changes
- clinically significant macular oedema as defined above
- encroachment of hard exudates towards the fovea.

Chronic vitreous haemorrhage which precludes a view of the retina can be treated by vitrectomy and endolaser. Tractional retinal detachment can be managed by vitrectomy with the use of heavy liquids and silicone oil. Restoration of visual acuity can be impressive, but is dependent on the underlying condition of the retina itself.

Clinical examination of the eyes and screening

(For further details on screening see page 45)

Visual acuity and retinal examination should be performed annually on all diabetic patients after 12 years of age, or more often if advancing changes are observed. Vision-threatening retinopathy rarely occurs in Type 1 diabetes in the first five years after diagnosis or before puberty. However, more than one-quarter of Type 2 diabetic patients have been found to have retinopathy at diagnosis, and screening should start immediately.

Visual acuity should be checked annually, or more often if significant retinopathy is present or if it has changed

Advanced eye disease—Retinitis proliferans

Recent argon laser photocoagulation

Longstanding photocoagulation scars

ABC of Diabetes

unexpectedly. This should be done with patients wearing their spectacles or through a “pinhole” if they are not.

Retinal examination. Routine fundal examination should be performed on all diabetic patients, using fundoscopy or retinal photography or preferably both. The pupils should be dilated and the fundus examined in a darkened room. Tropicamide 1% (Mydracil) eye drops are recommended as they have a short duration of action of just two to three hours. There is no reason to avoid pupillary dilatation in patients being treated for chronic open-angle glaucoma, although those on treatment for closed-angle glaucoma must not undergo pupillary dilatation.

Once background retinopathy is present the patients should be examined every six to 12 months or more often if there is any change of visual acuity, and referred to an ophthalmologist when indicated (see box). Pregnant patients require more frequent follow up as retinopathy may progress rapidly during pregnancy (see page 78).

Screening methods

Conventional examination, using an ophthalmoscope in a darkened room with the pupil dilated is a minimum requirement. Observers must be well trained, but even consultant ophthalmologists do not achieve the required 80% sensitivity.

Retinal photography through dilated pupils. The preferred method now uses digital photography which yields suitable images which can be electronically stored, making them easily available for consultation, review, and teaching. Conventional colour photographs also provide good images, whereas the quality of Polaroid photographs is less than ideal.

It would be ideal to provide both conventional fundoscopic and photographic screening procedures, and there is already some evidence that the combined screening procedure reduces the failure rate. A national screening programme has been proposed and has already been adopted in Wales.

The blind diabetic patient

Blind registration is available for those patients with visual acuity of less than 3/60 in their better eye or gross field defects, affording some financial help and social service support. Patients with a visual acuity of less than 6/60 in their better eye are eligible for registration as partially sighted. They must be registered by an ophthalmologist using the BD8 form. Printing in braille is valuable but many diabetic patients have impaired fine sensation in their fingertips, making it difficult for them to read it. Insulin “pens”, in which palpable clicks correspond to units of insulin are valuable for blind patients.

Pin hole

Digital camera used for retinal photography

Indications for referral to an ophthalmologist

- Reduced visual acuity from any cause
- Presence of proliferative or pre-proliferative changes
- Presence of clinically significant macular oedema
- Presence of hard exudates near the macula
- Presence of any form of progressing or extensive diabetic retinopathy especially when the lesions are near the macula

The figure showing frequency of retinopathy is adapted from Pickup JC, Williams G, eds. *Textbook of diabetes*, 2nd ed, Oxford: Blackwell Scientific Publications, 1997.

12 Peripheral neuropathies

Diabetic neuropathies constitute a diverse group of conditions. The commonest is a diffuse polyneuropathy which damages distal peripheral nerves (chiefly affecting the feet), together with the autonomic nervous system. The dying back of axons is associated with segmental demyelination. Polyneuropathy is a classic diabetic complication developing mainly in those with poor diabetic control, progressing (albeit at very variable rates) as the duration of diabetes lengthens and often, but not always, associated with other long-term diabetic complications. In contrast, mononeuropathies and acute painful neuropathies run a well-defined course from the relatively acute onset to almost complete recovery in six to 18 months. These reversible neuropathies, which may be the reason for initial presentation of diabetes, can occur after any duration of diabetes, are commoner in Type 2 diabetic men, and are not necessarily associated with other diabetic complications.

Pressure neuropathies are commoner in those with diabetes and include carpal tunnel syndrome (median nerve), ulnar neuropathy, and rarely foot drop (lateral popliteal nerve).

Symmetrical sensory neuropathy

Diffuse neuropathy affects peripheral nerves symmetrically, chiefly those of the feet and legs. It is almost always sensory, though motor involvement causing weakness, and wasting does occur rarely. Peripheral neuropathy is common in long-standing diabetic patients, but in Type 2 diabetic patients it may already be present at the onset of diabetes. Progression of neuropathy is reduced by good control of diabetes over many years. The potential of pharmacological agents to alter the course of neuropathy has been extensively studied, but so far none of the drugs investigated has demonstrated convincing clinically significant benefit.

Neuropathy is usually symptomless and therefore a hazard to the unwary patient, who is at risk of foot injury and infection. In more advanced neuropathies the patient is aware of sensory loss; numbness (and in some, a sensation of coldness) may progressively worsen until there is almost complete anaesthesia below the knee associated with proprioceptive loss which makes patients feel quite unsafe, but this is not common. Paraesthesiae are quite often described by patients: they range from a persistent minor inconvenience to a source of considerable discomfort and even pain needing medication to alleviate the symptoms. Management of painful neuropathy is described on page 57.

