Care has been taken to confirm the accuracy of the information presented and to describe generally accepted practices. However, the authors, editors, and publisher are not responsible for errors or omissions or for any consequences from application of the information in this book and make no warranty, expressed or implied, with respect to the currency, completeness, or accuracy of the contents of the publication. Application of this information in a particular situation remains the professional responsibility of the practitioner; the clinical treatments described and recommended may not be considered absolute and universal recommendations.

The authors, editors, and publisher have exerted every effort to ensure that drug selection and dosage set forth in this text are in accordance with the current recommendations and practice at the time of publication. However, in view of ongoing research, changes in government regulations, and the constant flow of information relating to drug therapy and drug reactions, the reader is urged to check the package insert for each drug for any change in indications and dosage and for added warnings and precautions. This is particularly important when the recommended agent is a new or infrequently employed drug.

Some drugs and medical devices presented in this publication have Food and Drug Administration (FDA) clearance for limited use in restricted research settings. It is the responsibility of the health care provider to ascertain the FDA status of each drug or device planned for use in his or her clinical practice.

## Purpose

---

The basic precepts underlying previous editions of *Clinical Drug Therapy* also guided the writing of this ninth edition. The overall purpose is to promote safe, effective, and rational drug therapy by

- Providing information that accurately reflects current practices in drug therapy
- Facilitating the acquisition, comprehension, and application of knowledge related to drug therapy. Application requires knowledge about the drug and the patient receiving it.
- Identifying knowledge and skills the nurse can use to smooth the interface between a drug and the patient receiving it

## Goals and Responsibilities of Nursing Care Related to Drug Therapy

---

- Preventing the need for drug therapy, when possible, by promoting health and preventing conditions that require drug therapy
- Using appropriate and effective nonpharmacologic interventions instead of, or in conjunction with, drug therapy when indicated. When used with drug therapy, such interventions may promote lower drug dosage, less frequent administration, and fewer adverse effects.
- Enhancing therapeutic effects by administering drugs accurately and considering patient characteristics that influence responses to drug therapy
- Preventing or minimizing adverse drug effects by knowing the major adverse effects associated with particular drugs, identifying and monitoring patients with characteristics that may increase their risks of experiencing adverse effects, and actively monitoring for the occurrence of adverse effects. When adverse effects occur, early recognition allows interventions to minimize their severity. Because all drugs may cause adverse effects, nurses must maintain a high index of suspicion that signs and symptoms, especially new ones, may be drug induced.
- Teaching patients and caregivers about the role and importance of their medications in treating particular illnesses, accurate administration of medications, nonpharmacologic treatments to use with or instead of pharmacologic treatments, and when to contact a health care provider

## Organizational Framework

---

The content of *Clinical Drug Therapy* is organized into ten sections, primarily by therapeutic drug groups and their effects on particular body systems. This approach helps students make logical connections between major drug groups and the conditions for which they are used. It also provides a foundation for learning about new drugs, most of which fit into known groups.

The first section contains the basic information required to learn, understand, and apply drug knowledge. The chapters in this section include information about drug names, classifications, prototypes, costs, laws and standards, schedules of controlled substances, drug approval processes, and learning strategies (Chapter 1); cellular physiology, drug transport, pharmacokinetic processes, the receptor theory of drug action, types of drug interactions, and factors that influence drug effects on body tissues (Chapter 2); dosage forms and routes and methods of accurate drug administration (Chapter 3); and guidelines for using the nursing process in drug therapy and general principles of drug therapy (Chapter 4).

Most drug sections include an initial chapter that reviews the physiology of a body system, followed by several chapters that discuss drug groups used to treat disorders of that body system. The seven physiology review chapters are designed to facilitate understanding of drug effects on a body system. These include the central nervous system; the autonomic nervous system; and the endocrine, hematopoietic and immune, respiratory, cardiovascular, and digestive systems. Other chapters within each section emphasize therapeutic classes of drugs and prototypical or commonly used individual drugs, those used to treat common disorders, and those likely to be encountered in clinical nursing practice. Drug chapter content includes a description of a condition (or conditions) for which a drug group is used; a general description of a drug group, including mechanism(s) of action, indications for use, and contraindications; and descriptions and tables of individual drugs, with recommended dosage ranges and routes of administration.

Additional clinically relevant information is presented under the headings of **Nursing Process**, **Principles of Therapy**, and **Nursing Actions**.

**Nursing Process** sections emphasize the importance of the nursing process in drug therapy, including assessment of the patient's condition in relation to the drug group, nursing diagnoses, expected outcomes, needed interventions, and evaluation of the patient's progress toward expected outcomes. **Patient Teaching Guidelines** are displayed separately from other interventions to emphasize their importance and for easy student reference.

**Principles of Therapy** sections present guidelines for maximizing benefits and minimizing adverse effects of drug

therapy in various circumstances and populations, including middle-aged and older adults, children and adolescents, and patients with impaired kidney or liver function. General principles are included in Chapter 4; specific principles related to drug groups are included in the chapters where those drug groups are discussed. This approach, rather than separate chapters on pediatric and geriatric pharmacology, for example, was chosen because knowledge about a drug is required before that knowledge can be applied to a specific population with distinctive characteristics and needs in relation to drug therapy.

Each drug chapter includes a **Nursing Actions** display that provides specific nursing responsibilities related to drug administration and patient observation.

Other drug sections include products used to treat infectious, ophthalmic, and dermatologic disorders plus drugs used during pregnancy, labor and delivery, and lactation.

## New to This Edition

This thoroughly updated edition includes new content and features:

- **Updated Drug Information.** Many new drugs have been added: some are additions to well-known drug groups; others represent advances in the drug therapy of some disease processes. In addition, continuing trends in drug dosage formulations are reflected in the increased numbers of fixed-dose combination drug products, long-acting preparations (i.e., 24 hours or longer), and dermatologic (skin patch) products.
- **Major Revision of Many Chapters.** Chapter revisions reflect current practices in drug therapy, integrate new drugs, and explain the major characteristics of new drug groups. The revisions also reflect a concerted effort to emphasize commonly-used drugs that are likely to be encountered in clinical practice. To this end, approximately 140 drugs were deleted from the chapters.
- **Evidence-based Practice Displays.** In a landmark report, *Crossing the Quality Chasm: A New Health System for the 21<sup>st</sup> Century* (2001), the Institute of Medicine urged health care providers to base care on the best scientific evidence available. In this revision, care has been taken to promote evidence-based practice in pharmacotherapeutics in the text as well as in the evidence-based practice displays.
- **Black Box Warnings.** A Black Box Warning appearing on the package insert or drug label for a prescription drug identifies a drug with a significant risk of serious or life-threatening adverse effects. It is the strongest warning required by the Food and Drug Administration. Throughout this revision, **BLACK BOX WARNINGS** are identified, alerting the nurse to the risk of serious adverse effects.
- **Applying Your Knowledge.** These threaded case studies provide real-world examples and lend significance to conceptual content. Each drug chapter opens with a patient scenario, which builds throughout the chapter. Case-based questions test students' critical thinking, and special "How Do You Avoid This Medication Error?" questions promote safe and accurate drug administration. The answers to these questions can be found at the end of the book.
- **Key Terms.** Terms that are key to understanding each chapter's content.
- **Key Concepts.** These concepts provide the most salient content for the student and appear at the end of each chapter.
- **Glossary.** Contains definitions of all of the key terms.

## Special Features

- **Readability.** Since the first edition of *Clinical Drug Therapy*, many students and faculty have commented about the book's clear presentation style.
- **Organizational Framework.** The book's organizational framework allows it to be used effectively as both a textbook and as a reference. Used as a textbook, students can read chapters in their entirety to learn the characteristics of major drug classes, their prototypical drugs or commonly used representatives, their uses and effects in prevention or treatment of disease processes, and their implications for nursing practice. Used as a reference book, students can readily review selected topics for classroom use or clinical application. Facilitating such uses are a consistent format and frequent headings that allow readers to identify topics at a glance.
- **Chapter Objectives.** Learning objectives at the beginning of each chapter focus students' attention on important chapter content.
- **Drugs at a Glance Tables.** These tables highlight and summarize pertinent drug information, including drug names, dosage ranges, and other related facts.
- **Boxed Displays.** These include information to promote understanding of drug therapy for selected conditions.
- **Herbal and Dietary Supplements.** Commonly used products are introduced in Chapter 4 and included in selected later chapters. Safety aspects are emphasized.
- **Patient Teaching Guidelines.** This feature is designed to meet several goals. One is to highlight the importance of teaching patients and caregivers how to manage drug therapy at home, where most medications are taken. This is done by separating teaching from other nursing interventions. Another goal is to promote active and knowledgeable patient participation in drug therapy regimens, which helps to maximize therapeutic effects and minimize adverse effects. In addition, written guidelines allow patients and caregivers to have a source of reference when questions arise in the home setting. A third goal is to make patient teaching easier and less time consuming. Using the guide-

lines as a foundation, the nurse can simply add or delete information according to a patient's individual needs. To assist both the nurse and patient further, the guidelines contain minimal medical jargon.

- **Principles of Therapy.** This unique section describes important drug- and patient-related characteristics that need to be considered in drug therapy regimens. Such considerations can greatly increase safety and therapeutic effects, and all health care providers associated with drug therapy should be aware of them. Most chapters contain principles with the headings of **Use in Children**, **Use in Older Adults**, **Use in Patients with Renal Impairment**, **Use in Patients with Hepatic Impairment**, and **Use in Home Care** to denote differences related to age, developmental level, pathophysiology, and setting. Some chapters include principles related to these headings as well: **Genetic and Ethnic Considerations**, **Use in Critical Illness**, and **Management of Drug Toxicity or Drug Withdrawal**.
- **Nursing Actions Displays.** These displays emphasize nursing interventions during drug therapy within the following categories: Administer accurately, Observe for therapeutic effects, Observe for adverse effects, and Observe for drug interactions. The inclusion of rationales for interventions provides a strong knowledge base and scientific foundation for clinical practice and critical thinking.
- **Review and Application Exercises.** Located at the end of each chapter, these exercises include two types of questions. Short Answer questions encourage students to rehearse clinical application strategies in a nonclinical, nonstressful, nondistracting environment. They also promote self-testing in chapter content and can be used to promote classroom discussion. NCLEX-style questions help students prepare for the licensing examination. Answers and rationales for these exercises can be found on the Instructor's Resource CD-ROM.
- **Appendices.** These include the International System of Units, therapeutic serum drug concentrations for selected drugs, anesthetics, and drugs for erectile dysfunction.
- **Extensive Index.** Listings of generic and trade names of drugs, nursing process, and other topics provide rapid access to desired information.

## Teaching–Learning Package

Nursing students must develop skills in critical thinking, information processing, decision making, collaboration, and problem solving. How can a nurse educator assist students to develop these skills in relation to drug therapy? The ancillary package assists both students and teachers in this development.

The **Study Guide** engages students' interest and active participation by providing a variety of learning exercises and opportunities to practice cognitive skills. **Assessing Your Understanding** promotes the learning of concepts, principles,

and characteristics and uses of major drug groups and can be completed independently or by small groups as in-class learning activities. Applying Your Knowledge scenarios promote appropriate data collection, critical analysis of both drug- and patient-related data, and application of the data in patient care. Practicing for NCLEX, which provides NCLEX-style review questions to help students apply and retain the key information from each chapter.

The companion Web site, <http://thepoint.lww.com>, provides online updates for faculty and students, links to newly approved drugs, and more.

The free **Student Resource CD-ROM** is an invaluable learning tool that provides 3-D animated demonstrations of pharmacology concepts, medication administration video, and monographs of the most commonly prescribed drugs.

## Resources for Instructors:

A set of tools to assist you in teaching your course is available on thePoint at <http://thepoint.lww.com>. ThePoint is a web-based system that allows you to manage your course and content and provides every resource instructors need in one easy-to-use site.

If, as an instructor, you want help structuring your lessons...

We've provided Guided Lecture Notes that are built on the learning objectives of each chapter. They consist of brief talking points and suggestions for how to present the material in the chapter and are supported by PowerPoint slides, which condense the material into bulleted lists, figures, and tables.

If you need suggestions, aside from straight lecturing, for engaging your students in the material...

We've provided Assignments for each chapter. These cover group assignments, written assignments, clinical assignments, and web-based assignments, so that you can capture the diverse learning styles of your students and be sure they approach the material from a variety of perspectives.

If you want to encourage your students to read the assigned chapter thoroughly before coming to class...

We've provided Pre-Lecture Quizzes (and answers), which are simple multiple-choice and true/false quizzes designed to test whether the student has read and grasped the material before the lecture or other classroom activities begin.

If you'd like your students to start applying what they've learned...

We've provided Discussion Topics and suggested answers to get students talking constructively about how their nursing knowledge works in real-world scenarios. As an added bonus, these discussions can take place online, adding a valuable technologic component to your teaching. We've also provided Case Studies and suggested answers, which encourage students to apply their new knowledge to the types of patient cases they'll likely encounter in practice.

If you're concerned about preparing your students for the NCLEX exams...

We've provided a Test Generator and a set of Student Review Questions, both of which include unique questions for each chapter. These questions are presented in traditional and in alternate-form NCLEX style, so students will become familiar with the format of the exams.

These varied materials allow each instructor to choose or adapt them relevant to his or her circumstances. The authors

and publisher hope these resources are truly helpful in easing the day-to-day rigors of teaching pharmacology and invite comments from instructors regarding the materials.

**Anne Collins Abrams, RN, MSN**  
**Carol Barnett Lammon, RN, PhD**  
**Sandra Smith Pennington, RN, PhD**

# How to Use Clinical Drug Therapy

Drugs at a Glance tables give students characteristics as well as routes and dosage ranges in an easy-to-read format. Prototype drugs are highlighted in the tables and in the text.

Learning Objectives let students know what they're going to learn in each and every chapter.

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Identify clinical uses of selected hormones.
2. Differentiate characteristics and functions of anterior and posterior pituitary hormones.
3. Recognize the limitations of hypothalamic and pituitary hormones as therapeutic agents.
4. Identify major nursing considerations in the care of patients receiving specific hypothalamic and pituitary hormones.

## Applying Your Knowledge

Jose Rojas is a 24-year-old man who has suffered a head injury while riding his motorcycle without a helmet. He has been admitted for observation, with multiple abrasions and a blow to the head. Mr. Rojas begins to produce massive amounts of clear, pale-yellow urine. The physician diagnoses him with diabetes insipidus and orders desmopressin 0.2 mL in two divided doses intranasally.

### Applying Your Knowledge 22-1

**How Can You Avoid This Medication Error?**  
The nurse prepares Mr. Rojas' medication and administers 0.2 mL of desmopressin intranasally.

## Nursing Process

### Assessment

- Assess for signs and symptoms of thyroid disorders (see Table 24-1). During the course of treatment with thyroid or antithyroid drugs, the patient's blood level of thyroid hormone may range from low to normal to high. At either end of the continuum, signs and symptoms may be dramatic and obvious. As blood levels change toward normal as a result of treatment, signs and symptoms become less obvious. If presenting signs and symptoms are treated too aggressively, they may change toward the opposite end of the continuum and indicate adverse drug effects. Thus, each patient receiving a drug that alters thyroid function must be assessed for indicators of hypothyroidism, euthyroidism, and hyperthyroidism.

nursing process continues on page 1060

Patient Teaching Guidelines give students specific information they may need to educate patients.

Table 24-2

Drugs at a Glance: Drugs for Hypothyroidism and Hyperthyroidism

Generic/Trade name	ROUTES AND DOSAGE RANGES	
	Adults	Children
<b>Drugs for Hypothyroidism</b>		
<b>P Levothyroxine</b> (Synthroid, Levothroid)	PO 0.05 mg/d initially, increased by 0.025 mg every 2-3 wk until desired response obtained; usual maintenance dose, 0.1-0.2 mg/d (100-200 mcg/d)  Myxedema coma, IV 0.4 mg in a single dose; then 0.1-0.2 mg daily  Thyroid-stimulating hormone (TSH) suppression in thyroid cancer, nodules, and euthyroid goiters, PO 2.6 mcg/kg/d for 7-10 d  Older adults, patients with cardiac disorders, and patients with hypothyroidism of long duration: PO 0.0125-0.025 mg/d for 6 wk, then dose is doubled every 6-8 wk until the desired response is obtained  Myxedema coma, same as adult dosage	Congenital hypothyroidism, PO as follows: >12 y: >150 mcg/d (or 2-3 mcg/kg/d) 6-12 y: 100-150 mcg/d (or 4-5 mcg/kg/d) 1-5 y: 75-100 mcg/d (or 5-6 mcg/kg/d) 6-12 mo: 50-75 mcg/d (or 6-8 mcg/kg/d) Birth-6 mo: 25-50 mcg/d (or 8-10 mcg/kg/d)
<b>Strong iodine solution</b> (Lugol's solution)	PO 2-6 drops 3 times per day for 10 d before thyroidectomy	PO 2-6 drops 3 times per day for 10 d before thyroidectomy
<b>Saturated solution of potassium iodide</b>	PO 5 drops 3 times per day for 10 d before thyroidectomy	PO 5 drops 3 times per day for 10 d before thyroidectomy
	PO, IV, dosage as calculated by a radiologist trained in nuclear medicine	PO, IV, dosage as calculated by a radiologist trained in nuclear medicine
	PO 40-160 mg/d in divided doses	
	PO 2-6 mg/d initially, increased by 0.025 mg every 2-3 wk until desired response obtained; usual maintenance dose, 0.1-0.2 mg/d (100-200 mcg/d)	>10 y: PO 150-300 mg/d in divided doses q8h; usual maintenance dose, 100-300 mg/d in 2 divided doses, q12h 6-10 y: 50-150 mg/d in divided doses q8h
	PO 15-60 mg/d initially, in divided doses q8h until the patient is euthyroid; maintenance, 5-15 mg/d in 2 or 3 doses	PO 0.4 mg/kg/d initially, in divided doses q8h; maintenance dose, one half initial dose

Applying Your Knowledge features help students apply concepts to patient care. Most chapters open with a patient scenario, which is then carried through the chapter. Applying Your Knowledge questions require students to take the content they have learned and apply it to the patient in the case study, and special "How Do You Avoid This Medication Error?" questions reinforce safe drug administration. Answers are provided at the end of the book, allowing students to monitor their progress.

Nursing Process material helps students think about drug therapy in terms of the nursing process.

## Patient Teaching Guidelines Oral Fluoroquinolones

### General Considerations

- Avoid exposure to sunlight during and for several days after taking one of these drugs. Stop taking the drug and notify the prescribing physician if skin burning, redness, swelling, rash, or itching occurs. Sunscreen lotions do not prevent photosensitivity reactions.
- Be very careful if driving or doing other tasks requiring alertness or physical coordination. These drugs may cause dizziness or lightheadedness.

### Self-Administration

- Take norfloxacin (Noroxin) levofloxacin solution and ofloxacin (Floxin) 1 hour before or 2 hours after meals on an

empty stomach. Ciprofloxacin (Cipro) may be taken with food to decrease GI upset. Gatifloxacin (Teguin), gemifloxacin (Factive), levofloxacin tabs, and moxifloxacin (Avelox) can be taken with or without regard to meals.

- Drink 2 to 3 quarts of fluid daily if able. This helps to prevent kidney problems.
- Do not take antacids containing magnesium or aluminum (e.g., Mylanta or Maalox); any products containing iron, magnesium, calcium (e.g., Tums), or zinc (e.g., multivitamins); sucralfate, or buffered didanosine preparations at the same time, or for several hours before or after a dose of the fluoroquinolone. (Consult product-specific information for individual drug recommendations.)

Evidence-based Practice Boxes give students information they need to improve the quality of care provided to patients. →

Black Box Warnings alert nursing students to the risk of serious or life threatening adverse effects associated with a drug.

Pramlintide is given by subcutaneous injection before meals. Opened vials of pramlintide may be stored in a refrigerator or at room temperature for up to 28 days. It cannot be mixed in the same injection with mealtime insulin. Reduction in insulin dosages by 50% is required with initiation of pramlintide therapy to reduce the incidence of hypoglycemia. A **BLACK BOX WARNING** alerts nurses to the danger of severe insulin-induced hypoglycemia with pramlintide therapy, especially in type 1 diabetics. Nausea, another frequent adverse effect of pramlintide, tends to decrease with time and may be reduced with careful titration of the dosage to the therapeutic level. Pramlintide may delay the absorption of concurrently administered oral medications.

**Evidence-Based Practice**

26-1 Use of Alternative Medicines in Diabetes Mellitus

It is well documented in the literature that a significant number of individuals with diabetes mellitus use complementary and alternative medicine (CAM). CAM includes acupuncture, relaxation techniques, massage, chiropractic, spiritual healing, herbal medicines, and vitamin supplements. Estimates of CAM use by patients with diabetes range as high as 57% in the literature and are comparable with CAM use by nondiabetic individuals. Studies reveal that generally diabetics use the same supplements and alternative remedies as nondiabetic individuals with the exception of increased use of chromium. The literature documents that some patients use CAM to lower blood glucose as well as to treat complications of diabetes; however, the majority of individuals report using CAM for a condition unrelated to diabetes. The use of CAM by diabetics raises several concerns. One obvious concern is the implications of using CAM in replacement of traditional therapies for diabetes such as insulin and oral hypoglycemic drugs; however, one study in the literature suggested that most diabetic patients use CAM in addition to traditional therapies rather than as a replacement for traditional medications. Another study documented that diabetic patients using CAM were more likely to also use preventive care practices such as obtaining a pneumococcal vaccination and visiting their health care provider on a regular basis. A second concern is the potential of CAM to do harm. With regard to herbal and vitamin supplements, harmful effects include potential interactions with traditional drugs as well as increased risk for hepatotoxicity, nephrotoxicity, and poor glycemic control. A third concern is the cost of CAM; one study reported that diabetics using CAM spend as much on the alternative therapies as they do on prescription drugs.

Because the use of CAM is widespread and has the potential for impacting blood glucose levels of diabetic patients, nurses should take careful drug histories, including questions about use of herbal and over-the-counter supplements. Nurses should also educate diabetic patients about the potential impact of complementary therapies on blood glucose levels when this information is available.

**Herbal and Dietary Supplements**

Increasing numbers of people are choosing alternative medications to complement or, in some cases, to replace prescription medications. With most herbs and dietary supplements, even the commonly used ones (e.g., echinacea, St. John's wort), the effects on blood glucose levels are unknown; well-controlled, long-term studies of effects have not been done; and interactions with antidiabetic drugs are unknown. Thus, anyone with diabetes who wishes to take an herbal or dietary supplement should consult a health care provider, read product labels carefully, seek the most authoritative information available, and monitor blood glucose closely when starting the supplement. Described below are some products that reportedly affect blood sugar and that should be used cautiously, if at all, by patients with diabetes.

Herbal and Dietary Supplement content is highlighted so students become aware of how these alternative therapies can affect traditional medications.

Nursing Actions Beta-Lactam Antibacterials	
NURSING ACTIONS	RATIONALE/EXPLANATION
<p><b>1. Administer accurately</b></p> <p>a. With penicillins:</p> <p>(1) Give most oral penicillins on an empty stomach, approximately 1 hour before or 2 hours after a meal. Penicillin V, amoxicillin, and amoxicillin/clavulanate may be given with food.</p>	<p>To decrease binding to foods and inactivation by gastric acid. The latter three drugs are not significantly affected by food.</p>

**Review and Application Exercises**

**Short Answer Exercises**

- Why must aminoglycosides be given parenterally for systemic infections?
- How are aminoglycosides excreted?
- What are risk factors for aminoglycoside-induced nephrotoxicity and ototoxicity?
- How would you assess a patient for nephrotoxicity or ototoxicity?
- What is the reason for giving an aminoglycoside and an antipseudomonal penicillin in the treatment of serious infections caused by *P. aeruginosa*?
- Why should an aminoglycoside and an antipseudomonal penicillin not be combined in a syringe or IV fluid for administration?
- Which laboratory tests need to be monitored regularly for a patient receiving a systemic aminoglycoside?
- What is the rationale for giving an oral aminoglycoside to treat hepatic coma?
- What are the main clinical uses of fluoroquinolones?
- What are adverse effects of fluoroquinolones, and how may they be prevented or minimized?
- Why is it important to maintain an adequate fluid intake and urine output while taking a fluoroquinolone?
- Why are fluoroquinolones not preferred drugs for children?

**NCLEX-Style Questions**

- A hospitalized patient is scheduled to receive levofloxacin 500 mg PO at 9:00 A.M. The medication administration record also indicates that Maalox 30 mL PO and hydrochlorothiazide 25 mg PO are due at 9:00 A.M. The nurse should
  - Administer all the medications as scheduled.
  - Hold the Maalox until 11:00 A.M.
  - Ask the physician to discontinue hydrochlorothiazide because of increased risk of ototoxicity.
  - Administer the Maalox and levofloxacin, but hold the hydrochlorothiazide.
- A critically ill patient is receiving tobramycin 1.5 mg/kg IV every 8 hours. The patient has recently stopped making urine, and the most recent laboratory results indicate that the creatinine level has risen from normal to 3.6 mg/dL. At the next scheduled administration time for tobramycin, the nurse should
  - Administer half the prescribed dose.
  - Hold the tobramycin and notify the physician.
  - Administer tobramycin as prescribed.
  - Draw a blood sample for testing the tobramycin level before the dose and then administer as prescribed.
- An outpatient client has just been given a prescription for moxifloxacin 400 mg PO once daily for acute bronchitis. The nurse should teach the patient
  - not to take moxifloxacin with a meal
  - to restrict fluid intake to avoid fluid overload
  - to take moxifloxacin with an antacid (e.g., Tums) to decrease the chance of stomach upset
  - to avoid prolonged exposure to sunlight

Nursing Actions give students specific instructions on administration of drugs and observations of patient responses, with rationales for each step.

Review and Application Exercises provide students with the opportunity to review what they just learned. These include both short-answer exercises and NCLEX-style questions.

# Acknowledgments

Sincere appreciation is expressed to the following people who assisted in the preparation of this book:

Contributors Susan Appel, Jennifer Binggeli, Kathleen Jenks, Marthe Moseley, and Patricia Wolff, and Mary Annette Wright

Tracey Goldsmith, PharmD, who reviewed all chapters.

## SECTION 1 Foundations of Drug Therapy 1

---

### CHAPTER 1

#### Introduction to Pharmacology 2

- A Message to Students 2
- Pharmacology and Drug Therapy 2
- Drug Sources 3
- Drug Classifications and Prototypes 3
- Drug Names 3
- Drug Marketing 3
- Pharmacoeconomics 3
- Prescription and Nonprescription Drugs 3
- Drug Approval Processes 6
- Sources of Drug Information 7
- Strategies for Studying Pharmacology 7

### CHAPTER 2

#### Basic Concepts and Processes 9

- Introduction 9
- Cellular Physiology 10
- Drug Transport Through Cell Membranes 10
- Pharmacokinetics 11
- Pharmacodynamics 15
- Variables That Affect Drug Actions 16
- Adverse Effects of Drugs 20
- Toxicology: Drug Overdose 22

### CHAPTER 3

#### Administering Medications 27

- Introduction 27
- General Principles of Accurate Drug Administration 28
- Legal Responsibilities 28
- Medication Errors 29
- Medication Systems 31
- Medication Orders 32
- Drug Preparations and Dosage Forms 33
- Calculating Drug Dosages 35
- Routes of Administration 36

### CHAPTER 4

#### Nursing Process in Drug Therapy 48

- Introduction 48
- Nursing Process in Drug Therapy 49
- Integrating Clinical Pathways with Nursing Process 54
- Integrating Evidence-Based Practice with Nursing Process 54
- Herbal and Dietary Supplements 55
- General Principles of Drug Therapy 60

## SECTION 2 Drugs Affecting the Central Nervous System 71

---

### CHAPTER 5

#### Physiology of the Central Nervous System 72

- Introduction 72
- Neurons 72
- Elements of Neurotransmission 74
- Drugs That Affect the Central Nervous System 77

### CHAPTER 6

#### Opioid Analgesics and Pain Management 79

- Introduction 79
- General Characteristics of Opioid Analgesics 82
- Subgroups and Individual Drugs 83
- Herbal and Dietary Supplements 88
- Principles of Therapy 90

### CHAPTER 7

#### Analgesic–Antipyretic–Anti-Inflammatory and Related Drugs 100

- Introduction 100
- General Characteristics of Analgesic–Antipyretic–Anti-Inflammatory and Related Drugs 103
- Classifications and Individual Drugs 106
- Herbal and Dietary Supplements 114
- Principles of Therapy 118

### CHAPTER 8

#### Antianxiety and Sedative-Hypnotic Drugs 130

- Introduction 130
- General Characteristics of Benzodiazepines 133
- Individual Drugs 135
- Herbal and Dietary Supplements 139
- Principles of Therapy 142

### CHAPTER 9

#### Antipsychotic Drugs 153

- Introduction 153
- General Characteristics of Antipsychotic Drugs 155
- Individual Drugs 156
- Principles of Therapy 163

### CHAPTER 10

#### Antidepressants and Mood Stabilizers 175

- Introduction 175
- General Characteristics of Antidepressant Drugs 178
- Types of Antidepressants and Individual Drugs 179
- Herbal Supplements 184
- Principles of Therapy 185

## CHAPTER 11

- 2 ■ Basic Concepts and Processes
- 3 ■ Administering Medications
- 4 ■ Nursing Process in Drug Therapy

# Introduction to Pharmacology

## KEY TERMS

- Biotechnology
- Brand or trade name
- Controlled substances
- Drug classifications
- Generic name
- Over-the-counter (OTC) drugs
- Pharmacoeconomics
- Pharmacotherapy
- Placebo
- Prescription drugs
- Prototype
- Systemic effects

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Differentiate between pharmacology and drug therapy.
2. Distinguish between generic and trade names of drugs.
3. Define a prototypical drug.
4. Select authoritative sources of drug information.
5. Discuss major drug laws and standards.
6. Describe the main categories of controlled substances in relation to therapeutic use and potential for abuse.
7. Identify nursing responsibilities in handling controlled substances correctly.
8. Discuss the role of the Food and Drug Administration.
9. Analyze the potential impact of drug costs on drug therapy regimens.
10. Develop personal techniques for learning about drugs and using drug knowledge in patient care.

## A Message to Students

You have probably been taking medicines and seeing other people take medicines most of your life. Perhaps you have given medicines to your children, parents, grandparents, or others. Have you ever wondered why it is usually okay to give children Tylenol but not aspirin? Why do a lot of middle-aged and older people take an aspirin a day? Why do people with high blood pressure, heart failure, or diabetes take angiotensin-converting enzyme (ACE) inhibitors, and what are ACE inhibitors? When should an antibiotic NOT be prescribed for an infection?

You are embarking on an exciting journey of discovery as you begin or continue your study of pharmacology. Much of what you learn will be useful in your personal and family life as well as in your professional life as a nurse. The purpose of this book is to help you learn about medications and why, how, when, and where they are used in daily life. Bon voyage!!

## Pharmacology and Drug Therapy

Pharmacology is the study of drugs (chemicals) that alter functions of living organisms. Drug therapy, also called *pharmacotherapy*, is the use of drugs to prevent, diagnose, or treat signs, symptoms, and disease processes. When prevention or cure is not a reasonable goal, relief of symptoms can greatly improve a patient's quality of life and ability to function in activities of daily living. Drugs given for therapeutic purposes are called medications.

Medications may be given for local or *systemic effects*. Drugs with local effects, such as sunscreen lotions and local anesthetics, act mainly at the site of application. Those with systemic effects are taken into the body, circulated through the bloodstream to their sites of action in

various body tissues, and eventually eliminated from the body. *Most drugs are given for their systemic effects.* Drugs may also be given for acute disorders, such as pain or infection, or to relieve signs and symptoms of long-term disease processes, such as hypertension or diabetes.

## Drug Sources

Where do medications come from? Historically, drugs were derived from plants, animals, and minerals. Now, most drugs are synthetic compounds manufactured in laboratories. Chemists, for example, often create a useful new drug by altering the chemical structure of an existing drug. Such techniques and other technologic advances have enabled the production of new drugs as well as synthetic versions of many drugs originally derived from plants and animals. Synthetic drugs are more standardized in their chemical characteristics, more consistent in their effects, and less likely to produce allergic reactions. Semisynthetic drugs (e.g., many antibiotics) are naturally occurring substances that have been chemically modified.

*Biotechnology* is also an important source of drugs. This process involves manipulating deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) and recombining genes into hybrid molecules that can be inserted into living organisms (*Escherichia coli* bacteria are often used) and repeatedly reproduced. Each hybrid molecule produces a genetically identical molecule, called a clone. Cloning makes it possible to identify the DNA sequence in a gene and to produce the protein product encoded by a gene, such as insulin. Cloning also allows production of adequate amounts of the drug for therapeutic or research purposes. Biotechnology drugs constitute an increasing percentage of drugs now undergoing development, and this trend is expected to continue into the foreseeable future.

## Drug Classifications and Prototypes

Drugs are classified according to their effects on particular body systems, their therapeutic uses, and their chemical characteristics. For example, morphine can be classified as a central nervous system depressant and a narcotic or opioid analgesic. The names of therapeutic classifications usually reflect the conditions for which the drugs are used (e.g., antidepressants, antihypertensives). However, the names of many drug groups reflect their chemical characteristics rather than their therapeutic uses (e.g., adrenergics, benzodiazepines). Many drugs fit into multiple groups because they have wide-ranging effects on the human body.

Individual drugs that represent groups of drugs are called *prototypes*. **P Prototypes**, often the first drug of a particular group to be developed, are usually the standard with which newer, similar drugs are compared. For example, morphine is the prototype of opioid analgesics; penicillin is the prototype of antibacterial drugs.

*Drug classifications* and prototypes are quite stable, and most new drugs can be assigned to a group and compared with an established prototype. However, some groups lack a universally accepted prototype, and some prototypes are replaced over time by newer, more commonly used drugs.

## Drug Names

Individual drugs may have several different names, but the two that are most commonly used are the generic name and the trade or brand name. The *generic name* (e.g., amoxicillin) is related to the chemical or official name and is independent of the manufacturer. *The generic name often indicates the drug group* (e.g., *drugs with generic names ending in “cillin” are penicillins*). The *trade or brand name* is designated and patented by the manufacturer. For example, amoxicillin is manufactured by several pharmaceutical companies, some of which assign a specific trade name (e.g., Amoxil, Trimox) and several of which use only the generic name. In drug literature, trade names are capitalized and generic names are presented in lowercase unless in a list or at the beginning of a sentence. Drugs may be prescribed and dispensed by generic or trade name.

## Drug Marketing

A new drug is protected by patent for several years, during which time only the pharmaceutical manufacturer that developed it can market it. This is seen as a return on the company's investment in developing a drug, which may require years of work and millions of dollars, and as an incentive for developing other drugs. Other pharmaceutical companies cannot manufacture and market the drug until the patent expires. However, for new drugs that are popular and widely used, other companies often produce similar drugs, with different generic and trade names. Generic drugs are required to be therapeutically equivalent and are less expensive than trade-name drugs.

## Pharmacoeconomics

*Pharmacoeconomics* involves the costs of drug therapy, including costs of purchasing, dispensing (i.e., salaries of pharmacists, pharmacy technicians), storage, administration (i.e., salaries of nurses, costs of supplies), laboratory and other tests used to monitor patient responses, and losses due to expiration. Length of illness or hospitalization is also considered. The goal of most pharmacoeconomic research is to identify drug therapy regimens that provide the desired benefits at the least cost.

## Prescription and Nonprescription Drugs

Legally, American consumers have two routes of access to therapeutic drugs. One route is by *prescription* from a licensed

health care provider, such as a physician, dentist, or nurse practitioner. The other route is by over-the-counter (OTC) purchase of drugs that do not require a prescription. These routes are regulated by various drug laws. Acquiring and using prescription drugs for nontherapeutic purposes by persons who are not authorized to have the drugs or for whom they are not prescribed is illegal.

## American Drug Laws and Standards

Current drug laws and standards have evolved over many years. Their main goal is to protect the public by ensuring that drugs marketed for therapeutic purposes are safe and effective. Their main provisions are further described below and summarized in Table 1-1.

The Food, Drug, and Cosmetic Act of 1938 and its amendments regulate the manufacture, distribution, advertising, and labeling of drugs. The law also requires that official drugs (i.e., those listed in the United States Pharmacopeia and

designated USP) must meet standards of purity and strength as determined by chemical analysis or by animal response to specified doses (bioassay). The Durham-Humphrey Amendment designates drugs that must be prescribed by a licensed physician or nurse practitioner and dispensed by a pharmacist. The Food and Drug Administration (FDA) is charged with enforcing the law. In addition, the Public Health Service regulates vaccines and other biologic products, and the Federal Trade Commission can suppress misleading advertisements of non-prescription drugs.

The Comprehensive Drug Abuse Prevention and Control Act was passed in 1970. Title II of this law, called the Controlled Substances Act, regulates the manufacture and distribution of narcotics, stimulants, depressants, hallucinogens, and anabolic steroids. These drugs are categorized according to therapeutic usefulness and potential for abuse (Box 1-1) and are labeled as *controlled substances* (e.g., morphine is a C-II or Schedule II drug).

**Table 1-1**

**American Drug Laws and Amendments**

YEAR	NAME	MAIN PROVISION(S)
1906	Pure Food and Drug Act	<ul style="list-style-type: none"> <li>■ Established official standards and requirements for accurate labeling of drug products</li> <li>■ Established the forerunner of FDA</li> </ul>
1912	Sherley Amendment	Prohibited fraudulent claims of drug effectiveness
1914	Harrison Narcotic Act	Restricted the importation, manufacture, sale, and use of opium, cocaine, marijuana, and other drugs that the Act defined as narcotics
1938	Food, Drug, and Cosmetic Act	<ul style="list-style-type: none"> <li>■ Revised and broadened FDA powers and responsibilities; gave the FDA control over drug safety</li> <li>■ Required proof of safety from the manufacturer before a new drug could be marketed</li> <li>■ Authorized factory inspections</li> <li>■ Established penalties for fraudulent claims and misleading labels</li> </ul>
1945	Amendment	Required governmental certification of biologic products, such as insulin and antibiotics
1952	Durham-Humphrey Amendment	Designated drugs that must be prescribed by a physician and dispensed by a pharmacist (e.g., controlled substances, drugs considered unsafe for use except under supervision by a health care provider, and drugs limited to prescription use under a manufacturer's new drug application)
1962	Kefauver-Harris Amendment	<ul style="list-style-type: none"> <li>■ Required a manufacturer to provide evidence (from well-controlled research studies) that a drug was effective for claims and conditions identified in the product's labeling</li> <li>■ Gave the federal government the authority to standardize drug names</li> </ul>
1970	Comprehensive Drug Abuse Prevention and Control Act; Title II, Controlled Substances Act	<ul style="list-style-type: none"> <li>■ Regulated distribution of narcotics and other drugs of abuse</li> <li>■ Categorized these drugs according to therapeutic usefulness and potential for abuse</li> <li>■ Updated or replaced all previous laws re: narcotics and other dangerous drugs</li> </ul>
1978	Drug Regulation Reform Act	<ul style="list-style-type: none"> <li>■ Established guidelines for research studies and data to be submitted to the FDA by manufacturers</li> <li>■ Shortened the time required to develop and market new drugs</li> </ul>

YEAR	NAME	MAIN PROVISION(S)
1983	Orphan Drug Act	<ul style="list-style-type: none"> <li>Decreased taxes and competition for manufacturers who would produce drugs to treat selected serious disorders affecting relatively few people</li> </ul>
1987		<ul style="list-style-type: none"> <li>Established new regulations designed to speed up the approval process for high-priority medications</li> </ul>
1992	Prescription Drug User Fee Act	<ul style="list-style-type: none"> <li>Allowed the FDA to collect user fees from pharmaceutical companies, with each new drug application, to shorten the review time (e.g., by hiring more staff)</li> <li>Specified a review time of 12 months for standard drugs and 6 months for priority drugs</li> </ul>
1993	NIH Revitalization Act	Requires inclusion of women and minorities in NIH-funded research studies, including Phase III clinical drug trials
1997	FDA Modernization Act	<ul style="list-style-type: none"> <li>Updated regulation of biologic products</li> <li>Increased patient access to experimental drugs and medical devices</li> <li>Accelerated review of important new drugs</li> <li>Allowed drug companies to disseminate information about off-label (non-FDA-approved) uses and costs of drugs</li> <li>Extended user fees</li> </ul>
2002	Best Pharmaceuticals for Children Act	<ul style="list-style-type: none"> <li>Encouraged pharmaceutical companies to conduct studies and label drugs for use in children</li> <li>Provided funds for 5 years for pediatric drug studies</li> </ul>

The Drug Enforcement Administration (DEA) enforces the Controlled Substances Act. Individuals and companies legally empowered to handle controlled substances must be registered with the DEA, keep accurate records of all transactions, and provide for secure storage. Prescribers are assigned a number by the DEA and must include the number on all prescriptions they write for a controlled substance. Prescriptions for Schedule II drugs cannot be refilled; a new prescrip-

tion is required. Nurses are responsible for storing controlled substances in locked containers, administering them only to people for whom they are prescribed, recording each dose given on agency narcotic sheets and on the patient's medication administration record, maintaining an accurate inventory, and reporting discrepancies to the proper authorities.

Historically, drug research was done mainly with young, white males. In 1993, Congress passed the National Institutes

### Box 1-1

## Categories of Controlled Substances

### Schedule I

Drugs that are not approved for medical use and have high abuse potentials: flunitrazepam (Rohypnol) gamma hydroxybutyric acid (GHB), heroin, lysergic acid diethylamide (LSD), marijuana, 3,4-methylenedioxy-methamphetamine (MDMA or ecstasy), mescaline, peyote, tetrahydrocannabinol.

### Schedule II

Drugs that are used medically and have high abuse potentials: opioid analgesics (e.g., codeine, hydromorphone, methadone, meperidine, morphine, oxycodone, oxymorphone), central nervous system (CNS) stimulants (e.g., cocaine, methamphetamine, methylphenidate), and barbiturate sedative-hypnotics (amobarbital, pentobarbital, secobarbital).

### Schedule III

Drugs with less potential for abuse than those in Schedules I and II, but abuse may lead to psychological or physical

dependence: androgens and anabolic steroids, ketamine, some CNS stimulants (e.g., benzphetamine), and mixtures containing small amounts of controlled substances (e.g., codeine, barbiturates not listed in other schedules).

### Schedule IV

Drugs with some potential for abuse: benzodiazepines (e.g., diazepam, lorazepam, temazepam), other sedative-hypnotics (e.g., phenobarbital, chloral hydrate), and some prescription appetite suppressants (e.g., mazindol, phentermine).

### Schedule V

Products containing moderate amounts of controlled substances. They may be dispensed by the pharmacist without a physician's prescription but with some restrictions regarding amount, record keeping, and other safeguards. Included are antidiarrheal drugs, such as diphenoxylate and atropine (Lomotil).

of Health (NIH) Revitalization Act, which formalized a policy of the NIH that women and minorities be included in human subject research studies funded by the NIH and that women and minorities be included in clinical drug trials. Now, major drug trials must recruit female subjects and include outcome data on women. In addition, all newly developed drugs must include gender-related effectiveness and safety information in the initial FDA application. Despite these regulations, however, there is still relatively little information about drug effects in women because many commonly used drugs were developed before enactment of these regulations.

In addition to federal laws, state laws also regulate the sale and distribution of controlled drugs. These laws may be more stringent than federal laws; if so, the stricter laws usually apply.

## Drug Approval Processes

The FDA is responsible for ensuring that new drugs are safe and effective before approving the drugs and allowing them to be marketed. The FDA reviews research studies (usually conducted or sponsored by pharmaceutical companies) about proposed new drugs; the organization does not test the drugs.

Since 1962, newly developed drugs are extensively tested before being marketed for general use. Initially, drugs are tested in animals and the FDA reviews the test results. Next, clinical trials in humans are done, usually with a randomized, controlled experimental design that involves selection of subjects according to established criteria, random assignment of subjects to experimental groups, and administration of the test drug to one group and a control substance to another group.

Testing proceeds through several phases if there is continuing evidence of drug safety and effectiveness. In Phase I, a few doses are given to a certain number of healthy volunteers to determine safe dosages, routes of administration, absorption, metabolism, excretion, and toxicity. In Phase II, a few doses are given to a certain number of subjects with the disease or symptom for which the drug is being studied, and responses are compared with those of healthy subjects. In Phase III, the drug is given to a larger and more representative group of subjects. In double-blind, placebo-controlled designs, half of the subjects receive the new drug and half receive a *placebo* (an inactive substance similar in appearance to the actual drug), with neither subjects nor researchers knowing who receives which formulation. In crossover studies, subjects serve as their own control; each subject receives the experimental drug during half of the study and a placebo during the other half. Other research methods include control studies in which some patients receive a known drug rather than a placebo; in subject matching, patients are paired with others of similar characteristics. Phase III studies help to determine whether the potential benefits of the drug outweigh the risks. Testing may be stopped during any of the early phases if inadequate effectiveness or excessive toxicity becomes evident. In Phase IV, the FDA evaluates the data from the first three phases for drug safety and effectiveness, allows the drug to be marketed for

general use, and requires manufacturers to continue monitoring the drug's effects.

Some approved and marketed drugs (e.g., Vioxx) are later withdrawn, usually because of serious adverse effects that become evident only when the drugs are used in a large, diverse population. In addition, in recent years the FDA has issued warnings about several drugs that can cause serious adverse effects (e.g., antidepressants, nonsteroidal anti-inflammatory drugs [NSAIDs] such as aspirin and ibuprofen, and oseltamivir [Tamiflu], an anti-flu drug). As a result, the FDA has been criticized for approving these and other drugs and allowing them to be marketed in the first place. Some authorities are urging major reforms in the drug approval process, the methods of reporting adverse drug effects, and postmarketing surveillance procedures.