Neurological examination almost always reveals absent ankle reflexes, and only rarely absent knee reflexes. Diminished light-touch and vibration perception are common and by careful examination can be shown to occur at an almost identical level in both legs, hence the description of “stocking” neuropathy. Some patients demonstrate a highly selective form of sensory impairment with gross loss of pain and thermal sensation (accompanied by severely abnormal autonomic function tests) while light-touch and vibration perception remain almost intact. Such a dissociated sensory loss can cause some confusion in the clinical assessment of neuropathy. Impairment of joint position sense is extremely unusual except in the most advanced cases. Further details of clinical sensory assessment are described on page 63.

Diabetic neuropathies

Progress

- Diffuse polyneuropathy
 - Symmetrical sensory neuropathy
 - Autonomic neuropathy

Recover

- Mononeuropathies
 - Proximal motor (femoral) neuropathy
 - Radiculopathies (especially truncal)
 - Cranial nerve palsies
- Acute painful neuropathies

Diabetic neuropathies

	Recover	Progress
	Mononeuropathies/ painful neuropathies	Sensory/autonomic neuropathy
Onset	acute	gradual
Duration of diabetes mellitus	any	long standing
Other complications	none	often
Sex	M > F	M = F*
Diabetes mellitus	Type 2 > Type 1	Type 1 = Type 2*

*Symptomatic autonomic neuropathy occurs chiefly in female Type 1 diabetic patients

Symmetrical sensory neuropathy

Testing vibration perception at the medial malleolus with a Rydell Seifer quantitative tuning fork

Testing light-touch sensation with a monofilament

Neuropathy and the hands

Diabetic neuropathy rarely causes symptoms in the hands, and when it does the disease is already advanced in the feet and legs. Numbness and clumsiness of the fingers are thus very unusual and more likely to be due to some other neurological disorder. Impairment of sensation is, however, enough to prevent blind diabetics from reading braille. Paraesthesiae and numbness in the fingers, especially at night, are usually due to carpal tunnel syndrome, which is commoner than in non-diabetics. It is easily and effectively relieved by minor surgery performed under local anaesthetic without admission to hospital.

Interosseous muscle wasting, especially of the first dorsal interosseous, is often seen. It is usually due to ulnar nerve compression at the elbow, and typical sensory defects in the fourth and fifth fingers are detectable. It causes little disability and there is no satisfactory treatment. Patients are advised not to lean on their elbows, thereby avoiding further damage to the ulnar nerve.

Neuropathy and the feet

Reduced sensation in the feet may result in unnoticed trauma from ill-fitting shoes, nails or stones when walking barefoot, or burns from hot water bottles or sitting too close to a fire. Self-inflicted wounds from crude attempts at chiropody are dangerous because they often become infected. Proprietary corn cures which contain salicylic acid can cause ulceration, sepsis and necrosis, and should never be used. Diabetic foot disorders are described in chapter 15.

Features of neuropathy of the hands

- Inability to read braille
- Carpal tunnel compression
- Ulnar nerve compression

Interosseous muscle wasting

13 Autonomic neuropathy

Diffuse damage to both parasympathetic and sympathetic nerves, probably developing in that order, is common in diabetic patients with diffuse peripheral neuropathy. Fortunately the disabling symptoms which result are not common, and even when they do occur some of them, especially diarrhoea, vomiting, and postural hypotension, are curiously intermittent.

Gastrointestinal system

Diarrhoea

This is a catastrophic watery diarrhoea with severe nocturnal exacerbations and faecal incontinence, preceded momentarily by characteristic abdominal rumblings. Malabsorption does not normally occur. The symptoms are intermittent, with normal bowel actions in between, and sometimes even constipation. These features persist for months or years, rarely disappearing altogether. The diagnosis is made, firstly, by excluding other causes of diarrhoea such as coeliac disease or pancreatic malfunction, and secondly, by establishing the presence of peripheral and autonomic neuropathy. The diarrhoea may be treated with any antidiarrhoeal agent, the best of which is codeine phosphate. Tetracycline in two or three doses of 250 mg has a dramatic effect in about half of patients; it should only be used at the onset of an attack. Some authorities suggest the use of tetracycline or metronidazole for two to three weeks but long-term antibiotics are not indicated. Clonidine can be tried but is of little value; octreotide can be effective but side effects are common.

Gastroparesis

Diminished gastric motility and delayed stomach emptying sometimes occur in diabetic patients with autonomic neuropathy, but rarely cause symptoms. Intermittent vomiting may occur, and in exceptional cases it is intractable. The diagnosis is established by the presence of a gastric splash, impaired gastric emptying on investigation by isotopic techniques, and screening during barium studies; endoscopy and other investigations are needed to exclude other gastric disorders. Any antiemetic can be useful, including metoclopramide or domperidone. Erythromycin acting as a motilin agonist has been used but is only of value when used intravenously. In the very rare cases of intractable vomiting, percutaneous endoscopic jejunostomy can help, and even more rarely radical surgery by two-thirds gastrectomy with Roux-en-Y loop may be required and can succeed.

Cardiovascular system: postural hypotension

Postural hypotension is defined by a fall in systolic blood pressure on standing of more than 20 mm Hg. Development of symptoms depends both on the actual fall of blood pressure (usually greater than 30 mm Hg) and on the actual systolic blood pressure when standing, which becomes impossible if it is less than 70 mm Hg. When assessing postural hypotension, the blood pressure should be taken with the patient lying down,

Insulin exacerbates postural hypotension

ABC of Diabetes

and the standing reading taken over approximately three minutes during which the time blood pressure continues to fall.

Treatment is only needed if symptoms occur and if they are troublesome, which is rare. Patients should stop drugs which might aggravate hypotension (notably tranquillisers, antidepressants, and diuretics), sleep with the head of the bed raised, and wear full length elastic stockings. The best results are obtained from measures which increase plasma volume, namely a high salt intake and fludrocortisone (increasing the dose slowly from 0.1 to 0.4 mg). Treatment failures are common, and the oedema which results from treatment may be disagreeable. Successful treatment has been reported with indomethacin; a combination of fludrocortisone, flurbiprofen, and ephedrine may help. Midodrine is an α agonist which is also of value and available on a named patient basis.

Gustatory sweating

Facial sweating (including scalp, neck, and shoulders) which occurs while eating tasty food, notably cheese, is a common symptom of autonomic neuropathy. Once present, it seems to persist indefinitely, although amelioration after renal transplantation occurs for no known reason.

When it becomes a severe embarrassment with sweat rolling down the face and chest at every meal, it can be effectively treated with an anticholinergic agent, namely propantheline bromide, although side effects are common, or by a topical application of glypyrronium powder. The cream should be applied on alternate days to the areas affected by sweating, avoiding contact with the mouth, nose, and eyes. The area should not be washed for four hours after application. Systemic absorption is low and the only contraindication is narrow-angle glaucoma, as there is the possibility of accidental direct instillation into the eye. Although recommended to be given on alternate days, many patients prefer to use it only on social occasions.

Respiratory arrests

Transient respiratory arrest occurs sometimes if susceptible neuropathic patients are given any agent which depresses respiration, notably anaesthetics or powerful analgesics such as morphine and its derivatives. These patients must be monitored carefully even during minor surgery. Rare unexplained deaths in patients with established autonomic neuropathy may be due to respiratory arrest.

Neurogenic bladder

Urinary retention is a serious and usually late complication of autonomic neuropathy. Apart from the discomfort, intractable urinary infections may develop. The diagnosis of bladder retention is now simple using ultrasound techniques.

Cystoscopy may be needed to exclude other causes of bladder neck obstruction. Treatment is now by self catheterisation two or three times daily.

Erectile dysfunction

Erectile dysfunction is a common problem, occurring more often in those with diabetes than in others, and is due to neuropathy or peripheral vascular disease, or both. It is also frequently has psychogenic causes and some drugs can also be responsible. It is important that appropriate advice and treatment is sought from trained counsellors.

Treatment of hypotension

- Stop drugs that may aggravate hypotension
- Sleep with head of bed raised
- Wear full length elastic stockings
- Appropriate medication

Gustatory sweating. The sweating is highlighted by starch-iodide powder

Grossly enlarged bladder before (left) and after (right) micturition

Autonomic neuropathy causes erectile impotence, which is permanent and irreversible. Retrograde ejaculation can also occur. The onset of organic impotence in neuropathy is always gradual, progressing over months or even years. Erectile ability fails first, and ejaculation declines later. Nocturnal erections are absent in these patients, whereas they are often retained in psychogenic impotence. It is often difficult to distinguish between organic and psychogenic erectile dysfunction in diabetic patients. The presence of peripheral and autonomic neuropathy makes an organic cause more likely, especially when other autonomic symptoms are present. After a full clinical examination, patients complaining of erectile dysfunction have free testosterone and serum prolactin levels measured in order to exclude other disorders, but levels are usually normal in patients with erectile dysfunction due to diabetes. There is no cure for autonomic impotence. Hormone treatment with testosterone is useless because it serves only to increase libido without improving erectile ability. In many cases, careful explanation of the cause to the affected couples will allay their fears and anxieties.

Treatment of erectile dysfunction

Diabetes centres should now offer a specialist service for advice on management of patients with erectile dysfunction. This should include psychosexual therapy which can succeed in 50% to 80% of patients who are well motivated and is also of value in conjunction with specific treatments.

Several effective specific treatments are now available: oral sildenafil is generally the first choice, and sublingual apomorphine serves as a second choice.

Oral sildenafil

This can be successful in almost two-thirds of the diabetic patients treated, which is rather less than in non-diabetic people where even higher rates of success have been reported. It is taken half to one hour before sexual activity (initial dose 50 mg; subsequently 50 to 100 mg according to response; not to be used more than once in 24 hours). Sexual stimulation and foreplay are necessary for it to be effective. It is contraindicated in those taking nitrates, those whose blood pressure is less than 90/50 mm Hg, after recent stroke or myocardial infarction, or in other situations where sexual activity is inadvisable. There are several potential side effects which are rarely troublesome (see *BNF*).

Sublingual apomorphine

This is rapidly absorbed and acts as a dopamine agonist. It is effective within 10 to 20 minutes, requiring sexual stimulation at the same time. The dose range is 2 to 3 mg. It is effective in approximately 50% of diabetic patients.

Prostaglandin preparations

Transurethral alprostadil can provide erections adequate for intercourse. An applicator for direct urethral application is provided.

Intracavernosal injection: alprostadil is now used less than previously but can be effective; modern injection systems have made its use acceptable. The side effects and contraindications are described in the *BNF*.

Vacuum devices

An external cylinder is fitted over the penis, enabling air to be pumped out, resulting in penile engorgement which is sustained by application of a ring fitted to the base of the penis. This technique is suitable for a wide range of patients and is

Features of erectile dysfunction

- Vacuum devices
- Penile prostheses

Intracavernosal injection of alprostadil

successful in most cases of erectile dysfunction, although when the problem is of long standing several attempts may be necessary before a successful erection is achieved.

Penile prostheses

Semirigid, malleable prostheses can be surgically inserted and are particularly valuable for younger patients with confirmed and permanent neuropathic impotence. Ejaculation in some patients is retained.