## Food and Drug Administration Approval

The FDA approves many new drugs annually. New drugs are categorized according to their review priority and therapeutic potential. A status of "1P" indicates a new drug reviewed on a priority (accelerated) basis and with some therapeutic advantages over drugs already available; a status of "1S" indicates standard review and drugs with few, if any, therapeutic advantages (i.e., the new drug is similar to one or more older drugs currently on the market). Most new drugs are "1S" prescription drugs.

The FDA also approves drugs for OTC availability, including the transfer of drugs from prescription to OTC status, and may require additional clinical trials to determine the safety and effectiveness of OTC use. For prescription drugs taken orally, transfer to OTC status may mean different indications for use and lower doses. FDA approval of a drug for OTC availability involves evaluation of evidence that the consumer can use the drug safely, using information on the product label, and shifts primary responsibility for safe and effective drug therapy from health care professionals to consumers. With prescription drugs, a health care professional diagnoses the condition, often with the help of laboratory and other diagnostic tests, and determines a need for the drug. With OTC drugs, the patient must make these decisions, with or without consultation with a health care provider.

Having drugs available OTC has potential advantages and disadvantages for consumers. Advantages include greater autonomy, faster and more convenient access to effective treatment, possibly earlier resumption of usual activities of daily living, fewer visits to a health care provider, and possibly increased efforts by consumers to learn about their symptoms/conditions and recommended treatments. Disadvantages include inaccurate self-diagnoses and potential risks of choosing a wrong or contraindicated drug, delaying treatment by a health care professional, and developing adverse drug reactions and interactions. When a drug is switched from prescription to OTC status, pharmaceutical companies' sales and profits increase and insurance companies' costs decrease. Costs to consumers increase because health insurance policies do not cover OTC drugs.

## Sources of Drug Information

There are many sources of drug data, including pharmacology and other textbooks, drug reference books, journal articles, and Internet sites. For the beginning student of pharmacology, a textbook is the best source of information because it describes groups of drugs in relation to therapeutic uses. Drug reference books are most helpful in relation to individual drugs. Two authoritative sources are the *American Hospital Formulary Service* and *Drug Facts and Comparisons*. The former is published by the American Society of Health-System Pharmacists and updated periodically. The latter is published by the Facts and Comparisons division of Lippincott Williams & Wilkins and is updated monthly (loose-leaf edition) or annually (hard-bound edition). A less authoritative source is the *Physicians' Desk Reference* (PDR), published yearly, which compiles manufacturers' package inserts for selected drugs.

Numerous drug handbooks (e.g., *Lippincott's Nursing Drug Guide*, published annually) and pharmacologic, medical, and nursing journals also contain information about drugs. Textbook chapters and journal articles often present information about drug therapy for patient's with specific disease processes and may thereby facilitate application of drug knowledge in clinical practice.

## Strategies for Studying Pharmacology

- Concentrate on therapeutic classifications and their prototypes. For example, morphine is the prototype of opioid analgesics (see Chap. 6). Understanding morphine makes learning about other opioid analgesics easier because they are compared with morphine.
- Compare a newly encountered drug with a prototype or similar drug when possible. Relating the unknown to the known aids learning and retention of knowledge.
- Try to understand how the drug acts in the body. This understanding allows you to predict therapeutic effects and to predict, prevent, or minimize adverse effects by early detection and treatment.
- Concentrate study efforts on major characteristics. Such characteristics include the main indications for use, common and potentially serious adverse effects, conditions in which the drug is contraindicated or must be used cautiously, and related nursing care needs.
- Keep an authoritative, up-to-date drug reference readily available. A drug reference is a more reliable source of drug information than memory, especially for dosage ranges. Use the reference freely whenever you encounter an unfamiliar drug or when a question arises about a familiar one. In some health care settings, nurses have access to computerized databases of drug information, and these should be consulted for any unfamiliar or infrequently administered drug.
- Use your own words when taking notes or writing drug information cards. Also, write notes, answers to review questions, definitions of new terms, and trade names of drugs encountered in clinical practice settings directly into your pharmacology textbook. The mental processing required for these activities helps in both initial learning and later retention and application of knowledge.
- Rehearse applying drug knowledge in nursing care by asking yourself, "What if I have a patient who is receiving this drug? What must I do to safely administer the drug? For what must I assess the patient before giving the drug and for what must I observe in the patient after drug administration? What if my patient is an elderly person or a child?"

## Key Concepts

- Drug therapy or pharmacotherapy is the use of drugs to prevent, diagnose, or treat signs, symptoms, and disease processes.
- Drugs given for therapeutic purposes are called medications.
- Drugs may be given for local or systemic effects; most are given for systemic effects.
- A prototype is an example of a group of drugs, often the first one of the group to be developed.
- Trade names of drugs are determined by manufacturers; generic names are independent of manufacturers.
- Controlled drugs are categorized according to therapeutic usefulness and potential for abuse.

## Review and Application Exercises

### Short Answer Exercises

1. What is the difference between local and systemic effects of drugs?
2. Can a patient experience systemic effects of local drugs and local effects of systemic drugs? Why or why not?
3. Why is it helpful for nurses to know the generic names of commonly used medications?
4. Why is it helpful to study prototypes of drug groups?
5. List at least three strategies for studying pharmacology.
6. List at least three authoritative sources of drug information.

### NCLEX-Style Questions

7. You are caring for a patient who has strong beliefs about not putting anything “un-natural” into her body. Your best response is to tell her that most modern medications are
  - a. natural products derived from plants
  - b. natural products derived from minerals
  - c. synthetic products manufactured in laboratories
  - d. synthetic modifications of natural products
8. You are taking care of a patient who is confused about the different medications she is prescribed, and she has noted that some of the names have changed over the course of time she has been on these medications. In your counseling to her it is most important that you keep in mind the following true statement:
  - a. A drug can belong to only one group or classification.
  - b. A prototype drug is the standard by which similar drugs are compared.
  - c. Drug groups and prototypes change frequently and knowledge about a prototype cannot guide knowledge about other drugs in the same class.
  - d. The generic name of a drug changes among manufacturers.
9. In understanding the use of controlled substances for your clients, it is important that you know that controlled drugs are
  - a. categorized according to prescription or nonprescription status
  - b. regulated by state and local laws more than federal laws
  - c. those that must demonstrate high standards of safety
  - d. scheduled according to medical use and potential for abuse
10. You have a patient who is asking what the difference is between a prescription for 800 mg of a medication that can be purchased over-the-counter in 200 mg per tablet formulations. To answer her, it is important that you know that *over-the-counter drugs*
  - a. are considered safe for any consumers to use
  - b. are not available for treatment of most commonly occurring symptoms
  - c. often differ in indications for use and recommended dosages from their prescription versions
  - d. are paid for by most insurance policies
11. A patient is very upset with a drug recall of a medication he has been on for a long time. He states that he feels like he can no longer trust anyone to protect him. In response to his questions about the process of drug development, it is important that you know that with a new drug, the Food and Drug Administration is responsible for
  - a. testing the drug with animals
  - b. testing the drug with healthy people
  - c. marketing the drug to health care providers
  - d. evaluating the drug for safety and effectiveness

# Basic Concepts and Processes

## KEY TERMS

- Absorption
- Agonist
- Agranulocytosis
- Antagonist
- Bioavailability
- Biotransformation
- Distribution
- Enterohepatic recirculation
- Enzyme induction
- Enzyme inhibition
- Excretion
- First-pass effect
- Hypersensitivity
- Leukopenia
- Metabolism
- Nephrotoxicity
- Pharmacodynamics
- Pharmacogenetics
- Pharmacokinetics
- Prodrug
- Protein binding
- Serum drug level
- Serum half-life

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Discuss cellular physiology in relation to drug therapy.
2. Describe the main pathways and mechanisms by which drugs cross biologic membranes and move through the body.
3. Explain each process of pharmacokinetics.
4. Discuss the clinical usefulness of measuring serum drug levels.
5. Describe major characteristics of the receptor theory of drug action.
6. Differentiate between agonist drugs and antagonist drugs.
7. List drug-related and patient-related variables that affect drug actions.
8. Discuss mechanisms and potential effects of drug–drug interactions.
9. Identify signs and symptoms that may occur with adverse drug effects on major body systems.
10. Discuss general management of drug overdose and toxicity.
11. Discuss selected drug antidotes.

## Applying Your Knowledge

Mrs. Green, an 89-year-old widow, has recently switched to a new antihypertension medication. She prides herself on being independent and able to manage on her own, despite failing memory and failing health. When you visit as a home health nurse, you assess therapeutic and adverse effects of her medications and compliance to the medical regimen prescribed.

## Introduction

All body functions, disease processes, and most drug actions occur at the cellular level. Drugs are chemicals that alter basic processes in body cells. They can stimulate or inhibit normal cellular functions; they cannot add functions. To act on body cells, drugs given for systemic effects must reach adequate concentrations in the blood and other tissue fluids surrounding the cells. Thus, they must enter the body and be circulated to their sites of action (target cells). After they act on cells, they must be eliminated from the body.

How do systemic drugs reach, interact with, and leave body cells? How do people respond to drug actions? The answers to these questions are derived from cellular physiology, pathways and mechanisms of drug transport, pharmacokinetics, pharmacodynamics, and other basic concepts and processes that form the foundation of rational drug therapy and the content of this chapter.

## Cellular Physiology

Cells are dynamic, busy “factories” (Box 2-1, Fig. 2-1) that take in raw materials, manufacture products required to maintain bodily functions, and deliver those products to their appropriate destinations in the body. Although cells differ from one tissue to another, their common characteristics include the ability to

- Exchange materials with their immediate environment
- Obtain energy from nutrients
- Synthesize hormones, neurotransmitters, enzymes, structural proteins, and other complex molecules
- Duplicate themselves (reproduce)

- Communicate with one another via various biologic chemicals, such as neurotransmitters and hormones

## Drug Transport Through Cell Membranes

Drugs must reach and interact with or cross the cell membrane to stimulate or inhibit cellular function. Most drugs are given for effects on body cells that are distant from the sites of administration (i.e., systemic effects). To move through the body and reach their sites of action, metabolism, and excretion (Fig. 2-2), drug molecules must cross numerous cell membranes. For example, molecules of most oral drugs must cross

### Box 2-1

### Cell Structures and Functions

**Protoplasm**, which comprises the internal environment of body cells, is composed of water, electrolytes (potassium, magnesium, phosphate, sulfate, bicarbonate), proteins, lipids, and carbohydrates. **Water** makes up 70% to 85% of most cells; cellular enzymes, electrolytes, and other chemicals are dissolved or suspended in the water. **Electrolytes** provide chemicals for cellular reactions and are required for some processes (e.g., transmission of electrochemical impulses in nerve and muscle cells). **Proteins** consist of “physical” proteins that form the structure of cells and “chemical” proteins that function mainly as enzymes within the cell. **Lipids**, mainly phospholipids and cholesterol, form the membranes that separate structures inside the cell and the cell itself from surrounding cells and body fluids. **Carbohydrates** play a major role in cell nutrition. Glucose is present in extracellular fluid and is readily available to supply the cell’s need for energy. In addition, a small amount of carbohydrate is stored within the cell as glycogen, which can be rapidly converted back to glucose when needed.

The **nucleus** regulates the types and amounts of proteins, enzymes, and other substances to be produced. The **cytoplasm** surrounds the nucleus and contains the working units of the cell. The **cytosol**, the clear fluid portion of the cytoplasm, contains dissolved proteins, electrolytes, and glucose. The **endoplasmic reticulum (ER)** contains ribosomes, which synthesize proteins, including enzymes that synthesize glycogen, triglycerides, and steroids and those that metabolize drugs and other chemicals. The ER is also important in the production of hormones by glandular cells and the production of plasma proteins by liver cells. Most proteins produced by the ribosomes are released into the cytosol where they act as enzymes or structural proteins of the cell. The **Golgi complex** stores the substances produced by the ER. It also packages these substances into secretory granules, which then move out of the Golgi complex into the cytoplasm and, after a stimulus, are released from the cell. **Mitochondria** generate energy for cellular activities and require oxygen. **Lysosomes** are membrane-enclosed vesicles that contain enzymes capable of digesting nutrients (proteins, carbohydrates, fats), damaged cellular structures, foreign substances (e.g., bacteria), and the cell

itself. When a cell becomes worn out or damaged, the membrane around the lysosome breaks and the enzymes (hydrolyases) are released. However, lysosomal contents also are released into extracellular spaces and may destroy surrounding cells. Normally, the enzymes are inactivated by enzyme inhibitors and excessive tissue destruction is prevented.

The **cell membrane**, a complex structure of phospholipids, proteins, cholesterol, and carbohydrates, separates intracellular contents from the extracellular environment; provides receptors for hormones and other biologically active substances; participates in electrical events that occur in nerve and muscle cells; and helps regulate growth and proliferation.

The cell membrane covers the entire surface of the cell and consists of a thin, double layer of lipids interspersed with proteins. The lipid layer is composed of phospholipid (fatty acid and phosphate) molecules. The proteins are usually combined with a carbohydrate and called glycoproteins. Some proteins provide structural pores through which water and water-soluble substances (e.g., sodium, potassium, and calcium ions) can diffuse between extracellular and intracellular fluids. Other proteins act as carriers to transport substances through the cell membrane. Still others act to regulate intracellular function or as enzymes to catalyze chemical reactions within the cell.

Cell membrane carbohydrates occur mainly in combination with proteins (glycoproteins) or lipids (glycolipids). Glycoproteins (composed of carbohydrate around a small, inner core of protein and called proteoglycans) often are attached to and cover the entire outside surface of the cell. As a result, the carbohydrate molecules are free to interact with extracellular substances and perform several important functions. First, many have a negative electrical charge that repels other negatively charged substances. Second, the “carbohydrate coat” of some cells attaches to the carbohydrate coat of other cells and thereby connects cells to each other. Third, many of the carbohydrates act as receptor molecules for binding hormones (e.g., insulin). The receptor–hormone combination then activates the attached inner core of protein to perform its enzymatic or other functions in the cell.

**Figure 2-1** ■ Cytoplasmic organelles of the cell.

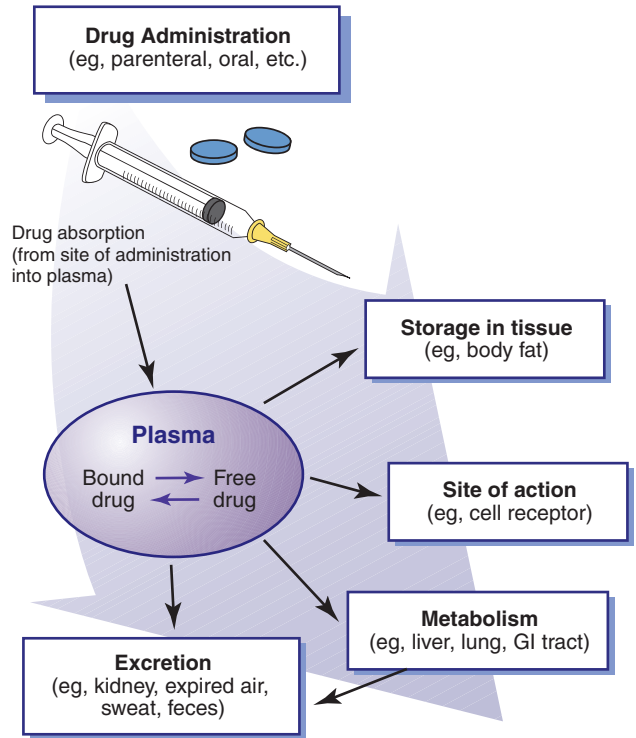

the membranes of cells in the gastrointestinal tract, liver, and capillaries to reach the bloodstream, circulate to their target cells, leave the bloodstream and attach to receptors on cells, perform their action, return to the bloodstream, circulate to the liver, reach drug-metabolizing enzymes in liver cells, re-enter the bloodstream (usually as metabolites), circulate to the kidneys, and be excreted in urine. Transport pathways and mechanisms used to move drug molecules through the body are described in Box 2-2 and Figure 2-3.

## Pharmacokinetics

*Pharmacokinetics* involves drug movement through the body (i.e., “what the body does to the drug”) to reach sites of action, metabolism, and excretion. Specific processes are absorption, distribution, metabolism (*biotransformation*), and excretion. Metabolism and excretion are often grouped together as drug elimination or clearance mechanisms. Overall, these processes largely determine serum drug levels; onset, peak, and duration of drug actions; therapeutic and adverse effects; and other important aspects of drug therapy.

### Absorption

*Absorption* is the process that occurs from the time a drug enters the body to the time it enters the bloodstream to be circulated. Onset of drug action is largely determined by the rate of absorption; intensity is determined by the extent of absorp-

**Figure 2-2** ■ Entry and movement of drug molecules through the body to sites of action, metabolism, and excretion.

tion. Numerous factors affect the rate and extent of drug absorption, including dosage form, route of administration, blood flow to the site of administration, gastrointestinal function, the presence of food or other drugs, and other variables. Dosage form is a major determinant of a drug’s *bioavailability* (the portion of a dose that reaches the systemic circulation and is available to act on body cells). An intravenous drug is virtually 100% bioavailable; an oral drug is virtually always less than 100% bioavailable because some of it is not absorbed from the gastrointestinal tract and some goes to the liver and is partially metabolized before reaching the systemic circulation.

Most oral drugs must be swallowed, dissolved in gastric fluid, and delivered to the small intestine (which has a large surface area for absorption of nutrients and drugs) before they are absorbed. Liquid medications are absorbed faster than tablets or capsules because they need not be dissolved. Rapid movement through the stomach and small intestine may increase drug absorption by promoting contact with absorptive mucous membrane; it also may decrease absorption because some drugs may move through the small intestine too rapidly to be absorbed. For many drugs, the presence of food in the stomach slows the rate of absorption and may decrease the amount of drug absorbed.

Drugs injected into subcutaneous (Sub-Q) or intramuscular (IM) tissues are usually absorbed more rapidly than oral drugs because they move directly from the injection site to the bloodstream. Absorption is rapid from IM sites because muscle tissue has an abundant blood supply. Drugs injected

## Box 2-2

## Drug Transport Pathways and Mechanisms

## Pathways

There are three main pathways of drug movement across cell membranes. The most common pathway is *direct penetration* of the membrane by lipid-soluble drugs, which are able to dissolve in the lipid layer of the cell membrane. Most systemic drugs are formulated to be lipid soluble so they can move through cell membranes, even oral tablets and capsules that must be sufficiently water soluble to dissolve in the aqueous fluids of the stomach and small intestine.

A second pathway involves passage through *protein channels* that go all the way through the cell membrane. Only a few drugs are able to use this pathway because most drug molecules are too large to pass through the small channels. Small ions (e.g., sodium and potassium) use this pathway, but their movement is regulated by specific channels with a gating mechanism (a flap of protein that opens briefly to allow ion movement and then closes).

The third pathway involves *carrier proteins* that transport molecules from one side of the cell membrane to the other. All of the carrier proteins are selective in the substances they transport; a drug's chemical structure determines which carrier will transport it.

## Mechanisms

Once absorbed into the body, drugs are transported to and from target cells by passive diffusion, facilitated diffusion, and active transport.

*Passive diffusion*, the most common mechanism, involves movement of a drug from an area of higher concentration to one of lower concentration. For example, after oral administration, the initial concentration of a drug is higher in the gastrointestinal tract than in the blood. This promotes movement of the drug into the bloodstream. When the drug is circulated, the concentration is higher in the blood than in body cells, so that the drug moves (from capillaries) into the fluids surrounding the cells or into the cells themselves. Passive diffusion continues until a state of equilibrium is reached between the amount of drug in the tissues and the amount in the blood.

*Facilitated diffusion* is a similar process, except that drug molecules combine with a carrier substance, such as an enzyme or other protein.

In *active transport*, drug molecules are moved from an area of lower concentration to one of higher concentration. This process requires a carrier substance and the release of cellular energy.

intravenously (IV) do not need to be absorbed because they are placed directly into the bloodstream.

Other absorptive sites include the skin, mucous membranes, and lungs. Most drugs applied to the skin are given for local effects (e.g., sunscreens). Systemic absorption is minimal

from intact skin but may be considerable when the skin is inflamed or damaged. Also, some drugs are formulated in adhesive skin patches for absorption through the skin (e.g., clonidine, fentanyl, nitroglycerin). Some drugs applied to mucous membranes also are given for local effects. However, systemic absorption occurs from the mucosa of the oral cavity, nose, eye, vagina, and rectum. Drugs absorbed through mucous membranes pass directly into the bloodstream. The lungs have a large surface area for absorption of anesthetic gases and a few other drugs.

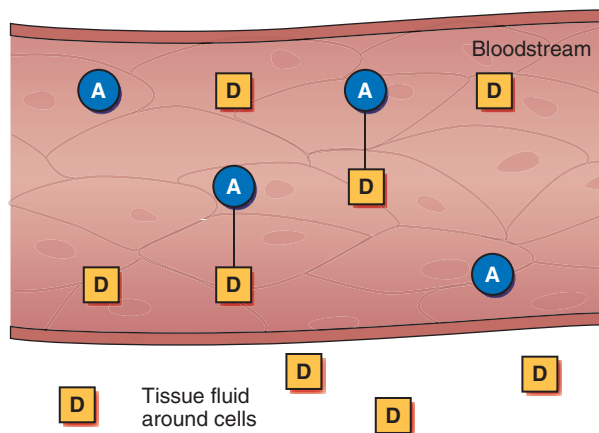

**Figure 2-3** ■ Drug transport pathways. Drug molecules cross cell membranes to move into and out of body cells by directly penetrating the lipid layer, diffusing through open or gated channels, or attaching to carrier proteins.

## Distribution

*Distribution* involves the transport of drug molecules within the body. After a drug is injected or absorbed into the bloodstream, it is carried by the blood and tissue fluids to its sites of action, metabolism, and excretion. Most drug molecules enter and leave the bloodstream at the capillary level, through gaps between the cells that form capillary walls. Distribution depends largely on the adequacy of blood circulation. Drugs are distributed rapidly to organs receiving a large blood supply, such as the heart, liver, and kidneys. Distribution to other internal organs, muscle, fat, and skin is usually slower.

*Protein binding* is an important factor in drug distribution (Fig. 2-4). Most drugs form a compound with plasma proteins, mainly albumin, which act as carriers. Drug molecules bound to plasma proteins are pharmacologically inactive because the large size of the complex prevents their leaving the bloodstream through the small openings in capillary walls and reaching their sites of action, metabolism, and excretion. Only the

**Figure 2-4** ■ Plasma proteins, mainly albumin (A), act as carriers for drug molecules (D). Bound drug (A–D) stays in the bloodstream and is pharmacologically inactive. Free drug (D) can leave the bloodstream and act on body cells.

free or unbound portion of a drug acts on body cells. As the free drug acts on cells, the decrease in plasma drug levels causes some of the bound drug to be released.

Protein binding allows part of a drug dose to be stored and released as needed. Some drugs also are stored in muscle, fat, or other body tissues and released gradually when plasma drug levels fall. These storage mechanisms maintain lower, more consistent blood levels and reduce the risk of toxicity. Drugs that are highly bound to plasma proteins or stored extensively in other tissues have a long duration of action.

Drug distribution into the central nervous system (CNS) is limited because the blood–brain barrier, which is composed of capillaries with tight walls, limits movement of drug molecules into brain tissue. This barrier usually acts as a selectively permeable membrane to protect the CNS. However, it also can make drug therapy for CNS disorders more difficult because drugs must pass through cells of the capillary wall rather than between cells. As a result, only drugs that are lipid soluble or have a transport system can cross the blood–brain barrier and reach therapeutic concentrations in brain tissue.

Drug distribution during pregnancy and lactation is also unique (see Chap. 65). During pregnancy, most drugs cross the placenta and may affect the fetus. During lactation, many drugs enter breast milk and may affect the nursing infant.

## Metabolism

*Metabolism* is the method by which drugs are inactivated or biotransformed by the body. Most often, an active drug is changed into inactive metabolites, which are then excreted. Some active drugs yield metabolites that are also active and that continue to exert their effects on body cells until they are metabolized further or excreted. Other drugs (called *prodrugs*) are initially inactive and exert no pharmacologic effects until they are metabolized. Most drugs are lipid soluble, a characteristic that aids their movement across cell membranes. However, the kidneys can excrete only water-soluble substances.

Therefore, one function of metabolism is to convert fat-soluble drugs into water-soluble metabolites. Hepatic drug metabolism or clearance is a major mechanism for terminating drug action and eliminating drug molecules from the body.

Most drugs are metabolized by cytochrome P450 (CYP) enzymes in the liver; red blood cells, plasma, kidneys, lungs, and gastrointestinal mucosa also contain drug-metabolizing enzymes. The CYP system consists of several groups of enzymes, some of which metabolize endogenous substances and some of which metabolize drugs. The drug-metabolizing groups are labeled CYP1, CYP2, and CYP3. Individual members of the groups usually metabolize specific drugs; more than one enzyme participates in the metabolism of some drugs. In terms of importance in drug metabolism, the CYP3A4 enzymes are thought to metabolize about 50% of drugs, CYP2D6 enzymes about 25%, CYP2C8/9 about 15%, and CYP1A2, 2C19, 2A6, and 2E1 in decreasing order for the remaining 10%.

CYP enzymes are complex proteins with binding sites for drug molecules (and endogenous substances). They catalyze the chemical reactions of oxidation, reduction, hydrolysis, and conjugation with endogenous substances, such as glucuronic acid or sulfate. With chronic administration, some drugs stimulate liver cells to produce larger amounts of drug-metabolizing enzymes (called *enzyme induction*). Enzyme induction accelerates drug metabolism because larger amounts of the enzymes (and more binding sites) allow larger amounts of a drug to be metabolized during a given time. As a result, larger doses of the rapidly metabolized drug may be required to produce or maintain therapeutic effects. Rapid metabolism may also increase the production of toxic metabolites with some drugs (e.g., acetaminophen). Drugs that induce enzyme production also may increase the rate of metabolism for endogenous steroidal hormones (e.g., cortisol, estrogens, testosterone, vitamin D). However, *enzyme induction does not occur for 1 to 3 weeks after an inducing agent is started*, because new enzyme proteins must be synthesized.

Metabolism also can be decreased or delayed in a process called *enzyme inhibition*, which most often occurs with concurrent administration of two or more drugs that compete for the same metabolizing enzymes. In this case, smaller doses of the slowly metabolized drug may be needed to avoid adverse effects and toxicity from drug accumulation. *Enzyme inhibition occurs within hours or days of starting an inhibiting agent*. Cimetidine, a gastric acid suppressor, inhibits several CYP enzymes (e.g., 1A, 2C, 2D, 3A) and can greatly decrease drug metabolism. The rate of drug metabolism also is reduced in infants (their hepatic enzyme system is immature), in people with impaired blood flow to the liver or severe hepatic or cardiovascular disease, and in people who are malnourished or on low-protein diets.

When drugs are given orally, they are absorbed from the gastrointestinal tract and carried to the liver through the portal circulation. Some drugs are extensively metabolized in the liver, with only part of a drug dose reaching the systemic circulation for distribution to sites of action. This is called the *first-pass effect* or presystemic metabolism.

## Excretion

*Excretion* refers to elimination of a drug from the body. Effective excretion requires adequate functioning of the circulatory system and of the organs of excretion (kidneys, bowel, lungs, and skin). Most drugs are excreted by the kidneys and eliminated (unchanged or as metabolites) in the urine. Some drugs or metabolites are excreted in bile and then eliminated in feces; others are excreted in bile, reabsorbed from the small intestine, returned to the liver (called *enterohepatic recirculation*), metabolized, and eventually excreted in urine. Some oral drugs are not absorbed and are excreted in the feces. The lungs mainly remove volatile substances, such as anesthetic gases. The skin has minimal excretory function. Factors impairing excretion, especially severe renal disease, lead to accumulation of numerous drugs and may cause severe adverse effects if dosage is not reduced.

## Serum Drug Levels

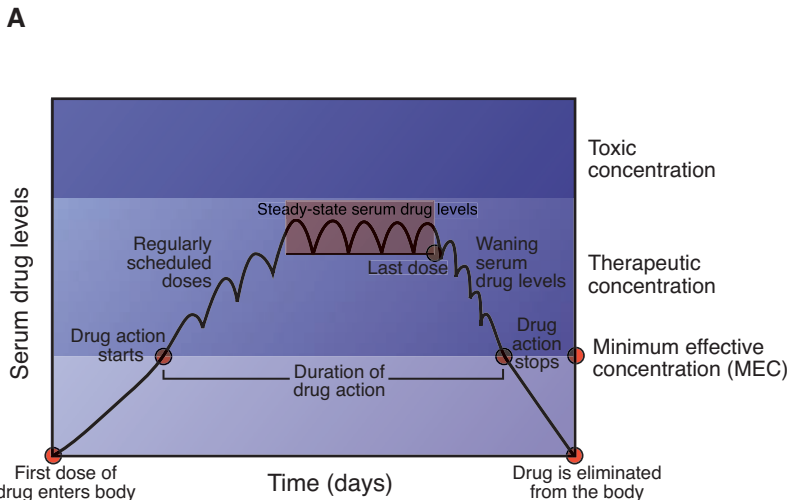

A *serum drug level* is a laboratory measurement of the amount of a drug in the blood at a particular time (Fig. 2-5). It reflects dosage, absorption, bioavailability, half-life, and the rates of metabolism and excretion. A minimum effective concentration

(MEC) must be present before a drug exerts its pharmacologic action on body cells; this is largely determined by the drug dose and how well it is absorbed into the bloodstream. A toxic concentration is an excessive level at which toxicity occurs. Toxic concentrations may stem from a single large dose, repeated small doses, or slow metabolism that allows the drug to accumulate in the body. Between these low and high concentrations is the therapeutic range, which is the goal of drug therapy—that is, enough drug to be beneficial but not enough to be toxic.

For most drugs, serum levels indicate the onset, peak, and duration of drug action. When a single dose of a drug is given, onset of action occurs when the drug level reaches the MEC. The drug level continues to climb as more of the drug is absorbed, until it reaches its highest concentration and peak drug action occurs. Then, drug levels decline as the drug is eliminated (i.e., metabolized and excreted) from the body. Although there may still be numerous drug molecules in the body, drug action stops when drug levels fall below the MEC. The duration of action is the time during which serum drug levels are at or above the MEC. When multiple doses of a drug are given (e.g., for chronic conditions), the goal is usually to give sufficient doses often enough to maintain serum drug levels in the therapeutic range and avoid the toxic range.

Drug action in relation to serum drug levels and time after a single dose.

Drug action in relation to serum drug levels with repeated doses.

**Figure 2-5** ■ Serum drug levels with single (A) and multiple (B) oral drug doses. Drug action starts when enough drug is absorbed to reach the minimum effective concentration (MEC), continues as long as the serum level is above the MEC, wanes as drug molecules are metabolized and excreted (if no more doses are given), and stops when the serum level drops below the MEC. The goal of drug therapy is to maintain serum drug levels in the therapeutic range.

In clinical practice, measuring serum drug levels is useful in several circumstances:

- When drugs with a narrow margin of safety are given, because their therapeutic doses are close to their toxic doses (e.g., digoxin, aminoglycoside antibiotics, lithium)
- To document the serum drug levels associated with particular drug dosages, therapeutic effects, or possible adverse effects
- To monitor unexpected responses to a drug dose such as decreased therapeutic effects or increased adverse effects
- When a drug overdose is suspected

## Serum Half-Life

*Serum half-life*, also called *elimination half-life*, is the time required for the serum concentration of a drug to decrease by 50%. It is determined primarily by the drug's rates of metabolism and excretion. A drug with a short half-life requires more frequent administration than one with a long half-life.

When a drug is given at a stable dose, four or five half-lives are required to achieve steady-state concentrations and to develop equilibrium between tissue and serum concentrations. Because maximal therapeutic effects do not occur until equilibrium is established, some drugs are not fully effective for days or weeks. To maintain steady-state conditions, the amount of drug given must equal the amount eliminated from the body. When a drug dose is changed, an additional four to five half-lives are required to re-establish equilibrium; when a drug is discontinued, it is eliminated gradually over several half-lives.

## Pharmacodynamics

*Pharmacodynamics* involves drug actions on target cells and the resulting alterations in cellular biochemical reactions and functions (i.e., “what the drug does to the body”).

### Receptor Theory of Drug Action

Like the physiologic substances (e.g., hormones, neurotransmitters) that normally regulate cell functions, most drugs exert their effects by chemically binding with receptors at the cellular level (Fig. 2-6). Most receptors are proteins located on the surfaces of cell membranes or within cells. Specific receptors include enzymes involved in essential metabolic or regulatory processes (e.g., dihydrofolate reductase, acetylcholinesterase); proteins involved in transport (e.g., sodium–potassium adenosine triphosphatase) or structural processes (e.g., tubulin); and nucleic acids (e.g., DNA) involved in cellular protein synthesis, reproduction, and other metabolic activities.

When drug molecules bind with receptor molecules, the resulting drug–receptor complex initiates physiochemical reactions that stimulate or inhibit normal cellular functions. One type of reaction involves activation, inactivation, or other alterations of intracellular enzymes. Because enzymes catalyze almost all cellular functions, drug-induced changes can markedly increase or decrease the rate of cellular metabolism.

**Figure 2-6** ■ Cell membrane contains receptors for physiologic substances such as hormones (H) and neurotransmitters (NT). These substances stimulate or inhibit cellular function. Drug molecules (Da and Db) also interact with receptors to stimulate or inhibit cellular function.

For example, an epinephrine–receptor complex increases the activity of the intracellular enzyme adenylyl cyclase, which then causes the formation of cyclic adenosine monophosphate (cAMP). cAMP, in turn, can initiate any one of many different intracellular actions, the exact effect depending on the type of cell.

A second type of reaction involves changes in the permeability of cell membranes to one or more ions. The receptor protein is a structural component of the cell membrane, and its binding to a drug molecule may open or close ion channels. In nerve cells, for example, sodium or calcium ion channels may open and allow movement of ions into the cell. This movement usually causes the cell membrane to depolarize and excite the cell. At other times, potassium channels may open and allow movement of potassium ions out of the cell. This action inhibits neuronal excitability and function. In muscle cells, movement of the ions into the cells may alter intracellular functions, such as the direct effect of calcium ions in stimulating muscle contraction.

A third reaction may modify the synthesis, release, or inactivation of the neurohormones (e.g., acetylcholine, norepinephrine, serotonin) that regulate many physiologic processes. Refer to Box 2-3 for additional elements and characteristics of the receptor theory.

### Nonreceptor Drug Actions

Relatively few drugs act by mechanisms other than combination with receptor sites on cells. Drugs that do not act on receptor sites include the following:

- Antacids act chemically to neutralize the hydrochloric acid produced by gastric parietal cells and thereby raise the pH of gastric fluid.

## Box 2-3

## Additional Elements of the Receptor Theory of Drug Action

- The site and extent of drug action on body cells are determined primarily by specific characteristics of receptors and drugs. Receptors vary in type, location, number, and functional capacity. For example, many different types of receptors have been identified. Most types occur in most body tissues, such as receptors for epinephrine (whether received from stimulation of the sympathetic nervous system or administration of drug formulations) and receptors for growth hormone, thyroid hormone, and insulin. Some occur in fewer body tissues, such as receptors for opioids in the brain and subgroups of receptors for epinephrine in the heart (beta<sub>1</sub>-adrenergic receptors) and lungs (beta<sub>2</sub>-adrenergic receptors). Receptor type and location influence drug action. *The receptor is often described as a lock into which the drug molecule fits as a key, and only those drugs able to bond chemically to the receptors in a particular body tissue can exert pharmacologic effects on that tissue.* Thus, all body cells do not respond to all drugs, even though virtually all cell receptors are exposed to any drug molecules circulating in the bloodstream.

The number of receptor sites available to interact with drug molecules also affects the extent of drug action. Drug molecules must occupy a minimal number of receptors to produce pharmacologic effects. Thus, if many receptors are available but only a few are occupied by drug molecules, few drug effects occur. In this instance, increasing the drug dosage increases the pharmacologic effects. Conversely, if only a few receptors are available for many drug molecules, receptors may be saturated. In this instance, if most receptor sites are occupied, increasing the drug dosage produces no additional pharmacologic effect.

Drugs vary even more widely than receptors. Because all drugs are chemical substances, chemical characteristics determine drug actions and pharmacologic effects. For example, a drug's chemical structure affects its ability to reach tissue fluids around a cell and bind with its cell receptors. Minor changes in drug structure may produce

major changes in pharmacologic effects. Another major factor is the concentration of drug molecules that reach receptor sites in body tissues. Drug- and patient-related variables that affect drug actions are further described later in this chapter.

- When drug molecules chemically bind with cell receptors, pharmacologic effects result from agonism or antagonism. *Agonists* are drugs that produce effects similar to those produced by naturally occurring hormones, neurotransmitters, and other substances. Agonists may accelerate or slow normal cellular processes, depending on the type of receptor activated. For example, epinephrine-like drugs act on the heart to increase the heart rate, and acetylcholine-like drugs act on the heart to slow the heart rate; both are agonists. *Antagonists* are drugs that inhibit cell function by occupying receptor sites. This strategy prevents natural body substances or other drugs from occupying the receptor sites and activating cell functions. After drug action occurs, drug molecules may detach from receptor molecules (i.e., the chemical binding is reversible), return to the bloodstream, and circulate to the liver for metabolism and the kidneys for excretion.
- Receptors are dynamic cellular components that can be synthesized by body cells and altered by endogenous substances and exogenous drugs. For example, prolonged stimulation of body cells with an excitatory agonist usually reduces the number or sensitivity of receptors. As a result, the cell becomes less responsive to the agonist (a process called receptor desensitization or down-regulation). Prolonged inhibition of normal cellular functions with an antagonist may increase receptor number or sensitivity. If the antagonist is suddenly reduced or stopped, the cell becomes excessively responsive to an agonist (a process called receptor up-regulation). These changes in receptors may explain why some drugs must be tapered in dosage and discontinued gradually if withdrawal symptoms are to be avoided.

- Osmotic diuretics (e.g., mannitol) increase the osmolarity of plasma and pull water out of tissues into the bloodstream.
- Drugs that are structurally similar to nutrients required by body cells (e.g., purines, pyrimidines) and that can be incorporated into cellular constituents, such as nucleic acids, interfere with normal cell functioning. Several anticancer drugs act by this mechanism.
- Metal chelating agents combine with toxic metals to form a complex that can be more readily excreted.

## Variables That Affect Drug Actions

Historically, expected responses to drugs were based on those occurring when a particular drug was given to healthy adult

men (18 to 65 years of age) of average weight (150 lb [70 kg]). However, other groups (e.g., women, children, older adults, different ethnic or racial groups, patients with diseases or symptoms that the drugs are designed to treat) receive drugs and respond differently from healthy adult men. As a result, newer clinical trials include more representatives of these groups. In any patient, however, responses may be altered by both drug- and patient-related variables.

## Drug-Related Variables

### Dosage

Dosage refers to the frequency, size, and number of doses; it is a major determinant of drug actions and responses, both therapeutic and adverse. If the amount is too small or administered infrequently, no pharmacologic action occurs because the drug does not reach an adequate concentration at target cells. If the

amount is too large or administered too often, toxicity (poisoning) may occur. Overdosage may occur with a single large dose or with chronic ingestion of smaller doses.

Dosages recommended in drug literature are usually those that produce particular responses in 50% of the people tested. These dosages usually produce a mixture of therapeutic and adverse effects. The dosage of a particular drug depends on many characteristics of the drug (reason for use, potency, pharmacokinetics, route of administration, dosage form, and others) and of the recipient (age, weight, state of health, and function of cardiovascular, renal, and hepatic systems). Thus, recommended dosages are intended only as guidelines for individualizing dosages.

### Route of Administration

Routes of administration affect drug actions and patient responses largely by influencing absorption and distribution. For rapid drug action and response, the IV route is most effective because the drug is injected directly into the bloodstream. For some drugs, the IM route also produces drug action within a few minutes because muscles have a large blood supply. The oral route usually produces slower drug action than parenteral routes. Absorption and action of topical drugs vary according to the drug formulation, whether the drug is applied to skin or mucous membranes, and other factors.

### Drug–Diet Interactions

A few drugs are used therapeutically to decrease food absorption in the intestinal tract. For example, orlistat (Xenical) decreases absorption of fats from food and is given to promote weight loss; ezetimibe (Zetia) decreases absorption of cholesterol from food and is given to lower serum cholesterol levels. However, most drug–diet interactions are undesirable because food often slows absorption of oral drugs by slowing gastric emptying time and altering gastrointestinal secretions and motility. Giving medications 1 hour before or 2 hours after a meal can minimize interactions that decrease drug absorption.

In addition, some foods contain certain substances that react with certain drugs. One such interaction occurs between tyramine-containing foods and monoamine oxidase (MAO) inhibitor drugs. Tyramine causes the release of norepinephrine, a strong vasoconstrictive agent, from the adrenal medulla and sympathetic neurons. Normally, norepinephrine is quickly inactivated by MAO. However, because MAO inhibitor drugs prevent inactivation of norepinephrine, ingesting tyramine-containing foods with an MAO inhibitor may produce severe hypertension or intracranial hemorrhage. MAO inhibitors include the antidepressants isocarboxazid and phenelzine and the antiparkinson drugs rasagiline and selegiline. Tyramine-rich foods to be avoided by patients taking MAO inhibitors include aged cheeses, sauerkraut, soy sauce, tap or draft beers, and red wines.

Another interaction may occur between warfarin (Coumadin), an oral anticoagulant, and foods containing vitamin K. Because vitamin K antagonizes the action of warfarin, large amounts of spinach and other green leafy vegetables may offset the anticoagulant effects and predispose the person to thromboembolic disorders.

A third interaction occurs between tetracycline, an antibiotic, and dairy products, such as milk and cheese. The drug combines with the calcium in milk products to form a nonabsorbable compound that is excreted in the feces.

Still another interaction involves grapefruit. Grapefruit contains a substance that strongly inhibits the metabolism of drugs normally metabolized by the CYP3A4 enzyme. This effect greatly increases the blood levels of some drugs (e.g., the widely used “statin” group of cholesterol-lowering drugs) and the effect lasts for several days. Patients who take medications metabolized by the 3A4 enzyme should be advised against eating grapefruit or drinking grapefruit juice.

### Drug–Drug Interactions

The action of a drug may be increased or decreased by its interaction with another drug in the body. Most interactions occur whenever the interacting drugs are present in the body; some, especially those affecting the absorption of oral drugs, occur when the interacting drugs are taken at or near the same time. The basic cause of many drug–drug interactions is altered drug metabolism. For example, drugs metabolized by the same enzymes compete for enzyme binding sites and there may not be enough binding sites for two or more drugs. Also, some drugs induce or inhibit the metabolism of other drugs. Protein binding is also the basis for some important drug–drug interactions.

Interactions that can increase the therapeutic or adverse effects of drugs include the following:

- *Additive effects* occur when two drugs with similar pharmacologic actions are taken (e.g., ethanol + sedative drug increases sedative effects).
- *Synergism* occurs when two drugs with different sites or mechanisms of action produce greater effects when taken together (e.g., acetaminophen [nonopioid analgesic] + codeine [opioid analgesic] increases analgesic effects).
- *Interference* by one drug with the metabolism of a second drug may result in intensified effects of the second drug. For example, cimetidine inhibits CYP1A, 2C, and 3A drug-metabolizing enzymes in the liver and therefore interferes with the metabolism of many drugs (e.g., benzodiazepine antianxiety and hypnotic drugs, several cardiovascular drugs). When these drugs are given concurrently with cimetidine, they are likely to cause adverse and toxic effects because blood levels of the drugs are higher. The overall effect is the same as taking a larger dose of the drug whose metabolism is inhibited or slowed.
- *Displacement* (i.e., a drug with a strong attraction to protein-binding sites may displace a less tightly bound drug) of one drug from plasma protein-binding sites by a second drug increases the effects of the displaced drug. This increase occurs because the displaced drug, freed from its bound form, becomes pharmacologically active. The overall effect is the same as taking a larger dose of the displaced drug. For example, aspirin displaces warfarin and increases the drug's anticoagulant effects.

Interactions in which drug effects are decreased include the following:

- An *antidote* drug can be given to antagonize the toxic effects of another drug. For example, naloxone is commonly used to relieve respiratory depression caused by morphine and related drugs. Naloxone molecules displace morphine molecules from their receptor sites on nerve cells in the brain so that the morphine molecules cannot continue to exert their depressant effects.
- Decreased intestinal absorption of oral drugs occurs when drugs combine to produce nonabsorbable compounds. For example, drugs containing aluminum, calcium, or magnesium bind with oral tetracycline (if taken at the same time) to decrease its absorption and therefore its antibiotic effect.
- Activation of drug-metabolizing enzymes in the liver increases the metabolism rate of any drug metabolized mainly by that group of enzymes and therefore decreases the drug's effects. Several drugs (e.g., phenytoin, rifampin) and cigarette smoking are known enzyme inducers.

## Patient-Related Variables

### Age

The effects of age on drug action are especially important in neonates, infants, and older adults. In children, drug action depends largely on age and developmental stage.

During pregnancy, drugs cross the placenta and may harm the fetus. Fetuses have no effective mechanisms for eliminating drugs because their liver and kidney functions are immature. Newborn infants (birth to 1 month) also handle drugs inefficiently. Drug distribution, metabolism, and excretion differ markedly in neonates, especially premature infants, because their organ systems are not fully developed. Older infants (1 month to 1 year) reach approximately adult levels of protein binding and kidney function, but liver function and the blood–brain barrier are still immature.

Children (1 to 12 years) have a period of increased activity of drug-metabolizing enzymes so that some drugs are rapidly metabolized and eliminated. Although the onset and duration of this period are unclear, a few studies have been done with particular drugs. Theophylline, for example, is eliminated much faster in a 7-year-old child than in a neonate or adult (18 to 65 years). After about 12 years of age, healthy children handle drugs similarly to healthy adults.