Diagnosis of autonomic neuropathy

Gustatory sweating is the only symptom which is almost pathognomic of diabetic autonomic neuropathy. Peripheral neuropathy (at least absent ankle jerks) must be present before the diagnosis can be made. A resting tachycardia, postural hypotension, or a gastric splash may be present.

Beside cardiovascular tests for autonomic neuropathy are now well established: their most important role is probably in the exclusion of autonomic neuropathy. Normal and abnormal values are shown the table.

The loss of heart rate variability during deep breathing due to vagal impairment is the most reliable and simplest test of autonomic neuropathy. It is best assessed using a cardiograph during deep respirations (six breaths per minute) taking average readings during six breaths; it can also be performed using an ordinary electrocardiograph during a single deep breath (five seconds in, five seconds out). The heart rate difference (maximum rate during inspiration minus minimum rate during expiration) in those under 55 years old is always greater than ten. Heart rate increase on standing up should be assessed, and there should normally be an overshoot as well.

The Valsalva manoeuvre can be included among the tests: a mercury sphygmomanometer is used, the patient blowing hard into the empty barrel of a 20 ml syringe to maintain the mercury column at 40 mm Hg for 10 seconds. Maximum heart rate during blowing, followed by minimum heart rate after cessation, are recorded. There should be a bradycardia after cessation of blowing; the ratio of maximum : minimum heart rate is normally greater than 1.21 and clearly abnormal when less than 1.10. The Valsalva test should not be performed in those with proliferative retinopathy. Many other sophisticated tests need special equipment.

The figure showing the intracavernosal injection of alprostadil is from Tomlinson J, ed. *ABC of Sexual Health*. London: BMJ Publishing Group, 1999.

Normal values for autonomic function tests*

	Normal	Abnormal
Heart rate variation (deep breathing) (beats/min)	> 15	< 10
Increase in heart rate on standing (at 15 seconds) (beats/min)	> 15	< 12
Heart rate on standing 30 : 15 ratio	> 1.04	< 1.00
Valsalva ratio	> 1.21	< 1.20
Postural systolic pressure fall at 2 min	< 10 mm Hg	> 30 mm Hg

*These test results decline with age. The figures apply generally in those less than 60 years old.

Heart rate changes in a normal subject (left) and a patient with autonomic neuropathy (right) showing loss of heart rate variation in autonomic neuropathy during deep breathing, at six breaths a minute (top), and loss of "overshoot" cardiac acceleration on standing (bottom)

14 Mononeuropathies and acute painful neuropathies

The rapid onset, severity, and eventual resolution of mononeuropathies contrast sharply with the long-term nature and irreversibility of diffuse peripheral neuropathy. The two forms of neuropathy occur quite independently of each other. Mononeuropathies are more frequently seen in Type 2 diabetic men and may even occur as the presenting symptom of diabetes.

Acute painful neuropathies

Acute painful neuropathies begin relatively acutely at any stage of diabetes, sometimes paradoxically eight to 12 weeks after starting insulin, or as the presentation of Type 2 diabetes. The acute and persistent pain can be disabling. Distribution of the pain is radicular over the territory of several adjacent nerve roots, affecting either the legs or the abdominal wall (the latter very rarely accompanied by muscle bulging from motor weakness). The thighs are affected in patients with femoral neuropathy. Both feet and legs can be affected symmetrically in a “stocking” distribution. Patients usually recover from these neuropathies in a period of six to 18 months. These neuropathies occur independently of peripheral sensory or autonomic neuropathy.

The pain causes exceptional distress because it is protracted and unremitting. Constant burning sensations, paraesthesiae or shooting pains occur, but the most characteristic symptom is a cutaneous hypersensitivity (allodynia) leading to acute discomfort on contact with clothing and bedclothes. The pain leads to insomnia and depression, and is sometimes accompanied by catastrophic weight loss. Patients are so distressed that they may seek several opinions on their condition, and often believe that they must have a malignant disease.

Treatment

This is difficult, but above all, the promise that the symptoms always eventually remit may sustain patients during the wretched months of their illness. It sometimes helps for them to meet a patient who has already recovered from neuropathic pain. Diabetic control should be optimal, and insulin should be given if necessary. Initially, simple analgesics such as paracetamol taken regularly should be tried. Tricyclic antidepressants have a specific effect in the management of neuropathic pain and are valuable in this condition: a useful combination is a preparation containing a phenothiazine (fluphenazine) with nortryptiline (Motival). Gabapentin is effective and carbamazepine may help. Capsaicin cream may have a small effect after itself causing some initial discomfort. Topiramate may be used for limited periods in those with severe and protracted pain. Drugs of addiction should be avoided although just occasionally and for a short period an opioid derivative can be used at bedtime to help distressed patients to sleep.

Application of Opsite (a thin adhesive film) can help alleviate contact discomfort. Electrical nerve stimulators applied to the site of pain may help, and patients can then take an active part in their treatment.

Diabetic radiculopathy area of exquisite contact sensitivity can easily and reproducibly be traced with a finger—shown in red

Bulging of the abdominal wall in a patient with truncal radiculopathy

Progression of acute painful neuropathy

Femoral neuropathy

(proximal motor neuropathy or diabetic amyotrophy)

Pain with or without wasting in one or both thighs is the cardinal feature of this disagreeable condition. The quality of the pain is similar to that in painful peripheral neuropathy described above, and management is along similar lines. The knee jerk is absent while the ankle jerk is often retained. Sensation in the thigh may be altered or impaired. In some cases, motor weakness in the thigh is profound, causing falls. Other neurological disorders must be considered and excluded. Full recovery within about one year is the rule. Active physiotherapy may be needed to strengthen the wasted thigh muscles and restore mobility.