In older adults (65 years and older), physiologic changes may alter all pharmacokinetic processes. Changes in the gastrointestinal tract include decreased gastric acidity, decreased blood flow, and decreased motility. Despite these changes, however, there is little difference in drug absorption. Changes in the cardiovascular system include decreased cardiac output and therefore slower distribution of drug molecules to their sites of action, metabolism, and excretion. In the liver, blood flow and metabolizing enzymes are decreased. Thus, many drugs are metabolized more slowly, have a longer action, and are more likely to accumulate with chronic administration. In the kidneys, there is decreased blood flow, decreased glomeru-

lar filtration rate, and decreased tubular secretion of drugs. All these changes tend to slow excretion and promote accumulation of drugs in the body. Impaired kidney and liver function greatly increase the risks of adverse drug effects. In addition, older adults are more likely to have acute and chronic illnesses that require the use of multiple drugs or long-term drug therapy. Thus, possibilities for interactions among drugs and between drugs and diseased organs are greatly multiplied.

### Body Weight

Body weight affects drug action mainly in relation to dose. The ratio between the amount of drug given and body weight influences drug distribution and concentration at sites of action. In general, people heavier than average may need larger doses, provided that their renal, hepatic, and cardiovascular functions are adequate. Recommended doses for many drugs are listed in terms of grams or milligrams per kilogram of body weight.

### Genetic and Ethnic Characteristics

Drugs are given to cause particular effects in recipients. However, when given the same drug in the same dose, by the same route, and in the same time interval, some people experience inadequate therapeutic effects and others experience unusual or exaggerated effects, including increased toxicity. These variations in drug response are often attributed to genetic or ethnic differences in drug metabolism.

#### Genetics

Genes determine the types and amounts of proteins produced in body cells and thereby control both the physical and chemical functions of the cells. When most drugs enter the body, they interact with proteins (e.g., in plasma, tissues, cell membranes, drug receptor sites) to reach their sites of action, and they interact with other proteins (e.g., drug-metabolizing enzymes in the liver and other organs) to be biotransformed and eliminated from the body. Genetic characteristics that alter any of these proteins can alter drug responses. For example, metabolism of isoniazid, an antitubercular drug, requires the enzyme acetyltransferase. People may metabolize isoniazid rapidly or slowly, depending largely on genetic differences in acetyltransferase activity. Clinically, rapid metabolizers may need larger-than-usual doses to achieve therapeutic effects, and slow metabolizers may need smaller-than-usual doses to avoid toxic effects.

In addition, several genetic variations (called polymorphisms) of the cytochrome P450 drug-metabolizing enzymes have been identified. Specific variations may influence any of the chemical processes by which drugs are metabolized. For example, CYP2D6 metabolizes several antidepressant, antipsychotic, and beta-blocker drugs. Some Caucasians (about 7%) metabolize these drugs poorly and are at increased risk of drug accumulation and adverse effects. CYP2C19 metabolizes diazepam, omeprazole, and some antidepressants. As many as 15% to 30% of Asians may metabolize these drugs poorly and develop adverse effects if dosage is not reduced.

Still another example of genetic variation in drug metabolism is that some people are deficient in glucose-6-phosphate dehydrogenase, an enzyme normally found in red blood cells

and other body tissues. These people may have hemolytic anemia when given antimalarial drugs, sulfonamides, analgesics, antipyretics, and other drugs.

Genetic testing to determine a person's reaction to drug therapy is increasing, but clinical use is limited. Much research is being done in this area, especially related to cardiovascular and anticancer drugs (see Pharmacogenetics, below).

### Ethnicity

Most drug information has been derived from clinical drug trials using white men. Interethnic variations became evident when drugs and dosages developed for Caucasians produced unexpected responses, including toxicity, when given to individuals from other ethnic groups. One common variation is that African Americans respond differently to some cardiovascular drugs. For example, for African Americans with hypertension, angiotensin-converting enzyme (ACE) inhibitors and beta-adrenergic blocking drugs are less effective and diuretics and calcium channel blockers are more effective. Also, African Americans with heart failure seem to respond better to a combination of hydralazine and isosorbide than do Caucasian patients with heart failure.

Another variation is that Asians usually require much smaller doses of some commonly used drugs, including beta blockers and several psychotropic drugs (e.g., alprazolam, an antianxiety agent, and haloperidol, an antipsychotic). Some documented interethnic variations are included in later chapters.

### Pharmacogenetics

*Pharmacogenetics* involves the study of genetic variations (e.g., gene mutations that produce changes in structure and function of drug-metabolizing enzymes) that result in interindividual differences in drug response. Research has increased with awareness that genetic and ethnic characteristics are important factors and that diverse groups must be included in clinical trials. There is also increased awareness that *each person is genetically unique and must be treated as an individual* rather than as a member of a particular ethnic group. Research is ongoing toward improving drug safety and “personalized medicine,” in which prescribers can use a person's genetic characteristics to design a drug therapy regimen to produce the best therapeutic effects and the least adverse effects.

### Gender

Most drug-related research has involved men, and the results have been extrapolated to women, sometimes with adjustment of dosage based on the usually smaller size and weight of women. Historically, gender was considered a minor influence on drug action except during pregnancy and lactation. Now, differences between men and women in responses to drug therapy are being increasingly identified, and since 1993, regulations require that major clinical drug trials include women. Data on drug therapy in women are still limited, however. Some identified differences include the following:

- Women who are depressed are more likely to respond to the selective serotonin reuptake inhibitors (SSRIs), such as

fluoxetine (Prozac), than to the tricyclic antidepressants (TCAs), such as amitriptyline (Elavil).

- Women with anxiety disorders may respond less well than men to some antianxiety medications.
- Women with schizophrenia seem to need smaller doses of antipsychotic medications than men. If given the higher doses required by men, women are likely to have adverse drug reactions.
- Women may obtain more pain relief from opioid analgesics (e.g., morphine) and less relief from nonopioid analgesics (e.g., acetaminophen, ibuprofen), compared to men.

Different responses in women are usually attributed to anatomic and physiologic differences. In addition to smaller size and weight, for example, women usually have a higher percentage of body fat, less muscle tissue, smaller blood volume, and other characteristics that may influence responses to drugs. In addition, women have hormonal fluctuations during the menstrual cycle. Altered responses have been demonstrated in some women taking clonidine, an antihypertensive; lithium, a mood-stabilizing agent; phenytoin, an anticonvulsant; propranolol, a beta-adrenergic blocking drug used in the management of hypertension, angina pectoris, and migraine; and antidepressants. In addition, a significant percentage of women with arthritis, asthma, depression, diabetes mellitus, epilepsy, and migraine experience increased symptoms premenstrually. The increased symptoms may indicate a need for adjustments in their drug therapy regimens. Women with clinical depression, for example, may need higher doses of antidepressant medications premenstrually, if symptoms exacerbate, and lower doses during the rest of the menstrual cycle.

There may also be differences in pharmacokinetic processes, although few studies have been done. With absorption, it has been noted that women absorb a larger percentage of an oral dose of two cardiovascular medications compared to men (25% more verapamil and 40% more aspirin). With distribution, women may have higher blood levels of medications that distribute into body fluids (because of the smaller amount of water in which the medication can disperse) and lower blood levels of medications that are deposited in fatty tissues (because of the generally higher percentage of body fat). With metabolism, the CYP3A4 enzyme metabolizes more medications than other enzymes, and women are thought to metabolize the drugs processed by this enzyme 20% to 40% faster than men (and therefore may have lower blood levels than men of similar weight given the same doses). The CYP1A2 enzyme is less active in women so that women who take the cardiovascular drugs clopidogrel or propranolol may have higher blood levels than men (and possibly greater risks of adverse effects if given the same doses as men). With excretion, renally excreted medications may reach higher blood levels because a major mechanism of drug elimination, glomerular filtration, is approximately 20% lower in women.

In general, women given equal dosages or equal weight-based dosages are thought to be exposed to higher concentrations of medications compared to men. Although available

data are limited, the main reasons postulated for the gender differences are that women have a lower volume of distribution, lower glomerular filtration, and lower hepatic enzyme activity (except for the medications metabolized by the CYP3A4 enzyme system, which is more active in women). As a result, all women should be monitored closely during drug therapy because they are more likely to experience adverse drug effects than are men.

### Pathologic Conditions

Various pathologic conditions may alter some or all pharmacokinetic (PK) processes and lead to decreased therapeutic effects or increased risks of adverse effects. Examples include the following:

- **Cardiovascular disorders** (e.g., myocardial infarction, heart failure, hypotension) may interfere with all PK processes, mainly by decreasing blood flow to sites of drug administration, action, metabolism (liver), and excretion (kidneys).
- **Gastrointestinal disorders** (e.g., vomiting, diarrhea, inflammatory bowel disease, trauma or surgery of the gastrointestinal tract) may interfere with absorption of oral drugs.
- **Hepatic disorders** (e.g., hepatitis, cirrhosis, decreased liver function) mainly interfere with metabolism. Severe liver disease or cirrhosis may interfere with all PK processes.
- **Renal disorders** (e.g., acute or chronic renal failure) mainly interfere with excretion. Severe kidney disease may interfere with all PK processes.
- **Thyroid disorders** mainly affect metabolism. Hypothyroidism slows metabolism, which prolongs drug action and slows elimination. Hyperthyroidism accelerates metabolism, which shortens drug action and hastens elimination.

### Psychological Considerations

Psychological considerations influence individual responses to drug administration, although specific mechanisms are unknown. An example is the placebo response. A placebo is a pharmacologically inactive substance. Placebos are used in clinical drug trials to compare the medication being tested with a “dummy” medication. Recipients often report both therapeutic and adverse effects from placebos.

Attitudes and expectations related to drugs in general, a particular drug, or a placebo influence patient response. They also influence compliance or the willingness to carry out the prescribed drug regimen, especially with long-term drug therapy.

### Tolerance and Cross-Tolerance

Drug *tolerance* occurs when the body becomes accustomed to a particular drug over time so that larger doses must be given to produce the same effects. *Tolerance* may be acquired to the pharmacologic action of many drugs, especially opioid analgesics, alcohol, and other CNS depressants. Tolerance to pharmacologically related drugs is called *cross-tolerance*. For example, a person who regularly drinks large amounts of alcohol becomes able to ingest even larger amounts before

becoming intoxicated—this is tolerance to alcohol. If the person is then given sedative-type drugs or a general anesthetic, larger-than-usual doses are required to produce a pharmacologic effect—this is cross-tolerance.

Tolerance and cross-tolerance are usually attributed to activation of drug-metabolizing enzymes in the liver, which accelerates drug metabolism and excretion. They also are attributed to decreased sensitivity or numbers of receptor sites.

## Adverse Effects of Drugs

As used in this book, the term *adverse effects* refer to any undesired responses to drug administration, as opposed to therapeutic effects, which are desired responses. Most drugs produce a mixture of therapeutic and adverse effects; all drugs can produce adverse effects. Adverse effects may produce essentially any symptom or disease process and may involve any body system or tissue. They may be common or rare, mild or severe, localized or widespread—depending on the drug and the recipient. Some adverse effects occur with usual therapeutic doses of drugs (often called side effects); most are more likely to occur and to be more severe with high doses. Common or serious adverse effects are described in Box 2-4. Although adverse effects may occur in anyone who takes medications, they are especially likely to occur with some drugs (e.g., insulin, warfarin) and in older adults, who often take multiple drugs.

For some drug groups and individual drugs that may cause serious or life-threatening adverse effects, the Food and Drug Administration (FDA) requires drug manufacturers to place a **BLACK BOX WARNING (BBW)** on the label of a prescription drug or in the literature describing it. A **BBW** is usually added after a significant number of serious adverse effects have occurred, often several years after a drug is marketed and after it is used in large numbers of people. The **BBW** is the strongest warning from the FDA and often includes prescribing or monitoring information intended to improve the safety of using the particular drug or drug group. In recent years, **BBWs** have been added to antidepressant drugs, nonopioid analgesics, and the antiviral drug oseltamivir (Tamiflu).

### Applying Your Knowledge 2-1

#### How Can You Avoid This Medication Error?

Mrs. Green is taking a number of medications, including three medications to control her hypertension. During your most recent visit (3 days ago), you instructed Mrs. Green to take her medication with a large glass of water and set up a daily pill calendar. You also checked her vital signs; her blood pressure was 148/70.

Today, you recheck her vital signs and her blood pressure is 96/60. You ask Mrs. Green about her medication and she tells you she has been taking it according to the calendar three times a day.

.....

## Box 2-4

## Common or Serious Adverse Drug Effects

**Central Nervous System (CNS) Effects**

CNS effects may result from CNS stimulation (e.g., agitation, confusion, disorientation, hallucinations, psychosis, seizures) or CNS depression (e.g., impaired level of consciousness, sedation, coma, impaired respiration and circulation). CNS effects may occur with many drugs, including most therapeutic groups, substances of abuse, and over-the-counter preparations.

**Gastrointestinal (GI) Effects**

GI effects (e.g., nausea, vomiting, constipation, diarrhea) commonly occur. Nausea and vomiting occur with many drugs as a result of local irritation of the GI tract or stimulation of the vomiting center in the brain. Diarrhea occurs with drugs that cause local irritation or increase peristalsis. More serious effects include bleeding or ulceration (most often with nonsteroidal anti-inflammatory agents such as ibuprofen) and severe diarrhea/colitis (most often with antibiotics).

**Hematologic Effects**

Hematologic effects (excessive bleeding, clot formation [thrombosis], bone marrow depression, anemias, *leukopenia*, agranulocytosis, thrombocytopenia) are relatively common and potentially life threatening. Excessive bleeding is often associated with anticoagulants and thrombolytics; bone marrow depression is associated with anticancer drugs.

**Hepatic Effects**

Hepatic effects (hepatitis, liver dysfunction or failure, biliary tract disorders) are potentially life threatening. The liver is especially susceptible to drug-induced injury because most drugs are circulated to the liver for metabolism and some drugs are toxic to liver cells. Hepatotoxic drugs include acetaminophen (Tylenol), isoniazid (INH), methotrexate (Trexall), phenytoin (Dilantin), and aspirin and other salicylates. In the presence of drug- or disease-induced liver damage, the metabolism of many drugs is impaired. Besides hepatotoxicity, many drugs produce abnormal values in liver function tests without producing clinical signs of liver dysfunction.

**Nephrotoxicity**

*Nephrotoxicity* (nephritis, renal insufficiency or failure) occurs with several antimicrobial agents (e.g., gentamicin and other aminoglycosides), nonsteroidal anti-inflammatory agents (e.g., ibuprofen and related drugs), and others. It is potentially serious because it may interfere with drug excretion, thereby causing drug accumulation and increased adverse effects.

**Hypersensitivity**

*Hypersensitivity* or allergy may occur with almost any drug in susceptible patients. It is largely unpredictable and unrelated to dose. It occurs in those who have previously been exposed to the drug or a similar substance (antigen) and who have

developed antibodies. When readministered, the drug reacts with the antibodies to cause cell damage and the release of histamine and other substances. These substances produce reactions ranging from mild skin rashes to anaphylactic shock. Anaphylactic shock is a life-threatening hypersensitivity reaction characterized by respiratory distress and cardiovascular collapse. It occurs within a few minutes after drug administration and requires emergency treatment with epinephrine. Some allergic reactions (e.g., serum sickness) occur 1 to 2 weeks after the drug is given.

**Drug Fever**

Drugs can cause fever by several mechanisms, including allergic reactions, damaging body tissues, interfering with dissipation of body heat, or acting on the temperature-regulating center in the brain. The most common mechanism is an allergic reaction. Fever may occur alone or with other allergic manifestations (e.g., skin rash, hives, joint and muscle pain, enlarged lymph glands, eosinophilia). It may begin within hours after the first dose if the patient has taken the drug before or within about 10 days of continued administration if the drug is new to the patient. If the causative drug is discontinued, fever usually subsides within 48 to 72 hours unless drug excretion is delayed or significant tissue damage has occurred (e.g., hepatitis). Many drugs have been implicated as causes of drug fever, including most antimicrobials.

**Idiosyncrasy**

Idiosyncrasy refers to an unexpected reaction to a drug that occurs the first time it is given. These reactions are usually attributed to genetic characteristics that alter the person's drug-metabolizing enzymes.

**Drug Dependence**

Drug dependence may occur with mind-altering drugs, such as opioid analgesics, sedative-hypnotic agents, antianxiety agents, and CNS stimulants. Dependence may be physiologic or psychological. Physiologic dependence produces unpleasant physical symptoms when the dose is reduced or the drug is withdrawn. Psychological dependence leads to excessive preoccupation with drugs and drug-seeking behavior.

**Carcinogenicity**

Carcinogenicity is the ability of a substance to cause cancer. Several drugs are carcinogens, including some hormones and anticancer drugs. Carcinogenicity apparently results from drug-induced alterations in cellular DNA.

**Teratogenicity**

Teratogenicity is the ability of a substance to cause abnormal fetal development when taken by pregnant women. Drug groups considered teratogenic include antiepileptic drugs and "statin" cholesterol-lowering drugs.

## Toxicology: Drug Overdose

Drug toxicity (also called poisoning or overdose) results from excessive amounts of a drug and may damage body tissues. It is a common problem in both adult and pediatric populations. It may result from a single large dose or prolonged ingestion of smaller doses and may involve alcohol or prescription, over-the-counter, or illicit drugs. Clinical manifestations are often nonspecific and may indicate other disease processes. Because of the variable presentation of drug intoxication, health care providers must have a high index of suspicion so that toxicity can be rapidly recognized and treated.

When toxicity occurs in a home or outpatient setting and the victim is collapsed or not breathing, call 911 for emergency aid. If the victim is responsive, someone needs to contact the National Poison Control Center by phone at 1-800-222-1222 or by computer at [www.1-800-222-1222.info](http://www.1-800-222-1222.info). The caller is connected to a local Poison Control Center and, if possible, needs to tell the responding pharmacist or physician the name

of the drug that was taken, the amount, and when. The poison control consultant may recommend treatment measures over the phone or that the victim be taken to a hospital emergency department.

When toxicity occurs in a hospitalized patient or when an outpatient is taken to a hospital, the patient or someone else may know the toxic agent (e.g., accidental overdose of a therapeutic drug, use of an illicit drug, a suicide attempt). Often, however, multiple drugs have been ingested, the causative drugs are unknown, and the circumstances may involve traumatic injury or impaired mental status that make the patient unable to provide useful information. The main goals of treatment are starting treatment as soon as possible after drug ingestion, supporting and stabilizing vital functions, preventing further damage from the toxic agent by reducing absorption or increasing elimination, and administering antidotes when available and indicated. General aspects of care are described in Box 2-5, selected antidotes are listed in Table 2-1, and specific aspects of care are described in relevant chapters.

### Box 2-5

### General Management of Toxicity

- The first priority is support of vital functions, as indicated by rapid assessment of vital signs and level of consciousness. In serious poisonings, an electrocardiogram is indicated and findings of severe toxicity (e.g., dysrhythmias, ischemia) justify aggressive treatment. Standard cardiopulmonary resuscitation (CPR) measures may be needed to maintain breathing and circulation. An intravenous (IV) line is usually needed to administer fluids and drugs, and invasive treatment or monitoring devices may be inserted. Endotracheal intubation and mechanical ventilation are often required to maintain breathing (in unconscious patients), correct hypoxemia, and protect the airway. Hypoxemia must be corrected quickly to avoid brain injury, myocardial ischemia, and cardiac dysrhythmias. Serious cardiovascular manifestations often require drug therapy. Hypotension and hypoperfusion may be treated with inotropic and vasopressor drugs to increase cardiac output and raise blood pressure. Dysrhythmias are treated according to Advanced Cardiac Life Support (ACLS) protocols. Recurring seizures or status epilepticus requires treatment with anticonvulsant drugs.
- For unconscious patients, as soon as an IV line is established, some authorities recommend a dose of naloxone (2 mg IV) for possible narcotic overdose and thiamine (100 mg IV) for possible brain dysfunction due to thiamine deficiency. In addition, a fingerstick blood glucose test should be done, and if hypoglycemia is indicated, a 50% dextrose solution (50 mL IV) should be given.
- After the patient is out of immediate danger, a thorough physical examination and efforts to determine the drug(s), the amounts, and the time lapse since exposure are needed. If the patient is unable to supply needed information, interview anyone else who may be able to do so. Ask about

the use of prescription and over-the-counter drugs, alcohol, and illicit substances.

- There are no standard laboratory tests for poisoned patients, but baseline tests of liver and kidney function are usually indicated. Screening tests for toxic substances are not very helpful because test results may be delayed, many substances are not detected, and the results rarely affect initial treatment. Specimens of blood, urine, or gastric fluids may be obtained for laboratory analysis. Serum drug levels are needed when acetaminophen, alcohol, aspirin, digoxin, lithium, or theophylline is known to be an ingested drug, to assist with treatment.
- For most orally ingested drugs, the initial and major treatment is a single dose of activated charcoal. Sometimes called the “universal antidote,” it is useful in many poisonings because it adsorbs many toxins and rarely causes complications. When given within 30 minutes of drug ingestion, it decreases absorption of the toxic drug by about 90%; when given an hour after ingestion, it decreases absorption by about 37%. Activated charcoal (1 g/kg of body weight or 50–100 g) is usually mixed with 240 mL of water (25–50 g in 120 mL of water for children) to make a slurry, which is gritty and unpleasant to swallow. It is often given by nasogastric tube. The charcoal blackens subsequent bowel movements. If used with whole bowel irrigation (WBI; see below), activated charcoal should be given before the WBI solution is started. If given during WBI, the binding capacity of the charcoal is decreased. Activated charcoal does not significantly decrease absorption of some drugs (e.g., ethanol, iron, lithium, metals). Multiple doses of activated charcoal may be given in some instances (e.g., ingestion of sustained-release drugs). One regimen is an initial dose of 50 to 100 grams, then 12.5 grams every 1, 2, or 4–6 hours for a few doses.

Adverse effects of activated charcoal include pulmonary aspiration and bowel obstruction from impaction of the charcoal–drug complex. To prevent these effects, unconscious patients should not receive the drug until the airway is secure against aspiration, and many patients are given a laxative (e.g., sorbitol) to aid removal of the charcoal–drug complex.

Ipecac-induced vomiting and gastric lavage are no longer routinely used because of minimal effectiveness and potential complications. Ipecac is no longer recommended to treat poisonings in children in home settings; parents should call a poison control center or a health care provider. Gastric lavage may be beneficial in serious overdoses if performed within an hour of drug ingestion. If the ingested agent delays gastric emptying (e.g., drugs with anticholinergic effects), the time limit may be extended. When used after ingestion of pills or capsules, the tube lumen should be large enough to allow removal of pill fragments.

- Whole bowel irrigation (WBI) with a polyethylene glycol solution (e.g., Colyte) may be used to remove toxic ingestions of long-acting, sustained-release drugs (e.g., many beta blockers, calcium channel blockers, and theophylline preparations); enteric-coated drugs; and toxins that do not bind

well with activated charcoal (e.g., iron, lithium). It may also be helpful in removing packets of illicit drugs, such as cocaine or heroin. When used, 500–2000 mL per hour are given orally or by nasogastric tube until bowel contents are clear. Vomiting is the most common adverse effect. WBI is contraindicated in patients with serious bowel disorders (e.g., obstruction, perforation, ileus), hemodynamic instability, or respiratory impairment (unless intubated).

- Urinary elimination of some drugs and toxic metabolites can be accelerated by changing the pH of urine (e.g., alkalinizing with IV sodium bicarbonate for salicylate overdose), diuresis, or hemodialysis. Hemodialysis is the treatment of choice in severe lithium and aspirin (salicylate) poisoning.
- Specific antidotes can be administered when available and as indicated by the patient’s clinical condition. Available antidotes vary widely in effectiveness. Some are very effective and rapidly reverse toxic manifestations (e.g., naloxone for opioids, specific Fab fragments for digoxin).

When an antidote is used, its half-life relative to the toxin’s half-life must be considered. For example, the half-life of naloxone, a narcotic antagonist, is relatively short compared with the half-life of the longer-acting opioids such as methadone, and repeated doses may be needed to prevent recurrence of the toxic state.

Table 2-1

Antidotes for Overdoses of Selected Therapeutic Drugs

OVERDOSED DRUG (POISON)	ANTIDOTE	ROUTE AND DOSAGE RANGES	COMMENTS
Acetaminophen (see Chap. 7)	Acetylcysteine (Mucomyst 10% or 20% oral solution, Acetadote 20% [200 mg/mL] injection solution)	PO 140 mg/kg initially, then 70 mg/kg q4h for 17 doses. IV (Acetadote only) Loading dose: 150 mg/kg, diluted in 200 mL 5% dextrose, infused over 15 min. Maintenance dose one: 50 mg/kg, diluted in 500 mL 5% dextrose, infused over 4 h. Maintenance dose two: 100 mg/kg, diluted in 1000 mL 5% dextrose, infused over 16 h	Dilute oral solution to a 5% solution with a cola or other soft drink for oral administration.  Follow instructions carefully and note that doses, amounts of diluent, and infusion times are different for the three total IV infusions.
Anticholinergics (atropine; see Chap. 20)	Physostigmine	IV, IM 2 mg; give IV slowly, over at least 2 min	Infrequently used because of its toxicity. Should not be given to patients with a seizure disorder, overdose of unknown drugs, or overdose of drugs known to cause seizures in overdose (e.g., cocaine, lithium). In such circumstances, the risks of seizures outweigh drug benefits.
Benzodiazepines (see Chap. 8)	Flumazenil	IV 0.2 mg over 30 sec; if no response, may give additional 0.3 mg over 30 sec. Additional doses of 0.5 mg may be given at 1-min intervals up to a total amount of 3 mg	Should not be given to patients with overdose of unknown drugs or drugs known to cause seizures in overdose (e.g., cocaine, lithium)

(continued on page 24)

Table 2-1

## Antidotes for Overdoses of Selected Therapeutic Drugs (continued)

OVERDOSED DRUG (POISON)	ANTIDOTE	ROUTE AND DOSAGE RANGES	COMMENTS
Beta blockers (see Chap. 18)	Glucagon	IV 50–150 mcg/kg (5–10 mg for adults) over 1 min initially, then 2–5 mg/h by continuous infusion as needed	Glucagon increases myocardial contractility and raises blood pressure. It does not act on beta-adrenergic receptors and is therefore not affected by beta-blocking drugs.
Calcium channel blockers (see Chaps. 50, 52)	Calcium gluconate 10%	IV 1 g over 5 min; may be repeated	Increases myocardial contractility
Cholinergics (see Chap. 19)	Atropine	Adults: IV 2 mg, repeated as needed Children: IV 0.05 mg/kg, up to 2 mg	If poisoning is due to organophosphates (e.g., insecticides), pralidoxime may be given with the atropine.
Digoxin (see Chap. 48)	Digoxin immune Fab (Digibind)	IV 40 mg (1 vial) for each 0.6 mg of digoxin ingested Reconstitute each vial with 4 mL Water for Injection, then dilute with sterile isotonic saline to a convenient volume and give over 30 min, through a 0.22-micron filter. If cardiac arrest seems imminent, may give the dose as a bolus injection.	Recommended for severe toxicity; reverses cardiac and extracardiac symptoms in a few minutes Note: Serum digoxin levels increase after antidote administration, but the drug is bound and therefore inactive.
Heparin (see Chap. 54)	Protamine sulfate	IV 1 mg/100 units of heparin, slowly, over at least 10 min; a single dose should not exceed 50 mg	
Iron (see Chap. 57)	Deferoxamine	IM 1 g q8h PRN IV 15 mg/kg/h if hypotensive	Indicated for serum iron levels >500 mg/dL or serum levels >350 mg/dL with GI or cardiovascular symptoms Can bind and remove a portion of an ingested dose; urine becomes red as iron is excreted
Isoniazid (INH)	Pyridoxine	IV 1 g per gram of INH ingested, at rate of 1 g q2–3 min. If amount of INH unknown, give 5 g; may be repeated.	Indicated for management of seizures and correction of acidosis
Lead	Succimer (Chemet)	Children: PO 10 mg/kg q8h for 5 days	
Opioid analgesics (Chap. 6)	Naloxone (Narcan)	Adults: IV 0.4–2 mg PRN Children: IV 0.1 mg/kg per dose	Can also be given IM, Sub-Q, or by endotracheal tube
Phenothiazine antipsychotic agents (see Chap. 9)	Diphenhydramine (Benadryl)	Adults: IV 50 mg Children: IV 1–2 mg/kg, up to a total of 50 mg	Given to relieve extrapyramidal symptoms (movement disorders)
Thrombolytics (see Chap. 54)	Aminocaproic acid (Amicar)	PO, IV infusion, 5 g initially, then 1–1.25 g/h for 8 h or until bleeding is controlled; maximum dose, 30 g/24h	
Tricyclic antidepressants (see Chap. 10)	Sodium bicarbonate	IV 1–2 mEq/kg initially, then continuous IV drip to maintain serum pH of 7.5	To treat cardiac dysrhythmias, conduction disturbances, and hypotension
Warfarin (see Chap. 54)	Vitamin K <sub>1</sub>	PO 5–10 mg daily IV (severe overdose) continuous infusion at rate no faster than 1 mg/min	

Most overdosed patients are treated in emergency rooms and discharged to their homes. A few are admitted to intensive care units (ICUs), often because of unconsciousness and the need for endotracheal intubation and mechanical ventilation. Unconsciousness is a major toxic effect of several commonly

ingested substances such as benzodiazepine antianxiety and sedative agents, tricyclic antidepressants, ethanol, and opioid analgesics. Serious cardiovascular effects (e.g., cardiac arrest, dysrhythmias, circulatory impairment) are also common and warrant admission to an ICU.

## Key Concepts

- Drugs can stimulate or inhibit normal cellular activities but cannot add new functions.
- Most drugs exert their effects by chemically combining with receptors at the cellular level.
- Receptor proteins can be altered by endogenous substances and exogenous drugs.
- Pharmacokinetic processes involve absorption, distribution, metabolism, and excretion.
- Serum drug levels reflect dosage, absorption, bioavailability, elimination half-life, and the rate of elimination.
- Drug-related variables that affect drug action include dosage, route, drug-diet and drug-drug interactions.
- Patient-related variables that affect drug action include age, body weight, genetic and ethnic characteristics, gender, pathologic conditions, and psychological status.
- All drugs can produce adverse effects; adverse effects may produce essentially any symptom or disease process and may involve any body system.
- Drug toxicity results from excessive amounts of a drug, whether received in a single large dose or multiple smaller doses.
- Activated charcoal is considered the “universal” antidote; most drugs do not have specific antidotes for overdoses.

## Review and Application Exercises

### Short Answer Exercises

1. Why do nurses need to understand cellular physiology in relation to drug therapy?
2. What are some factors that decrease absorption of an oral drug?
3. Drug dosage is a major determinant of both therapeutic and adverse drug effects. How can you use this knowledge in monitoring a patient’s response to drug therapy?
4. Does protein binding speed or slow drug distribution to sites of action? Why?
5. Are drugs equally distributed throughout the body? Why or why not?
6. What are the implications of hepatic enzyme induction and inhibition in terms of drug metabolism and elimination from the body?
7. For a drug in which biotransformation produces active metabolites, is drug action shortened or lengthened? What difference does this make in patient care?
8. Which pharmacokinetic processes are likely to be impaired with severe cardiovascular disease and with severe renal disease?
9. What are the main elements of the receptor theory of drug action?
10. When drug–drug interactions occur, are drug actions increased or decreased?

11. What are some reasons for individual differences in responses to drugs?

### NCLEX-Style Questions

12. You are reading a research report about use of a medication that describes the pharmacokinetics of a particular medication that your patient is on. You know that pharmacokinetics involves
  - a. drug effects on human cells
  - b. drug binding with receptors
  - c. drug absorption, distribution, metabolism, and elimination
  - d. drug stimulation of normal cell functions
13. The nurse practitioner has just changed your patient’s medication from an oral form to a patch formulation to avoid the “first-pass effect.” The NP has explained it to the patient, but the patient still has questions and asks you to explain again what is meant by the first-pass effect. You would be most correct in explaining that this has to do with how
  - a. drugs initially bind to plasma proteins
  - b. initial renal function is involved in drug excretion
  - c. the way drugs first reach their target cells
  - d. initial metabolism of an oral drug occurs before it reaches the systemic circulation

14. You are caring for a patient who has worsening liver disease. In monitoring his medication it is important that you know that a patient with liver disease may have impaired
- absorption
  - distribution
  - metabolism
  - excretion
15. A patient with an overdose of an oral drug usually receives
- a specific antidote
  - activated charcoal
  - syrup of ipecac
  - a strong laxative
16. You are looking up information about the effects of a drug on different receptors. You know that characteristics of receptors include which of the following?
- They are carbohydrates located in cell membranes or inside cells.
  - They are constantly synthesized and degraded in the body.
  - They bind with molecules of any drug circulating in the bloodstream.
  - They regulate the actions of all drugs.

# Administering Medications

## KEY TERMS

- Dosage forms
- Enteric-coated
- “Five rights”
- Parenteral
- Sustained release
- Topical
- Transdermal

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. List the “rights” of drug administration.
2. Discuss knowledge and skills needed to implement the “rights” of drug administration.
3. List requirements of a complete drug order or prescription.
4. Accurately interpret drug orders containing common abbreviations.
5. Differentiate drug dosage forms for various routes and purposes of administration.
6. Discuss advantages and disadvantages of oral, parenteral, and topical routes of drug administration.
7. Identify supplies, techniques, and observations needed for safe and accurate administration of drugs by different routes.

## Applying Your Knowledge

Juan Sanchez is transferred to your rehabilitation facility after a cerebral vascular accident (stroke) 2 weeks ago. When you review his chart, it indicates he has right-sided hemiparesis and memory deficits.

.....

## Introduction

Drugs given for therapeutic purposes are called *medications*. Giving medications to patients is an important nursing responsibility in many health care settings, including ambulatory care, hospitals, long-term care facilities, and patients’ homes. The basic requirements for accurate drug administration are often called the “*five rights*”:

1. Right *drug*
2. Right *dose*
3. Right *patient*
4. Right *route*
5. Right *time*

Some people add a sixth “right”: documentation. These “rights” require knowledge of the drugs to be given and the patients who are to receive them as well as specific nursing skills and interventions. When one of these “rights” is violated, medication errors can occur. Nurses need to recognize circumstances in which errors are likely to occur and intervene to prevent errors and protect patients. This chapter is concerned with safe and accurate medication administration.

## General Principles of Accurate Drug Administration

The following principles should be followed:

- Follow the “rights” consistently.
- Learn essential information about each drug to be given (e.g., indications for use, contraindications, therapeutic effects, adverse effects, any specific instructions about administration).
- Interpret the prescriber’s order accurately (i.e., drug name, dose, frequency of administration). Question the prescriber if any information is unclear or if the drug seems inappropriate for the patient’s condition.
- Read labels of drug containers for the drug name and concentration (usually in milligrams per tablet, capsule, or milliliter of solution). Many medications are available in different dosage forms and concentrations, and it is extremely important that the correct ones are used.
- Minimize the use of abbreviations for drug names, doses, routes of administration, and times of administration. This promotes safer administration and reduces errors. When abbreviations are used by prescribers or others, interpret them accurately or question the writers about intended meanings.
- Calculate doses accurately. Current nursing practice requires few dosage calculations (most are done by pharmacists). However, when they are needed, accuracy is essential. For medications with a narrow safety margin or potentially serious adverse effects, ask a pharmacist or a colleague to do the calculation also and compare the results. This is especially important when calculating children’s dosages.
- Measure doses accurately. Ask a colleague to double-check measurements of insulin and heparin, unusual doses (i.e., large or small), and any drugs to be given intravenously.
- Use the correct procedures and techniques for all routes of administration. For example, use appropriate anatomic landmarks to identify sites for intramuscular (IM) injections, follow the manufacturers’ instructions for preparation and administration of intravenous (IV) medications, and use sterile materials and techniques for injectable and eye medications.
- Seek information about the patient’s medical diagnoses and condition in relation to drug administration (e.g., ability to swallow oral medications; allergies or contraindications to ordered drugs; new signs or symptoms that may indicate adverse effects of administered drugs; heart, liver, or kidney disorders that may interfere with the patient’s ability to eliminate drugs).
- Verify the identity of all patients before administering medications; check identification bands on patients who have them (e.g., in hospitals or long-term care facilities).
- Omit or delay doses as indicated by the patient’s condition and report or record omissions appropriately.
- Be especially vigilant when giving medications to children, because there is a high risk of medication errors. One reason is children’s great diversity in age, from birth to 18 years, and in weight, from 2 to 3 kilograms to 100 kilograms or more. Another reason is that most drugs have not been tested in children. A third reason is that many drugs are marketed in dosage forms and concentrations suitable for adults. This often requires dilution, calculation, preparation, and administration of very small doses. A fourth reason is that children have limited sites for administration of IV drugs, and several may be given through the same site. In many cases, the need for small volumes of fluid limits flushing between drugs (which may produce undesirable interactions with other drugs and IV solutions).

## Legal Responsibilities

Registered and licensed practical nurses are legally empowered, under state nurse practice acts, to give medications ordered by licensed physicians and dentists. In some states, nurse practitioners may prescribe medications.

When giving medications, the nurse is legally responsible for safe and accurate administration. This means that the nurse may be held liable for not giving a drug or for giving a wrong drug or a wrong dose. In addition, the nurse is expected to have sufficient drug knowledge to recognize and question erroneous orders. If, after questioning the prescriber and seeking information from other authoritative sources, the nurse considers that giving a drug is unsafe, the nurse must refuse to give the drug. The fact that a physician wrote an erroneous order does not excuse the nurse from legal liability if he or she carries out that order.

The nurse also is legally responsible for actions delegated to people who are inadequately prepared for or legally barred from administering medications (e.g., nursing assistants). However, certified medical assistants (CMAs) may administer medications in physicians’ offices, and certified medication aides (nursing assistants with a short course of training, also called CMAs) often administer medications in long-term care facilities.

The nurse who consistently follows safe practices in giving medications does not need to be excessively concerned about legal liability. The basic techniques and guidelines described in this chapter are aimed at safe and accurate preparation and administration. Most errors result when these practices are not followed.

Legal responsibilities in other aspects of drug therapy are less clear-cut. However, in general, nurses are expected to monitor patients’ responses to drug therapy (e.g., therapeutic and adverse effects) and to teach patients safe and effective self-administration of drugs when indicated. These aspects are described more fully in Chapter 4.

## Medication Errors

Medication errors continue to receive increasing attention from numerous health care organizations and agencies. Much of this interest stems from a 1999 report of the Institute of Medicine, which estimated that 44,000 to 98,000 deaths occur each year in the United States because of medical errors, including medication errors. Potential adverse patient outcomes of medication and other errors include serious illness, conditions that prolong hospitalization or require additional treatment, and death. Medication errors commonly reported include giving an incorrect dose, not giving an ordered drug, and giving an unordered drug. Specific drugs often associated with errors and adverse drug events (ADEs) include insulin, heparin, and warfarin. The risk of ADEs increases with the number of drugs a patient uses.

Medication errors may occur at any step in the drug distribution process, from the manufacturer to the patient, includ-

ing prescribing, transcribing, dispensing, and administration. Many steps and numerous people are involved in giving the correct dose of a medication to the intended patient; each step or person has a potential for contributing to a medication error or preventing a medication error. All health care providers involved in drug therapy need to recognize risky situations, intervene to prevent errors when possible, and be extremely vigilant in all phases of drug administration. Recommendations for prevention of medication errors have been developed by several organizations, including the Institute of Medicine (IOM), the Agency for Healthcare Research and Quality (AHRQ), the Joint Commission on Accreditation of Healthcare Organizations (JCAHO), the Institute for Safe Medication Practices (ISMP), and the National Coordinating Council for Medication Error Reporting and Prevention (NCCMERP). Some sources of medication errors and recommendations to prevent them are summarized in Table 3-1.

**Table 3-1**

### Medication Errors: Sources and Prevention Strategies

#### SOURCES OF ERRORS

##### Drug manufacturers

Drugs may have similar names that can lead to erroneous prescribing, dispensing, or administration. For example, the antiseizure drug Lamictal (generic name, lamotrigine) has been confused with Lamisil, an anti-fungal drug, lamivudine, an antiviral drug, and others. The FDA estimates that about 10% of all reported medication errors result from drug name confusion.

In addition to similar names, many drugs, especially those produced by the same manufacturer, have similar packaging. This can lead to errors if container labels are not read carefully, especially if the products are shelved or stored next to each other.

Long-acting oral dosage forms with various, sometimes unclear indicators (e.g., LA, XL, XR), may be crushed, chewed, or otherwise broken so that the long-acting feature is destroyed. This can cause an overdose.

##### Health care agencies

Prescribers, pharmacists, and nurses may have a heavy workload, with resultant rushing of prescribing, dispensing, and administering medications. They may also experience distractions by interruptions, noise, and other events in the work environment that make it difficult to pay needed attention to the medication-related task.

#### RECOMMENDATIONS TO PREVENT ERRORS

- FDA evaluation of proposed trade names in manufacturers' new drug applications in seeking FDA approval for marketing.
  - When choosing a trade name for a new drug, avoid names that are similar to drugs already on the market.
  - Design packaging so that all drugs from an individual manufacturer don't look alike in terms of color, appearance, etc.
  - Clearly designate long-acting drug formulations.
  - Use Tall Man lettering on drug labels to distinguish between generic drugs with similar names (e.g., NICARDipine, NIFEdipine; vinBLAstine, vinCristine).
- 
- Provide prescribers with computerized order entry (CPOE) technology and standardized drug order sheets; discourage handwritten drug orders; minimize verbal orders and state procedures to follow when verbal orders are necessary.
  - Provide computerized technology (e.g., bar coding for patients; handheld scanning devices for nursing staff) to verify the drug, the dose, and the patient identity before administration of a dose and to record administration after a dose.
  - Provide sufficient pharmacy staff to dispense medications.
  - Provide sufficient nursing staff to administer medications.
  - Try to provide a quiet and orderly work environment, with limited human traffic, telephones, and other distractions.
  - Provide adequate equipment for the required medication-related tasks. For pharmacies, this includes an adequate computer system for accessing databases of drug information and for detecting risks for adverse drug effects and drug-drug interactions.

Table 3-1

## Medication Errors: Sources and Prevention Strategies (continued)

SOURCES OF ERRORS	RECOMMENDATIONS TO PREVENT ERRORS
<p><b>Prescribers</b> may write orders illegibly; order a drug that is not indicated by the patient's condition; fail to order a drug that is indicated; fail to consider the patient's age, size, kidney function, liver function, and disease process when selecting a drug or dosage; fail to consider other medications the patient is taking, including prescription, over-the-counter, and herbal drugs; lack sufficient knowledge about the drug; fail to monitor for, or instruct others to monitor for, effects of administered drugs; and fail to discontinue drugs appropriately.</p>	<ul style="list-style-type: none"> <li>■ Standardize drug administration materials and equipment (e.g., infusion pumps) throughout the agency.</li> <li>■ Be sure that all professional staff members know and follow safety standards and medication reconciliation processes mandated by the Joint Commission on Accreditation of Healthcare Organizations (JCAHO).</li> <li>■ Use computerized order entry when available.</li> <li>■ Be sure that any handwritten drug order is legible (e.g., printed in block letters if necessary), clear, and unambiguous.</li> <li>■ Avoid or minimize the use of abbreviations.</li> <li>■ Use generic names of medications rather than brand names and include the purpose of the drug.</li> <li>■ Avoid verbal orders when possible. If a verbal order is necessary, have the person taking the order write the order and read it back, spelling drug names, dosages, routes, and so forth when indicated.</li> <li>■ Review the patient's health status and other drugs being taken before ordering any new drug. Also, discontinue drugs appropriately when no longer needed.</li> <li>■ Maintain a current knowledge base about new drugs and changes in uses of drugs for the relevant area of clinical practice.</li> </ul>
<p><b>Pharmacists</b> may not know the patient's condition or recognize an inappropriate or erroneous physician's order. They may dispense incorrect medications, mislabel containers, or fail to determine other drugs being taken.</p>	<ul style="list-style-type: none"> <li>■ Promote and assist with computerized drug order systems and bar-coding technology, when possible.</li> <li>■ Verify or request clarification of unclear drug orders.</li> <li>■ Check the compatibility of newly ordered drugs with available information about a patient's health status and medications already being taken.</li> <li>■ Verify patient weight and recalculate any dosages based on weight or body surface area, especially for children.</li> <li>■ Review the original order before dispensing a medication, except in emergency situations.</li> <li>■ Prepare drugs in a work area with minimal distractions and interruptions.</li> <li>■ Separate look-alike and sound-alike medications on pharmacy shelves; do not store them next to each other.</li> <li>■ When possible, dispense medications in a single unit-dose, ready-to-administer form.</li> <li>■ Maintain current information about sound-alike and look-alike drugs; drugs often associated with medication errors and adverse effects (e.g., insulin, heparin, warfarin); drugs associated with high risks of serious drug-drug interactions; and drug dosage forms that should not be chewed or crushed, tablets that may and may not be split, and capsules that may or may not be opened.</li> <li>■ For large agencies with many drug orders, encourage specialization in certain areas (e.g., neonatal/pediatric drug therapy; oncology drugs and treatment regimens for various types of cancer).</li> <li>■ Encourage all health care providers to report medication errors, so that preventive interventions can be developed.</li> </ul>
<p><b>Nurses</b> may have inadequate knowledge about a drug or about the patient receiving the drug; not follow the "five rights"; and fail to question the medication order when indicated.</p>	<ul style="list-style-type: none"> <li>■ Be aware of agency policies and procedures about medication use, storage, administration, and recording.</li> <li>■ Maintain an up-to-date knowledge base about drugs and their administration.</li> <li>■ Make a diligent effort to learn about patients' health status and the drugs they're receiving.</li> <li>■ Question or clarify any unclear drug orders.</li> </ul>

**SOURCES OF ERRORS****Patients/consumers**

Outpatients may take drugs from several prescribers; fail to inform one prescriber about drugs prescribed by another health care provider; get prescriptions filled at more than one pharmacy; fail to get prescriptions filled or refilled; underuse or overuse an appropriately prescribed drug; take drugs left over from a previous illness or prescribed for someone else; fail to follow instructions for drug administration or storage; fail to keep appointments for follow-up care; and fail to ask for information when needed.

**RECOMMENDATIONS TO PREVENT ERRORS**

- Verify medication calculations with another nurse or a pharmacist, especially for children.
  - Recheck a single dose any time the amount seems unusually large or small.
  - Verify settings on drug infusion pumps with another nurse, when indicated.
  - Follow the “five rights” consistently.
  - Recheck the original drug order when a patient questions whether a particular drug dose should be taken.
  - Report errors, so that preventive efforts can be designed.
  - Discuss patients’ medications during change-of-shift reports, including new and discontinued drugs, patients’ responses to their medications, patient teaching about medications, and medications given 1 to 2 h before report or scheduled to be given 1–2 h in a 1- to 2-h window after each report.
- 
- Inform all health care providers about health status, any drug allergies, and all medications being taken (e.g., prescription, over-the-counter, herbal, and dietary supplements).
  - Ask prescribers to include the purpose of a drug on the label of all prescription medications.
  - If able, know names, strengths, doses, and the reason for use of all medications.
  - Follow instructions about when and how to take medications; do not increase amount or frequency of any medication without checking with a health care provider. Ask questions or request written instructions if needed.
  - If unable to take medications or if problems occur, discuss with a health care provider. Do not stop taking prescribed medications.
  - Maintain a current list of all medications being taken. Take the list or the medications to each visit to a health care provider.
  - Keep all medications in their original containers.
  - Read labels of medication containers every time a dose is taken.
  - Do not chew, crush, or break any tablets or capsules unless a health care provider says it is okay to do so.

## Medication Systems

Each health care facility has a system for distributing drugs. The unit-dose system, in which most drugs are dispensed in single-dose containers for individual patients, is widely used. In this system, drug orders are checked by a pharmacist or pharmacy technician, who then places the indicated number of doses in the patient’s medication drawer at scheduled intervals. When a dose is due to be taken, the nurse removes the medication and gives it to the patient. Unit-dose wrappings of oral drugs should be left in place until the nurse is in the presence of the patient and ready to give the medication. Each dose of a drug must be recorded on the patient’s medication administration record (MAR) as soon as possible after administration.

Increasingly, institutions are using automated, computerized, locked cabinets for which each nurse on a unit has a password or code for accessing the cabinet and obtaining a drug

dose. An inventory is maintained, and drugs are restocked as needed.

Controlled drugs, such as opioid analgesics, are usually kept as a stock supply in a locked drawer or automated cabinet and replaced as needed. Each dose is signed for and recorded on the patient’s MAR. Each nurse must comply with legal regulations and institutional policies for dispensing and recording controlled drugs.

### Changes to Prevent Medication Errors

Changes in medication systems are being increasingly implemented, largely in efforts to decrease medication errors and improve patient safety. These include the following:

- Computerized provider order entry (CPOE). In this system, a prescriber types a medication order directly into a

computer. This decreases errors associated with illegible handwriting and erroneous transcription or dispensing. CPOE, which is already used in many health care facilities, is widely recommended as the preferred alternative to error-prone handwritten orders.

- Bar coding. In 2004, the Food and Drug Administration (FDA) passed a regulation requiring drug manufacturers to put bar codes on current prescription medications and non-prescription medications that are commonly used in hospitals. New drugs must have bar codes within 60 days of their approval. In hospitals, bar codes operate with other agency computer systems and databases that contain a patient's medication orders and medication administration record (MAR). The bar code on the drug label contains the identification number, strength, and dosage form of the drug, and the bar code on the patient's identification band contains the MAR, which can be displayed when a nurse uses a handheld scanning device. When administering medications, the nurse scans the bar code on the drug label, on the patient's identification band, and on the nurse's personal identification badge. A wireless computer network processes the scanned information; gives an error message on the scanner or sounds an alarm if the nurse is about to give the wrong drug or the right drug at the wrong time; and automatically records the time, drug, and dose given on the MAR. The FDA estimates that it will take about 20 years for all U.S. hospitals to implement this system of bar codes for medication administration.
- For nurses, implementing the bar-coding technology increases the time requirements and interferes with their ability to individualize patient care in relation to medications. Such a system works well with routine medications, but nonroutine situations (e.g., variable doses or times of administration) may pose problems. In addition, in long-term care facilities, it may be difficult to maintain legible bar codes on patient identification bands. Despite some drawbacks, bar coding increases patient safety and therefore should be supported by nurses as it continues to develop.
- Limiting use of abbreviations. The ISMP has long maintained a list of abbreviations that are often associated with medication errors, and the JCAHO now requires accredited organizations to maintain a "Do not use" list (e.g., u or U for units, IU for international units, qd for daily, qod for every other day) that applies to all prescribers and transcribers of medication orders. Other abbreviations are not recommended, as well. In general, it is safer to write out drug names, routes of administration, and so forth and to minimize the use of abbreviations, symbols, and numbers that are often misinterpreted, especially when handwritten.
- Medication reconciliation. This is a process designed to avoid medication errors such as omissions, duplications, dosing errors, or drug interactions that occur when a patient is admitted to a health care agency, transferred from one

department or unit to another within the agency, or discharged home from the agency. It involves obtaining an accurate medication history about the prescription, over-the-counter, vitamins, and herbal medications taken at home, including dose and frequency of administration, upon entry into the health care agency. The list of medications developed from the medication history is compared to newly ordered medications and identified discrepancies are resolved. The list is placed in the medical record so that it is accessible to all health care providers, including the prescriber who writes the patient's admission drug orders. When the patient is transferred, the updated list must be communicated to the next health care provider. When a patient is discharged, an updated list should be given to the next provider and to the patient. The patient should be encouraged to keep the list up-to-date when changes are made in the medication regimen and to share the list with future health care providers.

## Medication Orders

Medication orders should include the full name of the patient; the name of the drug (preferably the generic name); the dose, route, and frequency of administration; and the date, time, and signature of the prescriber.

Orders in a health care facility may be typed into a computer (the preferred method) or handwritten on an order sheet in the patient's medical record. Occasionally, verbal or telephone orders are acceptable. When taken, they should be written on the patient's order sheet, signed by the person taking the order, and later countersigned by the prescriber. After the order is written, a copy is sent to the pharmacy, where the order is recorded and the drug is dispensed to the appropriate patient care unit. In many facilities, pharmacy staff prepares a computer-generated MAR for each 24-hour period.

For patients in ambulatory care settings, the procedure is essentially the same for drugs to be given immediately. For drugs to be taken at home, written prescriptions are given. In addition to the previous information, a prescription should include instructions for taking the drug (e.g., dose, frequency) and whether the prescription can be refilled. Prescriptions for Schedule II controlled drugs cannot be refilled.

To interpret medication orders accurately, the nurse must know commonly used abbreviations for routes, dosages, and times of drug administration (Table 3-2). Because of medication errors occurring with incorrect or misinterpreted abbreviations, many abbreviations that were formerly commonly used are now banned or no longer recommended by the Joint Commission on Accreditation of Healthcare Organizations (JCAHO), the Institute for Safe Medication Practices (ISMP), and other organizations concerned with increasing patient safety. Thus, it is safer practice to write out such words as "daily" or "three times daily," "at bedtime," "ounce," "teaspoon" or "tablespoon," or "right," "left," or "both eyes" rather

Table 3-2

## Common Abbreviations

## ROUTES OF DRUG ADMINISTRATION

IM	intramuscular
IV	intravenous
PO	by mouth, oral
SL	sublingual
Sub-Q	subcutaneous

## DRUG DOSAGES

cc	cubic centimeter
g	gram
mg	milligram
mcg	microgram
mL	milliliter
oz	ounce
tbsp	tablespoon
tsp	teaspoon

## TIMES OF DRUG ADMINISTRATION

ad lib	as desired
PRN	as needed
q4h	every 4 hours
stat	immediately

than using abbreviations, in both medication orders and in transcribing orders to the patient's MAR. If the nurse cannot read the physician's order or if the order seems erroneous, he or she must question the order before giving the drug.

### Applying Your Knowledge 3-1

#### How Can You Avoid This Medication Error?

You are administering 6 A.M. medications to a patient on a busy medical unit. You enter Mr. Gonzalez's room, gently shake him awake, and call him by name. He slowly awakens and appears groggy. You explain that you have his medications, which he takes and then quickly falls back to sleep. On exiting the room, you look at the room number and realize that you just gave medications to Mr. Sanchez.

## Drug Preparations and Dosage Forms

Drug preparations and dosage forms vary according to the drug's chemical characteristics, reason for use, and route of adminis-

tration. Some drugs are available in only one dosage form, and others are available in several forms. Characteristics of various dosage forms are described as follows and in Table 3-3.

*Dosage forms* of systemic drugs include liquids, tablets, capsules, suppositories, and transdermal and pump delivery systems. Systemic liquids are given orally, or PO (Latin *per os*, "by mouth"), or by injection. Those given by injection must be sterile.

Tablets and capsules are given PO. Tablets contain active drug plus binders, colorants, preservatives, and other substances. Capsules contain active drug enclosed in a gelatin capsule. Most tablets and capsules dissolve in the acidic fluids of the stomach and are absorbed in the alkaline fluids of the upper small intestine. *Enteric-coated* tablets and capsules are coated with a substance that is insoluble in stomach acid. This delays dissolution until the medication reaches the intestine, usually to avoid gastric irritation or to keep the drug from being destroyed by gastric acid. Tablets for sublingual (under the tongue) or buccal (held in cheek) administration must be specifically formulated for such use.

Several controlled-release dosage forms and drug delivery systems are available, and more continue to be developed. These formulations maintain more consistent serum drug levels and allow less frequent administration, which is more convenient for patients. Controlled-release oral tablets and capsules are called by a variety of names (e.g., timed release, *sustained release*, extended release), and their names usually include CR, SR, XL, or other indications that they are long-acting formulations. Most of these formulations are given once or twice daily. Some drugs (e.g., alendronate for osteoporosis, fluoxetine for major depression) are available in formulations that deliver a full week's dosage in one oral tablet. Because controlled-release tablets and capsules contain high amounts of drug intended to be absorbed slowly and act over a prolonged period of time, they should never be broken, opened, crushed, or chewed. Such an action allows the full dose to be absorbed immediately and constitutes an overdose, with potential organ damage or death. *Transdermal* (skin patch) formulations include systemically absorbed clonidine, estrogen, fentanyl, and nitroglycerin. These medications are slowly absorbed from the skin patches over varying periods of time (e.g., 1 week for clonidine and estrogen). Pump delivery systems may be external or implanted under the skin and refillable or long acting without refills. Pumps are used to administer insulin, opioid analgesics, antineoplastics, and other drugs.

Solutions, ointments, creams, and suppositories are applied topically to skin or mucous membranes. They are formulated for the intended route of administration. For example, several drugs are available in solutions for nasal or oral inhalation; they are usually self-administered as a spray into the nose or mouth.

Many combination products containing fixed doses of two or more drugs are also available. Commonly used combinations include analgesics, antihypertensive drugs, and cold remedies. Most are oral tablets, capsules, or solutions.

Table 3-3

## Drug Dosage Forms

DOSAGE FORMS AND THEIR ROUTES OF ADMINISTRATION	CHARACTERISTICS	CONSIDERATIONS/PRECAUTIONS
<b>Tablets</b>		
<i>Regular:</i> PO, GI tube (crushed and mixed with water)	<ul style="list-style-type: none"> <li>Contain active drug plus binders, dyes, preservatives</li> <li>Dissolve in gastric fluids</li> </ul>	8 oz of water recommended, to promote dissolution and absorption
<i>Chewable:</i> PO	<ul style="list-style-type: none"> <li>Colored and flavored, mainly for young children</li> </ul>	Children may think tablets are candy; keep out of reach to avoid accidental overdose
<i>Enteric coated:</i> PO	<ul style="list-style-type: none"> <li>Dissolve in small intestine; mainly used for medications that cause gastric irritation</li> </ul>	Do not crush; instruct patients not to chew or crush.
<i>Extended release (XL)</i> (also called sustained release (SR), long acting (LA) and other names: PO	<ul style="list-style-type: none"> <li>Slowly absorbed; effects prolonged, usually 12–24 h</li> <li>Contain relatively large amounts of active drug</li> </ul>	<b>Warning:</b> Crushing to give orally or through a GI tube administers an overdose, with potentially serious adverse effects or death!! <i>Never crush</i> ; instruct patients not to chew or crush.
<i>Sublingual:</i> Under the tongue <i>Buccal:</i> Held in cheek	<ul style="list-style-type: none"> <li>Dissolve quickly</li> <li>Medication absorbed directly into the bloodstream and exerts rapid systemic effects</li> </ul>	Few medications formulated for administration by SL or buccal routes
<b>Capsules</b>		
<i>Regular:</i> PO	<ul style="list-style-type: none"> <li>Contain active drug, fillers, and preservatives</li> <li>Gelatin capsules dissolve in gastric fluid and release medication.</li> </ul>	8 oz of fluid recommended to promote dissolution and absorption
<i>Extended release (XL); sustained release (SR); long-acting (LA):</i> PO	<ul style="list-style-type: none"> <li>Slowly absorbed; effects prolonged, usually 12–24 h</li> <li>Contain relatively large amounts of active drug</li> </ul>	<b>Warning:</b> Emptying a capsule to give the medication orally or through a GI tube administers an overdose, with potentially serious adverse effects or death!! Instruct patients not to bite, chew, or empty these capsules.
<b>Solutions</b>		
<i>Oral:</i> PO, GI tube	<ul style="list-style-type: none"> <li>Absorbed rapidly because they do not need to be dissolved</li> </ul>	Use of appropriate measuring devices and accurate measurement is extremely important.
<i>Parenteral:</i> IV, IM, Sub-Q, intradermal	<ul style="list-style-type: none"> <li>Medications and all administration devices must be sterile.</li> <li>IV produces rapid effects; Sub-Q is used mainly for insulin and heparin; IM is used for only a few drugs; intradermal is used mainly to inject skin-test material.</li> </ul>	Use of appropriate equipment and accurate measurement is extremely important. Insulin syringes should always be used for insulin, and tuberculin syringes are recommended for measuring small amounts of other drugs.
<b>Suspensions</b>		
PO, Sub-Q (e.g., NPH, Lente insulins)	<ul style="list-style-type: none"> <li>Particles of active drug are suspended in a liquid; the liquid must be rotated or shaken before measuring a dose.</li> </ul>	Drug particles settle to the bottom on standing. If not remixed, the liquid vehicle is given rather than the drug dose.
<b>Dermatologic Creams, Lotions, Ointments</b>		
Topically to skin	<ul style="list-style-type: none"> <li>Most are minimally absorbed through skin and exert local effects at the site of application; some (e.g., skin patches) are absorbed and exert systemic effects.</li> </ul>	Formulations vary with intended uses and are not interchangeable. When removed from the patient, skin patches must be disposed of properly to prevent someone else from being exposed to the active drug remaining in the patch.

DOSAGE FORMS AND THEIR ROUTES OF ADMINISTRATION	CHARACTERISTICS	CONSIDERATIONS/PRECAUTIONS
<b>Solutions and Powders for Oral or Nasal Inhalation, Including Metered Dose Inhalers (MDIs)</b>	<ul style="list-style-type: none"> <li>Oral inhalations are used mainly for asthma; nasal sprays for nasal allergies (allergic rhinitis).</li> <li>Effective with less systemic effect than oral drugs</li> <li>Deliver a specified dose per inhalation</li> </ul>	Several research studies indicate that patients often do not use MDIs correctly; correct use is essential to obtaining therapeutic effects and avoiding adverse effects.
<b>Eye Solutions and Ointments</b>	<ul style="list-style-type: none"> <li>Should be sterile</li> <li>Packaged in small amounts for individual use</li> </ul>	Can be systemically absorbed and cause systemic adverse effects
<b>Throat Lozenges</b>	<ul style="list-style-type: none"> <li>Used for cough and sore throat</li> </ul>	
<b>Ear Solutions</b>	<ul style="list-style-type: none"> <li>Used mainly for ear infections</li> </ul>	
<b>Vaginal Creams and Suppositories</b>	<ul style="list-style-type: none"> <li>Used to treat vaginal infections</li> </ul>	
<b>Rectal Suppositories and Enemas</b>	<ul style="list-style-type: none"> <li>Suppositories may be used to administer sedatives, analgesics, laxatives.</li> <li>Medicated enemas may be used for constipation or inflammatory bowel diseases.</li> </ul>	Effects somewhat unpredictable because absorption is erratic

## Calculating Drug Dosages

When calculating drug dosages, the importance of accuracy cannot be overemphasized. Accuracy requires basic skills in mathematics, knowledge of common units of measurement, and methods of using data in performing calculations.

### Systems of Measurement

The most commonly used system of measurement is the metric system, in which the meter is used for linear measure, the gram for weight, and the liter for volume. One milliliter (mL) equals 1 cubic centimeter (cc), and both equal 1 gram (g) of water. The household system, with units of drops, teaspoons, tablespoons, and cups, is infrequently used in health care agencies but may be used at home. Table 3-4 lists some commonly used equivalent measurements.

A few drugs are ordered and measured in terms of units or milliequivalents (mEq). Units express biologic activity in animal tests (i.e., the amount of drug required to produce a particular response). Units are unique for each drug. For example, concentrations of insulin and heparin are both expressed in units, but there is no relation between a unit of insulin and a unit of heparin. These drugs are usually ordered in the number of units per dose (e.g., NPH insulin 30 units subcutaneously [Sub-Q] every morning, or heparin 5000 units Sub-Q q12h) and labeled in number of units per milliliter (U 100 insulin contains 100 units/mL; heparin may have 1000, 5000, or 10,000 units/mL). Milliequivalents express the ionic activity of a drug. Drugs such as potassium chloride are ordered and labeled in the number of milliequivalents per dose, tablet, or milliliter.

## Mathematical Calculations

Most drug orders and labels are expressed in metric units of measurement. If the amount specified in the order is the same as that on the drug label, no calculations are required, and preparing the right dose is a simple matter. For example, if the order reads “ibuprofen 400 mg PO” and the drug label reads “ibuprofen 400 mg per tablet,” it is clear that one tablet is to be given.

**Table 3-4**

### Selected Equivalent Measurements

METRIC	HOUSEHOLD
<b>Weights</b>	
1000 mcg = 1 mg	
1000 mg = 1 g	
30 g	1 oz
454 g	1 lb
1000 g = 1 kg	2.2 lb
<b>Liquids</b>	
1 mL = 1 cc	
5 mL	1 tsp
30 mL	2 tbsp or 1 oz
250 mL	1 cup or 8 oz
500 mL	1 pint
1000 mL = 1 L	1 quart

What happens if the order calls for a 400-mg dose and 200-mg tablets are available? The question is, “How many 200-mg tablets are needed to give a dose of 400 mg?” In this case, the answer can be readily calculated mentally to indicate two tablets. This is a simple example that also can be used to illustrate mathematical calculations. This problem can be solved by several acceptable methods; the following formula is presented because of its relative simplicity for students lacking a more familiar method.

$$\frac{D}{H} = \frac{X}{V}$$

- $D$  = desired dose (dose ordered, often in milligrams)  
 $H$  = on-hand or available dose (dose on the drug label; often in mg per tablet, capsule, or milliliter)  
 $X$  = unknown (number of tablets, in this example)  
 $V$  = volume or unit (one tablet, in this example)

$$\frac{400 \text{ mg}}{200 \text{ mg}} = \frac{X \text{ tablet}}{1 \text{ tablet}}$$

Cross multiply:

$$\begin{aligned} 200X &= 400 \\ \frac{400}{200} &= 2 \text{ tablets} \end{aligned}$$

What happens if the order and the label are written in different units? For example, the order may read “amoxicillin 0.5 g” and the label may read “amoxicillin 500 mg/capsule.” To calculate the number of capsules needed for the dose, the first step is to convert 0.5 g to the equivalent number of milligrams, or convert 500 mg to the equivalent number of grams. *The desired or ordered dose and the available or label dose must be in the same units of measurement.* Using the equivalents (i.e., 1 g = 1000 mg) listed in Table 3-3, an equation can be set up as follows:

$$\frac{1 \text{ g}}{1000 \text{ mg}} = \frac{0.5 \text{ g}}{X \text{ mg}}$$

$$X = 0.5 \times 1000 = 500 \text{ mg}$$

The next step is to use the new information in the formula, which then becomes

$$\frac{D}{H} = \frac{X}{V}$$

$$\frac{500 \text{ mg}}{500 \text{ mg}} = \frac{X \text{ capsules}}{1 \text{ capsule}}$$

$$500X = 500$$

$$X = \frac{500}{500} = 1 \text{ capsule}$$

The same procedure and formula can be used to calculate portions of tablets or doses of liquids. These are illustrated in the following problems:

1. Order: 25 mg PO  
 Label: 50-mg tablet

$$\frac{25 \text{ mg}}{50 \text{ mg}} = \frac{X \text{ tablet}}{1 \text{ tablet}}$$

$$50X = 25$$

$$X = \frac{25}{50} = 0.5 \text{ tablet}$$

2. Order: 25 mg IM

Label: 50 mg in 1 cc

$$\frac{25 \text{ mg}}{50 \text{ mg}} = \frac{X \text{ cc}}{1 \text{ cc}}$$

$$50X = 25$$

$$X = \frac{25}{50} = 0.5 \text{ cc}$$

3. Order: 4 mg IV

Label: 10 mg/mL

$$\frac{4 \text{ mg}}{10 \text{ mg}} = \frac{X \text{ mL}}{1 \text{ mL}}$$

$$10X = 4$$

$$X = \frac{4}{10} = 0.4 \text{ mL}$$

## Routes of Administration

Routes of administration depend on drug characteristics, patient characteristics, and desired responses. The major routes are oral (by mouth), *parenteral* (injected), and *topical* (applied to skin or mucous membrane). Each has advantages, disadvantages, indications for use, and specific techniques of administration (Table 3-5). Common parenteral routes are subcutaneous (Sub-Q), intramuscular (IM), and intravenous (IV) injections. Injections require special drug preparations, equipment, and techniques. General characteristics are described below; specific considerations for the IV route are described in Box 3-1.

## Drugs for Injection

Injectable drugs must be prepared, packaged, and administered in ways to maintain sterility. Vials are closed containers with rubber stoppers through which a sterile needle can be inserted for withdrawing medication. Single-dose vials usually do not contain a preservative and must be discarded after a dose is withdrawn. Multiple-dose vials contain a preservative and may be reused if aseptic technique is maintained.

Ampules are sealed glass containers, the tops of which must be broken off to allow insertion of a needle and withdrawal of the medication. Broken ampules and any remaining medication are discarded. When vials or ampules contain a powder form of the drug, a sterile solution of water or 0.9% sodium chloride must be added and the drug dissolved before withdrawal. When available, a filter needle is used to withdraw the medication from an ampule or vial because broken glass or rubber fragments may need to be removed from the drug solution. The filter needle is replaced with a regular needle before injecting the patient.

Table 3-5

## Routes of Drug Administration

ROUTE AND DESCRIPTION	ADVANTAGES	DISADVANTAGES	COMMENTS
Oral	<ul style="list-style-type: none"> <li>Simple and can be used by most people</li> <li>Convenient; does not require complex equipment</li> <li>Relatively inexpensive</li> </ul>	<ul style="list-style-type: none"> <li>Dosage is unknown because some drug is not absorbed and some is metabolized in the liver before reaching the bloodstream.</li> <li>Slow drug action</li> <li>Irritation of gastrointestinal mucosa by some drugs</li> </ul>	The oral route should generally be used when possible, considering the patient's condition and ability to take or tolerate oral drugs.
Gastrointestinal (GI) tubes (e.g., nasogastric, gastrostomy)	<ul style="list-style-type: none"> <li>Allows use of GI tract in patients who cannot take oral drugs</li> <li>Can be used over long periods of time, if necessary</li> <li>May avoid or decrease injections</li> </ul>	<ul style="list-style-type: none"> <li>With nasogastric tubes, medications may be aspirated into the lungs</li> <li>Small-bore tubes often become clogged</li> <li>Requires special precautions to give correctly and avoid complications</li> </ul>	<ul style="list-style-type: none"> <li>Liquid preparations are preferred over crushed tablets and emptied capsules, when available.</li> <li>Tube should be rinsed before and after instilling medication.</li> </ul>
Subcutaneous (Sub-Q) injection—injection of drugs under the skin, into the underlying fatty tissue	<ul style="list-style-type: none"> <li>Relatively painless</li> <li>Very small needles can be used</li> <li>Insulin and heparin, commonly used medications, can be given Sub-Q</li> </ul>	<ul style="list-style-type: none"> <li>Only a small amount of drug (up to 1 mL) can be given</li> <li>Drug absorption is relatively slow</li> <li>Only a few drugs can be given Sub-Q</li> </ul>	The Sub-Q route is commonly used for only a few drugs because many drugs are irritating to Sub-Q tissues. Such drugs may cause pain, necrosis, and abscess formation if injected Sub-Q.
Intramuscular (IM) injection—injection of drugs into selected muscles	<ul style="list-style-type: none"> <li>May be used for several drugs</li> <li>Drug absorption is rapid because muscle tissue has an abundant blood supply</li> </ul>	<ul style="list-style-type: none"> <li>A relatively small amount of drug (up to 3 mL) can be given</li> <li>Risks of damage to blood vessels or nerves if needle is not positioned correctly</li> </ul>	It is very important to use anatomic landmarks when selecting IM injection sites.
Intravenous (IV) injection— injection of a drug into the bloodstream	<ul style="list-style-type: none"> <li>Allows medications to be given to a patient who cannot take fluids or drugs by GI tract</li> <li>Bypasses barriers to drug absorption that occur with other routes</li> <li>Rapid drug action</li> <li>Larger amounts can be given than by Sub-Q and IM routes</li> <li>Allows slow administration when indicated</li> </ul>	<ul style="list-style-type: none"> <li>Time and skill required for venipuncture and maintaining an IV line</li> <li>After it is injected, drug cannot be retrieved if adverse effects or overdoses occur</li> <li>High potential for adverse reactions due to rapid drug action and possible complications of IV therapy (i.e., bleeding, infection, fluid overload, extravasation)</li> <li>Phlebitis and thrombosis may occur and cause discomfort or pain, take days or weeks to subside, and limit the veins available for future therapy</li> </ul>	<ul style="list-style-type: none"> <li>The nurse should wear latex gloves to start IV infusions, for protection against exposure to blood-borne pathogens.</li> <li>Phlebitis and thrombosis result from injury to the endothelial cells that form the inner lining (intima) of veins and may be caused by repeated venipunctures, the IV catheter, hypertonic IV fluid, or irritating drugs.</li> </ul>

(continued on page 38)

Table 3-5

## Routes of Drug Administration (continued)

ROUTE AND DESCRIPTION	ADVANTAGES	DISADVANTAGES	COMMENTS
Topical administration—application to skin or mucous membranes. Application to mucous membranes includes drugs given by nasal or oral inhalation; by instillation into the lungs, eyes, or nose; and by insertion under the tongue (sublingual), into the cheek (buccal), and into the vagina or rectum.	<ul style="list-style-type: none"> <li>■ With application to intact skin, most medications act at the site of application, with little systemic absorption or systemic adverse effects.</li> <li>■ Some drugs are given topically for systemic effects (e.g., medicated skin patches). Effects may last several days, and the patches are usually convenient for patients.</li> <li>■ With application to mucous membranes, most drugs are well and rapidly absorbed</li> </ul>	<ul style="list-style-type: none"> <li>■ Some drugs irritate skin or mucous membranes and cause itching, rash, or discomfort</li> <li>■ With inflamed, abraded, or damaged skin, drug absorption is increased and systemic adverse effects may occur</li> <li>■ Application to mucous membranes may cause systemic adverse effects (e.g., beta blocker eye drops, used to treat glaucoma, can cause bradycardia just as oral beta blockers can)</li> <li>■ Specific drug preparations must be used for application to skin, eyes, sublingual, buccal, vaginal, and rectal sites.</li> </ul>	When available and effective, topical drugs are often preferred over oral or injected drugs, because of fewer and/or less severe systemic adverse effects.

## Box 3-1

## Principles and Techniques With Intravenous Drug Therapy

## Methods

**Intravenous (IV) injection** or IV push is the direct injection of a medication into the vein. The drug may be injected through an injection site on IV tubing or an intermittent infusion device. Most IV push medications should be injected slowly. The time depends on the particular drug, but is often 2 minutes or longer for a dose. Rapid injection should generally be avoided because the drug produces high blood levels and is quickly circulated to the heart and brain, where it may cause adverse or toxic effects. Although IV push may be useful with a few drugs or in emergency situations, slower infusion of more dilute drugs is usually preferred.

**Intermittent infusion** is administration of intermittent doses, often diluted in 50–100 mL of fluid and infused over 30–60 minutes. The drug dose is usually prepared in a pharmacy and connected to an IV administration set that controls the amount and flow rate. Intermittent infusions are often connected to an injection port on a primary IV line, through which IV fluids are infusing continuously. The purpose of the primary IV line may be to provide fluids to the patient or to keep the vein open for periodic administration of medications. The IV fluids are usually stopped for the medication infusion, then restarted. Drug doses may also be infused through an intermittent infusion device (e.g., a heparin lock) to conserve veins and allow freedom of motion between drug doses. The devices decrease the amount of IV fluids given to patients who do not need them (i.e., those who are able to ingest adequate amounts of oral fluids) and those who are at risk of fluid overload, especially children and older adults.

An intermittent infusion device may be part of an initial IV line or used to adapt a continuous IV for intermittent use. The devices include a heparin lock or a resealable adapter added to a peripheral or central IV catheter. These devices must be flushed routinely to maintain patency. If the IV catheter has more than one lumen, all must be flushed, whether being used or not. Saline is probably the most commonly used flushing solution; heparin may also be used if recommended by the device's manufacturer or required by institutional policy.

**Continuous infusion** indicates medications mixed in a large volume of IV fluid and infused continuously, over several hours. For example, vitamins and minerals (e.g., potassium chloride) are usually added to liters of IV fluids. Greater dilution of the drug and administration over a longer time decreases risks of accumulation and toxicity, as well as venous irritation and thrombophlebitis.

## Equipment

Equipment varies considerably from one health care agency to another. Nurses must become familiar with the equipment available in their work setting, including IV catheters, types of IV tubing, needles and needleless systems, types of volume control devices, and electronic infusion devices (IV pumps).

**Catheters** vary in size (both gauge and length), design, and composition (e.g., polyvinyl chloride, polyurethane, silicone). The most common design type is over the needle; the needle is used to start the IV, then it is removed. When choosing a catheter to start an IV, one that is much smaller than the

lumen of the vein is recommended. This allows good blood flow and rapidly dilutes drug solutions as they enter the vein. This, in turn, prevents high drug concentrations and risks of toxicity. Also, after a catheter is inserted, it is very important to tape it securely so that it does not move around. Movement of the catheter increases venous irritation and risks of thrombophlebitis and infection. If signs of venous irritation and inflammation develop, the catheter should be removed and a new one inserted at another site. Additional recommendations include application of a topical antibiotic or antiseptic ointment at the IV site after catheter insertion, a sterile occlusive dressing over the site, and limiting the duration of placement to a few days.

Many medications are administered through peripherally inserted central catheters (PICC lines) or central venous catheters, in which the catheter tips are inserted into the superior vena cava, next to the right atrium of the heart. Central venous catheters may have single, double, or triple lumens. Other products, which are especially useful for long-term IV drug therapy, include a variety of implanted ports, pumps, and reservoirs.

*If a catheter becomes clogged, do not irrigate it. Doing so may push a clot into the circulation and result in a pulmonary embolus, myocardial infarction, or stroke. It may also cause septicemia, if the clot is infected.*

**Needleless systems** are products with a blunt-tipped plastic insertion device and an injection port that opens. These systems greatly decrease needle-stick injuries and exposure to bloodborne pathogens.

**Electronic infusion devices** allow amounts and flow rates of IV drug solutions to be set and controlled by a computer. Although the devices save nursing time because the nurse does not need to continually adjust flow rates, the biggest advantage is the steady rate of drug administration. The devices are used in most settings where IV drugs and IV fluids are administered, but they are especially valuable in pediatrics, where very small amounts of medication and IV fluid are needed, and in intensive care units, where strong drugs and varying amounts of IV fluid are usually required. Several types of pumps are available, even within the same health care agency. It is extremely important that nurses become familiar with the devices used in their work setting, so that they can program them accurately and determine whether or not they are functioning properly (i.e., delivering medications as ordered).

### Site Selection

IV needles are usually inserted into a vein on the hand or forearm; IV catheters may be inserted in a peripheral site or centrally. In general, recommendations are

- Start at the most distal location. This conserves more proximal veins for later use, if needed. Veins on the back of the hand and on the forearm are often used to provide more comfort and freedom of movement for patients.
- Use veins with a large blood volume flowing through them when possible. Many drugs cause irritation and phlebitis in small veins.
- When possible, avoid the antecubital vein on the inner surface of the elbow, veins over or close to joints, and

veins on the inner aspect of the wrists. Reasons include the difficulty of stabilizing and maintaining an IV line at these sites and inner wrist venipunctures are very painful. *Do not perform venipuncture in foot or leg veins.* The risks of serious or fatal complications are too high.

- Rotate sites when long-term use (more than a few days) of IV fluid or drug therapy is required. Venous irritation occurs with longer duration of site use and with the administration of irritating drugs or fluids. When it is necessary to change an IV site, use the opposite arm if possible.

### Drug Preparation

Most IV drugs are prepared for administration in pharmacies and this is the safest practice. When a nurse must prepare a medication, considerations include the following.

- Only drug formulations manufactured for IV use should be given IV. Other formulations contain various substances that are not sterile, pure enough, or soluble enough to be injected into the bloodstream. *In recent years, there have been numerous reports of medication errors resulting from IV administration of drug preparations intended for oral use!!* Such errors can and should be prevented. For example, when liquid medications intended for oral use are measured or dispensed in a syringe (as they often are for children, adults with difficulty in swallowing tablets and capsules, or for administration through a gastrointestinal [GI] tube), the syringe should have a blunt tip that will not connect to or penetrate IV tubing injection sites.
- Use sterile technique during all phases of IV drug preparation.
- Follow the manufacturer's instructions for mixing and diluting IV medications. Some liquid IV medications need to be diluted prior to IV administration, and powdered medications must be reconstituted with the recommended diluent. The diluent recommended by the drug's manufacturer should be used because different drugs require different diluents. In addition, be sure any reconstituted drug is completely dissolved to avoid particles that may be injected into the systemic circulation and lead to thrombus formation or embolism. A filtered aspiration needle should be used when withdrawing medication from a vial or ampule, to remove any particles in the solution. The filter needle should then be discarded, to prevent filtered particles from being injected when the medication is added to the IV fluid. Filters added to IV tubing also help to remove particles.
- Check the expiration date on all IV medications. Many drugs have a limited period of stability after they are reconstituted or diluted for IV administration.
- IV medications should be compatible with the infusing IV fluids. Most are compatible with 5% dextrose in water or saline solutions.
- If adding a medication to a container of IV fluid, invert the container to be sure the additive is well mixed with the solution.
- For any IV medication that is prepared or added to an IV bag, label the medication vial or IV bag with the name of the patient, drug, dosage, date, time of mixing, expiration date, and the preparer's signature.

## Box 3-1

## Principles and Techniques With Intravenous Drug Therapy (continued)

## Drug Administration

- Most IV medications are injected into a self-sealing site in any of several IV set-ups, including a scalp-vein needle and tubing; a plastic catheter connected to a heparin lock or other intermittent infusion device; or IV tubing and a plastic bag containing IV fluid.
- Before injecting any IV medication, be sure the IV line is open and functioning properly (e.g., catheter not clotted, IV fluid not leaking into surrounding tissues, phlebitis not present). If leakage occurs, some drugs are very irritating to subcutaneous tissues and may cause tissue necrosis.
- Maintain sterility of all IV fluids, tubings, injection sites, drug solutions, and equipment coming into contact with the IV system. Because medications and fluids are injected directly into the bloodstream, breaks in sterile technique can lead to serious systemic infection (septicemia) and death.
- When two or more medications are to be given one after the other, flush the IV tubing and catheter (with the infusing IV fluid or with sterile 0.9% sodium chloride injection) so that the drugs do not come into contact with each other.
- In general, administer slowly to allow greater dilution of the drug in the bloodstream. Most drugs given by IV push (direct injection) can be given over 2–5 minutes and most drugs diluted in 50–100 mL of IV fluid can be infused in 30–60 minutes.
- When injecting or infusing medications into IV solutions that contain other additives (e.g., vitamins, insulin, minerals such as potassium or magnesium), be sure the medications are compatible with the other substances. Consult compatibility charts (usually available on nursing units) or pharmacists when indicated.
- IV flow rates are usually calculated in mL/hour and drops per minute.

Many injectable drugs (e.g., morphine, heparin) are available in prefilled syringes with attached needles. These units are inserted into specially designed holders and used like other needle-syringe units. *Note that many such units, especially those from the same manufacturer, are similar and their use may lead to medication errors if the label is not read carefully.*

## Equipment for Injections

Sterile needles and syringes are used to measure and administer parenteral medications; they may be packaged together or separately. Needles are available in various gauges and lengths. The term *gauge* refers to lumen size, with larger numbers indicating smaller lumen sizes. For example, a 25-gauge needle is smaller than an 18-gauge needle. Choice of needle gauge and length depends on the route of administration, the viscosity (thickness) of the solution to be given, and the size of the patient. Usually, a 25-gauge,  $\frac{5}{8}$ -inch needle is used for Sub-Q injections and a 22- or 20-gauge, 1½-inch needle is used for IM injections. Other needle sizes are available for special uses, such as for insulin or intradermal injections. When needles are used, avoid recapping them and dispose of them in appropriate containers. Such containers are designed to prevent accidental needle-stick injuries to health care and housekeeping personnel.

In many settings, needleless systems are used. These systems involve a plastic tip on the syringe that can be used to enter vials and injection sites on IV tubing. Openings created by the tip reseal themselves. Needleless systems were developed because of the risk of injury and spread of bloodborne

pathogens, such as the viruses that cause acquired immunodeficiency syndrome and hepatitis B.

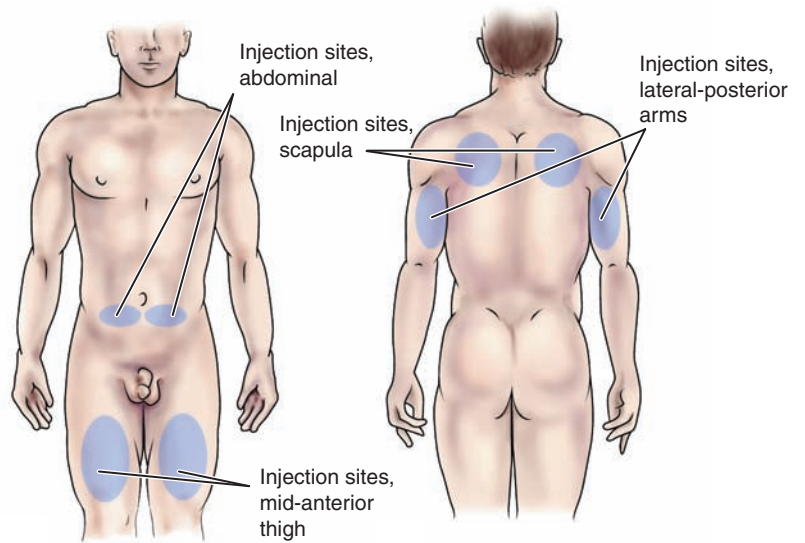

Syringes also are available in various sizes. The 3-milliliter size is often used. It is usually plastic and is available with or without an attached needle. Syringes are calibrated so that drug doses can be measured accurately. However, the calibrations vary according to the size and type of syringe.

Insulin and tuberculin syringes are used for specific purposes. Insulin syringes are calibrated to measure up to 100 units of insulin. Safe practice requires that *only* insulin syringes be used to measure insulin and that they be used for no other drugs. Tuberculin syringes have a capacity of 1 milliliter. They should be used for small doses of any drug because measurements are more accurate than with larger syringes.

## Sites for Injections

Common sites for Sub-Q injections are the upper arms, abdomen, back, and thighs (Fig. 3-1). Sites for IM injections are the deltoid, dorsogluteal, ventrogluteal, and vastus lateralis muscles. These sites must be selected by first identifying anatomic landmarks (Fig. 3-2). Common sites for IV injections are the veins on the back of the hands and on the forearms (Fig. 3-3). Less common sites include intradermal (into layers of the skin), intra-arterial (into arteries), intra-articular (into joints), and intrathecal (into spinal fluid). Nurses may perform intradermal and intra-arterial injections (if an established arterial line is present); physicians perform intra-articular and intrathecal injections.

**Figure 3-1** ■ Subcutaneous injection sites.

**Figure 3-2** ■ Anatomic landmarks and intramuscular (IM) injection sites: (A) ventrogluteal muscle, (B) deltoid muscle, (C) vastus lateralis and rectus femoris muscle, and (D) dorso-gluteal muscle.

**Figure 3-3** ■ Veins of the hand and forearm that may be used to administer intravenous fluids and medications.

## Nursing Actions Drug Administration

### NURSING ACTIONS

### RATIONALE/EXPLANATION

#### 1. Follow general rules for administering medications safely and effectively.

- Prepare and give drugs in well-lighted areas, as free of interruptions and distractions as possible.
- Perform hand hygiene before preparing medications and, if needed, during administration.
- Use sterile technique in preparing and administering injections.
- Read the medication administration record (MAR) carefully. Read the label on the drug container, and compare with the MAR in terms of drug, dosage or concentration, and route of administration. Scan bar codes, if available.
- Do not leave medications unattended.
- Identify the patient by comparing the identification wristband to the medication sheet. Scan barcodes if available.
- Identify yourself, if indicated, and state your reason for approaching the patient. For example, "I'm ... I have your medication for you."

To prevent errors in selecting ordered drugs, calculating dosages, and identifying patients

To prevent infection and cross-contamination

To prevent infection. Sterile technique involves using sterile needles, syringes, drug solutions, and cleansing injection sites with an antiseptic.

For accurate drug administration. Most nursing texts instruct the nurse to read a drug label three times: when removing the container, while measuring the dose, and before returning the container.

To prevent ingestion by anyone other than the intended person and to prevent contamination or spilling of medications. This is the best way to verify identity. Calling by name, relying on the name on a door or bed, and asking someone else are unreliable methods, although they must be used occasionally when the patient lacks a name band.

Explaining actions helps to decrease patient anxiety and increase cooperation in taking prescribed medication.

**NURSING ACTIONS**

- h. Position the patient appropriately for the intended route of administration.
- i. Provide water or other supplies as needed.
- j. Do not leave medications at the bedside as a general rule. Common exceptions are nitroglycerin tablets and eye medications.
- k. Do not give a drug when signs and symptoms of toxicity are present. Notify the prescriber, and record that the drug was omitted and why.
- l. Record drug administration (or omission) as soon as possible and according to agency policies.
- m. Evaluate whether missed scheduled doses should be given at a later time or omitted. Generally, give drugs ordered once or twice daily at a later time. For others, omit the one dose, and give the drug at the next scheduled time.
- n. For medications ordered as needed (PRN), assess the patient's condition; check the physician's orders or MAR for the name, dose, and frequency of administration; and determine the time of the most recently administered dose.
- o. For narcotics and other controlled substances, sign drugs out on separate narcotic records according to agency policies.
- p. If, at any time during drug preparation or administration, any question arises regarding the drug, the dose, or whether the patient is supposed to receive it, check the original prescriber's order. If the order is not clear, call the prescriber for clarification before giving the drug.

**2. For oral medications:**

- a. With adults
  - (1) To give tablets or capsules, open the unit-dose wrapper, place medication in a medicine cup, and give the cup to the patient. For solutions, hold the cup at eye level, and measure the dosage at the bottom of the meniscus. For suspensions, shake or invert containers to mix the medication before measuring the dose.
  - (2) Have the patient in a sitting position when not contraindicated.
  - (3) Give before, with, or after meals as indicated by the specific drug.
  - (4) Give most oral drugs with a full glass (8 oz) of water or other fluid.
- b. With young children, liquids or chewable tablets are usually given.
  - (1) Measure and give liquids to infants with a dropper or syringe, placing medication on the tongue or buccal mucosa and giving slowly.
  - (2) Medications are often mixed with juice, applesauce, or other vehicle.
- c. Do not give oral drugs if the patient is:
  - (1) NPO (receiving nothing by mouth)
  - (2) Vomiting
  - (3) Excessively sedated or unconscious

**RATIONALE/EXPLANATION**

To prevent complications, such as aspiration of oral drugs into the lungs  
 To promote comfort of the patient and to ensure drug administration  
 To prevent omitting or losing the drug or hoarding of the drug by the patient

Additional doses of a drug increase toxicity. However, drugs are not omitted without a careful assessment of the patient's condition and a valid reason.  
 To maintain an accurate record of drugs received by the patient

Patients may be unable to take the drug at the scheduled time because of diagnostic tests or many other reasons. A temporary change in the time of administration—usually for one dose only—may be necessary to maintain therapeutic effects.

Administration of PRN medications requires nursing assessment and decision making. Analgesics, antiemetics, and antipyretics are often ordered PRN.

To meet legal requirements for dispensing controlled substances

To promote safety and prevent errors. The same procedure applies when the patient questions drug orders at the bedside. For example, the patient may state he has been receiving different drugs or different doses.

To maintain clean technique and measure doses accurately. Suspensions settle on standing, and if not mixed, diluent may be given rather than the active drug.

To decrease risks of aspirating medication into lungs. Aspiration may lead to difficulty in breathing and aspiration pneumonia.

Food in the stomach usually delays drug absorption and action. It also decreases gastric irritation, a common side effect of oral drugs.

To promote dissolution and absorption of tablets and capsules. Also, to decrease gastric irritation by diluting drug concentration.

Children under 5 years of age are often unable to swallow tablets or capsules.

For accurate measurement and administration. Giving slowly decreases risks of aspiration.

To increase the child's ability and willingness to take the medication. If this is done, use a small amount, and be sure the child takes all of it.