Cranial nerve palsies

Third and sixth nerve palsies presenting with diplopia of sudden onset are characteristic. Pain behind the eye occurs sometimes in third nerve palsies; the pupil is usually spared, and ptosis does not normally occur. Full examination and careful follow up are needed, but extensive investigation is not normally required. Complete recovery occurs spontaneously in about three months.

The figure showing recovery from femoral neuropathy is adapted from Coppack SW, et al. *Quart J Med* 1991;79:307-13. The photograph of cranial nerve palsy is reproduced from Spillane, JD. *An atlas of clinical neurology*. Oxford: Oxford University Press.

Recovery from femoral neuropathy

Cranial nerve palsy

15 The diabetic foot

Foot ulceration, sepsis, and amputation are universally known and feared by almost every person on hearing that they have diabetes. Yet at the same time, these are potentially the most preventable of all diabetic complications by the simplest techniques of education and care; and if lesions do occur, the majority can be cured by immediate and energetic treatment, for which good provision must be made.

Diabetic foot disorders

Neuropathy and ischaemia are the principal disorders underlying foot problems. Whenever a patient presents with an active lesion it is essential to decide at an early stage whether the foot problem is:

- (a) neuropathic with an intact circulation
- (b) ischaemic with (usually) or without neuropathy (neuro-ischaemic foot)
- (c) critically ischaemic needing very urgent attention.

A combination of ulceration and sepsis in an ischaemic foot carries a higher risk of gangrene, and early arterial assessment and management are key to avoiding major amputation.

Men of low socioeconomic class are most prone, and Asian patients least liable, to diabetic foot disorders.

Precipitating causes of foot ulceration and infection

- Friction in ill fitting or new shoes
- Untreated callus
- Self treated callus
- Foot injuries (for example, unnoticed trauma in shoes or when walking barefoot)
- Burns (for example, excessively hot bath, hot water bottle, hot radiators, hot sand on holiday)
- Corn plaster
- Nail infections (paronychia)
- Artifactual: rarely, self-inflicted foot lesions are described and occasionally failure to heal is due to this cause
- Heel friction in patients confined to bed: it is essential that all patients confined to bed should have their heels elevated to avoid the friction which regularly causes heel blisters and sepsis, needing weeks or months of treatment, and sometimes requiring major amputation with consequent and very serious medicolegal implications.

Note: Most of the above are avoidable.

Staging the diabetic foot

- 1 Normal
- 2 High risk
- 3 Ulcerated
- 4 Cellulitic
- 5 Necrotic
- 6 Major amputation

Diabetic foot problems

Neuropathic foot

- Painless
- Calluses, ulcers, sepsis, osteomyelitis
- Charcot joints, oedema, good pulses

Critically ischaemic foot

- Painful, pink, cold, no pulses

Corn plaster injury

Foot deformities predisposing to ulceration

- Callus
- Clawed toes
- Bunions
- Pes cavus
- Hallux rigidus
- Hammer toe
- Charcot foot
- Deformities from previous trauma or surgery
- Nail deformities
- Oedema

Heel ulcer

The neuropathic foot

Ulcers develop on the tips of the toes and on the plantar surfaces of the metatarsal heads and are often preceded by callus formation. If the callus is not removed then haemorrhage and tissue necrosis occur below the plaque of callus, leading to ulceration. Ulcers can be secondarily infected by staphylococci, streptococci, gram negative organisms, and anaerobic bacteria, which can quickly lead to cellulitis, abscess formation, and osteomyelitis. Sepsis complicating apical toe ulcers can lead to in situ thrombosis of the digital arteries, resulting in gangrene of the toe. The foot is invariably warm, with intact, often bounding pulses.

The ischaemic (neuro-ischaemic foot)

The absence of foot pulses must always alert physicians to the possible presence of ischaemia which requires specific assessment and often treatment as well. Lesions on the margins of the foot and absence of callus are characteristic features. Gangrene may be present as well. It is essential to identify critical ischaemia with its characteristic pink, painful (sometimes extreme and persistent pain during day and night) and pulseless, sometimes cold, foot. The ankle/brachial pressure index assessed by Doppler ultrasonography can give a useful guide to the presence or absence of ischaemia (see page 61).

Clinical features	
Neuropathic foot	Ischaemic (neuro-ischaemic)
<ul style="list-style-type: none"> • Warm with intact pulses • Diminished sensation; callus • Ulceration (usually on tips of toes and plantar surfaces under metatarsal heads) • Sepsis • Local necrosis • Oedema • Charcot joints 	<ul style="list-style-type: none"> • Pulseless, not warm • Usually diminished sensation • Ulceration (often on margins of foot, tips of toes, heels) • Sepsis • Necrotic gangrene • Critical ischaemia (urgent attention) foot pink, painful, pulseless and often cold

The pink, painful, ischaemic foot

Neuropathic ulcers

Neuropathic ulcer

Ischaemic ulcer

Management

Infected diabetic foot lesions should be treated only by those with sufficient experience and facilities. General practitioners very rarely have such experience and should normally refer patients for specialist care.

The ulcerated foot

- Arrange urgent foot ulcer care from the specialist foot care team.
- Expect the team to ensure as a minimum:
 - local wound management, appropriate dressings, and debridement as indicated
 - antibiotic treatment as appropriate
 - investigation and management of vascular insufficiency
 - specialist footwear to distribute foot pressures appropriately
 - good blood glucose control.