Oral drugs and fluids may interfere with diagnostic tests or be otherwise contraindicated. Most drugs can be given after diagnostic tests are completed. If the patient is having surgery, preoperative drug orders are cancelled. New orders are written postoperatively.

Oral drugs and fluids increase vomiting. Fluid and electrolyte problems may result from loss of gastric acid.

To avoid aspiration of drugs into the lungs

## Nursing Actions Drug Administration (continued)

### NURSING ACTIONS

#### 3. For medications given by nasogastric or gastrostomy tube:

- Use a liquid preparation when possible. If necessary, crush a tablet or empty a capsule into about 30 mL of water and mix well. Do not crush enteric-coated or sustained-release products, and do not empty sustained-release capsules.
- Use a clean bulb syringe or other catheter-tipped syringe.
- Before instilling medication, aspirate gastric fluid and check pH or use another method to check tube placement.
- Rinse the tube, instill medication by gravity flow, and rinse the tube again with at least 50 mL of water. Do not allow the syringe to empty completely between additions.
- Clamp off the tube from suction or drainage for at least 30 minutes.

#### 4. For subcutaneous (Sub-Q) injections:

- Use only sterile drug preparations labeled or commonly used for Sub-Q injections.
- Use a 25-gauge, 5/8-inch needle for most Sub-Q injections.
- Select an appropriate injection site, based on patient preferences, drug characteristics, and visual inspection of possible sites. In long-term therapy, such as with insulin, rotate injection sites. Avoid areas with lumps, bruises, or other lesions.
- Cleanse the site with an alcohol sponge.
- Tighten the skin or pinch a fold of skin and tissue between thumb and fingers.
- Hold the syringe like a pencil, and insert the needle quickly at a 45- or 90-degree angle. Use enough force to penetrate the skin and subcutaneous tissue in one smooth movement.
- Release the skin so that both hands are free to manipulate the syringe. Pull back gently on the plunger (aspirate). If no blood enters the syringe, inject the drug. If blood is aspirated into the syringe, remove the needle, and reprepare the medication.
- Remove the needle quickly and apply gentle pressure for a few seconds.

#### 5. For intramuscular (IM) injections:

- Use only drug preparations labeled or commonly used for IM injections. Check label instructions for mixing drugs in powder form.
- Use a 1½-inch needle for most adults and a 5/8- to 1½-inch needle for children, depending on the size of the patient.
- Use the smallest-gauge needle that will accommodate the medication. A 22-gauge is satisfactory for most drugs; a 20-gauge may be used for viscous medications.
- Select an appropriate injection site, based on patient preferences, drug characteristics, anatomic landmarks, and visual inspection of possible sites. Rotate sites if frequent injections are being given, and avoid areas with lumps, bruises, or other lesions.

### RATIONALE/EXPLANATION

Particles of tablets or powders from capsules may obstruct the tube lumen. Altering sustained-release products increases risks of overdose and adverse effects.

The syringe allows aspiration and serves as a funnel for instillation of medication and fluids into the stomach. To be sure the tube is in the stomach

Gravity flow is safer than applying pressure. Water “pushes” the drug into the stomach and rinses the tube, thereby maintaining tube patency. Additional water or other fluids may be given according to fluid needs of the patient. Add fluids to avoid instilling air into the stomach unnecessarily. To avoid removing the medication from the stomach

Many parenteral drugs are too irritating to subcutaneous tissue for use by this route.

This size needle is effective for most patients and drugs. These techniques allow the patient to participate in his or her care; avoid tissue damage and unpredictable absorption, which occur with repeated injections in the same location; and increase patient comfort and cooperation

To prevent infection

Either is acceptable for most patients. If the patient is obese, tightening the skin may be easier. If the patient is very thin, the tissue fold may keep the needle from hitting bone.

To give the drug correctly with minimal patient discomfort

To prevent accidental injection into the bloodstream. Blood return in the syringe is an uncommon occurrence. Aspiration is not recommended with heparin injections and possibly not needed with insulin injections.

To prevent bleeding

Some parenteral drug preparations cannot be given safely by the IM route.

A long needle is necessary to reach muscle tissue, which underlies subcutaneous fat.

To decrease tissue damage and patient discomfort

To increase patient comfort and participation and to avoid tissue damage. Identification of anatomic landmarks is mandatory for safe administration of IM drugs.

**NURSING ACTIONS**

- e. Cleanse the site with an alcohol sponge.
- f. Tighten the skin, hold the syringe like a pencil, and insert the needle quickly at a 90-degree angle. Use enough force to penetrate the skin and subcutaneous tissue into the muscle in one smooth motion.
- g. Aspirate (see 4g, Sub-Q injections).
- h. Remove the needle quickly and apply pressure for several seconds.

**6. For intravenous (IV) injections:**

- a. Use only drug preparations that are labeled for IV use.
- b. Check label instructions for the type and amount of fluid to use for dissolving or diluting the drug.
- c. Prepare drugs just before use, as a general rule. Also, add drugs to IV fluids just before use.
- d. For venipuncture and direct injection into a vein, apply a tourniquet, select a site in the arm, cleanse the skin with an antiseptic (e.g., povidone-iodine or alcohol), insert the needle, and aspirate a small amount of blood into the syringe to be sure that the needle is in the vein. Remove the tourniquet, and inject the drug slowly. Remove the needle and apply pressure until there is no evidence of bleeding.
- e. For administration by an established IV line:
  - (1) Check the infusion for patency and flow rate. Check the venipuncture site for signs of infiltration and phlebitis before each drug dose.
  - (2) For direct injection, cleanse an injection site on the IV tubing, insert the needle, and inject the drug slowly.
  - (3) To use a volume-control set, fill it with 50–100 mL of IV fluid, and clamp it so that no further fluid enters the chamber and dilutes the drug. Inject the drug into an injection site after cleansing the site with an alcohol sponge and infuse, usually in 1 hour or less. After the drug is infused, add solution to maintain the infusion.
  - (4) To use a “piggyback” method, add the drug to 50–100 mL of IV solution in a separate container. Attach the IV tubing and a needle. Insert the needle in an injection site on the main IV tubing after cleansing the site. Infuse the drug over 15–60 minutes, depending on the drug.
- f. When more than one drug is to be given, flush the line between drugs. Do not mix drugs in syringes or in IV fluids unless the drug literature states that the drugs are compatible.

**7. For application to skin:**

- a. Use drug preparations labeled for dermatologic use. Cleanse the skin, remove any previously applied medication, and apply the drug in a thin layer. For broken skin or open lesions, use sterile gloves, tongue blade, or cotton-tipped applicator to apply the drug.

**RATIONALE/EXPLANATION**

To prevent infection  
To give the drug correctly with minimal patient discomfort

To prevent bleeding

Others are not pure enough for safe injection into the bloodstream or are not compatible with the blood pH (7.35–7.45). Some drugs require special preparation techniques to maintain solubility or pharmacologic activity. Most drugs in powder form can be dissolved in sterile water or sodium chloride for injection. Most drug solutions can be given with dextrose or dextrose and sodium chloride IV solutions.

Some drugs are unstable in solution. In most agencies, drugs are mixed and added to IV fluids in the pharmacy. This is the preferred method because sterility can be better maintained. For safe and accurate drug administration with minimal risk to the patient. The length of time required to give the drug depends on the specific drug and the amount. Slow administration, over several minutes, allows immediate discontinuation if adverse effects occur.

The solution must be flowing freely for accurate drug administration. If infiltration or phlebitis is present, do not give the drug until a new IV line is begun.

Most tubings have injection sites to facilitate drug administration.

This method is used for administration of antibiotics on an intermittent schedule. Dilution of the drug decreases adverse effects.

This method is also used for intermittent administration of antibiotics and other drugs. Whether a volume-control or piggyback apparatus is used depends on agency policy and equipment available.

Physical and chemical interactions between the drugs may occur and cause precipitation, inactivation, or increased toxicity. Most nursing units have charts depicting drug compatibility, or information may be obtained from the pharmacy.

To promote therapeutic effects and minimize adverse effects

(continued on page 46)

## Nursing Actions Drug Administration (continued)

### NURSING ACTIONS

### RATIONALE/EXPLANATION

#### 8. For instillation of eye drops:

- a. Use drug preparations labeled for ophthalmic use. Wash hands, open the eye to expose the conjunctival sac, and drop the medication into the sac, without touching the dropper tip to anything. Provide a tissue for blotting any excess drug. If two or more eye drops are scheduled at the same time, wait 1–5 minutes between instillations.

With children, prepare the medication, place the child in a head-lowered position, steady the hand holding the medication on the child's head, gently retract the lower lid, and instill the medication into the conjunctival sac.

Ophthalmic preparations must be sterile to avoid infection. Blot any excess drug from the inner canthus near the nose to decrease systemic absorption of the drug.

Careful positioning and restraint to avoid sudden movements are necessary to decrease risks of injury to the eye.

#### 9. For instillation of nose drops and nasal sprays:

- a. Have the patient hold his or her head back, and drop the medication into the nostrils. Give only as ordered. With children, place in a supine position with the head lowered, instill the medication, and maintain the position for 2–3 minutes. Then, place the child in a prone position.

When nose drops are used for rhinitis and nasal congestion accompanying the common cold, overuse results in a rebound congestion that may be worse than the original symptom.

#### 10. For instillation of ear medications:

- a. Open the ear canal by pulling the ear up and back for adults, down and back for children, and drop the medication on the side of the canal.

To straighten the canal and promote maximal contact between medication and tissue

#### 11. For rectal suppositories:

- a. Lubricate the end with a water-soluble lubricant, wear a glove or finger cot, and insert into the rectum the length of the finger. Place the suppository next to the mucosal wall.
- b. If the patient prefers and is able, provide supplies for self-administration.

To promote absorption.

Allowing self-administration may prevent embarrassment to the patient. Be sure the patient knows the correct procedure.

#### 12. For vaginal medications:

- a. Use gloves or an applicator for insertion. If an applicator is used, wash thoroughly with soap and water after each use.
- b. If the patient prefers and is able, provide supplies for self-administration.

Some women may be embarrassed and prefer self-administration. Be sure the patient knows the correct procedure.

## Key Concepts

- The “five rights” of safe and accurate drug administration are right drug, right dose, right patient, right route, and right time.
- Basic knowledge and techniques for accurate drug administration include knowledge of the drug, knowledge of the patient, interpretation of prescriber orders and labels of drug containers, calculations and measurements of doses, and correct techniques for all dosage forms and routes of administration.
- Each health care facility has a system for distributing drugs; each nurse in an agency must follow legal and agency policies related to drug administration.
- When dosage calculations are required, they *must* be accurate to avoid medication errors and harm to patients.
- Question and clarify any unclear drug orders.
- Document medication administration according to agency policies.
- Identify potential sources of medication errors and intervene to prevent errors when possible.

## Review and Application Exercises

### Short Answer Exercises

- When giving an oral medication, what are some interventions to aid absorption and hasten therapeutic effects?
- What are the advantages and disadvantages of the PO route and the IV route of drug administration?
- For a patient who receives all medications through a nasogastric feeding tube, which dosage forms are acceptable? Which are unacceptable, and why?
- What are some legal factors that influence a nurse's administration of medications?
- When administering medications, what safety precautions are needed with various routes?
- What safety precautions must the nurse practice consistently to avoid self-injury and exposure to bloodborne pathogens?
- With a patient who refuses an important medication, what approaches or interventions might persuade the patient to take the medication? Would the same approach be indicated if the medication were a vitamin supplement or a laxative?
- You are caring for a patient who has been taking his medications with only a small sip of water. You counsel him to drink an 8-oz glass of water with his tablets or capsules, because you know that it aids in which of the following pharmacokinetic processes?
  - absorption
  - distribution
  - biotransformation
  - excretion
- When administering medications by nasogastric tube, which of the following nursing actions is indicated?
  - Verify the position of the tube before giving the drugs.
  - Aspirate and discard stomach contents.
  - Mix medications with tube-feeding formulas.
  - Have the patient sit in a chair.
- Maintaining sterile technique is necessary while administering which of the following types of medication?
  - oral suspensions
  - vaginal suppositories
  - nasal inhalation products
  - injections
- Anatomic landmarks are very important in which of the following routes of drug administration?
  - oral
  - inhalation
  - intramuscular
  - topical (to skin)

### NCLEX-Style Questions

- An important safety measure in drug administration is
  - calling the patient by name
  - using appropriate techniques for the ordered route of administration
  - asking a coworker about an ordered drug
  - leaving medications at the bedside

# Nursing Process in Drug Therapy

## KEY TERMS

- Clinical pathways
- Evidence-based practice
- Medication history
- Nursing Process: assessment, nursing diagnosis, planning/goals, interventions, evaluation

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Assess patients for conditions and factors that are likely to influence drug effects, including age, weight, health status, and lifestyle.
2. Obtain a medication history about the patient's use of prescription, over-the-counter (OTC), and social drugs as well as herbal and dietary supplements.
3. Identify nondrug interventions to prevent or decrease the need for drug therapy.
4. Discuss interventions to increase therapeutic effects and decrease adverse effects of drug therapy.
5. Discuss guidelines for rational choices of drugs, dosages, routes, and times of administration.
6. Observe patients for therapeutic and adverse responses to drug therapy.
7. Teach patients and family members how to use prescription and OTC drugs safely and effectively.
8. When indicated, teach patients about the potential effects of herbal and dietary supplements.
9. For patients who use herbal and dietary supplements, provide—or assist them in obtaining—reliable information.
10. Describe major considerations in drug therapy for children, adults, and patients with impaired renal or hepatic function or critical illness.
11. Discuss application of the nursing process in home care settings.
12. Apply evidence-based data about patients and therapeutic drugs in all steps of the nursing process.

## Applying Your Knowledge

You are making the first home visit for Robert Walker, an 80-year-old patient with arthritis and hypertension. Upon reading his file, you learn that Mr. Walker lives alone but has a daughter who lives in the area. She visits him once a week and runs his errands. You note he is taking the following medications: ibuprofen 400 mg every 4 hours, furosemide 20 mg once daily, captopril 25 mg twice a day, and famotidine 20 mg at bedtime.

## Introduction

Drug therapy involves the use of drugs to prevent or treat disease processes and manifestations. It may save lives, improve the quality of life, and otherwise benefit recipients. It also may cause

adverse effects. Adverse effects and failure to achieve therapeutic effects may occur with correct use, but they are more likely to occur with incorrect use. Prescribers (e.g., physicians, dentists, and nurse practitioners), pharmacists, patients, and nurses all have important roles to play in the safe and effective use of drugs.

For most nurses, drug therapy is one of many responsibilities in patient care. To fulfill this responsibility, the nurse must be knowledgeable about pharmacology (drugs and their effects on the body), physiology (normal body functions), and pathophysiology (alterations in mental and physical functions due to disease processes) and must be adept at using all steps of the nursing process.

Chapter 1 included general information about drugs and suggested strategies for studying pharmacology. Chapter 2 described cellular physiology, concepts, and processes essential to understanding drug effects in humans and general management of drug toxicity. Chapter 3 emphasized drug administration. Although the importance of safe and accurate administration cannot be overemphasized, this is only one aspect of the nursing process in drug therapy. The nurse also must monitor patient responses to drug therapy, both therapeutic and adverse, and teach patients about drugs, both prescribed and OTC. To help the nurse continue to acquire knowledge and skills related to drug therapy, this chapter includes nursing process guidelines, general principles of drug therapy, and general nursing actions. Guidelines, principles, and actions related to specific drugs are included in chapters throughout this text.

## Nursing Process in Drug Therapy

The nursing process is a systematic way of gathering and using information to plan and provide individualized patient care and to evaluate the outcomes of care. It involves both cognitive and psychomotor skills. Knowledge of, and skill in, the nursing process are required for drug therapy as in other aspects of patient care. The five steps of the nursing process are assessment, nursing diagnosis, planning and establishing goals for nursing care, interventions, and evaluation. Assessment and interventions are “action” phases, whereas analysis of assessment data, establishing nursing diagnoses and goals, and evaluation are “thinking” phases. However, knowledge and informed, rational thinking should underlie all data collection, decision making, and interventions.

### Assessment

Assessment involves collecting data about patient characteristics known to affect drug therapy. This includes observing and interviewing the patient, interviewing family members or others involved in patient care, completing a physical assessment, reviewing medical records for pertinent laboratory and diagnostic test reports, and other methods. Initially (before drug therapy is started or on first contact), assess age, weight, vital signs, health status, pathologic conditions, and ability to function in usual activities of daily living. The effects of these

patient-related factors on drug therapy are discussed in Chapter 2. In addition, assess for previous and current use of prescription, nonprescription, and nontherapeutic (e.g., alcohol, caffeine, nicotine, cocaine, marijuana) drugs. A *medication history* (Box 4-1) is useful, or the information can be incorporated into any data collection tool. Specific questions and areas of assessment include the following:

- What are current drug orders?
- What does the patient know about current drugs? Is teaching needed?
- What drugs has the patient taken before? Include any drugs taken regularly, such as those for hypertension, diabetes mellitus, or other chronic conditions. Ask patient about over-the-counter drugs for colds, headaches, or indigestion, because some people do not think of these preparations as drugs.
- Has the patient ever had an allergic reaction to a drug? If so, what signs and symptoms occurred and how were they managed?
- Is the patient able to communicate verbally; can he or she swallow oral medications?
- Does the patient have pathologic conditions that influence drug therapy? For example, all seriously ill patients should be assessed for impaired function of vital organs.
- Assess for current use of herbal or dietary supplements (e.g., echinacea, glucosamine/chondroitin, vitamins). If so, ask for names, how much is taken and how often, for how long, their reason for use, and perceived benefits or adverse effects.

In addition to nursing assessment data, use progress notes (of any other health care providers), laboratory reports, and other sources to obtain baseline data for monitoring therapeutic or adverse drug effects. Laboratory tests of liver, kidney, and bone marrow function are often helpful because some drugs may damage these organs. Also, if liver or kidney damage exists, drug metabolism or excretion may be altered. Consult authoritative sources for information about the patient’s disease processes and ordered drugs, if needed.

After assessment data are obtained, they need to be analyzed to determine the patient’s nursing care needs. Although listed as the first step in the nursing process for discussion purposes, assessment is a component of all steps and occurs with every contact with the patient. Ongoing assessment of a patient’s health status and response to treatment is needed to determine whether nursing care requirements have changed. In general, nurses must provide care based on available information while knowing that assessment data are always relatively incomplete.

### Applying Your Knowledge 4-1

Review Mr. Walker’s current medication regimen. Look up the medications, and note the drug class for each. Why do you think this patient is taking them? Are the dosages appropriate for an 80-year-old?

.....

## Box 4-1

## Medication History

Name \_\_\_\_\_ Age \_\_\_\_\_

Health problems, acute and chronic

Are you allergic to any medications?

If yes, describe specific effects or symptoms.

**Part 1: Prescription Medications**

1. Do you take any prescription medications on a regular basis?

2. If yes, ask the following about each medication.

Name

Dose

Frequency

Specific times

How long taken

Reason for use

3. Do you have any difficulty in taking your medicines? If yes, ask to specify problem areas.

4. Have you had any symptoms or problems that you think are caused by your medicines? If yes, ask to specify.

5. Do you need help from another person to take your medicines?

6. Do you take any prescription medications on an irregular basis? If yes, ask the following about each medication.

Name

Dose

Frequency

Reason

How long taken

**Part 2: Nonprescription Medications**

Do you take over-the-counter medications?

*Medication*

<i>Problem</i>	<i>Yes/No</i>	<i>Name</i>	<i>Amount</i>	<i>Frequency</i>
Pain				
Headache				
Sleep				
Cold				
Indigestion				
Heartburn				
Diarrhea				
Constipation				
Other				

**Part 3: Social Drugs***Yes/No**Amount/day*

Coffee

Tea

Cola drinks

Alcohol

Tobacco

**Part 4: Herbal or Dietary Supplements**

Do you take any herbal or dietary supplements (e.g., ginkgo, glucosamine/chondroitin,)? If so, ask for names, how much and how often taken, reason for use, perceived effectiveness, any adverse effects.

**Nursing Diagnoses**

These statements, as developed by the North American Nursing Diagnosis Association, describe patient problems or needs and are based on assessment data. They should be individualized according to the patient's condition and the drugs prescribed. Thus, the nursing diagnoses needed to adequately

reflect the patient's condition vary considerably. Because almost any nursing diagnosis may apply in specific circumstances, this text emphasizes those diagnoses that generally apply to drug therapy.

- Deficient Knowledge: Drug therapy regimen (e.g., drug ordered; reason for use; expected effects; monitoring of

response by health care providers, including diagnostic tests and office visits)

- Deficient Knowledge: Safe and effective self-administration (when appropriate)
- Risk for Injury related to adverse drug effects
- Noncompliance: Overuse
- Noncompliance: Underuse

## Planning/Goals

This step involves the expected outcomes of prescribed drug therapy. As a general rule, *goals should be stated in terms of patient behavior, not nurse behavior*. For example, the patient will

- Receive or take drugs as prescribed
- Experience relief of signs and symptoms
- Avoid preventable adverse drug effects
- Self-administer drugs safely and accurately
- Verbalize essential drug information
- Keep appointments for monitoring and follow-up
- Use any herbal and dietary supplements with caution and report such use to health care providers

## Interventions

This step involves implementing planned activities and includes any task performed directly with a patient or indirectly on a patient's behalf. Areas of intervention are broad and may include assessment, promoting compliance with prescribed drug therapy, and solving problems related to drug therapy, among others.

General interventions related to drug therapy include promoting health, preventing or decreasing the need for drug therapy, using nondrug measures to enhance therapeutic effects or decrease adverse effects, teaching, individualizing care, administering drugs, and observing patient responses. Some examples include

- Promoting healthful lifestyles in terms of nutrition, fluids, exercise, rest, and sleep
- Performing hand hygiene and other measures to prevent infection
- Ambulating, positioning, and exercising
- Assisting to cough and deep breathe
- Applying heat or cold
- Increasing or decreasing sensory stimulation
- Scheduling activities to promote rest or sleep
- Recording vital signs, fluid intake, urine output, and other assessment data

The intervention of teaching patients and caregivers about drug therapy is essential because most medications are self-administered and patients need information and assistance

to use therapeutic drugs safely and effectively. Adequate knowledge, skill, and preparation are required to fulfill teaching responsibilities. Teaching aids to assist the nurse in this endeavor include Box 4-2: Preparing to Teach a Patient or Caregiver; Patient Teaching Guidelines: Safe and Effective Use of Prescription Medications; and Patient Teaching Guidelines: Safe and Effective Use of Over-the-Counter (OTC) Medications. Later drug-related chapters contain more specific patient teaching guidelines for the drugs discussed in those particular chapters.

This chapter includes general principles or guidelines; later drug chapters include those related to particular drug groups. Using established guidelines to individualize nursing care can increase one's knowledge base about safe, effective, and rational drug therapy. These interventions, which reflect integration of knowledge about drugs and the patients receiving them, are presented under the heading of "Principles of Therapy."

Interventions, presented as a separate feature entitled "Nursing Actions," provide specific guidelines related to administering drugs accurately, assessing patients for therapeutic and adverse effects, and observing for drug interactions. Rationales for the interventions are included. This chapter includes general interventions or actions; later drug chapters include those related to particular drug groups.

## Evaluation

This step involves evaluating the patient's status in relation to stated goals and expected outcomes. Some outcomes can be evaluated within a few minutes of drug administration (e.g., relief of acute pain after administration of an analgesic), but most require longer periods of time. Over time, the patient is likely to experience brief contacts with many health care providers, which increases the difficulty of evaluating outcomes of drug therapy. However, difficulties can be managed by using appropriate techniques and criteria of evaluation.

General techniques include directly observing the patient's status; interviewing the patient or others about the patient's response to drug therapy; and checking appropriate medical records, including medication records and diagnostic test reports.

General criteria include progress toward stated outcomes, such as relief of symptoms, accurate administration, avoidance of preventable adverse effects, and compliance with instructions for follow-up monitoring by a health care provider. Specific criteria indicate the parameters that must be measured to evaluate responses to particular drugs (e.g., blood sugar with antidiabetic drugs, blood pressure with antihypertensive drugs).

### Applying Your Knowledge 4-2

Consider the case of Mr. Walker. When you look at his medication assessment, can you identify possible nursing diagnoses?

.....

## Box 4-2

## Preparing to Teach a Patient or Caregiver

- Assess learning needs, especially when new drugs are added or new conditions are being treated. This includes finding out what the person already knows about a particular drug. Do not assume that teaching is unneeded, even if the patient has been taking a drug for a while.
- Assess ability to manage a drug therapy regimen (i.e., read printed instructions and drug labels, remember dosage schedules, self-administer medications by ordered routes). A medication history (see Box 4-1) helps to assess the patient's knowledge about drug therapy.
- From assessment data, develop an individualized teaching plan. This saves time for both nurse and patient by avoiding repetition of known material. It also promotes compliance with prescribed drug therapy.
- Try to decrease anxiety. Patients and caregivers may feel overwhelmed by complicated medication regimens. Provide positive reinforcement for effort.
- Choose an appropriate time (e.g., when the patient is mentally alert and not in acute distress from pain or other symptoms) and a place with minimal noise and distractions, when possible.
- Proceed slowly, in small steps; emphasize essential information; and provide opportunities to express concerns or ask questions.
- Provide a combination of verbal and written instructions, which is more effective than either alone. Minimize medical jargon and be aware that patients may have difficulty understanding and retaining the material being taught because of the stress of the illness.
- When explaining a drug to a hospitalized patient, describe the name (preferably both the generic and a trade name), purpose, expected effects, and so on. The purpose can usually be stated in terms of symptoms to be relieved or other expected benefits. In many instances, the drug is familiar and can be described from personal knowledge. If the drug is unfamiliar, use available resources (e.g., drug reference books, computer drug databases, pharmacists) to learn about the drug and provide accurate information to the patient.
- When teaching a patient about medications to be taken at home, provide specific information and instructions about each drug, including how to take them and how to observe for beneficial and adverse effects. If adverse effects occur, teach them how to manage minor ones and which ones to report to a health care provider. In addition, discuss ways to develop a convenient routine for taking medications, so that usual activities of daily living are minimally disrupted. Allow time for questions and try to ensure that the patient understands how, when, and why to take the medications.
- When teaching a patient about potential adverse drug effects, the goal is to provide needed information without causing unnecessary anxiety. Most drugs produce undesirable effects; some are minor, some are potentially serious. Many people stop taking a drug rather than report adverse reactions. If reactions are reported, it may be possible to continue the drug by reducing dosage, changing the time of administration, or other measures. If severe reactions occur, the drug should be stopped and the prescriber should be notified.
- Emphasize the importance of taking medications as prescribed throughout the teaching session and perhaps at times of other contacts. Common patient errors include taking incorrect doses, taking doses at the wrong times, omitting doses, and stopping a medication too soon. Treatment failure can often be directly traced to these errors.
- Reassess learning needs when medication orders are changed (e.g., when medications are added because of a new illness or stopped).

## Patient Teaching Guidelines

## Safe and Effective Use of Prescription Medications

## General Considerations

- Use drugs cautiously and only when necessary because all drugs affect body functions and may cause adverse effects.
- Use nondrug measures, when possible, to prevent the need for drug therapy or to enhance beneficial effects and decrease adverse effects of drugs.
- Do not take drugs left over from a previous illness or prescribed for someone else, and do not share prescription drugs with anyone else. The likelihood of having the right drug in the right dose is remote, and the risk of adverse effects is high in such circumstances.
- Keep all health care providers informed about all the drugs being taken, including over-the-counter (OTC) products and herbal or dietary supplements.
- Take drugs as prescribed and for the length of time prescribed; notify a health care provider if unable to take a medication. Therapeutic effects greatly depend on taking medications correctly. Altering the dose or time may cause underdosage or overdosage. Stopping a medication may cause a recurrence of the problem for which it was given or withdrawal symptoms. Some medications need to be tapered in dosage and gradually discontinued. If problems occur with taking a drug, report them to a health care provider. An adjustment in dosage or other aspect of administration may solve the problem.
- Follow instructions for follow-up care (e.g., office visits, laboratory or other diagnostic tests that monitor therapeutic or adverse effects of drugs). Some drugs require more frequent monitoring than others. However, safety requires

periodic checks with essentially all medications. With long-term use of a medication, responses may change over time with aging, changes in kidney function, and so on.

- Take drugs in current use (or an up-to-date list) to appointments with a health care provider.
- Get all prescriptions filled at the same pharmacy, when possible. This is an important safety factor in helping to avoid multiple prescriptions of the same or similar drugs and to minimize undesirable interactions of newly prescribed drugs with those already in use.
- Report any drug allergies to all health care providers, and wear a medical identification emblem that lists allergens.
- Ask questions (and write down the answers) about newly prescribed medications, such as:
  - What is the medicine's name?
  - What is it supposed to do (i.e., what symptoms or problems will it relieve)?
  - How and when do I take it, and for how long?
  - Should it be taken with food or on an empty stomach?
- While taking this medicine, should I avoid certain foods, beverages, other medications, certain activities? (For example, alcoholic beverages and driving a car should be avoided with medications that cause drowsiness or decrease alertness.)
  - What side effects are likely and what do I do if they occur?
  - Will the medication affect my ability to sleep or work?
  - What should I do if I miss a dose?
  - Is there a drug information sheet I can have?
- Store medications out of reach of children and, to prevent accidental ingestion, never refer to medications as “candy.”
- When taking prescription medications, talk to a doctor, pharmacist, or nurse before starting an OTC medication or herbal or dietary supplement. This is a safety factor to avoid undesirable drug interactions.
- Inform health care providers if you have diabetes or kidney or liver disease. These conditions require special precautions with drug therapy.
- If pregnant, consult your obstetrician before taking any medications prescribed by another physician.
- If breast-feeding, consult your obstetrician or pediatrician before taking any medications prescribed by another health care provider.

#### Self-Administration

- Develop a routine for taking medications (e.g., at the same time and place each day). A schedule that minimally disrupts usual activities is more convenient and more likely to be followed accurately.
- Take medications in a well-lighted area and read labels of containers to ensure taking the intended drug. Do not take medications if you are not alert or cannot see clearly.
- Most tablets and capsules should be taken whole. If unable to take them whole, ask a health care provider before splitting, chewing, or crushing tablets or taking the medication out of capsules. Some long-acting preparations are dangerous if altered so that the entire dose is absorbed at the same time.
- As a general rule, take oral medications with 6–8 oz of water, in a sitting or standing position. The water helps tablets and capsules dissolve in the stomach, “dilutes” the drug so that it is less likely to upset the stomach, and promotes absorption of the drug into the bloodstream.
- Take most oral drugs at evenly spaced intervals around the clock. For example, if ordered once daily, take about the same time every day. If ordered twice daily or morning and evening, take about 12 hours apart.
- Follow instructions about taking a medication with food, on an empty stomach, or with other medications.
- If a dose is missed, most authorities recommend taking the dose if remembered soon after the scheduled time and omitting the dose if it is not remembered for several hours. If a dose is omitted, the next dose should be taken at the next scheduled time. Do not double the dose.
- If taking a liquid medication (or giving one to a child), measure with a calibrated medication cup or measuring spoon. A dose cannot be measured accurately with household teaspoons or tablespoons because they are different sizes and deliver varying amounts of medication. If the liquid medication is packaged with a measuring cup that shows teaspoons or tablespoons, that should be used to measure doses, for adults or children.
- Use oral or nasal inhalers, eye drops, and skin medications according to instructions. If not clear how a medication is to be used, be sure to ask a health care provider. Correct use is essential for therapeutic effects.
- Report problems or new symptoms to a health care provider.
- Store medications safely, in a cool, dry place. Do not store them in a bathroom; heat, light, and moisture may cause them to decompose. Do not store them near a dangerous substance, which could be taken by mistake. Keep medications in the container in which they were dispensed by the pharmacy, where the label identifies it and gives directions. Do not mix different medications in a single container.
- Discard outdated medications; do not keep drugs for long periods. Drugs are chemicals that may deteriorate over time, especially if exposed to heat and moisture.

## Patient Teaching Guidelines

## Safe and Effective Use of Over-the-Counter (OTC) Medications

- Read product labels carefully. The labels contain essential information about the name, ingredients, indications for use, usual dosage, when to stop using the medication or when to see a health care provider, possible adverse effects, and expiration dates.
- Use a magnifying glass, if necessary, to read the fine print. If you do not understand the information on labels, ask a physician, pharmacist, or nurse.
- Do not take OTC medications longer or in higher doses than recommended.
- Note that all OTC medications are not safe for everyone. Many OTC medications warn against use with certain illnesses (e.g., hypertension). Consult a health care provider before taking the product if you have a contraindicated condition. If taking any prescription medications, consult a health care provider before taking any OTC drugs to avoid undesirable drug interactions and adverse effects. Some specific precautions include the following:
  - Avoid alcohol if taking sedating antihistamines, cough or cold remedies containing dextromethorphan, or sleeping pills. Because all these drugs cause drowsiness alone, combining any of them with alcohol may result in excessive and potentially dangerous sedation.
  - Avoid OTC sleeping aids if you are taking a prescription sedative-type drug (e.g., for anxiety or nervousness).
  - Ask a health care provider before taking products containing aspirin if you are taking an anticoagulant (e.g., Coumadin).
  - Ask a health care provider before taking other products containing aspirin if you are already taking a regular dose of aspirin to prevent blood clots, heart attack, or stroke. Aspirin is commonly used for this purpose, often in doses of 81 mg (a child's dose) or 325 mg.
- Do not take a laxative if you have stomach pain, nausea, or vomiting, to avoid worsening the problem.
- Do not take a nasal decongestant (e.g., Sudafed), a multisymptom cold remedy containing phenylephrine products, i.e., formulated to remove pseudoephedrine (e.g., Actifed), or an antihistamine-decongestant combination (e.g., Claritin D) if you are taking a prescription medication for high blood pressure. Such products can raise blood pressure and decrease or cancel the blood pressure-lowering effect of the prescription drug. This could lead to severe hypertension and stroke.
- Store OTC drugs in a cool, dry place, in their original containers; check expiration dates periodically and discard those that have expired.
- If pregnant, consult your obstetrician before taking any OTC medications.
- If breast-feeding, consult your pediatrician or family doctor before taking any OTC medications.
- For children, follow any age limits on the label.
- Measure liquid OTC medications with the measuring device that comes with the product (some have a dropper or plastic cup calibrated in milliliters, teaspoons, or tablespoons). If such a device is not available, use a measuring spoon. It is not safe to use household teaspoons or tablespoons because they are different sizes and deliver varying amounts of medication.
- Do not assume continued safety of an OTC medication you have taken for years. Older people are more likely to have adverse drug reactions and interactions because of changes in the heart, kidneys, and other organs that occur with aging and various disease processes.

## Integrating Clinical Pathways with Nursing Process

Within a health care agency, nursing responsibilities related to drug therapy may be designated in *clinical pathways*, which are guidelines for the care of patients with particular conditions. Major components include a medical diagnosis, aspects of care related to the medical diagnosis, desired patient outcomes, and time frames (usually days) for achieving the desired outcomes during the expected length of stay.

Medical diagnoses for which clinical pathways are developed are those often encountered in an agency and those that often result in complications or prolonged lengths of stay (e.g., patients having coronary artery bypass grafts or myocardial infarction). Development and implementation of the clinical pathways should be an interdisciplinary, collaborative effort. Thus, all health care professionals involved in the care of a patient should be represented. For patients, a comprehensive pathway extending from illness onset through treatment and recovery could promote continuity of care among agencies and health care providers. In hospital settings, case managers, who

may be non-nurses, usually assess patients' conditions daily to evaluate progress toward the desired outcomes.

Depending on the medical diagnoses, many clinical pathways have specific guidelines related to drug therapy. These guidelines may include any step of the nursing process. With assessment, for example, the clinical pathway may state, "Assess for bleeding if on anticoagulant."

## Integrating Evidence-Based Practice with Nursing Process

Evidence-based nursing practice requires a conscientious and continuing effort to provide high-quality care to patients by obtaining and analyzing the best available scientific evidence from research. Then, the scientific evidence is integrated with the nurse's clinical expertise and the patient's preferences and values to yield "best practices" for a patient with a particular disease process or health problem. Evidence-based practice is further described below, and selected elements are described in Box 4-3.

Evidence-based practice (EBP) may include any step of the nursing process, and it does not accept tradition or “that’s the way we’ve always done it” as sufficient rationale for any aspect of nursing care. Requirements for implementing evidence-based practice include

- Using research. Although professional nurses have always been encouraged to use research, EBP structures and formalizes the process. The nurse must use computer skills to search for the best evidence in making decisions about patient care. The search needs to be systematic; obtained data need to be critically analyzed for quality and relevance to the clinical situation.
- Keeping up-to-date in regard to research studies related to one’s area of clinical practice. This includes reading research reports and analyzing them to determine their applicability.
- Considering levels of evidence to support clinical decision making. Level A is the strongest level.
- Interpreting research evidence in relation to one’s clinical expertise and patient choices to provide a scientific rationale for one’s clinical decisions.

- Applying the available information to improve nursing care of an individual or group of patients.
- Evaluating the effectiveness of application—did the intervention improve the patient’s condition?

In this text, EBP is presented in boxed features in some chapters and in various sections of some chapters. An example is the use of a particular drug or drugs to treat certain health problems. Although most nurses do not prescribe and therefore do not choose a patient’s drug therapy regimen, it is still important for a nurse to know why a drug is used. This knowledge helps in monitoring patients’ responses and in teaching patients and may help patients adhere to the prescribed regimen.

## Herbal and Dietary Supplements

Herbal and dietary supplements are commonly used, and patients who take them are likely to be encountered in any clinical practice setting. Herbal medicines, also called *botanicals*,

### Box 4-3

### Selected Elements of Evidence-based Practice

#### Types of Research Studies (Evidence)

**Meta-analysis** involves a rigorous process of analyzing, comparing, and summarizing multiple studies (e.g., well-designed randomized controlled trials, if available) on a particular topic and combining the results statistically as if they were from one large study.

**Systematic reviews** usually focus on a clinical topic and answer a specific question. An extensive literature search is conducted to identify all studies with well-designed methodology. The studies are analyzed, critically evaluated, and summarized according to predetermined criteria. For a systematic review, experts follow a rigorous and well-defined process to identify, critically evaluate, synthesize, and summarize the evidence on a particular topic. (The *Cochrane Database of Systematic Reviews* is a highly-respected source of systematic reviews).

**Randomized controlled trials (RCTs)** study the effect of a treatment (e.g., a drug) on real patients. Such studies include randomizing (a hallmark of high quality research) and blinding (so that neither researcher nor patient knows who is receiving the treatment or intervention) to reduce the likelihood of biasing the results. They also allow comparison between intervention groups and control groups (no intervention). Because RCTs with a large numbers of subjects produce more reliable results than smaller studies, many RCTs are conducted at multiple clinical sites and in multiple countries.

**Cohort studies** involve large groups of patients who have a specific condition or who receive a particular treatment. These patients are compared with another group who does not have

the condition or does not receive the treatment being studied. Cohort studies are observational and not as reliable as RCTs.

**Case control studies** compare patients with a specific condition to people who do not have the condition. They are less reliable than RCTs and cohort studies because they collect mainly retrospective data from medical records and patient interviews.

**Case series and case reports** collect reports on the treatment of individual patients or a report on a single patient. Because they are reports of cases and use no control groups with which to compare outcomes, they have no statistical validity.

#### Levels of Evidence

Although a number of hierarchies or levels of evidence are described in the literature about evidence-based practice, the following levels are used in this text.

**Level A** indicates that data are derived from multiple randomized clinical trials, meta-analysis, or systematic reviews and provides the strongest evidence or support for clinical decision making and practice. There are also evidence-based clinical practice guidelines. Such guidelines delineate a plan of care for patients with particular health problems (e.g., acute myocardial infarction, asthma). Evidence-based guidelines are based on rigorous scientific evidence (i.e., systematic reviews or RCTs). In many instances, however, when systematic reviews and RCTs are not available, guidelines based on consensus opinions of a group of experts may be the “best

## Box 4-3

## Selected Elements of Evidence-based Practice (continued)

available evidence” and can assist in clinical decision making. Guidelines on numerous health problems are available from the National Guidelines Clearinghouse (NGC). The NGC is maintained by the Agency for Healthcare Quality and Research, a division of the U.S. Department of Health and Human Services. However, each guideline contains a disclaimer statement that the NGC “does not develop, produce, approve, or endorse the guidelines” and that the guidelines summarized and distributed by NGC are “produced under the auspices of medical specialty societies, relevant professional associations, public or private organizations, other government agencies, health care organizations or plans, and similar entities.” Readers with questions about guideline content should contact the guideline developer.

**Level B** usually indicates that data are derived from a randomized controlled trial, the next strongest evidence for changing or improving practice, after systematic reviews.

**Level C** indicates that data are derived from consensus opinions of experts, case studies, or standard-of-care recommendations.

**Level D** or **U** may be used to indicate that data are insufficient, unreliable, or fail to support one or more clinical practices.

#### Electronic Resources

High-quality Web sites are sponsored by the National Library of Medicine, university health science libraries, hospital

libraries, and health care associations and organizations. Most of these resources offer free access to information about patient care. Others require paid subscriptions (e.g., Cochrane reports, most journals). Nurses need to check to see whether their health care or educational organization has an institutional subscription and, if so, how to access the databases. Most of the following Web sites were derived from Dee (2005). The article describes the sites and provides tips for searching them.

PubMed [www.ncbi.nlm.nih.gov/PubMed](http://www.ncbi.nlm.nih.gov/PubMed)

*phytochemicals*, and *nutraceuticals*, are derived from plants; other dietary supplements may be derived from a variety of sources. The 1994 Dietary Supplement Health and Education Act (DSHEA) defined a dietary supplement as “a vitamin, a mineral, an herb or other botanical used to supplement the diet.” Under this law, herbs can be labeled according to their possible effects on the human body, but the products cannot claim to diagnose, prevent, relieve, or cure specific human diseases unless approved by the Food and Drug Administration (FDA).

It has become evident that nurses need to know about their patient’s use of herbal and dietary supplements to provide safe care. An additional impetus came from the Institute of Medicine of the National Academies, which released a report on complementary and alternative medicine (CAM) in 2005 in which they recommended that “health profession schools incorporate sufficient information about ... CAM into the standard curriculum at all levels to enable licensed professionals to competently advise their patients about CAM” (cited in Hughes, Jacobs, & Berman., 2007).

More specifically, there are five major concerns associated with the nursing role in relation to herbal products and drug therapy, as follows:

1. Many of the products may not be safe because active ingredients and effects on humans are often unknown. Some con-

tain heavy metals (e.g., lead) and other contaminants (e.g., pesticides); some contain prescription or nonprescription drugs. In addition, ingredients are not standardized and often differ from those listed on the product label.

2. Use of supplements may keep the patient from seeking treatment from a health care provider when indicated. This may allow disease processes to worsen and be more difficult to treat.
3. The products may interact with prescription drugs to decrease therapeutic effects or increase adverse effects. Dangerous interactions have been identified with St. John’s wort and some herbs that affect blood clotting mechanisms.
4. Most products have not been studied sufficiently to evaluate their safety or effectiveness. In many studies, the products have not been standardized in terms of types or amounts of active ingredients. In addition, most reported studies have been short-term and with few subjects.
5. Many patients who use supplements do not tell their health care providers. This omission can lead to dangerous interactions when the supplements are combined with prescription or OTC drugs.

In general, nurses need to have an adequate knowledge base to assess and assist patients who use herbal products to do

so safely. To develop and maintain a knowledge base, nurses (and patients) need to seek information from authoritative, objective sources rather than product labels, advertisements, or personal testimonials from family members, friends, or celebrities. Some resources are listed below:

- Table 4-1 describes some commonly used supplements. In later chapters, selected supplements with some scientific support for their use are described in more detail. For example, in Chapter 7 some products reported to be useful in relieving pain, fever, inflammation, or migraines are described.
- Patient Teaching Guidelines. In this chapter, general information is provided (see Patient Teaching Guidelines: General Information About Herbal and Dietary Supplements). In later chapters, guidelines may emphasize avoidance or caution in using supplements thought to interact adversely with prescribed drugs or particular patient conditions.

- Assessment guidelines. In this chapter, general information about the use or nonuse of supplements is assessed. In later chapters, specific supplements that may interact with particular drug group(s) are discussed. For example, some supplements are known to increase blood pressure (see Chap. 52) or risk of excessive bleeding (see Chap. 54).
- End-of-chapter references.
- A good source of information is the National Center for Complementary and Alternative Medicine (NCCAM) at the National Institutes of Health:

NAME/USES	CHARACTERISTICS	REMARKS
<p><b>Black Cohosh</b></p> <ul style="list-style-type: none"> <li>■ Most often used to relieve symptoms of menopause (e.g., flushes, vaginal dryness, irritability)</li> <li>■ May also relieve premenstrual syndrome (PMS) and dysmenorrhea</li> </ul>	<ul style="list-style-type: none"> <li>■ Well tolerated; in overdose may cause nausea, vomiting, dizziness, visual disturbances, and reduced pulse rate</li> <li>■ Most clinical trials done with Remifemin, in small numbers of women; other trade names include Estroven and Femtrol</li> </ul>	<ul style="list-style-type: none"> <li>■ Did not relieve hot flashes in a 12-month, randomized, double-blind, placebo-controlled NIH* study of 351 menopausal or perimenopausal women aged 45–55, reported in <i>Annals of Internal Medicine</i> (2006) by Newton et al.</li> <li>■ Not recommended for use longer than 6 months</li> </ul>
<p><b>Capsaicin</b> (Chap. 6)</p> <ul style="list-style-type: none"> <li>■ Used to treat pain associated with neuralgia, neuropathy, and osteoarthritis</li> <li>■ Self-defense as the active ingredient in “pepper spray”</li> </ul>	<ul style="list-style-type: none"> <li>■ A topical analgesic that may inhibit the synthesis, transport, and release of substance P, a pain transmitter</li> <li>■ Derived from cayenne pepper</li> <li>■ Adverse effects include skin irritation, itching, redness, and stinging</li> </ul>	<p>Applied topically</p>
<p><b>Chamomile</b></p> <p>Used mainly for antispasmodic effects in the gastrointestinal (GI) tract; may relieve abdominal cramping</p>	<ul style="list-style-type: none"> <li>■ Usually ingested as a tea; may delay absorption of oral medications</li> <li>■ May cause contact dermatitis and severe hypersensitivity reactions, including anaphylaxis, in people allergic to ragweed, asters, and chrysanthemums</li> <li>■ May increase risks of bleeding</li> </ul>	<p>Few studies and little data to support use and effectiveness in GI disorders</p>
<p><b>Chondroitin</b> (Chap. 7)</p> <p>Arthritis</p>	<ul style="list-style-type: none"> <li>■ Derived from the trachea cartilage of slaughtered cattle</li> <li>■ Usually taken with glucosamine</li> <li>■ Adverse effects may include GI upset, nausea, and headache</li> </ul>	<p>Several studies support use</p>

(continued on page 58)

Table 4-1

## Herbal and Dietary Supplements (continued)

NAME/USES	CHARACTERISTICS	REMARKS
<p><b>Creatine</b></p> <p>Athletes take creatine supplements to gain extra energy, to train longer and harder, and to improve performance</p>	<ul style="list-style-type: none"> <li>■ An amino acid produced in the liver and kidneys and stored in muscles</li> <li>■ Causes weight gain, usually within 2 weeks of starting use</li> <li>■ Legal and available in health food stores as a powder to be mixed with water or juice, as a liquid, and as tablets and capsules</li> </ul>	<ul style="list-style-type: none"> <li>■ Not recommended for use by children because studies have not been done and effects are unknown</li> <li>■ Nurses and parents need to actively discourage children and adolescents from using creatine supplements.</li> </ul>
<p><b>Echinacea</b></p> <p>Most often used for the common cold, but also advertised for many other uses (immune system stimulant, anti-infective)</p>	<ul style="list-style-type: none"> <li>■ Many species, but <i>E. purpurea</i> most often used medicinally</li> <li>■ Effects on immune system include stimulation of phagocytes and monocytes</li> <li>■ Contraindicated in persons with immune system disorders</li> <li>■ Hepatotoxic with long-term use</li> </ul>	<ul style="list-style-type: none"> <li>■ Hard to interpret validity of claims because various species and preparations used in reported studies</li> <li>■ Some evidence (Level B) to support use in patients with the common cold, with possibly shorter durations and less severe symptoms</li> </ul>
<p><b>Feverfew</b> (Chap. 7)</p> <p>Migraines, menstrual irregularities, arthritis</p>	<ul style="list-style-type: none"> <li>■ May increase risk of bleeding</li> <li>■ May cause hypersensitivity reactions in people allergic to ragweed, asters, daisies, or chrysanthemums</li> <li>■ May cause a withdrawal syndrome if use is stopped abruptly</li> </ul>	Some studies support use in patients with migraine
<p><b>Garlic</b></p> <p>Used to lower serum cholesterol and for other uses</p>	<ul style="list-style-type: none"> <li>■ Active ingredient thought to be allicin</li> <li>■ Has antiplatelet activity and may increase risk of bleeding</li> <li>■ Adverse effects include allergic reactions (asthma, dermatitis), dizziness, nausea, vomiting</li> </ul>	Some evidence that garlic has a small cholesterol-lowering effect; no reliable evidence to support other uses
<p><b>Ginger</b></p> <p>Used mainly to treat nausea, including motion sickness and postoperative nausea</p>	<ul style="list-style-type: none"> <li>■ Inhibits platelet aggregation; may increase clotting time</li> <li>■ Gastroprotective effects in animal studies</li> </ul>	Should not be used for morning sickness associated with pregnancy—may increase risk of miscarriage
<p><b>Ginkgo Biloba</b></p> <p>Used mainly to improve memory and cognitive function in people with Alzheimer's disease; may be useful in treating peripheral arterial disease</p>	<ul style="list-style-type: none"> <li>■ May increase blood flow to the brain and legs, improve memory, and decrease intermittent claudication (leg pain with walking)</li> <li>■ Inhibits platelet aggregation; may increase risks of bleeding with any drug that has antiplatelet effects (e.g., aspirin)</li> <li>■ Adverse effects include GI upset, headache, bleeding, allergic skin reaction</li> </ul>	<ul style="list-style-type: none"> <li>■ Good evidence (Level A) for small effects in treating dementia and claudication.</li> <li>■ NIH* is conducting a clinical trial with more than 3,000 volunteers to see if ginkgo prevents the onset of dementia (specifically, Alzheimer's disease), slows cognitive decline and functional disability, and reduces the incidence of cardiovascular disease</li> </ul>

NAME/USES	CHARACTERISTICS	REMARKS
<p><b>Ginseng</b> Used to increase stamina, strength, endurance, and mental acuity</p>	<ul style="list-style-type: none"> <li>■ Has various pharmacologic effects that vary with dose and duration of use</li> <li>■ Adverse effects include hypertension, nervousness, depression, insomnia, skin rashes, epistaxis, palpitations, vomiting</li> <li>■ May increase risks of bleeding with any drug that has antiplatelet effects (e.g., aspirin)</li> <li>■ Increases risk of hypoglycemic reactions if taken with antidiabetic drugs</li> <li>■ Should not be taken with other herbs or drugs that inhibit monoamine oxidase (e.g., St. John's wort, selegiline); headache, mania, and tremors may occur</li> </ul>	<ul style="list-style-type: none"> <li>■ Insufficient evidence to support use for any indication</li> <li>■ A ginseng abuse syndrome, with insomnia, hypotonia, and edema, has been reported. Caution patients to avoid ingesting excessive amounts.</li> <li>■ Instruct patients with cardiovascular disease, diabetes mellitus, or hypertension to check with their health care provider before taking ginseng.</li> <li>■ Instruct any patient taking ginseng to avoid long-term use. Siberian ginseng should not be used longer than 3 weeks.</li> </ul>
<p><b>Glucosamine</b> (Chap. 7) Osteoarthritis</p>	<ul style="list-style-type: none"> <li>■ Usually used with chondroitin</li> <li>■ Has beneficial effects on cartilage</li> <li>■ Adverse effects mild, may include GI upset, drowsiness</li> </ul>	<p>Several studies support use</p>
<p><b>Melatonin</b> (Chap. 8) Used mainly for treatment of insomnia and prevention and treatment of jet lag</p>	<ul style="list-style-type: none"> <li>■ Several studies of effects on sleep, energy level, fatigue, mental alertness, and mood indicate some improvement, compared with placebo</li> <li>■ Contraindicated in persons with hepatic insufficiency or a history of cerebrovascular disease, depression, or neurologic disorders</li> <li>■ Adverse effects include altered sleep patterns, confusion, headache, sedation, tachycardia</li> </ul>	<p>Patients with renal impairment should use cautiously.</p>
<p><b>St. John's Wort</b> (Chap. 10) Used for treatment of depression, advertised as an "herbal Prozac"</p>	<ul style="list-style-type: none"> <li>■ Active component may be hypericin or hyperforin</li> <li>■ Adverse effects include confusion, dizziness, GI upset, photosensitivity</li> <li>■ Interacts with many drugs; can decrease effectiveness of birth control pills, anticancer drugs, antivirals used to treat acquired immunodeficiency syndrome (AIDS), and organ transplant drugs (e.g., cyclosporine)</li> </ul>	<ul style="list-style-type: none"> <li>■ Good evidence (Level A) for improvement in mild to moderate depression; not effective in major or serious depression</li> <li>■ Should not be combined with monoamine oxidase inhibitors (MAOI) or selective serotonin reuptake inhibitor (SSRI) antidepressants</li> <li>■ Use has declined since serious herb-drug interactions reported.</li> </ul>
<p><b>Saw Palmetto</b> Used to prevent and treat urinary symptoms in men with benign prostatic hyperplasia (BPH)</p>	<ul style="list-style-type: none"> <li>■ May have antiandrogenic effects</li> <li>■ Adverse effects may include GI upset, headache; diarrhea may occur with high doses.</li> </ul>	<ul style="list-style-type: none"> <li>■ Some evidence (Level B) of small beneficial effects with doses of 320 mg/day</li> </ul>
<p><b>Valerian</b> (Chap. 8) Used mainly to promote sleep and allay anxiety and nervousness; also has muscle relaxant effects</p>	<ul style="list-style-type: none"> <li>■ Adverse effects with acute overdose or chronic use include blurred vision, drowsiness, dizziness, excitability, hypersensitivity reactions, insomnia; also, risk of liver damage from combination products containing valerian and from overdoses averaging 2.5 g</li> <li>■ Additive sedation if taken with other CNS depressants</li> </ul>	<ul style="list-style-type: none"> <li>■ Should not be combined with sedative drugs and should not be used regularly</li> <li>■ Many extract products contain 40%–60% alcohol.</li> <li>■ Insufficient evidence to support use for treatment of insomnia</li> </ul>

GI, gastrointestinal; NIH, National Institutes of Health.

## Patient Teaching Guidelines

## General Information About Herbal and Dietary Supplements

- Herbal and dietary products are chemicals that have drug-like effects in people. Unfortunately, their effects are largely unknown and may be dangerous for some people because there is little reliable information about them. For most products, little research has been done to determine either their benefits or their adverse effects.
- The safety and effectiveness of these products are not regulated by laws designed to protect consumers, as are pharmaceutical drugs. As a result, the types and amounts of ingredients may not be identified on the product label. In fact, most products contain several active ingredients and it is often not known which ingredient, if any, has the desired pharmacologic effect. In addition, components of plants can vary considerably, depending on the soil, water, and climate where the plants are grown. Quality is also a concern, as heavy metals (e.g., lead), pesticides, and other contaminants have been found in some products.
- These products can be used more safely if they are manufactured by a reputable company that states the ingredients are standardized (meaning that the dose of medicine in each tablet or capsule is the same).
- The product label should also state specific percentages, amounts, and strengths of active ingredients. With herbal medicines especially, different brands of the same herb vary in the amounts of active ingredients per recommended dose. Dosing is also difficult because a particular herb may be available in several different dosage forms (e.g., tablet, capsule, tea, extract) with different amounts of active ingredients.
- These products are often advertised as “natural.” Many people interpret this to mean the products are safe and better than synthetic products. This is not true; “natural” does not mean safe, especially when taken concurrently with other herbals, dietary supplements, or drugs.
- When taking herbal or dietary supplements, follow the instructions on the product label. Inappropriate use or taking excessive amounts may cause dangerous side effects.
- Inform health care providers when taking any kind of herbal or dietary supplement to reduce risks of severe adverse effects or drug-supplement interactions.
- Most herbal and dietary supplements should be avoided during pregnancy or lactation and in young children.
- The American Society of Anesthesiologists recommends that all herbal products be discontinued 2–3 weeks before any surgical procedure. Some products (e.g., echinacea, feverfew, garlic, ginkgo, ginseng, valerian, and St. John’s wort) can interfere with or increase the effects of some drugs, affect blood pressure or heart rhythm, or increase risks of bleeding; some have unknown effects when combined with anesthetics, other perioperative medications, and surgical procedures.
- Store herbal and dietary supplements out of the reach of children.

## General Principles of Drug Therapy

### Goals and Guidelines

The goals of drug therapy are to maximize beneficial effects and to minimize adverse effects. To help meet these goals, general guidelines include the following:

- Expected benefits should outweigh potential adverse effects. Thus, drugs usually should not be prescribed for trivial problems or problems for which nondrug measures are effective.
- Drug therapy should be individualized. Many variables influence a drug’s effects on the human body. Failure to consider these variables may decrease therapeutic effects or increase risks of adverse effects.
- Drug effects on quality of life should be considered in designing a drug therapy regimen. Quality-of-life issues are also being emphasized in research studies, with expectations of measurable improvement as a result of drug therapy.

### Drug Selection and Dosage

Numerous factors must be considered when choosing a drug and dosage range for a particular patient, including the following:

- Minimizing the number of drugs and the frequency of administration increases patient compliance with the prescribed drug regimen and decreases risks of serious adverse effects, including hazardous drug–drug interactions. Notable exceptions to this basic rule are that multiple drugs are commonly used to treat asthma, hypertension, and serious infections.
- Fixed-dose combination drugs, rather than individual drugs that allow greater flexibility of dosage, are commonly used, mainly because patients are more likely to take them. Many of the combination products can be taken once daily, which also promotes compliance.
- The least amount of the least potent drug that yields therapeutic benefit should be given to decrease adverse reactions. For example, if a mild nonopioid and a strong opioid analgesic are both ordered, give the nonopioid drug *if it is effective in relieving pain*.
- In drug literature, recommended dosages are listed in amounts likely to be effective for most people. However, they are only guidelines to be interpreted according to the patient’s condition. For example, patients with serious illnesses may require larger doses of some drugs than patients with milder illnesses; patients with severe kidney disease need much smaller doses of renally excreted drugs.

- A drug can be started rapidly or slowly. If it has a long half-life and optimal therapeutic effects do not usually occur for several days or weeks, the prescriber may order a limited number of relatively large (*loading*) doses followed by a regular schedule of smaller (*maintenance*) doses. When drug actions are not urgent, therapy may be initiated with a maintenance dose.

## Drug Therapy in Special Populations

### Drug Therapy in Children

Drug therapy in neonates (birth to 1 month), infants (1 month to 1 year), and children (1 to 12 years) requires special consideration because of the child's changing size, developmental level, and organ function. Physiologic differences alter drug pharmacokinetics (Table 4-2), and drug therapy is less predictable than in adults. Neonates are especially vulnerable

to adverse drug effects because of their immature liver and kidney function; neonatal therapeutics are discussed further in Chapter 65.

For many drugs, manufacturers' literature states "safety and effectiveness for use in children have not been established." Still, most drugs given to adults also are given to children, and general principles, techniques of drug administration, and nursing process guidelines apply. Additional principles and guidelines include the following:

- All aspects of pediatric drug therapy must be guided by the child's age, weight, and level of growth and development.
- Safe therapeutic dosage ranges are less well defined for children than for adults. Some drugs are not recommended for use in children, and therefore dosages have not been established. For many drugs, doses for children are extrapolated

Table 4-2

Neonates, Infants, and Children: Physiologic Characteristics and Pharmacokinetic Consequences

PHYSIOLOGIC CHARACTERISTICS	PHARMACOKINETIC CONSEQUENCES
Increased thinness and permeability of skin in neonates and infants	Increased absorption of topical drugs (e.g., corticosteroids may be absorbed sufficiently to suppress adrenocortical function)
Immature blood–brain barrier in neonates and infants	Increased distribution of drugs into the central nervous system because myelinization (which creates the blood–brain barrier to the passage of drugs) is not mature until approximately 2 years of age
Increased percentage of body water (70%–80% in neonates and infants, compared with 50%–60% in children older than 2 years of age and adults)	Usually increased volume of distribution in infants and young children, compared with adults. This would seem to indicate a need for larger doses. However, prolonged drug half-life and decreased rate of drug clearance may offset. The net effect is often a need for decreased dosage.
Altered protein binding until approximately 1 year of age, when it reaches adult levels	The amount and binding capacity of plasma proteins may be reduced. This may result in a greater proportion of unbound or pharmacologically active drug and greater risks of adverse drug effects. Dosage requirements may be decreased or modified by other factors. Drugs with decreased protein binding in neonates, compared with older children and adults, include ampicillin (Principen, others), diazepam (Valium), digoxin (Lanoxin), lidocaine (Xylocaine), nafcillin, phenobarbital, phenytoin (Dilantin), salicylates (e.g., aspirin), and theophylline (Theolair).
Decreased glomerular filtration rate in neonates and infants, compared with older children and adults. Kidney function develops progressively during the first few months of life and is fairly mature by 1 year of age.	In neonates and infants, slowed excretion of drugs eliminated by the kidneys. Dosage of these drugs may need to be decreased, depending on the infant's age and level of growth and development.
Decreased activity of liver drug-metabolizing enzyme systems in neonates and infants	Decreased capacity for biotransformation of drugs. This results in slowed metabolism and elimination, with increased risks of drug accumulation and adverse effects.
Increased activity of liver drug-metabolizing enzyme systems in children	Increased capacity for biotransformation of some drugs. This results in a rapid rate of metabolism and elimination. For example, theophylline is cleared about 30% faster in a 7-year-old child than in an adult and approximately four times faster than in a neonate.

from those established for adults. When pediatric dosage ranges are listed in drug literature, these should be used. Often, however, dosages are expressed as the amount of drug to be given per kilogram of body weight or square meter of body surface area, and the amount needed for a specific dose must be calculated as a fraction of the adult dose. Body surface area (BSA) is based on height and weight and can be estimated using a nomogram (Fig. 4-1). Use the estimated BSA in the following formula to calculate the child's dose:

Body surface area (in square meters)

$$1.73 \text{ square meters (m}^2\text{)} \\ \times \text{ adult dose} = \text{child's dose}$$

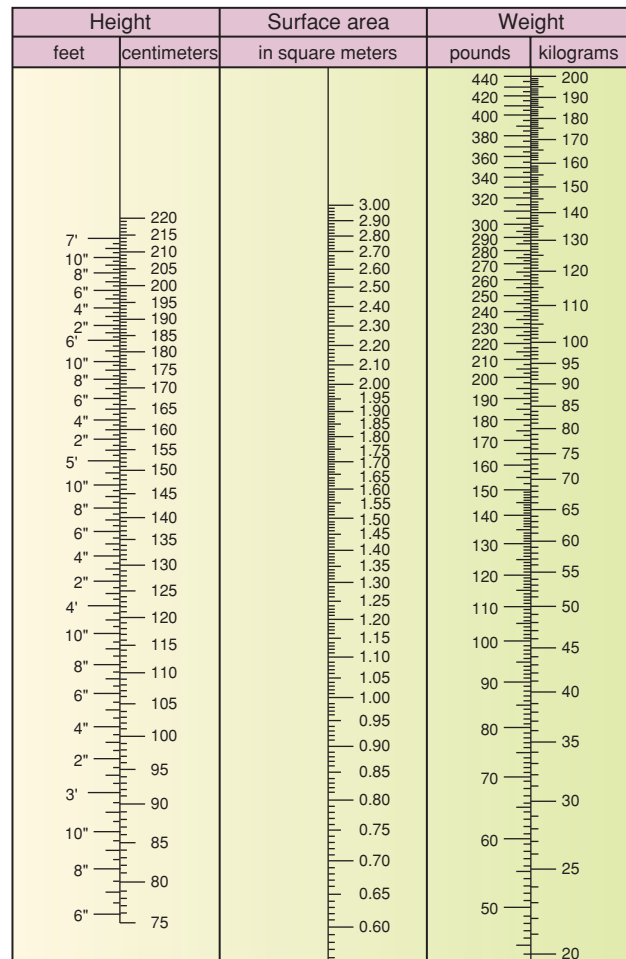

- Dosages obtained from calculations can be used initially and then increased or decreased according to the child's response.

- Use the oral route of drug administration when possible. Try to obtain the child's cooperation; never force oral medications because forcing may lead to aspiration.
- Site selection for intramuscular injections depends on age and size. In infants, use thigh muscles because the deltoid muscles are small and the gluteal muscles do not develop until the child is walking. In children older than 18 months of age, use deltoid muscles; injections are considered less painful than in thigh muscles. In children older than 3 years of age, ventrogluteal injections are considered less painful than those in anterior thigh or dorsogluteal areas.
- Children are fearful of injections. With an immunization schedule that calls for 20 or more injections during childhood plus procedures required by illnesses, interventions are needed to decrease the pain and fear associated with injections, venipunctures, and other "shots." One technique is the application of EMLA (eutectic mixture of lidocaine and

**Nomogram for estimating the surface area of infants and young children**

**Nomogram for estimating the surface area of older children and adults**

**Figure 4-1** ■ Body surface nomograms. To determine the surface area of the patient, draw a straight line between the point representing his or her height on the left vertical scale to the point representing weight on the right vertical scale. The point at which this line intersects the middle vertical scale represents the patient's surface area in square meters (courtesy of Abbott Laboratories).

prilocaine local anesthetics). A disadvantage is that EMLA must be applied an hour before the painful injection. Having parents present and using distraction techniques may also be helpful.

- For safety, keep all medications in childproof containers, out of reach of children, and do not refer to medications as “candy.”

### Drug Therapy in Older Adults

Aging is a continuum; precisely when a person becomes an “older adult” is not clearly established, but in this book, the term *older adult* refers to people 65 years of age and older. In this population, general nursing process guidelines and principles of drug therapy apply. In addition, adverse effects are likely because of physiologic changes associated with aging (Table 4-3), pathologic changes due to disease processes, multiple drugs for acute and chronic disorders, impaired memory and cognition, and difficulty in complying with drug orders. Overall, the goal of drug therapy may be “care” rather than “cure,” with efforts to prevent or control symptoms and to maintain the patient’s ability to function in usual activities of daily living. Additional principles include the following:

- Although age in years is important, older adults are quite heterogeneous in their responses to drug therapy and responses differ widely within the same age group. Responses also differ in the same person over time. Physiologic age (i.e., organ function) is more important than chronologic age.
- It may be difficult to separate the effects of aging from the effects of disease processes or drug therapy, particularly long-term drug therapy. Symptoms attributed to aging or disease may be caused by medications. This occurs because older adults are usually less able to metabolize and excrete drugs efficiently. As a result, drugs are more likely to accumulate. *When a patient develops new symptoms or becomes less capable of functioning in usual activities of daily living, consider the possibility of adverse drug effects.* Because new signs and symptoms are often attributed to aging or disease, they may be ignored or treated by prescribing a new drug, when stopping or reducing the dose of an “old” drug is the needed intervention.
- Use nondrug interventions to decrease the need for drugs and to increase their effectiveness or decrease their adverse effects. For example, insomnia is a common complaint among older adults. Preventing it (e.g., by avoiding excessive caffeine and napping) is much safer than taking sedative-hypnotic drugs.
- Medications—both prescription and OTC—should be taken only when necessary. When drug therapy is required, the choice of drug should be based on available drug information regarding effects in older adults.
- Any prescriber should review current medications, including nonprescription drugs and herbal remedies, before prescribing new drugs.

- The basic principle of giving the smallest effective number of drugs applies especially to older adults. A regimen of several drugs increases the risks of adverse drug reactions and interactions. In addition, many older adults are unable to correctly self-administer more than three or four drugs.
- All drugs should be given for the shortest effective time. This interval is not established for most drugs, and many are continued for years. Health care providers must reassess drug regimens periodically to see whether drugs, dosages, or other aspects need to be revised. This is especially important when a serious illness or significant changes in health status have occurred.
- The smallest number of effective doses should be prescribed. This allows less disruption of usual activities and promotes compliance with the prescribed regimen.
- When any drug is started, the dosage should usually be smaller than for younger adults. The dosage can then be increased or decreased according to response. If increased dosage is indicated, increments should be smaller and made at longer intervals in older adults. This conservative, safe approach is often called “start low, go slow.”
- For older adults receiving long-term drug therapy at home, assist them to take drugs safely and effectively:
  - If vision is impaired, label drug containers with large lettering for easier readability. A magnifying glass also may be useful.
  - Be sure the patient can open drug containers. For example, avoid childproof containers for an older adult with arthritic hands.
  - Use appropriate devices to schedule drug doses and decrease risks of omitting or repeating doses. Helpful devices include written schedules, calendars, charts, and drug containers with each dose prepared and clearly labeled as to the day and time it is to be taken. With the latter system, the patient can tell at a glance whether a dose has been taken.
  - Enlist family members or friends when necessary.

### Applying Your Knowledge 4-3

Given Mr. Walker’s age and his drug regimen, what factors related to medication administration should the nurse consider to ensure safe, accurate, and effective drug administration?

### Drug Therapy in Patients With Renal Impairment

Many patients have or are at risk for impaired renal function. Patients with disease processes such as diabetes or hypertension may have renal insufficiency on first contact, and this may be worsened by illness, major surgery or trauma, or administration of nephrotoxic drugs. In patients with initially normal renal

Table 4-3

## Older Adults: Physiologic Characteristics and Pharmacokinetic Consequences

PHYSIOLOGIC CHARACTERISTICS	PHARMACOKINETIC CONSEQUENCES
Decreased gastrointestinal secretions and motility	Minimal effects on absorption of most oral drugs; effects on extended-release formulations are unknown
Decreased cardiac output	<ul style="list-style-type: none"> <li>■ Slower absorption from some sites of administration (e.g., gastrointestinal tract, subcutaneous or muscle tissue); effects on absorption from skin and mucous membranes are unknown</li> <li>■ Decreased distribution to sites of action in tissues, with potential for delaying the onset and reducing the extent of therapeutic effects</li> </ul>
Decreased blood flow to the liver and kidneys	Delayed metabolism and excretion, which may lead to drug accumulation and increased risks of adverse or toxic effects
Decreased total body water and lean body mass per kg of weight; increased body fat	Water-soluble drugs (e.g., ethanol, lithium) are distributed into a smaller area, with resultant higher plasma concentrations and higher risks of toxicity with a given dose. Fat-soluble drugs (e.g., diazepam) are distributed to a larger area, accumulate in fat, and have a longer duration of action in the body.
Decreased serum albumin	<p>Decreased availability of protein for binding and transporting drug molecules. This increases serum concentration of free, pharmacologically active drug, especially for those that are normally highly protein bound (e.g., aspirin, warfarin). This may increase risks of adverse effects. However, the drug also may be metabolized and excreted more rapidly, thereby offsetting at least some of the risks.</p> <p>In addition, drug interactions occur with co-administration of multiple drugs that are highly protein bound. The drugs compete for protein-binding sites and are more likely to cause adverse effects with decreased levels of serum albumin. As above, the result is larger concentrations of free drug.</p>
Decreased blood flow to the liver; decreased size of the liver; decreased number and activity of the cytochrome P450 (CYP) oxidative drug-metabolizing enzymes	Slowed metabolism and detoxification of many drugs, with increased risks of drug accumulation and toxic effects. (Numerous drugs metabolized by the CYP enzymes are often prescribed for older adults, including beta blockers, calcium channel blockers, antimicrobials, the statin cholesterol-lowering drugs, and antiulcer drugs. Metabolism of drugs metabolized by conjugative reactions [e.g., acetaminophen, diazepam, morphine, steroids] does not change significantly with aging).
Decreased blood flow to the kidneys; decreased number of functioning nephrons; decreased glomerular filtration rate; and decreased tubular secretion	<ul style="list-style-type: none"> <li>■ Impaired drug excretion, prolonged half-life, and increased risks of toxicity</li> <li>■ Age-related alterations in renal function are consistent and well described. When renal blood flow is decreased, less drug is delivered to the kidney for elimination. Renal mass is also decreased and older adults may be more sensitive to drugs that further impair renal function (e.g., nonsteroidal anti-inflammatory drugs such as ibuprofen, which older adults often take for pain or arthritis).</li> </ul>

function, renal failure may develop from depletion of intravascular fluid volume, shock due to sepsis or blood loss, seriously impaired cardiovascular function, major surgery, nephrotoxic drugs, or other conditions. Acute renal failure (ARF) may occur in any illness in which renal blood flow or function is impaired. Chronic renal failure (CRF) usually results from disease processes that destroy renal tissue.

With ARF, renal function may recover if the impairment is recognized promptly, contributing factors are eliminated or treated effectively, and medication dosages are adjusted according to the extent of renal impairment. With CRF, effective

treatment can help to conserve functioning nephrons and delay progression to end-stage renal disease (ESRD). If ESRD develops, dialysis or transplantation is required.

In relation to drug therapy, the major concern is that the kidneys are unable or less able to excrete drugs and drug metabolites. Guidelines have been established for the use of many drugs; health care providers need to use these recommendations to maximize the safety and effectiveness of drug therapy. Some general guidelines are discussed here; specific guidelines for particular drug groups are included in the appropriate chapters.

Drug therapy must be used very cautiously because of the high risks of drug accumulation and adverse effects. When possible, nephrologists should design drug therapy regimens. However, all health care providers need to be knowledgeable about risk factors for development of renal impairment, illnesses and their physiologic changes (e.g., hemodynamic, renal, hepatic, and metabolic alterations) that affect renal function, and the effects of commonly used drugs on renal function.

Renal status should be monitored in any patient with renal insufficiency or risk factors for developing renal insufficiency. Signs and symptoms of ARF include decreased urine output (less than 600 mL/24 hours), increased blood urea nitrogen, or increased serum creatinine (over 2 mg/dL or an increase of 0.5 mg/dL or more over a baseline value of less than 3.0 mg/dL). In addition, an adequate fluid intake is required to excrete drugs by the kidneys. Any factors that deplete extracellular fluid volume (e.g., inadequate fluid intake; diuretic drugs; loss of body fluids with blood loss, vomiting, or diarrhea) increase the risk of worsening renal impairment in patients with impairment or of causing impairment in those with previously normal function.

Patients with renal impairment may respond to a drug dose or serum concentration differently from patients with normal renal function because of physiologic and biochemical changes. Thus, drug therapy must be individualized according to the extent of renal impairment. This individualization is usually determined by measuring serum creatinine, which is then used to calculate creatinine clearance. Estimations of creatinine clearance are more accurate for patients with stable renal function and average muscle mass (for their age, weight, and height). Estimations are less accurate for emaciated and obese patients and for those with changing renal function, as often occurs in acute illness. If a patient is oliguric (less than 400 mL urine/24 hours), for example, the creatinine clearance should be estimated to be less than 10 mL/min, regardless of the serum creatinine concentration. Also, in elderly patients, serum creatinine is an unreliable indicator of renal function because these patients usually have diminished muscle mass. As a result, they may have a normal serum level of creatinine even if their renal function is markedly reduced.

Some medications can increase serum creatinine levels and create a false impression of renal failure. These drugs, which include cimetidine and trimethoprim, interfere with secretion of creatinine into kidney tubules. As a result, serum creatinine levels are increased without an associated decrease in renal function.

Drug selection should be guided by baseline renal function and the known effects of drugs on renal function, when possible. Many commonly used drugs may adversely affect renal function, including nonsteroidal anti-inflammatory drugs such as ibuprofen (e.g., Advil). Some drugs are excreted exclusively (e.g., aminoglycoside antibiotics, lithium), and most are excreted, to some extent, by the kidneys. Some drugs are contraindicated in renal impairment (e.g., tetracyclines, except doxycycline); others can be used if safety guidelines are followed (e.g., reducing dosage, monitoring serum drug levels and

renal function tests, avoiding dehydration). Drugs known to be nephrotoxic should be avoided when possible. In some instances, however, there are no effective substitutes and nephrotoxic drugs must be given. Some commonly used nephrotoxic drugs include aminoglycoside antibiotics, amphotericin B (an antifungal drug), and cisplatin (an anticancer drug).

Dosage of many drugs needs to be decreased in patients with renal failure, including dosage of aminoglycoside antibiotics, most cephalosporin antibiotics, fluoroquinolones, and digoxin. In general, the most effective dosage adjustments are based on the patient's clinical responses and serum drug levels.

### Drug Therapy in Patients With Hepatic Impairment

Most drugs are eliminated from the body by hepatic metabolism, renal excretion, or both. Hepatic metabolism depends mainly on blood flow and enzyme activity in the liver and protein binding in the plasma. Patients at risk for impaired liver function include those with primary liver disease (e.g., hepatitis, cirrhosis) and those with disease processes that impair blood flow to the liver (e.g., heart failure, major surgery, trauma) or hepatic enzyme production. An additional factor is hepatotoxic drugs. Fortunately, although the liver is often damaged, it has a great capacity for cell repair and may be able to function with as little as 10% of undamaged hepatic cells.

In relation to drug therapy, acute liver impairment may interfere with drug metabolism and elimination, whereas chronic cirrhosis or severe liver impairment may affect all pharmacokinetic processes. It is difficult to predict the effects of drug therapy because of wide variations in liver function and few helpful diagnostic tests. In addition, with severe hepatic impairment, extrahepatic sites of drug metabolism (e.g., intestine, kidneys, lungs) may become more important in eliminating drugs from the body. Thus, guidelines for drug selection, dosage, and duration of use are not well established. Some general guidelines for increasing drug safety and effectiveness are discussed here; known guidelines for particular drug groups are included in the appropriate chapters.

During drug therapy, patients with impaired liver function require close monitoring for signs and symptoms (e.g., nausea, vomiting, jaundice, liver enlargement) and abnormal results of laboratory tests of liver function. Liver function tests should be monitored in patients with or at risk for liver impairment, especially when patients are receiving potentially hepatotoxic drugs. Indicators of hepatic impairment include serum bilirubin levels above 4 to 5 mg/dL, a prothrombin time greater than 1.5 times control, a serum albumin below 2.0 g/dL, and elevated serum alanine (ALT) and aspartate (AST) aminotransferases. In some patients, abnormal liver function test results may occur without indicating severe liver damage and are often reversible.

Drug selection should be based on knowledge of drug effects on hepatic function. Hepatotoxic drugs should be avoided when possible. If they cannot be avoided, they should be used in the smallest effective doses, for the shortest effective time. Commonly used hepatotoxic drugs include

acetaminophen, isoniazid, and cholesterol-lowering statins. Alcohol is toxic to the liver by itself and increases the risks of hepatotoxicity with other drugs.

In addition to hepatotoxic drugs, many other drugs can cause or aggravate liver impairment by decreasing hepatic blood flow and drug-metabolizing capacity. For example, epinephrine and related drugs may cause vasoconstriction in the hepatic artery and portal vein, the two main sources of the liver's blood supply. Beta-adrenergic blocking agents (e.g., propranolol) decrease hepatic blood flow by decreasing cardiac output. Several drugs (e.g., cimetidine, fluoxetine) inhibit hepatic metabolism of many co-administered drugs. The consequence may be toxicity from the inhibited drugs if the dose is not decreased.

Dosage should be reduced for drugs that are extensively metabolized in the liver, because if doses are not reduced, serum drug levels are higher, elimination is slower, and toxicity is more likely to occur in a patient with hepatic disease. For example, some oral drugs are normally extensively metabolized during their "first pass" through the liver, so that a relatively small portion of an oral dose reaches the systemic circulation. In patients with cirrhosis, the blood carrying the drug molecules is shunted around the liver so that oral drugs go directly into the systemic circulation. Some drugs whose dosages should be decreased in patients with hepatic failure include cefoperazone, cimetidine, clindamycin, diazepam, labetalol, lorazepam, morphine, phenytoin, ranitidine, theophylline, and verapamil.

### Drug Therapy in Patients With Critical Illness

The term *critical illness*, as used here, denotes patients who are experiencing acute, serious, or life-threatening illness. Critically ill patients are at risk for multiple organ dysfunction, including cardiovascular, renal, and hepatic impairments, that influence all aspects of drug therapy. Drug elimination is often impaired because of decreased blood flow and decreased function of the liver and kidneys.

Although much of critical care nursing is performed in an intensive care unit (ICU), nurses in other settings also care for these patients. For example, nurses in emergency departments often initiate and maintain treatment for several hours; nurses on other hospital units care for patients who are transferred to or from ICUs; and patients formerly cared for in an ICU are on medical-surgical hospital units, in long-term care facilities, or even at home. Moreover, many nursing students are introduced to critical care during their educational programs, many new graduates seek employment in critical care settings, and experienced nurses may transfer to an ICU. Thus, all nurses need to know about drug therapy in critically ill patients. Some general guidelines are discussed here; more specific guidelines related to particular drugs are included in the appropriate chapters.

Drug therapy in critically ill patients is often more complex, more problematic, and less predictable than in most other populations. One reason is that patients often have multiple

organ impairments that alter drug effects and increase the risks of adverse drug reactions. Another reason is that patients often require aggressive treatment with large numbers, large doses, and combinations of highly potent drugs that the patient's body may be unable to process effectively.

In this at-risk population, safe and effective drug therapy requires that all involved health care providers be knowledgeable about common critical illnesses, the physiologic changes (e.g., hemodynamic, renal, hepatic, and metabolic alterations) that can be caused by the illnesses, and the drugs used to treat the illnesses. Nurses need to be especially diligent in administering drugs and vigilant in observing patient responses.

Drugs used in patients with critical illness represent most drug classifications and are also discussed in other chapters. Commonly used drugs include analgesics, antimicrobials, cardiovascular agents, gastric acid suppressants, neuromuscular blocking agents, and sedatives. In many instances, the main goals of drug therapy are to support vital functions and relieve life-threatening symptoms.

Drug selection should be guided by the patient's clinical status (e.g., symptoms, severity of illness) and organ function, especially cardiovascular, renal, and hepatic functions.

Route of administration should also be guided by the patient's clinical status. Most drugs are given intravenously (IV) because critically ill patients are often unable to take oral medications and require many drugs, rapid drug action, and relatively large doses. In addition, the IV route achieves more reliable and measurable blood levels.

Dosage requirements may vary among patients and within the same patient at different times during an illness. A standard dose may be therapeutic, subtherapeutic, or toxic. Thus, it is especially important that initial dosages are individualized according to the severity of the condition being treated and the patient's characteristics (e.g., age, weight, organ function) and that maintenance dosages are titrated according to patient responses and changes in organ function (e.g., as indicated by symptoms or laboratory tests). In general, to maintain consistent serum drug levels, once-daily drug doses should be given about the same time each day and multiple daily doses should be given at even intervals around the clock.

Laboratory tests are often needed before and during drug therapy to assess the patient's condition (e.g., cardiovascular, renal, and hepatic functions; fluid and electrolyte balance) and response to treatment. For example, serum protein levels should be monitored because drug binding may be significantly altered. Serum albumin, which binds acidic drugs (e.g., phenytoin, diazepam), is often decreased during critical illness. If there is not enough albumin to bind a drug, blood levels of the drug are higher and may cause adverse effects. Also, unbound molecules are metabolized and excreted more readily so that therapeutic effects may be decreased. Alpha<sub>1</sub>-acid glycoprotein binds basic drugs, and its synthesis may increase during critical illness. As a result, the bound portion of a dose increases for some drugs (e.g., propranolol) and therapeutic blood levels may not be achieved unless higher doses are given. In addition, these drugs are eliminated more slowly than usual.

## Drug Therapy in Home Care

As a result of increased outpatient care and brief hospitalizations, patients often recover from illness or surgery at their homes. Skilled nursing care (e.g., managing medication regimens) is often required. Most general principles and nursing responsibilities related to drug therapy apply in home care as in other health care settings. Additional considerations include the following:

- In most instances, the role of the nurse is to teach the patient or caregiver to administer medications and monitor their effects.
- In a patient's home, the nurse is a guest and must work within the environment to establish rapport, elicit cooperation, and provide nursing care. The initial contact is usually by telephone, and one purpose is to schedule a home visit, preferably at a convenient time for the patient and caregiver. In addition, state the main purpose and approximate length of the visit. Establish a method for contact in case the appointment must be canceled by either party.
- Assess the patient's attitude toward the prescribed medication regimen and his or her ability to provide self-care. If the patient is unable to provide self-care, ask who will administer medications and observe for medication effects. Determine the learning needs of the patient or caregiver in relation to the medication regimen.
- Ask to see all prescribed and OTC medications that the patient takes, and ask how and when the patient takes each one. With this information, the nurse may be able to reinforce the patient's compliance or identify potential problem areas (e.g., differences between instructions and patient usage of medications, drugs with opposing or duplicate effects, continued use of medications that were supposed to be discontinued, drugs discontinued because of adverse effects).
- Ask if the patient takes any herbal medicines or dietary supplements. If so, try to determine the amount, frequency, duration of use, reasons for use, and perceived beneficial or adverse effects. Explain that you need this information because some herbal and dietary supplements may cause various health problems or react adversely with prescription or OTC medications.
- Assess the environment for potential safety hazards (e.g., risk of infection with corticosteroids and other immunosuppressants, risk of falls and other injuries with opioid analgesics and other drugs with sedating effects). In addition, assess the patient's ability to obtain medications and keep appointments for follow-up visits to health care providers.
- Provide whatever information and assistance is needed for home management of the drug therapy regimen.
  - Most people are accustomed to taking oral drugs, but they may need information about timing in relation to food intake, whether a tablet can be crushed, when to omit a drug, and other aspects.
  - With other routes, the nurse may initially need to demonstrate administration or coach the patient or caregiver through each step.
- Demonstrating and having the patient or caregiver do a return demonstration is a good way to teach psychomotor skills (e.g., giving a medication through a GI tube, preparing and administering an injection, or manipulating an IV infusion pump). A written instruction sheet is also helpful. Studies indicate that a combination of verbal and written instructions is more effective than either alone.
- In addition to safe and accurate administration, teach the patient and caregiver to observe for beneficial and adverse effects. If adverse effects occur, teach them how to manage minor ones and which ones to report to a health care provider.
- Between home visits, maintain contact with patients and caregivers to monitor progress, answer questions, identify problems, and provide reassurance. Patients and caregivers should be given a telephone number to call with questions about medications, adverse effects, and so forth. The nurse may wish to schedule a daily time for receiving and making nonemergency calls. For patients and nurses with computers and Internet access, e-mail may be a convenient and efficient method of communication.

## Nursing Actions

## Monitoring Drug Therapy

### NURSING ACTIONS

#### 1. Prepare medications for administration.

- a. Assemble appropriate supplies and equipment.
- b. Calculate doses when indicated.

### RATIONALE/EXPLANATION

If giving medications to a group of patients, start preparing about 30 minutes before the scheduled administration time when possible, to avoid rushing and increasing the risk of errors. Medications and supplies are usually kept on a medication cart in a hospital or long-term care facility. Except for very simple calculations, use pencil and paper to decrease the risk of errors. If unsure about the results, ask a colleague or a pharmacist to do the calculation. Compare results. Accuracy is vital.

(continued on page 68)

## Nursing Actions Monitoring Drug Therapy (continued)

### NURSING ACTIONS

- c. Check vital signs when indicated.
- d. Check laboratory reports when indicated.
- e. Check drug references when indicated.

### 2. Administer drugs accurately (see Chap. 3).

- a. Practice the five rights of drug administration (right drug, right patient, right dose, right route, and right time).
- b. Use correct techniques for different routes of administration.
- c. Follow label instructions regarding mixing or other aspects of giving specific drugs.
- d. In general, do not give antacids with any other oral drugs. When both are ordered, administer at least 2 hours apart.

### 3. Observe for therapeutic effects.

- a. Look for improvement in signs and symptoms, laboratory or other diagnostic test reports, or ability to function.
- b. Ask questions to determine whether the patient is feeling better.

### 4. Observe for adverse effects.

- a. Look for signs and symptoms of new problems or worsening of previous disorders. If noted, compare the patient's symptoms with your knowledge base about adverse effects associated with the drugs or consult a drug reference.
- b. Check laboratory (e.g., complete blood count [CBC], electrolytes, blood urea nitrogen and serum creatinine, liver function tests) and other diagnostic test reports for abnormal values.
- c. Assess for decreasing ability to function at previous levels.
- d. Ask questions to determine how the patient is feeling and whether he or she is having difficulties that may be associated with drug therapy.

### 5. Observe for drug interactions.

- a. Consider a possible interaction when a patient does not experience expected therapeutic effects or develops adverse effects.
- b. Look for signs and symptoms of new problems or worsening of previous ones. If noted, compare the patient's symptoms with your knowledge base about interactions associated with the drugs or consult a drug reference to validate your observations.

### RATIONALE/EXPLANATION

Check blood pressure (recent recordings) before giving antihypertensive drugs. Check temperature before giving an antipyretic.

Commonly needed reports include serum potassium levels before giving diuretics; prothrombin time or international normalized ratio (INR) before giving Coumadin; culture and susceptibility reports before giving an antibiotic.

This is often needed to look up new or unfamiliar drugs; other uses include assessing a drug in relation to a particular patient (e.g., Is it contraindicated? Is it likely to interact with other drugs the patient is taking? Does the patient's ordered dose fit within the dosage range listed in the drug reference? Can a tablet be crushed or a capsule opened without decreasing therapeutic effects or increasing adverse effects?)

These rights are ensured if the techniques described in Chapter 3 are consistently followed. The time may vary by approximately 30 minutes. For example, a drug ordered for 9 A.M. can be usually given between 8:30 A.M. and 9:30 A.M. No variation is allowed in the other rights.

For example, sterile equipment and techniques are required for injection of any drug.

Some drugs require specific techniques of preparation and administration.

Antacids decrease absorption of many oral drugs.

In general, the nurse should know the expected effects and when they are likely to occur.

Specific observations depend on the specific drug or drugs being given.

All drugs are potentially harmful, although the incidence and severity of adverse reactions vary among drugs and patients. People most likely to have adverse reactions are those with severe liver or kidney disease, those who are very young or very old, those taking several drugs, and those receiving large doses of any drug. Specific adverse effects for which to observe depend on the drugs being given.

Interactions may occur whenever the patient is receiving two or more drugs concurrently and the number of possible interactions is very large. Although no one can be expected to know or recognize all potential or actual interactions, it is helpful to build a knowledge base about important interactions with commonly used drugs (e.g., warfarin, sedatives, cardiovascular drugs).

## Key Concepts

- Nurses must be knowledgeable about drugs and the patients receiving them.
- Nurses need to apply the nursing process in drug therapy as in other aspects of care.
- Children, older adults, people with renal or hepatic dysfunction, and those with critical illness require special consideration in relation to safe and effective drug therapy.
- Nurses are responsible for safe and effective administration of medications and observation of responses in patients of various ages and in a variety of health care settings.
- Teaching patients and caregivers about medications is a necessary and important role.
- Evidence-based nursing practice requires continued searching for and using “best practice” interventions, as based on research and other authoritative evidence.