Treatment of diabetic foot ulcers

Management of the ulcer falls into three parts: removal of callus, eradication of infection, and reduction of weight bearing forces, often requiring bed rest with the foot elevated. Excess keratin should be pared away with a scalpel blade by the

Six aspects of patient treatment
<ul style="list-style-type: none"> • Wound control • Microbiological control • Mechanical control • Vascular management • Metabolic control • Education

Radiograph showing osteomyelitis

podiatrist to expose the floor of the ulcer and allow efficient drainage of the lesion. A radiograph should be taken to assess the possibility of osteomyelitis whenever a deep penetrating ulcer is present, or when lesions fail to heal or continue to recur.

A bacterial swab should be taken from the floor of the ulcer after the callus has been removed; culture of excised tissue may yield even more reliable information. A superficial ulcer may be treated on an outpatient basis, and oral antibiotics prescribed according to the organisms isolated, until the ulcer has healed. The most likely organisms to infect a superficial ulcer are staphylococci, streptococci and sometimes anaerobes. Thus treatment is started with amoxycillin, flucloxacillin, and metronidazole, and adjusted when results of bacteriological culture are available. Choice and duration of antibiotic administration require considerable expertise and laboratory guidance. The patient should be instructed to carry out daily dressing of the ulcer. A simple non-adherent dressing should be applied after cleaning the ulcer with physiological saline.

Deep indolent ulcers also require local wound care and antibiotics; application of a total contact plaster cast, lightweight scotch cast boot or air cast boots which conform to the contours of the foot, thereby reducing shear forces on the plantar surface, may be used. Great care must be taken, especially with the fitting of plasters, to prevent chafing and subsequent ulcer formation elsewhere on the foot or ankle.

Any foot lesion which has not healed in one month requires further investigation and a different approach.

Urgent treatment

- 1 Bed rest.
- 2 Intravenous antibiotics. In the first 24 hours before bacteriological cultures are available it is necessary to provide a wide spectrum of antibiotic cover. Thus quadruple therapy may be necessary consisting of amoxycillin, flucloxacillin with metronidazole (to treat anaerobes), and either ceftazidime 1 g three times daily or gentamicin to treat gram negative organisms. This treatment can be adapted when results of bacteriological culture are available. The emergence of multiple resistant *Staphylococcus aureus* (MRSA) is presenting a very serious problem, firstly because it can be responsible for the ravages of sepsis, and secondly because these patients become "lepers", needing isolation while in hospital. Available treatments include intravenous vancomycin and intramuscular teicoplanin.
- 3 An intravenous insulin pump may be necessary to control the blood glucose.
- 4 Surgical debridement to drain pus and abscess cavities and to remove all necrotic and infected tissue including devitalised and infected bone resulting from osteomyelitis. Deep tissue swabs should be sent to the laboratory. If necrosis has developed in the digit, a ray amputation to remove the toe and part of its associated metatarsal is necessary and is usually very successful in the neuropathic foot with intact circulation. Skin grafting is occasionally needed and accelerates wound healing.

The ischaemic foot

Sepsis in the presence of ischaemia is a dangerous combination and should be treated urgently as described above. When ischaemia is suspected, or an ulcer does not respond to medical treatment, vascular investigation is required.

- Doppler studies to measure the pressure index (the ankle/brachial ratio of systolic blood pressure):
 - pressure index > 1.2 indicates rigid or calcified vessels or both
 - pressure index > 1 is normal (or calcified)

Gross sepsis leading to abscess formation

Danger signs: urgent treatment needed

- Redness and swelling of a foot which even when neuropathic causes some discomfort and pain; this clinical picture often indicates a developing abscess, and urgent surgery may be needed to save the leg
- Cellulitis, discolouration, and crepitus (gas in soft tissues)
- A pink, painful, pulseless foot even without gangrene indicates critical ischaemia which needs very urgent arterial investigation followed by surgical intervention whenever possible

All the above require immediate hospital admission, urgent treatment, and appropriate investigation

Radiograph of atheromatous narrowing of the femoral artery before and after balloon dilatation by angioplasty

ABC of Diabetes

- pressure index < 0.9 indicates ischaemia present
- pressure index < 0.6 indicates severe ischaemia.

Note: Vascular calcification is common so that spuriously high readings can be obtained. This must be taken into account when the pressure index reading is evaluated.

- Arterial imaging by techniques including duplex scanning, magnetic resonance angiography, and conventional arteriography is performed with a view to angioplasty or arterial reconstruction, or both. Infrapopliteal angioplasty or distal bypass to the tibial or peroneal vessels are now well established procedures and are important for limb salvage in the diabetic foot.
- Amputation of the toe is usually unsuccessful in the neuroischaemic foot (in contrast to the neuropathic foot with an intact circulation) unless the foot can be revascularised. If this is not possible, then a dry necrotic toe should be allowed to autoamputate. After attempts to control infection, below knee amputation is indicated in those with rampant progressive infection or extensive tissue destruction.

Rest pain in the severely ischaemic limb can be relieved by successful revascularisation, but if that fails, pain relief with opiates may be necessary. Paravertebral lumbar block has been disappointing in promoting healing, but occasionally rest pain is ameliorated. If all these measures fail and pain remains intractable, then below knee amputation may be needed.

Renal protection during arteriography

The intravenous dye used during angiography can precipitate acute oliguric renal failure in patients with early renal impairment. The following preventive measures should be taken:

- avoid dehydration
- give intravenous fluids starting four hours before the procedure
- intravenous insulin sliding scale should be used
- monitor urine output
- check creatinine before and on the day after the procedure.

Note: Metformin should be stopped 48 hours before an angiographic procedure and resumed 48 hours after the procedure has been completed.