## Review and Application Exercises

### Short Answer Exercises

1. Why do nurses need to know the therapeutic and adverse effects of the drugs they give?
2. Given a newly assigned patient, what information is needed about present and previous medications or herbal and dietary supplements?
3. With children, what are some potential difficulties with drug administration, and how can they be prevented or minimized?
4. With older adults, what are some potential difficulties with drug administration, and how can they be prevented or minimized?
5. For older adults, explain what is meant by “start low, go slow” and why it is a good approach to drug therapy.
6. Why is patient teaching about drug therapy needed, and what information should usually be included?
7. Describe at least three important nursing considerations for patients who have renal or hepatic impairment or critical illness.
8. For the home care nurse assisting with a medication regimen, what are some likely differences between the nursing care needed by a child and an adult?
9. For a patient who reports using particular herbal or dietary supplements, how can the nurse evaluate whether they are safe or unsafe in view of the patient’s condition and drug therapy regimen?
10. During an initial nursing assessment, the patient reports that he is allergic to a particular medicine. The nurse should
  - a. ask what symptoms occurred with the allergic reaction
  - b. conduct a detailed medical history and physical examination
  - c. disregard the information as unimportant
  - d. suspect that the patient overdosed on the drug
11. Interventions to increase safety and effectiveness of drug therapy include
  - a. avoiding the use of nondrug measures during drug therapy
  - b. using multiple drugs to relieve most symptoms or problems
  - c. teaching patients about their drug therapy regimens
  - d. avoiding instructions to alter usual activities of daily living
12. When evaluating a patient’s response to drug therapy, the nurse should keep in mind that
  - a. few drugs cause adverse effects.
  - b. drugs may cause virtually any symptom or problem.
  - c. patients usually report adverse drug effects without being asked.
  - d. therapeutic effects are more important than adverse effects.
13. Considerations in individualizing drug therapy for a child include
  - a. age and development
  - b. equivalent drug selection and dosage for adults
  - c. length of illness
  - d. the child’s usual diet
14. In teaching a patient about adverse effects of a newly ordered drug, which of the following should be included?
  - a. a detailed list of all potential adverse effects
  - b. percentages of particular adverse effects that occurred during clinical trials of the drug
  - c. adverse effects that the patient is likely to see or feel
  - d. research data about rare adverse effects

### NCLEX-Style Questions

10. During an initial nursing assessment, the patient reports that he is allergic to a particular medicine. The nurse should
  - a. ask what symptoms occurred with the allergic reaction
  - b. conduct a detailed medical history and physical examination
  - c. disregard the information as unimportant
  - d. suspect that the patient overdosed on the drug

# Drugs Affecting the Central Nervous System

## Chapter Outline

- 5 ■ Physiology of the Central Nervous System
- 6 ■ Opioid Analgesics and Pain Management
- 7 ■ Analgesic–Antipyretic–Anti-Inflammatory and Related Drugs
- 8 ■ Antianxiety and Sedative-Hypnotic Drugs
- 9 ■ Antipsychotic Drugs
- 10 ■ Antidepressants and Mood Stabilizers
- 11 ■ Antiseizure Drugs
- 12 ■ Antiparkinson Drugs
- 13 ■ Skeletal Muscle Relaxants
- 14 ■ Substance Abuse Disorders
- 15 ■ Central Nervous System Stimulants

# Physiology of the Central Nervous System

## KEY TERMS

- Acetylcholine
- Dopamine
- Gamma-aminobutyric acid (GABA)
- Glutamate
- Neuron
- Neurotransmission
- Neurotransmitters
- Norepinephrine
- Receptors
- Serotonin
- Synapse

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Describe the process of neurotransmission.
2. Describe major neurotransmitters and their roles in central nervous system (CNS) functioning.
3. Discuss signs and symptoms of CNS depression.
4. Discuss general types and characteristics of CNS depressant drugs.

## Introduction

The central nervous system (CNS), which is composed of the brain and spinal cord, acts as the control center for regulating physical and mental body processes. Afferent or sensory neurons carry messages to the CNS, and efferent or motor neurons carry messages away from the CNS. More specifically, the CNS constantly receives information about blood levels of oxygen and carbon dioxide, body temperature, and sensory stimuli and sends messages to effector organs to adjust the environment toward homeostasis. It is also concerned with higher intellectual functions (e.g., thought, learning, reasoning, problem solving, and memory) and with muscle function, both skeletal and smooth.

The CNS carries out its functions by transmitting electrical and chemical signals among components of the CNS and between the CNS and other parts of the body. Structural components and functions of the CNS are described in Box 5-1; more specific characteristics of neurons and neurotransmission are described below. These characteristics are reviewed to aid in the understanding of drugs that act by altering CNS functions.

## Neurons

The CNS is composed of two types of cells: The *neuron* is the basic functional unit, and the *glia* protect, support, and nourish the neuron. Most neurons are composed of a cell body, a dendrite, and an axon. A dendrite has a branching structure with many synapses or sites for receiving stimuli or messages, which are then conducted toward the cell body. An axon is a finger-like projection that carries impulses away from the cell body. The end of the axon branches into presynaptic fibers that end with small, knob-like structures called vesicles. These structures project into the synapse and contain the granules where neurotransmitters are stored. Many axons are covered by myelin, which protects and insulates the axon. An axon together with its myelin sheath is called a nerve fiber. Nerve fibers that transmit the same type of impulses (e.g., pain signals) are found together in a common pathway or tract.

## Box 5-1

## CNS Structures and Functions

**Cerebral Cortex**

The cerebral cortex is involved in all conscious processes (e.g., learning, memory, reasoning, verbalization, and voluntary body movements). Some parts receive incoming nerve impulses and are called sensory areas. Other parts send impulses to peripheral structures and are called motor areas. Around the sensory and motor areas are the “association” areas, which occupy the greater portion of the cortex. These areas analyze the information received by the sensory areas and decide on the appropriate response (e.g., stimulation of motor centers to produce movement or speech).

**Thalamus**

The thalamus receives impulses carrying sensations such as heat, cold, pain, and muscle position sense. These sensations produce a crude awareness in the thalamus; they are relayed to the cerebral cortex, where they are interpreted regarding location, quality, intensity, and significance. The thalamus also relays motor impulses from the cortex to the spinal cord.

**Hypothalamus**

The hypothalamus has extensive neurologic and endocrine functions. In the CNS, it is connected with the thalamus, medulla oblongata, spinal cord, reticular activating system, and limbic system. In the autonomic nervous system, it is the center for motor control. In the endocrine system, it controls the secretion of all pituitary hormones, is anatomically connected to the posterior pituitary gland, and regulates the activity of the anterior pituitary. The hypothalamus helps maintain homeostasis by constantly adjusting water balance, temperature, hormone levels, blood pressure, and other body functions. It is stimulated or inhibited by nerve impulses from different portions of the nervous system and by concentrations of nutrients, electrolytes, water, and hormones in the blood.

Specific neuroendocrine functions of the hypothalamus include the following:

- Producing oxytocin and antidiuretic hormone (ADH), which are stored in the posterior pituitary gland and released in response to nerve impulses from the hypothalamus. Oxytocin initiates uterine contractions to begin labor and delivery and helps release milk from breast glands during breast-feeding. ADH helps maintain fluid balance by controlling water excretion.
- Regulating body temperature. When body temperature is elevated, sweating and dilation of blood vessels in the skin increase heat loss and lower the temperature. When body temperature is low, sweating stops and vasoconstriction occurs to decrease heat loss and raise the temperature.
- Assisting in regulation of blood pressure by its effects on the vasomotor center located in the medulla oblongata and pons. This center maintains a state of partial contraction in blood vessels (vasomotor tone or vasoconstriction). When nerve impulses from the hypothalamus excite the vasomotor center, vasomotor tone is increased, and blood pressure

is raised. When the impulses inhibit the vasomotor center, vasomotor tone is decreased, with the overall effect of relative vasodilation and lowering of blood pressure.

- Regulating anterior pituitary hormones, including thyroid-stimulating hormone, ACTH, and growth hormone. The hypothalamus secretes a “releasing factor” for each anterior pituitary hormone.
- Regulating food and water intake by the hypothalamic thirst, appetite, hunger, and satiety centers.
- Regulating the physical changes associated with emotions (e.g., increased blood pressure and heart rate). The hypothalamus, thalamus, and cerebral cortex interact to produce the feelings associated with emotions.

**Medulla Oblongata**

The medulla contains groups of neurons that form the vital cardiac, respiratory, and vasomotor centers. For example, if the respiratory center is stimulated, respiratory rate and depth are increased. If the respiratory center is depressed, respiratory rate and depth are decreased. The medulla also contains reflex centers for coughing, vomiting, sneezing, swallowing, and salivating. The medulla and pons varolii also contain groups of neurons from which cranial nerves 5 through 12 originate.

**Reticular Activating System**

The reticular activating system is a network of neurons that extends from the spinal cord through the medulla and pons to the thalamus and hypothalamus. It receives impulses from all parts of the body, evaluates the significance of the impulses, and decides which impulses to transmit to the cerebral cortex. It also excites or inhibits motor nerves that control both reflex and voluntary movement. Stimulation of these neurons produces wakefulness and mental alertness, and depression causes sedation and loss of consciousness.

**Limbic System**

The limbic system borders and interconnects with the thalamus, hypothalamus, basal ganglia, hippocampus, amygdala, and septum. It participates in regulation of feeding behavior, the sleep–wake cycle, emotions (e.g., pleasure, fear, anger, sadness), and behavior (e.g., aggression, laughing, crying). Many nerve impulses from the limbic system are transmitted through the hypothalamus; thus, physiologic changes in blood pressure, heart rate, respiration, and hormone secretion occur in response to emotions.

**Cerebellum**

The cerebellum, which is connected with motor centers in the cerebral cortex and basal ganglia, coordinates muscle activity. For example, when several skeletal muscles are involved, some are contracted and some are relaxed for smooth, purposeful movements. It also helps maintain balance and posture by receiving nerve impulses from the inner ear that produce appropriate reflex responses.

## Box 5-1

## CNS Structures and Functions (continued)

**Basal Ganglia**

The basal ganglia are concerned with skeletal muscle tone and orderly activity. Normal function is influenced by dopamine. Degenerative changes in one of these areas, the substantia nigra, cause dopamine to be released in decreased amounts. This process is a factor in the development of Parkinson's disease.

**Pyramidal and Extrapyramidal Systems**

The pyramidal and extrapyramidal systems are pathways out of the cerebral cortex that intermingle in the spinal cord. Disease processes affecting higher levels of the CNS involve both tracts. In the pyramidal tract, nerve fibers originate in the cerebral cortex, go down the brain stem to the medulla, where the fibers cross, and continue down the spinal cord, where they end at various levels. Impulses are then carried from the spinal cord to skeletal muscle. Because the fibers cross in the medulla, impulses from the right side of the cerebral cortex control skeletal muscle movements of the left side of the body and impulses from the left control muscle movements of the right side. In the extrapyramidal system, fibers originate mainly in the premotor area of the cerebral cortex and travel to the basal ganglia and brain stem. The fibers are called extrapyramidal because they do not enter the medullary pyramids and cross over.

**Brain Metabolism**

To function properly, the brain must have an adequate and continuous supply of oxygen, glucose, and thiamine. *Oxygen*

is carried to the brain by the carotid and vertebral arteries. The brain requires more oxygen than any other organ. Cerebral cortex cells are very sensitive to lack of oxygen (hypoxia), and interruption of blood supply causes immediate loss of consciousness. Brain stem cells are less sensitive to hypoxia. *Glucose* is required as an energy source for brain cell metabolism. Hypoglycemia (low blood sugar) may cause mental confusion, dizziness, convulsions, loss of consciousness, and permanent damage to the cerebral cortex. *Thiamine* is required for production and use of glucose. Thiamine deficiency can reduce the use of glucose by nerve cells and can cause degeneration of the myelin sheath. Such degeneration in central neurons leads to a form of brain damage known as Wernicke-Korsakoff encephalopathy. Degeneration in peripheral nerves leads to polyneuritis and muscle atrophy, weakness, and paralysis.

**Spinal Cord**

The spinal cord is continuous with the medulla and extends down through the vertebral column to the sacral area. It consists of 31 segments, each of which is the point of origin for a pair of spinal nerves. The cord is a pathway between the brain and the peripheral nervous system. It carries impulses to and from the brain, along sensory and motor nerve fibers, and is a center for reflex actions. Reflexes are involuntary responses to certain nerve impulses received by the spinal cord (e.g., knee-jerk and pupillary reflexes).

## Elements of Neurotransmission

Neurons must be able to communicate with other neurons and body tissues. This communication involves a complex network of electrical and chemical signals that receive, interpret, modify, and send messages. Characteristics that allow neurons to communicate with other body cells include excitability (the ability to produce an action potential or be stimulated) and conductivity (the ability to convey electrical impulses). Specific components of the communication network include neurotransmitters, synapses, and receptors.

**Neurotransmitters**

*Neurotransmitters* are chemical substances that carry messages from one neuron to another or from a neuron to other body tissues, such as cardiac or skeletal muscle. They are synthesized and stored in presynaptic nerve terminals and released in response to an electrical impulse (action potential) arriving at the end of the first neuron (presynaptic fiber). The basis for the action potential is the transient opening of ion chan-

nels. The entry of calcium ions is required for neurotransmitter release from storage sites in small sacs called synaptic vesicles.

When released from the synaptic vesicles, molecules of neurotransmitter cross the synapse, bind to receptors in the cell membrane of the postsynaptic neuron (Fig. 5-1), and excite or inhibit postsynaptic neurons. Free neurotransmitter molecules (i.e., those not bound to receptors) are rapidly removed from the synapse by three mechanisms: transportation back into the presynaptic nerve terminal (reuptake) for reuse, diffusion into surrounding body fluids, or destruction by enzymes.

The main types of neurotransmitters are amines, amino acids, and peptides, which are derived from body proteins. Most acute CNS responses are caused by fast-acting neurotransmitters (e.g., acetylcholine, dopamine, norepinephrine, serotonin) and amino acids (aspartate, gamma-aminobutyric acid [GABA], glutamate, and glycine). Most prolonged CNS responses are caused by slow-acting neurotransmitters (e.g., adrenocorticotrophic hormone [ACTH or corticotropin] and antidiuretic hormone [ADH]).

Several factors affect the availability and function of neurotransmitters, including the following:

**Figure 5-1** ■ Neurotransmission in the central nervous system. Neurotransmitter molecules (e.g., norepinephrine, acetylcholine), released by the presynaptic nerve, cross the synapse and bind with receptor proteins in the cell membrane of the postsynaptic nerve.

- The availability of precursor proteins and enzymes required to synthesize particular neurotransmitters
- The number and binding capacity of receptors in the cell membranes of presynaptic and postsynaptic nerve endings
- Acid–base imbalances (acidosis decreases and alkalosis increases synaptic transmission)
- Hypoxia, which causes CNS depression (coma occurs within seconds without oxygen)
- Drugs, which may alter neurotransmitter synthesis, release, degradation, or binding to receptors to cause either CNS stimulation or depression

## Synapses

Neurons in a chain are separated by a microscopic gap called a *synapse*. Synapses may be electrical, in which sodium and potassium ions conduct an electrical impulse from one neuron to another, or chemical, in which a neurotransmitter conducts the message to the next neuron. The chemical synapse is more commonly used to communicate with other neurons or target cells. Neurotransmitter release and removal occur in the synapses.

## Receptors

*Receptors* are proteins embedded in the cell membranes of neurons. In the CNS, most receptors are on postsynaptic neurons; a few are on presynaptic nerve terminals. A neurotransmitter must bind to receptors to exert an effect on the next neuron in the chain. Some receptors act rapidly to open ion channels, and others interact with intracellular proteins to initiate a second messenger system. For example, when norepinephrine binds with adrenergic receptors, intracellular events include activation of the enzyme adenylyl cyclase and the production of cyclic adenosine monophosphate (cAMP). In this case, the

cAMP is a second messenger that activates cellular functions and the physiologic responses controlled by the adrenergic receptors. A neurotransmitter–receptor complex may have an excitatory or inhibitory effect on the postsynaptic neuron.

Receptors are constantly being synthesized and degraded. They increase in number and activity (up-regulation) when there is underactivity at the synapse. They decrease in number and activity (down-regulation) when there is overactivity. Overall, receptors work with other control mechanisms of the nervous system to readjust abnormally stimulated or depressed nerve function toward normal.

## Neurotransmission Systems

Neurotransmitters, synapses, and receptors work together to produce communication networks that may be called *neurotransmission* systems. It is the interactions between and among these systems that promote order or disorder in the body's physical and mental processes. Major neurotransmission systems are the cholinergic, dopaminergic, GABA-ergic, noradrenergic, and serotonergic.

The **cholinergic system** uses *acetylcholine* as its neurotransmitter. Acetylcholine is located in many areas of the brain, with high concentrations in the motor cortex and basal ganglia. It is also a neurotransmitter in the autonomic nervous system and at peripheral neuromuscular junctions. Acetylcholine exerts excitatory effects at synapses and nerve–muscle junctions and inhibitory effects at some peripheral sites, such as organs supplied by the vagus nerve. In the CNS, acetylcholine is associated with level of arousal, memory, motor function, and speech.

The **dopaminergic system** uses *dopamine* as its neurotransmitter. Dopamine is found in the substantia nigra, the mid-brain, and the hypothalamus. It also is found outside the brain, in renal and mesenteric blood vessels.

In the CNS, dopamine is inhibitory in the basal ganglia but may be excitatory in other areas. Repeated stimulation of dopamine receptors decreases their numbers (down-regulation) and their sensitivity to dopamine (desensitization). Prolonged blockade of dopamine receptors increases their numbers and sensitivity to dopamine. Some receptors (called autoreceptors) occur on the presynaptic nerve terminal. When released, dopamine stimulates these receptors and a negative feedback system is initiated that inhibits further dopamine synthesis and release.

Two groups of dopamine receptors have been identified. They are differentiated by the intracellular events that follow dopamine–receptor binding. One group includes D1 and D5 receptors, which activate adenylyl cyclase to produce cAMP. The other group includes D2, D3, and D4 receptors. D2 receptors are thought to inhibit activation of adenylyl cyclase and subsequent production of cAMP, suppress calcium ion currents, and activate potassium ion currents. The functions of D3 and D4 receptors have not been delineated. Overall, dopamine actions at the cellular level depend on the subtype of receptor to which it binds and the simultaneous effects of other neurotransmitters at the same target neurons.

The **GABA-ergic system** uses GABA as its neurotransmitter. *Gamma-aminobutyric acid* (GABA) is abundant in the brain and spinal cord. It is the major inhibitory neurotransmitter in the CNS, with a role in many neuronal circuits (estimated at nearly one third of CNS synapses). GABA receptors have been divided into two main types, A and B. The GABA<sub>A</sub> receptor is a chloride ion channel that opens when GABA is released from presynaptic neurons. The GABA<sub>B</sub> receptor is associated with potassium conductance. There is evidence of multiple subtypes of GABA receptors and important functional differences among them.

The **noradrenergic system** uses *norepinephrine* as its neurotransmitter. Norepinephrine is a catecholamine that is found in relatively large amounts in the hypothalamus and the limbic system and in smaller amounts in most areas of the brain, including the reticular formation. Norepinephrine is mainly an excitatory neurotransmitter that stimulates the brain to generalized increased activity. However, it is inhibitory in a few areas because of inhibitory receptors at some nerve synapses.

Norepinephrine receptors in the CNS are divided into alpha- and beta-adrenergic receptors and their subtypes. Activation of alpha<sub>1</sub>, beta<sub>1</sub>, and beta<sub>2</sub> receptors stimulates activity of intracellular adenylyl cyclase and the production of cAMP. Activation of alpha<sub>2</sub> receptors inhibits adenylyl cyclase activity and decreases production of cAMP. In addition, alpha<sub>2</sub> receptors on the presynaptic nerve ending regulate norepinephrine release (e.g., when high levels of extracellular norepinephrine act on presynaptic alpha<sub>2</sub> receptors, the effect is similar to that of a negative feedback system that inhibits the release of norepinephrine). Overall, the noradrenergic system is associated with mood, motor activity, regulation of arousal, and reward. It is thought to play an important role in producing rapid eye movement (REM) sleep, during which dreaming occurs.

The **serotonergic system** uses *serotonin* as its neurotransmitter. Serotonin-synthesizing neurons are widely distributed in the CNS. Because serotonin is synthesized from the amino acid tryptophan, the amount of tryptophan intake in the diet and the enzyme tryptophan hydroxylase control the rate of serotonin production. CNS serotonin is usually an inhibitory neurotransmitter and is associated with mood, the sleep-wake cycle, habituation, and sensory perceptions, including inhibition of pain pathways in the spinal cord. Serotonin is thought to produce sleep by inhibiting CNS activity and arousal. Serotonin receptors are associated with mood, anxiety, and temperature regulation. Activation of some receptors leads to hyperpolarization and neuronal inhibition. Several subtypes of serotonin receptors have been identified.

Serotonin is also found outside the CNS, mainly in mast cells of the lungs and platelets. It plays a major role in the blood coagulation process, during which it is released from platelets and causes vasoconstriction. It may also be involved in the vascular spasm associated with some pulmonary allergic reactions (during which it is released from mast cells) and

migraine headaches. However, peripheral serotonin cannot cross the blood-brain barrier.

The **amino acid system** includes several amino acids that may serve as both structural components for protein synthesis and neurotransmitters. *Aspartate* is an excitatory neurotransmitter found in high concentrations in the brain. *Glycine* is an inhibitory neurotransmitter found in the brain stem and spinal cord. Glycine receptors are similar to GABA<sub>A</sub> receptors; subtypes have been identified but their functions are unknown.

*Glutamate*, the most important excitatory neurotransmitter, occurs in high concentrations in most areas of the CNS. Several subtypes of glutamate receptors have been identified, each with a unique distribution in the CNS. The functions of these receptor subtypes have not been established, but research suggests that the *N*-methyl *D*-aspartate (NMDA) glutamate receptor subtype plays a role in memory. Some glutamate is needed for normal neurotransmission, but high concentrations can lead to neuronal cell death. Events leading to neuronal death are triggered by excessive activation of NMDA receptors and movement of calcium ions into the neurons. This process may be similar to the neurotoxicity associated with brain injury (e.g., from ischemia, hypoglycemia, or hypoxia), where increased release and impaired reuptake of glutamate lead to excessive stimulation of glutamate receptors and subsequent cell death. Altered glutamate metabolism may also lead to the formation of free radicals, which are implicated in neuronal cell death associated with some neurodegenerative diseases and toxic chemicals, including some drugs of abuse.

### Neurotransmission Systems in Selected Central Nervous System Disorders

Abnormalities in neurotransmission systems (e.g., dysfunction or destruction of the neurons that normally produce neurotransmitters; altered receptor response to neurotransmitters) are implicated in many CNS disorders. For example, decreased acetylcholine is a characteristic of Alzheimer's disease; dopamine abnormalities occur in psychosis and Parkinson's disease; GABA abnormalities occur in anxiety, hyperarousal states, and seizure disorders; glutamate has been implicated in the pathogenesis of epilepsy, schizophrenia, stroke, and Huntington's disease; and serotonin abnormalities are thought to be involved in mental depression and sleep disorders.

Although most research has focused on single neurotransmitters and their respective receptors, CNS function in both health and disease is largely determined by interactions among neurotransmission systems. In health, for example, complex mechanisms regulate the amounts and binding capacities of neurotransmitters and receptors, as well as the balance between excitatory and inhibitory forces. When abnormalities occur in any of these elements, the resulting dysregulation and imbalances lead to signs and symptoms of CNS disorders. Overall, then, neurotransmission systems function interdependently; one system may increase, decrease, or otherwise modify the effects of another system.

Except for mental depression, most psychiatric symptoms result from CNS stimulation and usually involve physical and mental hyperactivity. Such hyperactivity reflects observable behaviors and nonobservable thoughts and feelings. In most people, manifestations may include pleasant feelings of mild euphoria and high levels of enthusiasm, energy, and productivity. In people with severe anxiety or psychosis, manifestations include unpleasant feelings of tension, psychomotor agitation, nervousness, and decreased ability to rest and sleep. Many psychiatric disorders, therapeutic drugs, and drugs of abuse may cause varying degrees of CNS stimulation. In general, the pathogenesis of excessive CNS stimulation may involve one or more of the following mechanisms:

- Excessive amounts of excitatory neurotransmitters (e.g., norepinephrine, glutamate)
- Increased numbers or sensitivity of excitatory receptors
- Insufficient amounts of inhibitory neurotransmitters (e.g., GABA)
- Decreased numbers or sensitivity of inhibitory receptors

## Drugs That Affect the Central Nervous System

Drugs that affect the CNS, sometimes called centrally active drugs, are broadly classified as depressants or stimulants.

CNS depressants (e.g., antipsychotics, opioid analgesics, sedative-hypnotics) produce a general depression of the CNS when given in sufficient dosages. Mild CNS depression is characterized by lack of interest in surroundings and inability to focus on a topic (short attention span). Moderate CNS depression is characterized by drowsiness or sleep; decreased muscle tone; decreased ability to move; and decreased perception of sensations such as pain, heat, and cold. Severe CNS depression is characterized by unconsciousness or coma, loss of reflexes, respiratory failure, and death.

Central nervous system stimulants produce a variety of effects. Mild stimulation is characterized by wakefulness, mental alertness, and decreased fatigue. Increasing stimulation produces hyperactivity, excessive talking, nervousness, and insomnia. Excessive stimulation can cause convulsions, cardiac dysrhythmias, and death.

## Key Concepts

- The CNS regulates physical and mental body processes through complex communication systems between and among CNS structures.
- Afferent neurons carry messages to the CNS; efferent neurons carry messages from the CNS to other body tissues.
- Messages are transmitted by the interaction of neurotransmitters and receptors across the synapse.
- Major neurotransmitters are acetylcholine, dopamine, GABA, glutamate, norepinephrine, and serotonin. Some excite and some inhibit CNS functions.
- Each neurotransmitter has its specific receptors.
- CNS depressant drugs are more often used to treat CNS disorders than CNS stimulants.

## Review and Application Exercises

### Short Answer Exercises

1. Where are neurotransmitters synthesized and stored?
2. What events occur at the synapse between two neurons?
3. After a neurotransmitter is released and acts on receptors, how are the remaining molecules inactivated?
4. What are the main functions of acetylcholine, dopamine, GABA, norepinephrine, and serotonin?
5. What part of the brain is concerned mainly with thoughts, reasoning, and learning?
6. What part of the brain contains vital respiratory and cardiovascular centers?
7. How would you expect a person with CNS depression to look and behave?
8. How would you expect a person with excessive CNS stimulation to look and behave?

### NCLEX-Style Questions

9. Up-regulation of receptors occurs when
  - a. receptors are degraded faster than they are synthesized.
  - b. receptors increase in number and activity.
  - c. there is a decrease in both the number and activity of the receptors.
  - d. addictive drugs are supplied to patients in diminished amount.
10. A patient has Parkinson's disease. In caring for him and administering medications, the nurse understands his symptoms and his drug regimen as being related to
  - a. an increase in the neurotransmitter serotonin
  - b. a decrease in the neurotransmitter serotonin
  - c. an increase in the neurotransmitter dopamine
  - d. a decrease in the neurotransmitter dopamine

11. The neurotransmitter system most associated with rapid eye movement (REM) sleep is
  - a. the cholinergic system
  - b. the GABA-ergic system
  - c. the noradrenergic system
  - d. the serotonergic system
12. When caring for a patient with serious sleep disorders that are linked to an imbalance in neurotransmitters, the nurse knows that this patient is most likely to have an abnormal level of
  - a. serotonin
  - b. GABA
  - c. acetylcholine
  - d. dopamine
13. A patient is being admitted to a unit with a diagnosis of Wernicke-Korsakoff syndrome. The nurse knows that this condition is triggered by a deficiency in
  - a. acetylcholine
  - b. calcium
  - c. thiamine
  - d. insulin

# Opioid Analgesics and Pain Management

## KEY TERMS

- Analgesia
- Breakthrough pain
- Endogenous analgesia system
- Endorphins
- Neuropathic
- Nociceptors
- Nonceiling opioid
- Opioid receptors
- Pain
- Patient-controlled analgesia
- Tolerance

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Discuss major types and characteristics of pain.
2. Discuss the nurse's role in assessing and managing patients' pain.
3. List characteristics of opioid analgesics in terms of mechanism of action, indications for use, and major adverse effects.
4. Describe morphine as the prototype of opioid analgesics.
5. Differentiate between ceiling and nonceiling opioids.
6. Explain why higher doses of opioid analgesics are needed when the drugs are given orally.
7. Contrast the use of opioid analgesics in opioid-naive and opioid-tolerant patients.
8. Assess level of consciousness and respiratory status before and after administering opioids.
9. Teach patients about safe, effective use of opioid analgesics.
10. Describe characteristics and treatment of opioid toxicity.
11. Discuss principles of therapy for using opioid analgesics in special populations.
12. Discuss nonopioid drugs used in pain management.

## Applying Your Knowledge

Moe Harris is a 53-year-old man who had a lumbar laminectomy with spinal fusion today.

Mr. Harris has experienced chronic low back pain for more than 10 years. During this time, he has been treated with a number of over-the-counter (OTC) and prescription medications for his pain. These drugs have included ibuprofen and hydrocodone with acetaminophen. He is a construction worker, married with three children, a nonsmoker, and drinks beer regularly.

Mr. Harris returns from the postanesthesia recovery room to your care at 10:00 A.M. His vital signs are stable on initial assessment. To treat his pain, the physician has ordered the following:

Morphine 4–8 mg IV, every 2–4 hours as needed, to be given over 5 minutes

After 24 hours, oxycodone 5 mg with acetaminophen 500 mg PO every 4–6 hours, PRN, not to exceed six doses in 24 hours

## Introduction

*Pain* is the most common symptom prompting people to seek health care. This unpleasant, uncomfortable sensation usually indicates tissue damage and impels a person to remove the cause of the

damage or seek relief from the pain. When not managed effectively, pain may greatly impair quality of life and ability to perform activities of daily living. The Joint Commission on the Accreditation of Healthcare Organizations (JCAHO) includes assessment and management of pain for all patients in the standards by which it evaluates health care organizations. Opioid (narcotic) analgesics are drugs that relieve moderate to severe pain. To aid understanding of drug actions, selected characteristics of pain and endogenous pain-relieving substances are described.

## Physiology of Pain

Pain occurs when tissue damage activates the free nerve endings (pain receptors or nociceptors) of peripheral nerves. *Nociceptors* are abundant in arterial walls, joint surfaces, muscle fascia, periosteum, skin, and soft tissues; they are scarce in most internal organs. Causes of tissue damage may be physical (e.g., heat, cold, pressure, stretch, spasm, ischemia) or chemical (e.g., pain-producing substances are released into the extracellular fluid surrounding the nerve fibers that carry the pain signal). These pain-producing substances activate pain receptors, increase the sensitivity of pain receptors, or stimulate the release of inflammatory substances.

For a person to feel pain, the signal from the nociceptors in peripheral tissues must be transmitted to the spinal cord, then to the hypothalamus and cerebral cortex in the brain. The signal is carried to the spinal cord by two types of nerve cells, A-delta fibers and C fibers. A-delta fibers, which are myelinated and found mainly in skin and muscle, transmit fast, sharp, well-localized pain signals. These fibers release glutamate and aspartate (excitatory amino acid neurotransmitters) at synapses in the spinal cord. C fibers, which are unmyelinated and found in muscle, abdominal viscera, and periosteum,

conduct the pain signal slowly and produce a poorly localized, dull, or burning type of pain. Tissue damage resulting from an acute injury often produces an initial sharp pain transmitted by A-delta fibers followed by a dull ache or burning sensation transmitted by C fibers. C fibers release somatostatin and substance P at synapses in the spinal cord. Glutamate, aspartate, substance P, and perhaps other chemical mediators enhance transmission of the pain signal.

The dorsal horn of the spinal cord is the control center or relay station for information from the A-delta and C nerve fibers, for local modulation of the pain impulse, and for descending influences from higher centers in the central nervous system (CNS; e.g., attention, emotion, memory). Here, nociceptive nerve fibers synapse with non-nociceptive nerve fibers (neurons that carry information other than pain signals). The brain also contains descending pathways that inhibit nociceptive input. Some brain nuclei are serotonergic and project to the dorsal horn of the spinal cord, where they suppress nociceptive transmission. Another inhibitory pathway is noradrenergic and originates in the pons. Thus, increasing the concentration of norepinephrine and serotonin in the synapse inhibits transmission of nerve impulses that carry pain signals to the brain and spinal cord.

In the brain, the thalamus is a relay station for incoming sensory stimuli, including pain. Perception of pain is a primitive awareness in the thalamus, and sensation is not well localized. From the thalamus, pain messages are relayed to the cerebral cortex, where they are perceived more specifically and analyzed to determine actions needed.

Pain may be classified according to origin in body structures (e.g., somatic, visceral, *neuropathic*), duration (e.g., acute, chronic), or cause (e.g., cancer). These types of pain are described in Box 6-1.

### Box 6-1

### Types and Characteristics of Pain

**Acute pain** may be caused by injury, trauma, spasm, disease processes, and treatment or diagnostic procedures that damage body tissues. It is often described as sharp or cutting. The intensity of the pain is usually proportional to the amount of tissue damage and the pain serves as a warning system by demanding the sufferer's attention and compelling behavior to withdraw from or avoid the pain-producing stimulus.

Acute pain is called fast pain because it is felt quickly after a pain stimulus is applied. It is aroused by mechanical and thermal stimuli and conducted to the spinal cord by A-delta fibers in the peripheral nerves. Glutamate is the neurotransmitter secreted in the spinal cord at the A-delta nerve fiber endings.

Acute pain is often accompanied by anxiety and objective signs of discomfort (e.g., facial expressions of distress; moaning or crying; positioning to protect the affected part; tenderness, edema, and skin color or temperature changes in the affected part; and either restlessness and excessive movement or limited movement, if movement increases pain). It usually responds to treatment with analgesic drugs and resolves as tissue repair mechanisms heal the damaged area.

**Chronic pain** (i.e., lasting 3 months or longer) demands attention less urgently, may not be characterized by visible signs, and is often accompanied by emotional stress, increased irritability, depression, social withdrawal, financial distress, loss of libido, disturbed sleep patterns, diminished appetite, weight loss, and decreased ability to perform usual activities of daily living. It may occur with or without evidence of tissue damage and may include acute pain that persists beyond the typical recovery time for the precipitating tissue injury, pain related to a chronic disease, pain without an identifiable cause, and pain associated with cancer. It may arise from essentially any part of the body. It may be continuous or episodic or a combination of both.

Chronic pain may also be called slow pain. It can be elicited by mechanical, thermal, and chemical stimuli and is described as burning, aching, or throbbing. Slow, chronic pain is transmitted by C nerve fibers to the spinal cord and brain. Substance P is the neurotransmitter at C nerve fiber endings; it is released slowly and accumulates over seconds or minutes.

**Cancer pain** has characteristics of both acute and chronic pain and it may be constant or intermittent. Chronic cancer pain is often caused by tumor spread into pain-sensitive tissues and the resulting tissue destruction. It usually progresses as the disease advances and can be severe and debilitating. Acute pain is often associated with diagnostic procedures or treatment measures (e.g., surgery, chemotherapy). It may also occur with disease progression, with activity, or with the development of drug tolerance.

**Somatic pain** results from stimulation of nociceptors in skin, bone, muscle, and soft tissue. It is usually well localized and described as sharp, burning, gnawing, throbbing, or cramping. It may be intermittent or constant and acute or chronic. Sprains and other traumatic injuries are examples of acute somatic pain; the bone and joint pain of arthritis is an example of chronic somatic pain, although acute exacerbations may also occur. Somatic pain of low to moderate intensity may stimulate the sympathetic nervous system and produce increased blood pressure, pulse, and respiration; dilated pupils; and increased skeletal muscle tension, such as rigid posture or clenched fists.

**Visceral pain**, which is diffuse and not well localized, results when nociceptors are stimulated in abdominal or thoracic organs and their surrounding tissues. It includes pain associated with cholecystitis, pancreatitis, uterine disorders,

and liver disease and is often described as deep, dull, aching, or cramping. It may be referred to a different part of the body (e.g., pain from the liver can be referred to the right shoulder area; ischemic pain from the heart can be referred to the left arm or neck area). Severe visceral pain stimulates the parasympathetic nervous system and produces decreased blood pressure and pulse, nausea and vomiting, weakness, syncope, and possibly loss of consciousness.

**Neuropathic pain** is caused by lesions or physiologic changes that injure peripheral pain receptors, nerves, or the CNS. It is characterized by excessive excitability in the damaged area or surrounding normal tissues, so that nerve cells discharge more easily. As a result, pain may arise spontaneously or from a normally nonpainful stimulus such as a light touch. It is a relatively common cause of chronic pain and is usually described as severe, shooting, burning, or stabbing. It occurs with peripheral neuropathies associated with diabetes mellitus (diabetic neuropathy), herpes zoster infections (postherpetic neuralgia), traumatic nerve injuries, and some types of cancer or cancer treatments. It is difficult to treat because standard analgesics (e.g., nonsteroidal anti-inflammatory drugs and opioids) are less effective in neuropathic pain than in other types of pain. Antidepressants and anticonvulsants are often used along with analgesics.

## Endogenous Analgesia System

The CNS has its own system for relieving pain by suppressing the transmission of pain signals from peripheral nerves. The system can be activated by nerve signals entering the brain or by morphine-like drugs. Important elements include opioid receptors and endogenous peptides with actions similar to those of morphine. *Opioid receptors* are highly concentrated in some regions of the CNS, including the ascending and descending pain pathways and portions of the brain essential to the *endogenous analgesia system*. The opioid peptides (i.e., *endorphins*, *enkephalins*, *dynorphins*) interact with opioid receptors to inhibit perception and transmission of pain signals. Endorphin release can be triggered by excitement, stress, or aerobic exercise. Enkephalins are believed to interrupt the transmission of pain signals at the spinal cord level by inhibiting the release of substance P from C nerve fibers. The

endogenous analgesia system may also inhibit pain signals at other points in the pain pathway.

## Drug Therapy for Pain Management

Opioid analgesics are used to prevent or relieve moderate to severe pain. Nonopioid drugs are also used, and a combination of drugs that act by different mechanisms is often the most effective regimen for pain management. Nonopioid drugs belong to several classifications and either have analgesic effects themselves or modify disease processes in a way that reduces pain. Nonopioid analgesics are used in the management of both acute and chronic pain; other nonopioids are used mainly for chronic neuropathic pain or bone pain. In either case, the drugs are often used concurrently with opioids to provide more effective pain relief. Nonopioid drugs used in pain management are listed in Box 6-2 and

### Box 6-2

### Nonopioid Drugs Used to Manage Pain

Nonopioid analgesics and other drugs are commonly used to prevent or relieve acute and chronic pain. These drugs may be given in combination or concurrently with opioid analgesics for severe pain. They are called adjuvants, co-analgesics, or pain-modifying drugs.

#### Nonopioid Analgesics

These drugs are mainly acetaminophen and nonsteroidal anti-inflammatory drugs (NSAIDs). Acetaminophen acts on

the parts of the brain that receive pain signals and is one of the safest analgesics for management of mild pain or as a supplement in management of more intense pain. It is especially useful in nonspecific musculoskeletal pain or pain associated with osteoarthritis. The maximum daily dose of acetaminophen is 4000 milligrams, and the drug should be avoided or dosage reduced in patients with renal insufficiency or liver failure. NSAIDs (e.g., ibuprofen) reduce the production of prostaglandins, which in turn reduces inflammatory chemicals

## Box 6-2

## Nonopioid Drugs Used to Manage Pain (continued)

that cause, increase, or maintain pain signals. NSAIDs are useful in treating many pain conditions that are caused or aggravated by inflammation. They may be used for moderate to severe pain alone or with opioids. Adverse effects include GI bleeding. In patients who require the drugs for long-term treatment of pain, a proton pump inhibitor such as omeprazole (Prilosec) can be given to decrease the risk of GI bleeding.

### Antiepileptic Drugs (AEDs)

These drugs are mainly used to treat neuropathic pain, in which they decrease the irritability of overexcited nerve cells that occurs in both epilepsy and neuropathic pain. Decreasing neuronal irritability means the nerve cells carrying pain signals are less likely to discharge spontaneously or in response to stimuli. Gabapentin is commonly used for peripheral neuropathy and postherpetic neuralgia; lamotrigine is beneficial in pain associated with diabetes, human immunodeficiency virus (HIV) infection, and stroke, but dosage must be titrated slowly because of potentially severe adverse effects; and pregabalin is approved for treatment of diabetic neuropathy.

### Antidepressants

Tricyclic antidepressants (TCAs) have long been used to relieve neuropathic pain. They inhibit the reuptake of norepinephrine and serotonin in nerve synapses, thereby making these neurotransmitters more available to inhibit pain signals. The drugs cause numerous adverse effects, especially in older adults, but their ability to promote sleep and relieve depression (which often accompanies chronic pain) may be beneficial enough to outweigh their disadvantages.

Venlafaxine and duloxetine are newer antidepressants that also inhibit the reuptake of serotonin and norepinephrine. Duloxetine is FDA approved to treat diabetic neuropathy.

### Bisphosphonates

Bisphosphonates (e.g., alendronate, risedronate), drugs most often used to prevent or treat osteoporosis, can relieve pain related to metastatic bone cancer and multiple myeloma.

### Corticosteroids

These drugs can reduce inflammation, irritability, and spontaneous discharge in injured nerves and other tissues. They are used to treat neuropathic, visceral, and bone pain. In cancer treatment, they may be given for pain associated with brain metastases and spinal cord compression. Dexamethasone is often used.

### Local Anesthetics

Several lidocaine preparations are available to prevent or relieve pain. An oral preparation can be given to relieve mouth and throat pain but is not recommended for long term use. A transdermal gel and patch (Lidoderm) may be used to relieve the pain of postherpetic neuralgia. Epidural or intrathecal lidocaine (or bupivacaine) can be given with an opioid to reduce neuropathic pain. A mixture of local anesthetics (e.g., eutectic mixture of local anesthetics [EMLA]) may be applied topically in children to decrease the pain of injections and other procedures.

discussed mainly in other chapters; opioid analgesics are discussed below.

## General Characteristics of Opioid Analgesics

Opioid analgesics relieve moderate to severe pain by inhibiting the transmission of pain signals from peripheral tissues to the brain, reducing the perception of pain sensation in the brain, producing sedation, and decreasing the emotional upsets often associated with pain. They also inhibit the production of pain and inflammation by prostaglandins and leukotrienes in peripheral tissues. Most of these drugs are Schedule II drugs under federal narcotic laws and may lead to drug abuse and dependence. These drugs are called opioids because they act like morphine in the body.

Opioids are well absorbed with oral, intramuscular, or subcutaneous administration. Oral drugs undergo significant first-pass metabolism in the liver, which means that oral doses must be larger than injected doses to have equivalent therapeutic effects. The drugs are extensively metabolized in the liver, and metabolites are excreted in urine. Morphine and meperidine

form pharmacologically active metabolites. Thus, liver impairment can interfere with metabolism, and kidney impairment can interfere with excretion. Drug accumulation and increased adverse effects may occur if dosage is not reduced.

Opioids exert widespread pharmacologic effects, especially in the CNS and the gastrointestinal (GI) system. These effects occur with usual doses and may be therapeutic or adverse, depending on the reason for use. CNS effects include *analgesia*; CNS depression, ranging from drowsiness to sleep to unconsciousness; decreased mental and physical activity; respiratory depression; nausea and vomiting; and pupil constriction. Sedation and respiratory depression are major adverse effects and are potentially life threatening. Newer opioids were developed in an effort to find drugs as effective as morphine in relieving pain while causing less sedation, respiratory depression, and dependence. However, this effort has not been successful: equianalgesic doses of these drugs produce sedative and respiratory depressant effects comparable with those of morphine. In the GI tract, opioids slow motility and may cause constipation and smooth muscle spasms in the bowel and biliary tract.

Because of the potentially fatal adverse effects and risks of drug abuse and dependence, all opioid analgesics have

**BLACK BOX WARNINGS.** Specific comments and precautions include the following:

- Fentanyl, hydromorphone, methadone, morphine, oxycodone, and oxymorphone have the highest risk of fatal overdoses because of respiratory depression and the highest potential for abuse.
- Most of these drugs are available under generic names and multiple brand names. They also are available in several different dosage formulations, each of which must be used appropriately, for safety and effectiveness. For example, morphine, oxycodone, and oxymorphone are available in both immediate-release and extended-release tablets or capsules. Health care providers and patients must be cautioned to avoid crushing or chewing the tablets or opening capsules, because immediate release of the drug constitutes an overdose. Two exceptions are the Avinza and Kadian capsule formulations of morphine. These capsules contain beads or pellets that can be released from the capsule and sprinkled over applesauce for administration in patients who cannot swallow pills or capsules. However, the beads and pellets should not be crushed or chewed.
- With fentanyl, Actiq and Fentora formulations are indicated only for breakthrough pain in patients who are also taking long-term opioids for chronic pain such as cancer. Duragesic skin patches are indicated only for opioid-tolerant patients who require an opioid analgesic. Insys is indicated only for postoperative pain. These formulations require special techniques of administration.
- Prescribed opioids should be kept locked up, even in home settings, to decrease use or theft of the drugs by people other than the patient for whom they are prescribed (e.g., drug abusers and dealers).

## Mechanism of Action

Opioids relieve pain by binding to opioid receptors in the brain, spinal cord, and peripheral tissues. When bound to an opioid drug, opioid receptors function like gates that close and thereby block or decrease transmission of pain impulses from one nerve cell to the next. Opioid receptors also activate the endogenous analgesia system. The major types of receptors are mu, kappa, and delta. Most opioid effects (analgesia; CNS depression, with respiratory depression and sedation; euphoria; decreased GI motility; and physical dependence) are attributed to activation of the mu receptors. Analgesia, sedation, and decreased GI motility also occur with activation of kappa receptors. Delta receptors are important in the endogenous analgesia system but may not bind with opioid drugs.

## Indications for Use

The main indication for the use of opioid analgesics is to prevent or relieve acute or chronic pain. Specific conditions in which opioids are used include acute myocardial infarction, biliary colic, renal colic, burns and other traumatic injuries, postoperative states, and cancer. These drugs are usually given for chronic pain only when other measures and milder drugs are ineffective, as in terminal cancer. Other clinical uses include

- Before and during surgery to promote sedation, decrease anxiety, facilitate induction of anesthesia, and decrease the amount of anesthesia required
- Before and during invasive diagnostic procedures, such as angiograms and endoscopic examinations
- During labor and delivery (obstetric analgesia)
- Treatment of GI disorders, such as abdominal cramping and diarrhea
- Treatment of acute pulmonary edema (morphine is used)
- Treatment of severe, unproductive cough (codeine may be used)

## Contraindications to Use

Opioid analgesics are contraindicated or must be used very cautiously in people with respiratory depression, chronic lung disease, liver or kidney disease, prostatic hypertrophy, increased intracranial pressure, or hypersensitivity reactions to opioids and related drugs.