The neuropathic joint (Charcot's joint)

Loss of pain sensation together with possible rarefaction of the bones of the neuropathic foot may have serious consequences; abnormal mechanical stresses usually prevented by pain may occur, and the susceptible bones are then damaged by relatively minor trauma. Patients present with a hot swollen foot, sometimes aching, and the appearances are often mistaken for infection. Injury may have occurred days or weeks earlier, or may not even have been noticed. Sometimes Charcot changes develop after minor amputations which change the normal weight bearing stresses. Radiographs at this stage are normal, but gross damage appears and develops rapidly during the following weeks, leading to gross deformity of the foot. The destructive process does not continue indefinitely but stops after weeks or months. Bony changes are most often seen at the tarsal-metatarsal region of the foot, but they occur also at the ankle or at the metatarso-phalangeal region. Changes at other sites are rare.

Early diagnosis is essential. The initial presentation of unilateral warmth and swelling in a neuropathic foot is extremely suggestive of a developing Charcot joint. Bone scans are more sensitive indicators of new bone formation than radiography and should be used to confirm the diagnosis. It is

Critical ischaemia with ischaemic gangrene of great toe

Duration of known diabetes at time of amputation

The neuropathic Charcot joint

essential to exclude infection as the cause of these changes, where the differential diagnosis can be difficult: a gallium white cell scan and a magnetic resonance imaging scan can help and are appropriate and important investigations.

Management initially comprises rest, ideally bed rest or use of non-weight bearing crutches, until the oedema and local warmth have resolved. Alternatively, the foot can be immobilised in a well moulded total contact plaster which is initially non-weight bearing. Immobilisation is continued until bony repair is complete, usually in two to three months. The use of bisphosphonates in preventing bone damage from occurring in the evolution of the Charcot foot is under investigation and appears promising. In long-term management, special shoes and insoles should be fitted to accommodate deformity and prevent ulceration, which is the major hazard of the Charcot foot.

Neuropathic oedema

Neuropathic oedema consists of swelling of the feet and lower legs associated with severe peripheral neuropathy: it is uncommon. The pathogenesis may be related to vasomotor changes and arterio-venous shunting. Ephedrine 30 mg three times daily has been shown to be useful in reducing peripheral oedema by reduction of blood flow and increase of sodium excretion.

Long-term care after wound healing is complete

Appropriate footwear, ongoing podiatry, and regular reassessment are required.

Footwear

Redistribution of weight bearing forces on vulnerable parts of the foot can be achieved by special footwear. Moulded insoles made from substances with energy absorbing properties such as plastozote and microcellular rubber are suitable for long-term redistribution of weight bearing forces. Special shoes to accommodate the shape of the foot, and moulded insoles are often necessary. In cases of severe deformity, shoes may be constructed individually for the patient. However, in most patients, extra depth “stock” shoes will usually suffice. Failure to wear appropriate shoes is commonly a cause of foot ulceration or recurrence in those who have previously had problems.

Examination of the foot: screening and prevention

The foot must be examined routinely at the onset of diabetes and at every annual review thereafter. The key issues in assessment are listed in order of importance.

Essential

- Patient should be aware of the need for foot care.
- Identify the critically ischaemic foot.
- Active lesions should be sought (for example, hidden lesions between the toes) and treated immediately.
- Deformities, callus, skin cracks, and discoloration need to be detected and managed.
- A simple sensory test should be performed for example, a monofilament sensory test under the great toe (inability to detect 10 g or more indicates risk of foot ulceration).
- Examine the pulses (dorsalis pedis and posterior tibial).

Neuropathic oedema is associated with severe peripheral neuropathy

Isotope bone scans of a normal foot (left) and a neuropathic foot (right) showing high blood flow

Footwear

For everyday use, especially when on your feet for long periods

- Wear a lace-up shoe, with plenty of room for the toes, and either flat or low heeled
- Do not wear slip-ons or court shoes, except for special occasions
- Do not wear slippers at home

Care and preventive measures

- Active lesions should be treated immediately
- Written advice and education on foot care should be provided
- Advice is needed on appropriate shoes to accommodate foot deformities
- Regular podiatry to remove excess callus and provide nail care is essential

ABC of Diabetes

Other assessments

- Assess ankle reflex.
- Assess other sensory modalities for example pinprick, vibration perception at the medial malleolus or tip of the great toe.

Advice and education must follow the examination.

Guidelines for foot care

Low current risk foot

(normal sensation, palpable pulses)

- Individual foot care education.

At risk foot

(neuropathy, absent pulses, or other risk factor described above)

- Enhance foot care education.
- Inspect feet every three to six months.
- Advise on appropriate footwear.
- Review need for vascular assessment.
- If previous ulcer, deformity or skin changes manage as high risk.

High risk foot

(Ischaemia deformity, skin changes, or previous ulcer)

- Arrange frequent review (one to three monthly) from foot care team.
- At each review, evaluate:
 - intensified foot care education
 - specialist footwear and insoles
 - skin and nail care according to need.
- Ensure special arrangements for people with disabilities or immobility.

The ulcerated foot

The care pathway is described on page 60.

Conclusions

Many foot problems can be prevented, and all diabetic patients should be aware of the potential problem of foot damage. Every patient should be issued with information containing straightforward safety instructions.

A good podiatrist must be available for diabetic patients. Ill-fitting shoes are the cause of many problems. New shoes should always be broken in by wearing them initially for only short periods. If the foot is in any way misshapen, for example, from bunions, hammer toes, Charcot deformities or as a result of surgery, shoes must be specially made to fit. It is a great advantage if a shoe fitter attends the chiropody clinic; it is possible to make simple shoes fit on the spot (Dru shoes for example) while awaiting delivery of more elaborate fitted shoes made in a workshop.

Close liaison between the podiatrist, orthotist, nurse, physician, and surgeon is vital in the care of the diabetic foot. The diabetic foot clinic is the optimum forum for provision of intensive podiatry, close surveillance and prompt treatment of foot infection, and the provision of specially constructed shoes.

Care of your feet

DO

- Wash feet daily with mild soap and warm water
- Check feet daily
- Seek urgent treatment for any problems
- See a podiatrist regularly
- Wear sensible shoes

DO NOT

- Use corn cures
- Use hot water bottles
- Walk barefoot
- Cut corns or callosities
- Treat foot problems yourself

Danger signs

- Check your feet every morning
- Come to the clinic *immediately* if you notice
 - Swelling
 - Colour change of a nail, toe, or part of a foot
 - Pain or throbbing
 - Breaks in the skin, including cracks, blisters, or sores

16 Diabetic nephropathy

The development of proteinuria in any diabetic patient is ominous. It is associated with a risk of severe retinopathy and neuropathy, and above all carries a major increased risk in mortality from coronary artery disease, as well as progression to renal failure in some patients. Yet developments in this field to improve the prognosis have been substantial. The overall prevalence of proteinuria in Type 1 diabetes has decreased over half a century from more than 50% of patients down to between 10 and 20%, presumably as a result of better overall diabetic care. Furthermore, at the earliest sign of proteinuria, administration of medication and very tight blood pressure control ameliorate the course of the disease and substantially delay the development of renal failure. And for those who are less fortunate, transplantation and dialysis restore a good quality of life to the majority.

Proteinuria occurs in both Type 1 diabetes and Type 2 diabetes. African-Caribbean and Asian Type 2 diabetic patients have a much higher prevalence of this disease and its associated morbidity.

Cumulative incidence of nephropathy in patients diagnosed with Type 1 diabetes over a 20-year span

Incidence of diabetic nephropathy in Type 1 diabetic patients

Cumulative incidence of coronary heart disease in Type 1 diabetic patients with and without proteinuria

Onset of nephropathy

The earliest detectable development in Type 1 diabetes of small amounts of proteinuria (microalbuminuria) occurs more than five years after diagnosis. Both micro and gross albuminuria are detected at diagnosis in many with Type 2 diabetes, both because diabetes may already be long standing and in some instances because of established hypertension or other renal diseases.

Initiating factors and progression promoters in diabetic nephropathy

Factors leading to initiation and those determining rate of progression of diabetic renal disease are gaining increasing recognition.

Both development and early progression of diabetic nephropathy are most likely to occur following years of poor

Nephropathy—initiating factors and progression promoters

Initiating factors

- Persistently poor diabetic control
- Hypertension in Type 2 diabetes
- Genetic factors

Progression promoters

- Blood pressure
- Proteinuria
- Persistently poor diabetic control
- Dyslipidaemia
- Genetic factors
- Smaller kidneys (or glomeruli)
- Smoking
- High dietary protein

ABC of Diabetes

diabetic control; tight control over a decade both delays onset of the disease and slows progression chiefly of its early phase, although there is some effect in established disease as well. There is also a familial propensity to nephropathy in both Type 1 and Type 2 diabetes, although the precise genetic factors responsible have not been identified.

Stages of nephropathy

Early physiological changes

At the onset of Type 1 diabetes there is evidence of hyperfiltration with increased glomerular filtration rate, and large kidneys and glomeruli. These defects can be reversed by meticulous diabetic control; there is however no good evidence that these changes predispose to the subsequent development of nephropathy.

The most powerful factor in slowing progression of the disease is the skilful and timely use of angiotensin converting enzyme (ACE) inhibitors and angiotensin receptor blockers, together with the strict management of hypertension when it occurs

Stages of progression of diabetic nephropathy

	Normal (I)	Incipient (II)	Persistent (III)	Clinical (IV)	End stage (V)
Albuminuria (mg/24 h)	<20	20-300 (microalbuminuria)	≥300 (up to 15 g/day)	≥300 (up to 15 g/day)	≥300 (can fall)
Glomerular filtration rate (ml/min)	High/normal Hyperfiltration	Normal/high	Normal or decreased	Decreased	Greatly decreased
Serum creatinine (μmol/l)	Normal 60-100	Normal 60-120	High normal 80-120	High 120-400	Very high >400
Blood pressure (mm Hg)	Normal	Slightly increased	Increased	Increased	Increased
Clinical signs	None	None	Anaemia ± oedema, increased blood pressure, may be none	Anaemia ± oedema, increased blood pressure, may be none	Anaemia oedema, increased blood pressure, uraemic symptoms

Course of nephropathy

The natural course of diabetic nephropathy is the progression through five stages from normal renal function to end-stage renal failure as shown in the table. Incipient nephropathy, identified by the appearance of microalbuminuria, is the earliest clinical stage and is not associated with significant clinical signs or any changes other than a very small increase in blood pressure. At this stage urine testing by conventional methods will give negative or only trace positive results.

As the disease progresses albuminuria increases until end-stage nephropathy, when it may decrease; there are wide variations in the amount of protein excretion. The glomerular filtration rate shows a progressive decline, which varies considerably between patients and is usefully assessed by calculating the inverse creatinine value (1/serum creatinine concentration) which can be plotted against time and is generally linear. Blood pressure rises progressively. The nephropathy is commonly asymptomatic until it is advanced, when oedema and breathlessness develop. Anaemia often occurs relatively early in the course of the disease before renal failure is established, and much sooner than in non-diabetic renal disease, as a result of diminished erythropoietin production, which can be corrected by injections of erythropoietin, sometimes with considerable clinical benefit.

Hyperlipidaemia is common in nephropathy, as are other risk factors for vascular disease, including changes in the concentrations of fibrinogen and other clotting factors.