## Subgroups and Individual Drugs

The two main subgroups of opioid analgesics are agonists and agonists/antagonists. The larger group of agonists includes morphine and morphine-like drugs. These agents have activity at mu and kappa opioid receptors and thus produce prototypical opioid effects. As their name indicates, the agonists/antagonists have both agonist and antagonist activity. In addition, numerous combinations of an opioid and acetaminophen or ibuprofen, nonopioid analgesics (see Chap. 7), are available and commonly used in most health care settings. Opioid antagonists are antidote drugs that reverse the effects of opioid agonists. Individual drugs are described in the following sections; trade names and dosages are listed in Table 6-1.

## Opioid Agonists

**P Morphine**, the prototype, is an opium alkaloid that is used mainly to relieve moderate to severe pain. It is a Schedule II controlled drug most often given orally and parenterally. Patient response depends on route of administration and dosage. After IV injection, maximal analgesia and respiratory depression usually occur within 10 to 20 minutes. After IM injection, these effects occur in about 30 minutes. With Sub-Q injection, effects may be delayed up to 60 to 90 minutes. With oral administration of fast-acting (e.g., immediate-release) formulations, peak activity occurs in about 60 minutes. The duration of action is 5 to 7 hours. Long-acting tablets or capsules are given once or twice daily, with the goal of providing pain relief around the clock.

Morphine is about 30% bound to plasma proteins, and its half-life is 2 to 4 hours. It is metabolized in the liver and conjugated to an active metabolite that is excreted by the kidneys. Morphine and its metabolite accumulate in patients with impaired liver or kidney function and may cause prolonged sedation if dosage is not reduced.

Table 6-1

## Drugs at a Glance: Opioid Analgesics

## ROUTES AND DOSAGE RANGES

Generic/Trade Name	Adults	Children
<b>Agonists</b>		
Codeine	Pain: PO, Sub-Q, IM 15–60 mg q4–6h PRN; usual dose 30 mg; maximum, 360 mg/24 h Cough: PO 10–20 mg q4h PRN; maximum, 120 mg/24 h	1 y or older, Pain: PO, Sub-Q, IM 0.5 mg/kg q4–6h PRN 2–6 y, Cough: PO 2.5–5 mg q4–6h; maximum, 30 mg/24 h 6–12 y, Cough: PO 5–10 mg q4–6h; maximum, 60 mg/24 h
Fentanyl (Actiq, Duragesic, Fentora, Ionsys, Sublimaze) Note: Actiq, Fentora, and Ionsys are special preparations for specific uses. Check manufacturers' instructions for dosage and administration instructions.	Preanesthetic sedation, IM 0.05–0.1 mg 30–60 min before surgery Analgesic adjunct to general anesthesia, IV total dose of 0.002–0.05 mg/kg, depending on the surgical procedure Adjunct to regional anesthesia, IM or slow IV (over 1–2 min) 0.05–0.1 mg PRN Postoperative analgesia, IM 0.05–0.1 mg, repeat in 1–2 h if needed General anesthesia, IV 0.05–0.1 mg/kg with oxygen and a muscle relaxant (maximum dose 0.15 mg/kg with open heart surgery, other major surgeries, and complicated neurologic or orthopedic procedures) Chronic pain, Duragesic transdermal system 2.5–10 mg every 72 h	Weight at least 10 kg: Conscious sedation or preanesthetic sedation, 5–15 mcg/kg of body weight (100–400 mcg), depending on weight, type of procedure, and other factors. Maximum dose, 400 mcg, regardless of age and weight. 2–12 y: General anesthesia induction and maintenance, IV 2–3 mcg/kg
Hydromorphone (Dilaudid)	PO 2–4 mg q4–6h PRN IM, Sub-Q, IV 1–2 mg q4–6h PRN (may be increased to 4 mg for severe pain) Rectal suppository 3 mg q6–8h	Dosage not established
Meperidine (Demerol)	IM, IV, Sub-Q, PO 50–100 mg q2–4h Obstetric analgesia, IM, Sub-Q 50–100 mg q2–4h for three or four doses	IM, Sub-Q, PO 1.1–1.75 mg/kg, up to adult dose, q3–4h
Methadone (Dolophine)	IM, Sub-Q, PO 2.5–10 mg q3–4h PRN	Not recommended
<b>P Morphine</b> (prototype) (MS Contin, Roxanol, others)	PO immediate-release, 5–30 mg q4h PRN PO controlled-release, 30 mg or more q8–12h IM, Sub-Q 5–20 mg/70 kg q4h PRN IV injection, 2–10 mg/70 kg, diluted in 5 mL water for injection and injected slowly, over 5 min, PRN IV continuous infusion, 0.1–1 mg/mL in 5% dextrose in water solution, by controlled infusion pump Epidurally, 2–5 mg/24 h; intrathecally, 0.2–1 mg/24 h Rectal, 10–20 mg q4h	IM, Sub-Q 0.05–0.2 mg/kg (up to 15 mg) q4h
Oxycodone (OxyContin, Roxicodone, others)	PO, immediate release, 5 mg q6h PRN (OxyIR, Oxydose, OxyFAST); 10–30 mg q4h PRN for other formulations PO, controlled release, 10 mg q12h, increased if necessary	Not recommended for children less than 12 years of age

Generic/Trade Name	ROUTES AND DOSAGE RANGES	
	Adults	Children
<b>Agonists</b>		
Oxymorphone (Numorphan, Opana)	PO (Opana), 10–20 mg q4–6h PO, extended release (Opana ER), 5 mg q12h, increased by 5–10 mg q12h every 3–7 days until pain relieved IM, Sub-Q 1–1.5 mg q4–6h PRN IV 0.5 mg q4–6h PRN Rectal, 5 mg q4–6h PRN Obstetric analgesia, IM 0.5–1 mg	Dosage not established
Propoxyphene (Darvon)	Propoxyphene hydrochloride PO 65 mg q4h PRN (maximal daily dose, 390 mg)	Not recommended
	Propoxyphene napsylate PO 100 mg q4h PRN (maximal daily dose, 600 mg)	Not recommended
Tramadol (Ultram)	PO 50–100 mg q4–6h PRN (maximum, 400 mg/d) Renal impairment (Crcl under 30 mL/min): PO 50–100 mg q12h (maximum dose, 200 mg/d) Hepatic impairment (cirrhosis): PO 50 mg q12h Older adults (65–75 y): Same as adults, unless they also have renal or hepatic impairment Older adults (over 75 y): less than 300mg daily, in divided doses	Dosage not established
<b>Agonists/Antagonists</b>		
Butorphanol (Stadol)	IM, IV 1–4 mg q3–4h PRN Nasal spray 1 mg (one spray in one nostril) q3–4h PRN Older adults IM 1–2 mg q6–8h PRN Renal or hepatic impairment IM 1–2 mg q6–8h	Not recommended for children less than 18 years of age
Nalbuphine (Nubain)	IM, IV, Sub-Q 10 mg/70 kg q3–6h PRN	Not recommended
Opioid antagonist Naloxone (Narcan)	Overdose, IV 0.4–2 mg, repeat every 2–3 minutes if needed. Give IM or Sub-Q if unable to give IV. Postoperative reversal, IV 0.1–0.2 mg q2–3 minutes until desired level of reversal is attained	Birth to 5 y or weight less than 20 kg: 0.1 mg/kg; may repeat every 2–3 minutes if needed Age over 5 y or weight 20 kg or more: 2 mg/dose; may repeat every 2–3 minutes if needed

Crcl, creatinine clearance, PRN, as needed.

Oral administration of morphine is common for chronic pain associated with cancer. When given orally, relatively high doses are required, because part of each dose is metabolized in the liver and never reaches the systemic circulation. Concentrated solutions (e.g., Roxanol) and controlled-release tablets (e.g., MS Contin) have been developed for oral administration of these high doses.

In some cases of severe pain that cannot be controlled by other methods, morphine is administered as a continuous IV infusion. Other routes of administration include epidural, in

which the drug is instilled through a catheter placed in the epidural space and slowly diffuses into the spinal cord, and intrathecal, in which the drug is injected directly into the spinal cord. Epidural and intrathecal morphine provide pain relief with very small doses, once or twice daily. When patients cannot take oral medications and injections are undesirable, rectal suppositories can be given.

**Codeine** is an opium alkaloid and Schedule II drug used for analgesic and antitussive effects. Codeine produces weaker analgesic and antitussive effects and milder adverse effects

than morphine. Compared with other opioid analgesics, codeine is more effective when given orally and is less likely to lead to abuse and dependence. The injected drug is more effective than the oral drug in relieving pain, but onset (15 to 30 minutes), peak (30 to 60 minutes), and duration of action (4 to 6 hours) are about the same. Half-life is about 3 hours. Larger doses are required for analgesic than for antitussive effects. Codeine is often given with acetaminophen for additive analgesic effects.

Codeine is metabolized to morphine, which is responsible for its analgesic effects, by the cytochrome P450 2D6 family of enzymes. As many as 10% of whites, Asians, and African Americans have inadequate amounts or activity of the 2D6 enzymes and may therefore receive less pain relief with usual therapeutic doses.

**Fentanyl** (Sublimaze, others) is a potent opioid agonist that is widely used for preanesthetic medication, postoperative analgesia, and chronic pain that requires an opioid analgesic. Fentanyl is commonly given IV and may also be given IM. In addition, other formulations have been developed for other routes administration. **These formulations are not interchangeable—each must be used appropriately.**

Two transdermal formulations are available. One (Ionsys) is for short-term treatment of acute postoperative pain in hospitalized adults who require opioid analgesics. It is an adhesive skin patch that uses a tiny electric current to deliver a dose of fentanyl through intact skin and into the bloodstream. The patch, which has a button the patient can press for a preset dose of 40 micrograms, is placed on the patient's upper arm or chest and should be activated **only** by the patient (to avoid overdosing). When the Ionsys patch is removed, serum drug levels decline gradually. The other skin patch (Duragesic) is used in the treatment of chronic pain. The active drug is deposited in the skin and slowly absorbed systemically. Duragesic has a slow onset of action (12 to 24 hours), but it lasts about 72 hours. When a Duragesic patch is removed, the drug continues to be absorbed from the skin deposits for 24 hours or longer. With both transdermal formulations, patients should have a fast-acting formulation available for acute pain. An oral lozenge on a stick (Actiq) and a buccal tablet (Fentora) are approved to treat acute (breakthrough) pain in people who have been receiving opioids and have become opioid-tolerant. Because of a risk of respiratory depression, recommended dosages must not be exceeded with any formulation.

**Hydrocodone**, a Schedule III drug, is similar to codeine in its analgesic and antitussive effects. It is available in oral combination products for cough and with acetaminophen or ibuprofen for pain. Its half-life is about 4 hours, and its duration of action is 4 to 6 hours. Hydrocodone is metabolized to hydromorphone by the cytochrome P450 2D6 enzymes.

**Hydromorphone** (Dilaudid) is a semisynthetic derivative of morphine that has the same actions, uses, contraindications, and adverse effects as morphine. It is more potent on a milligram basis and more effective orally than morphine. Effects occur in 15 to 30 minutes, peak in 30 to 90 minutes, and last 4 to 5 hours. Hydromorphone is metabolized in the liver to inactive metabolites that are excreted through the kidneys.

**Meperidine** (Demerol) is a synthetic drug similar to morphine in action and adverse effects. After injection, analgesia occurs in 10 to 20 minutes, peaks in 1 hour, and lasts 2 to 4 hours. After an oral dose, about half is metabolized in the liver and never reaches the systemic circulation. Meperidine is infrequently used for therapeutic purposes, mainly because it produces a neurotoxic metabolite (normeperidine). Normeperidine accumulates with chronic use, large doses, or renal failure and produces CNS stimulation characterized by agitation, hallucinations, and seizures. The half-life of normeperidine is 15 to 30 hours, depending on renal function, and the effects of normeperidine are not reversible with opioid antagonist drugs.

**Methadone** (Dolophine) is a synthetic drug similar to morphine but with a longer duration of action. It is usually given orally, with which onset and peak of action occur in 30 to 60 minutes. Effects last 4 to 6 hours initially and longer with repeated use. Half-life is 15 to 30 hours, which also lengthens with repeated use. Methadone is used for severe pain and in the detoxification and maintenance treatment of opiate addicts. In 2006, the Food and Drug Administration (FDA) issued an alert about serious adverse effects (e.g., death, overdose, and serious cardiac dysrhythmias) reported in patients taking methadone. The FDA recommended that methadone dosage for pain should be carefully selected and titrated and that patients should be taught not to exceed prescribed dosage or frequency of administration.

**Oxycodone** (Roxicodone, others) is a derivative of codeine used to relieve moderate pain; its pharmacologic actions are similar to those of other opioid analgesics. It is a Schedule II drug of abuse. With oral administration, action starts in 15 to 30 minutes, peaks in 60 minutes, and lasts 4 to 6 hours. Its half-life is unknown. It is metabolized by the cytochrome P450 2D6 enzymes and excreted through the kidneys.

Oxycodone has been widely used for years, alone or in combination with acetaminophen. Several years ago, controlled-release tablets (OxyContin) in 10-, 20-, 40-, and 80-milligram sizes were marketed for extended treatment of moderate to severe pain (the 80-milligram tablets should be used only by patients who have developed drug tolerance through long-term use of lesser doses). When given every 12 hours, the tablets relieve pain around-the-clock. These effects are advantageous to patients with terminal cancer or other chronic pain conditions. However, OxyContin soon became a popular drug of abuse, leading to many deaths and much criminal activity. Most deaths have resulted from inappropriate use (i.e., not legally prescribed for the user) and by chewing, crushing and snorting through the nose, or crushing and injecting the drug. Chewing or crushing destroys the long-acting feature and constitutes an overdose. Subsequently, the manufacturer and the FDA have issued precautions for prescribing OxyContin and warnings not to crush the product.

**Oxymorphone** (Numorphan, Opana) is a derivative of morphine with actions, uses, and adverse effects similar to those of morphine. It was formerly available as a solution for injection and as a rectal suppository but was infrequently used. In 2006, oral tablets (immediate-release and extended-release Opana) were approved by the FDA.

**Propoxyphene** (Darvon) is a synthetic, Schedule IV drug that is chemically related to methadone. It is used for mild to moderate pain but is no more effective than aspirin or acetaminophen, with which it is usually given. Propoxyphene is abused (alone and with alcohol or other CNS depressant drugs), and deaths have occurred from overdoses. In addition, its metabolism produces an active metabolite, norpropoxyphene, which is eliminated in urine. Norpropoxyphene is not an opioid, but it has a long half-life and accumulates with repeated use of propoxyphene. Accumulation is associated with dysrhythmias and pulmonary edema; there have also been reports of apnea, cardiac arrest, and death. Norpropoxyphene cannot be removed by hemodialysis, and naloxone, an opioid antagonist, does not reverse its effects. As a result of these characteristics, propoxyphene has a **BLACK BOX WARNING** that it should not be prescribed for patients at risk for suicide or addiction, that it should be used with caution by patients who take tranquilizers or antidepressant drugs or who use alcohol to excess, and that patients should not exceed recommended dosage and should limit alcohol intake. The drug should be avoided by older adults and should not be used long term. Despite these dangers and warnings, the drug continues to be prescribed.

**Tramadol** (Ultram) is an oral, synthetic, centrally active analgesic for moderate to severe pain. It is effective and well tolerated in older adults and in people with acute or chronic pain, back pain, fibromyalgia, osteoarthritis, and neuropathic pain. Because it has a low potential for producing tolerance and abuse, it may be used long term for the management of chronic pain. It is not chemically related to opioids and is not a controlled drug. Its mechanism of action includes binding to mu opioid receptors and inhibiting reuptake of norepinephrine and serotonin in the brain, actions that interfere with transmission of pain signals. Analgesia occurs within 1 hour of administration and peaks in 2 to 3 hours with immediate-release tablets. Tramadol causes significantly less respiratory depression than morphine but may cause other morphine-like adverse effects (e.g., drowsiness, nausea, constipation, orthostatic hypotension).

Tramadol is well absorbed after oral administration, even if taken with food. It is minimally bound to plasma proteins, and its half-life is 6 to 7 hours. It is metabolized by the cytochrome P450 3A4 and 2D6 enzymes and forms an active metabolite. About 30% of a dose is excreted unchanged in the urine, and 60% is excreted as metabolites. Dosage should be reduced in people with renal or hepatic impairment. Tramadol is available in oral immediate-release tablets alone and in combination with acetaminophen (Ultracet) as well as an extended-release tablet (Ultram ER) that can be given once daily.

### Applying Your Knowledge 6-1

At 12:00 P.M., you check on Mr. Harris. He complains of post-operative pain. He rates his pain as an 8 on a 10-point scale. Which pain medication will you give, and how much will you administer?

## Opioid Agonists/Antagonists

These agents have agonist activity at some receptors and antagonist activity at others. Because of their agonist activity, they are potent analgesics with a lower abuse potential than pure agonists. However, they are considered second-line drugs for treatment of moderate to severe pain. Because of their antagonist activity, they should not be given to people who have been receiving opioid analgesics, and they may produce withdrawal symptoms in people with opioid dependence.

**Butorphanol** (Stadol) is a synthetic, Schedule IV agonist similar to morphine in analgesic effects and ability to cause respiratory depression. It is used for moderate to severe pain and is given parenterally or topically to nasal mucosa by a metered spray (Stadol NS). After IM or IV administration, analgesia peaks in 30 to 60 minutes. After nasal application, analgesia peaks within 1 to 2 hours. Adverse effects include drowsiness and nausea and vomiting. Butorphanol is not recommended for use in children younger than 18 years of age.

**Nalbuphine** (Nubain) is a synthetic analgesic used for moderate to severe pain. It is not a controlled drug. It is given IV, IM, or Sub-Q. After IV injection, action starts in 2 to 3 minutes, peaks in 15 to 20 minutes, and lasts for 3 to 6 hours. After IM or Sub-Q injection, action begins in less than 15 minutes, peaks in 30 to 60 minutes, and lasts for 3 to 6 hours. Half-life is 5 hours. The most common adverse effect is sedation; others are minimal at recommended doses.

## Opioid Antagonist

An opioid antagonist (antidote) reverses analgesia and the CNS and respiratory depression caused by opioid agonists. It competes with opioids for opioid receptor sites in the brain and thereby prevents opioid binding with receptors or displaces opioids already occupying receptor sites. When an opioid cannot bind to receptor sites, it is “neutralized” and cannot exert its effects on body cells. An opioid antagonist does not relieve the depressant effects of other drugs, such as sedative-hypnotic, antianxiety, and antipsychotic agents. The chief clinical use of an opioid antagonist is to relieve CNS and respiratory depression induced by an opioid.

**Naloxone** (Narcan) has long been the drug of choice to treat respiratory depression caused by an opioid. Therapeutic effects occur within minutes after IV, IM, or Sub-Q injection and last 1 to 2 hours. Naloxone has a shorter duration of action than opioids, and repeated injections are usually needed. For a long-acting drug such as methadone, injections may be needed for 2 to 3 days. Naloxone produces few adverse effects, and repeated injections can be given safely. This drug should be readily available in all health care settings in which opioids are given. Dosages are listed in Table 6-1.

### Applying Your Knowledge 6-2

At 1:00 P.M., you visit Mr. Harris’s room. You note he is difficult to arouse and has a respiratory rate of 10 breaths per minute. What should be your nursing response?

Table 6-2

## Selected Combination Opioid–Nonopioid Products

OPIOID–NONOPIOID	STRENGTH (mg)/SELECTED NAMES	ADULT DOSAGE RANGES
Codeine/acetaminophen	30/300 (generic, Tylenol #3)	0.5–2 tabs q4h
Hydrocodone/acetaminophen	5/325 (generic)	1–2 tabs q4–6h, up to 12 tabs/d
	5/500 (generic, Hydrocet, Lorcet HD, Lortab, Vicodin)	1–2 tabs q4–6h, up to 8 tabs/d
	7.5/750 (generic, Vicodin ES)	1 tab q4–6h, up to 5 tabs/d
	10/500 (generic, Lorcet HD, Lortab 10/500)	1 tab q4–6h, up to 6 tabs/d
Hydrocodone/ibuprofen	7.5/200 (Vicoprofen)	1 tab q4–6 h, up to 5 tabs/d
Oxycodone/acetaminophen	5/325 (Percocet, Roxicet)	1 tab q6h
	5/500 (Roxicet 5/500, Tylox)	1 cap q6h
Oxycodone/ibuprofen	5/400 (Combunox)	1 tab, up to 4 tabs/d, not to exceed 7 d
Tramadol/acetaminophen	37.5/325 (generic, Ultracet)	2 tabs q4–6h

Note: Maximum recommended dosage for acetaminophen is 4000 mg/d and for ibuprofen, 2400 mg/d.

## Herbal and Dietary Supplement

**Capsaicin** (Zostrix), a product derived from cayenne chili peppers, is applied topically to the skin to relieve pain associated with osteoarthritis, rheumatoid arthritis, postherpetic neuralgia after a herpes zoster infection (shingles), diabetic neuropathy, postsurgical pain (including pain after mastectomy and amputation), and other complex pain syndromes. It may be most effective in relieving arthritic pain in joints close to skin surfaces (e.g., fingers, elbows, knees). Its analgesic effects are attributed to depletion of substance P in nerve cells. Substance P enhances transmission of painful stimuli from peripheral tissues to the spinal cord. An additional analgesic effect may result from interference with production of prostaglandins and leukotrienes.

Capsaicin is available in a gel, creams, and lotions, in concentrations ranging from 0.025% to 0.25%. It is most effective when applied three or four times daily; effects last 4 to 5 hours. The main adverse effects are itching and stinging. Capsaicin also is the active ingredient in a pepper spray used for self-defense.

### Applying Your Knowledge 6-3

#### How Can You Avoid This Medication Error?

On the night after his surgery, Mr. Harris requests medication for pain. You note on his chart that the physician has ordered oral pain medication 24 hours after surgery. When Mr. Harris requests medication for pain, you administer Lortab 5/500.

## Nursing Process

### Assessment

Pain is a subjective experience (whatever the person says it is), and humans display a wide variety of responses. Although pain thresholds (the point at which a tissue-damaging stimulus produces a sensation of pain) are similar, people differ in their perceptions, behaviors, and tolerance of pain. Differences in pain perception may result from psychological components. Stressors such as anxiety, depression, fatigue, anger, and fear tend to increase pain; rest, mood elevation, and diversionary activities tend to decrease pain. Differences in behaviors may or may not indicate pain to observers, and overt signs and symptoms are not reliable indicators of the presence or extent of pain. Especially with chronic pain, overt signs and symptoms may be absent. Differences in the amount or duration of pain a person is willing to suffer before seeking relief often reflect the person's concern about the meaning of the pain and the type or intensity of the painful stimulus. Thus, pain is a complex physiologic, psychological, and sociocultural phenomenon that must be thoroughly assessed if it is to be managed effectively.

The nurse must assess every patient in relation to pain, initially to determine appropriate interventions and later to determine whether the interventions were effective in preventing or relieving pain. Although the patient is usually the best source of data, other people may be questioned about the patient's words and behaviors that indicate pain. This is especially important with young children. During assessment, keep in mind that acute pain may coexist with or be superimposed on chronic pain. Specific assessment data include

- **Location.** Determining the location may assist in relieving the pain or identifying its underlying cause. Ask the patient to show you where it hurts, if possible, and whether the pain stays in one place or radiates to other parts of the body. The term *referred pain* is used when pain arising from tissue damage in one area of the body is felt in another area. Patterns of referred pain may be helpful in diagnosis. For example, pain of cardiac origin may radiate to the neck, shoulders, chest muscles, and down the arms, often on the left side. This type of pain usually results from myocardial ischemia due to atherosclerotic plaque in coronary arteries. Stomach pain is usually referred to the epigastrium and may indicate gastritis or peptic ulcer. Gallbladder and bile duct pain is often localized in the right upper quadrant of the abdomen. Uterine pain is usually felt as abdominal cramping or low back pain. Deep or chronic pain is more difficult to localize than superficial or acute pain.
- **Intensity or severity.** Because pain is a subjective experience and cannot be objectively measured, assessment of severity is based on the patient's description and the nurse's observations. Various scales have been developed to measure and quantify pain. These include verbal descriptor scales in which the patient is asked to rate pain as mild, moderate, or severe; numeric scales, with 0 representing no pain and 10 representing severe pain; and visual analog scales, in which the patient chooses the location indicating the level of pain on a continuum.
- **Relation to time, activities, and other signs and symptoms.** Specific questions include
  - When did the pain start?
  - What activities were occurring when the pain started?
  - Does the pain occur with exercise or when at rest?
  - Do other signs and symptoms occur before, during, or after the pain?
  - Is this the first episode or a recurrent pain?
  - How long does the pain last?
  - What, if anything, decreases or relieves the pain?
  - What, if anything, aggravates the pain?
- **Other data.** For example, do not assume that postoperative pain is due to the incision and requires opioid analgesics for relief. A person who has had abdominal surgery may have headache, musculoskeletal discomfort, or "gas pains." Also, restlessness may be caused by hypoxia or anxiety rather than pain.
- **With patients on opioid analgesics for more than a few days, assess periodically for drug tolerance and the need for higher doses or more frequent administration. Do not assume that increased requests for pain medication indicate inappropriate drug-seeking behavior associated with drug dependence.**

## Nursing Diagnoses

- Acute Pain
- Chronic Pain
- Impaired Gas Exchange related to sedation and decreased mobility
- Risk for Injury related to sedation and decreased mobility
- Constipation related to slowed peristalsis
- Deficient Knowledge: Effects and appropriate use of opioid analgesics
- Noncompliance: Drug dependence related to overuse

## Planning/Goals

The patient will

- Avoid or be relieved of pain.
- Use opioid analgesics appropriately.
- Avoid preventable adverse effects.
- Be monitored for excessive sedation and respiratory depression.
- Be able to communicate and perform other activities of daily living when feasible.

## Interventions

Use measures to prevent, relieve, or decrease pain when possible. General measures include those that promote optimal body functioning and those that prevent trauma, inflammation, infection, and other sources of painful stimuli. Specific interventions include the following:

- Encourage pulmonary hygiene techniques (e.g., coughing, deep breathing, ambulation) to promote respiration and prevent pulmonary complications, such as pneumonia and atelectasis.
- Use sterile technique when caring for wounds, urinary catheters, or IV lines.
- Use exercises, ambulation, and position changes to promote circulation and musculoskeletal function.
  - Rub or massage the painful area (e.g., knee pain with osteoarthritis) if feasible and helpful. This intervention is thought to stimulate other nerve fibers that block the nerve fibers carrying pain signals from entering the spinal cord.
- Handle any injured tissue gently, to avoid further trauma.
- Prevent bowel or bladder distention.
- Apply heat or cold.
- Use relaxation or distraction techniques.
- If a patient is in pain on initial contact, try to relieve the pain as soon as possible. After pain is controlled, plan with the patient to avoid or manage future episodes.
- If a patient is not in pain initially but anticipates surgery or an uncomfortable diagnostic procedure, plan with the patient ways to minimize and manage discomfort.

*Nursing Process continues on page 90*

## Evaluation

- Ask patients about their levels of comfort or relief from pain.
- Observe behaviors that indicate the presence or absence of pain.
- Observe participation and ability to function in usual activities of daily living.
- Observe for presence or absence of sedation and respiratory depression.
- Observe for inappropriate drug-seeking behavior (possibly indicating dependence).

## Principles of Therapy

### Goals of Therapy

The goals of therapy are to relieve pain and discomfort, promote rest and relaxation, allow performance of usual activities

of daily living, as health status permits, and minimize the anxiety, depression, and other emotional upsets that develop when pain is not managed effectively. Studies indicate that health care providers often fail to meet these goals with patients experiencing pain. Concerns about respiratory depression, excessive sedation, and drug dependence often contribute to reluctance and delay in administering opioid analgesics. Much of the difficulty has been attributed to inadequate or improper use of opioid analgesics (e.g., prescribing the wrong drug, inadequate dosage, or too-long intervals between doses). Even when opioid analgesics are ordered appropriately, nurses or patients and family members may not administer the drugs effectively. Basic tenets of a more humane approach to pain management are that no person should suffer pain needlessly, that pain occurs when the patient says it does, and that pain should be relieved by whatever means are required, including pharmacologic and nonpharmacologic treatments; that doses of opioids should be titrated to achieve maximal effectiveness; and that dependence rarely results from drugs taken for physical pain. Proponents of this view emphasize the need to assess and monitor all patients receiving opioid analgesics.

## Patient Teaching Guidelines

### Opioid (Narcotic) Analgesics

#### General Considerations

- Use nonpharmacologic treatments of pain (e.g., exercise, heat and cold applications) instead of or along with analgesics, when effective.
- For pain that is not relieved by nondrug treatments, a non-narcotic analgesic (e.g., acetaminophen or ibuprofen) may be taken.
- For pain that is not relieved by a non-narcotic analgesic, a narcotic may be alternated with a non-narcotic analgesic or a combination product containing a narcotic and non-narcotic may be effective. Use of a narcotic analgesic for acute pain is acceptable and unlikely to lead to addiction.
- Most combination products (e.g., Lorcet, Lortab, Percocet, Vicodin, Tylenol No. 3) contain acetaminophen and there is a risk of liver failure from high doses of acetaminophen or from lower doses in people who already have liver damage (e.g., alcohol abusers). The maximum recommended dose within 24 hours, whether taken alone or in a combination product, is 4000 milligrams (e.g., 8 tablets or capsules containing 500 mg each). If unsure whether a combination product contains acetaminophen, ask a health care provider. In addition to pain relievers, many cold and flu over-the-counter products also contain acetaminophen. The maximum amount of 4000 milligrams should include all sources of acetaminophen. Acetaminophen use leading to liver failure is often implicated in patients requiring a liver transplant.
- For acute episodes of pain that occur at irregular intervals, most opioids may be taken as needed; for acute pain that occurs daily and for chronic pain, the drugs should be taken on a regular schedule, around-the-clock.
- When a choice of pain-relieving medication is available, use the least amount of the mildest drug that is likely to be effective in a particular situation.

- Take only as prescribed. If desired effects are not achieved, report to your health care provider. Do not increase the dose and do not take medication more often than prescribed. Although these principles apply to all medications, they are especially important with opioid analgesics because of potentially serious adverse effects and because analgesics may mask pain for which medical attention is needed.
- Do not drink alcohol or take other drugs that cause drowsiness (e.g., some antihistamines, sedative-type drugs for nervousness or anxiety, sleeping pills) while taking opioids for pain. Combining drugs with similar effects may lead to excessive sedation and difficulty in breathing.
- Do not smoke, cook, drive a car, or operate machinery when drowsy or dizzy or when vision is blurred from medication.
- Sit or lie down at least 30–60 minutes after receiving an opioid by injection. Injected drugs may cause dizziness, drowsiness, and falls when walking around. If it is necessary to get up, ask someone for assistance.
- When hospitalized, ask a health care provider about methods of pain management. For example, if anticipating surgery, ask how postoperative pain will be managed, how you need to report pain and request pain medication, and so on. It is better to take adequate medication and be able to cough, deep breathe, and walk around than to avoid or minimize pain medication and be unable to perform activities that promote recovery and healing. Do not object to having bedrails up or asking for assistance when receiving a strong narcotic analgesic. These are safety measures to prevent falls or other injuries because these drugs may cause drowsiness, weakness, unsteady gait, and blurred vision.

- Constipation is a common adverse effect of opioid analgesics. It may be prevented or managed by eating high-fiber foods, such as whole-grain cereals, fruits, and vegetables; drinking 2–3 quarts of fluid daily; and being as active as tolerated. If you take these medicines for more than a few days, or if you're the caregiver for someone who takes them, ask a health care provider about a bowel program to prevent constipation. A possible regimen is a daily stool softener (e.g., docusate) and a daily or every other day laxative (e.g., bisacodyl), preferably started at the same time as the narcotic. Docusate and bisacodyl are available over-the-counter.

### Self-Administration

- Take oral narcotic analgesics with 6–8 oz of water, with or after food to reduce nausea.
- Do not crush or chew long-acting tablets (e.g., MS Contin, OxyContin). The tablets are formulated to release the active drug slowly, over several hours. Crushing or chewing causes immediate release of the drug, with a high risk of overdose and adverse effects, and shortens the duration of pain-relieving effects.
- Omit one or more doses if severe adverse effects occur (e.g., excessive drowsiness, difficulty in breathing, severe nausea, vomiting, or constipation), and report to a health care provider.

## Drug Selection

Prescribers have a wide choice of drugs to use in pain management and several factors should be considered, including the type of pain. Most prescribers use acetaminophen or nonsteroidal anti-inflammatory analgesics (e.g., ibuprofen) for mild pain; continue one of these and add an opioid (e.g., codeine, hydrocodone, or tramadol) for moderate pain; and give a strong opioid (e.g., morphine, fentanyl, hydromorphone) alone for acute, severe pain or combined with nonopioid drugs for chronic severe pain (e.g., cancer or neuropathic pain). Because it is often difficult to control severe pain with a single analgesic, a combination of drugs with different mechanisms of action may be more effective. Combinations may also be effective with lower doses and limit the adverse effects that occur with higher doses. More specific considerations are described below.

Morphine is often the opioid of choice for moderate to severe pain because it is effective, available in several dosage strengths, can be given by several routes, is useful on a short- or long-term basis, and its adverse effects are well known. In addition, it is a “nonceiling” drug (meaning that there is no upper limit to the dosage that can be given to patients who have developed tolerance to previous dosages). This characteristic is especially valuable in patients with severe cancer-related pain, because drug dosage can be increased and titrated to relieve pain when pain increases or *tolerance* develops. Thus, some patients have safely received extremely large doses. Other non-ceiling drugs are hydromorphone and methadone. Several opioids are available in long-acting formulations, including fentanyl (Duragesic skin patch), hydromorphone (Palladone extended-release capsules), morphine (MS Contin, Oramorph SR, Avinza, Kadian), oxycodone (OxyContin controlled-release tablets), and tramadol (Ultram ER), which may be an important factor in drug selection. For patients receiving long-acting opioids, a fast-acting opioid also needs to be available for breakthrough pain.

When more than one analgesic is ordered, the least potent drug that is effective in relieving pain should be used. For example, a nonopioid analgesic, such as acetaminophen, rather than an opioid analgesic, should be given when feasible.

Nonopioid analgesics may be alternated or given concurrently with opioid analgesics, especially in chronic pain. This

strategy increases patient comfort, reduces the likelihood of drug abuse and dependence, and decreases tolerance to the pain-relieving effects of the opioid analgesics.

Numerous fixed-dose combinations of acetaminophen or ibuprofen and an opioid are available and widely used (see Table 6-2). Prescribers need to assess patients for the use of other products containing an opioid or acetaminophen before prescribing one of these combinations because overuse of these products can result in serious adverse effects.

## Route Selection

Opioid analgesics can be given by several routes, either noninvasively (orally, rectally, or transdermally) or invasively (Sub-Q, IM, IV, or by spinal infusion). *When the route is changed (e.g., from oral to injection or vice versa), the dose must also be changed to prevent over dosage or under dosage.* Oral drugs are preferred when feasible, and most patients achieve relief with short-acting or sustained-release oral preparations.

Some drugs can be given by IM or Sub-Q injections for rapid relief of acute pain, but IV injection is usually preferred. Small, frequent IV doses are often effective in relieving pain with minimal risk of serious adverse effects. This is especially advantageous during a serious illness or after surgery. Continuous IV infusion may be used to treat severe pain. A technique called *patient-controlled analgesia* (PCA) allows self-administration. Devices consist of a container of diluted drug connected to an IV line and infusion pump or a specially designed IV bag and special tubing. These devices deliver a dose when the patient pushes a button. Some PCA pumps can also deliver a basic amount of analgesic by continuous infusion, with the patient injecting additional doses when needed. The amount of drug delivered with each dose and the intervals between doses are preset and limited. PCA requires an alert, cooperative patient who can press a button when pain occurs. Studies indicate that analgesia is more effective, patient satisfaction is high, and smaller amounts of drug are used than with as needed administration. PCA is especially useful for patients with postoperative pain or high opioid requirements.

Three other routes may be used to manage acute pain. One is the fentanyl skin patch (Ionsys) described earlier. It is indicated only for short-term treatment of hospitalized,

postoperative patients and is the only noninvasive route available for PCA.

Another route involves injection of morphine or fentanyl directly into the CNS through a catheter placed into the epidural or intrathecal space by an anesthesiologist or other physician. This method provides effective analgesia while minimizing depressant effects. The epidural route can be used to administer PCA, and less opioid is required for pain relief than with the IV route. The third route involves the injection of a local anesthetic to provide local or regional analgesia, alone or combined with an opioid. These routes require special administration and monitoring procedures for safe use.

For patients with chronic pain and contraindications to oral or injected medications, some opioids are available in rectal suppositories or skin patches. Morphine, oxycodone, and hydromorphone can be given rectally with similar potencies and half-lives as when given orally. For patients who cannot take oral medications and whose opioid requirement is too large for rectal administration, the transdermal route is preferred over IV, IM, or Sub-Q injections. A fentanyl skin patch (Duragesic) is commonly used. When first applied, pain relief is delayed about 12 hours (as the drug is gradually absorbed). Because of the delayed effects, doses of a short-acting opioid should be ordered and given as needed during the first 48 hours after the patch is applied. With continued use, the old patch is removed and a new one applied every 72 hours. Opioid overdose can occur with fentanyl patches if the patient has fever (hastens drug absorption) or liver impairment (slows drug metabolism). Analgesics given by a combination of routes may be the most effective regimen.

## Drug Dosage

Dosages of opioids should be sufficient to relieve pain without causing unacceptable adverse effects. Thus, dosages should be individualized according to the type and severity of pain; the patient's age, size, and health status; whether the patient is opiate naive (has not received sufficient opioids for development of tolerance) or opiate tolerant (has previously taken opioids and drug tolerance has developed, so that larger-than-usual doses are needed to relieve pain); whether the patient has worsening disease; and other characteristics that influence responses to pain. Additional guidelines include the following:

- Small to moderate doses relieve constant, dull pain, and moderate to large doses relieve intermittent, sharp pain caused by trauma or conditions affecting the viscera.
- When an opioid is ordered in variable amounts, the smaller amount should be given as long as it is effective in relieving pain.
- Dosages of opioids should be reduced for patients who also are receiving other CNS depressants (e.g., antianxiety, antidepressant, antihistaminic, antipsychotic, or other drugs that cause sedation).
- Dosages often differ according to the route of administration. Oral doses undergo extensive metabolism on their first

pass through the liver, so oral doses are usually much larger than injected doses.

- Dosages change when patients are switched from one opioid to another (usually because the first opioid loses its effectiveness, produces unacceptable adverse effects, or is not available in a suitable dosage form for a different route of administration).

## Frequency of Administration

Opioid analgesics may be given as needed, within designated time limits, or on a regular schedule. Traditionally, the drugs were often scheduled every 4 to 6 hours as needed (PRN). Numerous studies indicate that such a schedule is often ineffective in managing patients' pain. Because opioids are used for moderate to severe pain, they should in general be scheduled to provide effective and consistent pain relief.

When analgesics are ordered PRN, have a clear-cut system by which the patient requests medication. The patient should know that an analgesic is available and will be given promptly when needed. If a drug cannot be given, explain the reasons to the patient. In addition, offer or give the drug when indicated by the patient's condition rather than waiting for the patient to request medication.

For acute pain, opioids are most effective when given parenterally and at the onset of pain. In chronic, severe pain, opioids are most effective when given on a regular schedule, around the clock.

When feasible, give an analgesic prior to activities known to be uncomfortable or painful (e.g., coughing and deep-breathing exercises, dressing changes, other therapeutic and diagnostic procedures). Allow adequate time for the pain medication to take effect.

Opioids are not recommended for prolonged periods except for advanced cancer. Health care facilities usually have an automatic "stop order" for opioids after 48 to 72 hours; this means that the drug is discontinued when the time limit expires if it is not reordered.

## Drug Use in Specific Situations

### Cancer

It is important for health care providers to remember that patients with cancer may experience both acute pain (e.g., pain associated with diagnostic tests, surgery or other treatments, disease progression, development of tolerance to opioids) and chronic pain. When opioids are required by patients with chronic pain, the main consideration is patient comfort, not preventing drug addiction. Effective treatment requires that pain be relieved and prevented from recurring; titration of opioid dosage is usually the best approach. With disease progression and the development of drug tolerance, extremely large doses and frequent administration (of *nonceiling opioids*) may be required. Additional guidelines include the following:

- Analgesics should be given on a regular schedule, around-the-clock. Patients should be awakened, if necessary, to prevent pain recurrence.

- Oral, rectal, and transdermal routes of administration are generally preferred over injections.
- A nonopioid analgesic (e.g., acetaminophen, ibuprofen) may be used alone for mild pain.
- Oxycodone or codeine can be used for moderate pain, often with a nonopioid analgesic. A combination of the two types of drugs produces additive analgesic effects and may allow smaller doses of the opioid.
- Morphine or another strong opioid (e.g., hydromorphone, fentanyl, oxycodone, methadone) is given for severe pain. Although the dose of morphine can be titrated upward for adequate analgesia, unacceptable adverse effects (e.g., excessive sedation, respiratory depression, nausea and vomiting) may limit the dose. Oral administration is preferred; the initial oral dosage of morphine is usually 10 to 20 mg every 3 to 4 hours.
- When long-acting forms of opioids are given on a regular schedule, fast-acting forms also need to be available for *breakthrough pain* (acute pain that occurs spontaneously or with activity). If supplemental or “rescue” doses are needed frequently, the baseline dose of long-acting medication may need to be increased.
- In addition to analgesics, other drugs may be used to increase patient comfort. For example, some antidepressants and anticonvulsants decrease neuropathic pain. Antiemetics may be given for nausea and vomiting; stool softeners and laxatives are usually needed on a regular schedule to manage constipation. Tolerance does not develop to the constipating effects of opioids.

### Biliary, Renal, or Ureteral Colic

When opioids are used to relieve the acute, severe, pain associated with colic, an antispasmodic drug such as atropine may be needed as well. Opioids may increase smooth muscle tone and cause spasm. Atropine does not have strong antispasmodic properties of its own in usual doses, but it reduces the spasm-producing effects of opioids.

### Postoperative Use

When opioids are used postoperatively, the goal is to relieve pain without excessive sedation so that patients can do deep-breathing exercises, cough, ambulate, and participate in other activities to promote recovery. Strong opioids are usually given parenterally for a few days. Then, oral opioids or nonopioid analgesics are given.

### Burns

In severely burned patients, opioids should be used cautiously. A common cause of respiratory arrest in burned patients is excessive administration of analgesics. Agitation in a burned person may indicate hypoxia or hypovolemia rather than pain. When opioids are necessary, they are usually given IV in small doses. Drugs given by other routes are absorbed erratically in the presence of shock and hypovolemia and may not relieve pain. In addition, unabsorbed drugs may be rapidly absorbed

when circulation improves, with the potential for excessive dosage and toxic effects.

## Opioid Toxicity: Recognition and Management

Acute toxicity or opioid overdose can occur from therapeutic use or from abuse by drug-dependent people. Overdose may produce severe respiratory depression and coma. The main goal of treatment is to restore and maintain adequate respiratory function. This can be accomplished by inserting an endotracheal tube and starting mechanical ventilation or by giving an opioid antagonist, such as naloxone. Thus, emergency supplies should be readily available in any setting where opioids are used.

## Opioid Withdrawal: Prevention and Management

Abstinence from opioids after chronic use produces a withdrawal syndrome characterized by anxiety; restlessness; insomnia; perspiration; pupil dilation; piloerection (goose flesh); anorexia, nausea, and vomiting; diarrhea; elevation of body temperature, respiratory rate, and systolic blood pressure; muscle cramps; and dehydration. Although all opioids produce similar withdrawal syndromes, the onset, severity, and duration vary. With morphine, symptoms begin within a few hours of the last dose, reach peak intensity in 36 to 72 hours, and subside over 8 to 10 days. With methadone, symptoms begin in 1 to 2 days, peak in about 3 days, and subside over several weeks. Heroin, meperidine, methadone, morphine, oxycodone, and oxymorphone are associated with more severe withdrawal symptoms than other opioids. If an opioid antagonist such as naloxone (Narcan) is given, withdrawal symptoms occur rapidly and are more intense but of shorter duration. Despite the discomfort that occurs, withdrawal from opioids is rarely life threatening unless other problems are present. An exception is opioid withdrawal in neonates, which has a high mortality rate if not treated effectively. Signs and symptoms in neonates include tremor, jitteriness, increased muscle tone, screaming, fever, sweating, tachycardia, vomiting, diarrhea, respiratory distress, and possibly seizures.

Recognition and treatment of early, mild symptoms of withdrawal can prevent progression to severe symptoms. Both opioids and nonopioids are used for treatment. Opioids may be used in two ways to provide a safe, therapeutic withdrawal. One technique is to give the opioid from which the person is withdrawing, which immediately reverses the signs and symptoms of withdrawal. Then, dosage is gradually reduced over several days. Another technique is to substitute a long-acting opioid (e.g., methadone) for a short-acting opioid. Methadone is usually given in an adequate dose to control symptoms, once or twice daily, and then is gradually tapered over 5 to 10 days. In neonates undergoing opioid withdrawal, methadone or paregoric may be used.

Clonidine, an antihypertensive drug, is a nonopioid that may be used to treat opioid withdrawal. Clonidine reduces

the release of norepinephrine in the brain and thus reduces symptoms associated with excessive stimulation of the sympathetic nervous system (e.g., anxiety, restlessness, insomnia). Blood pressure must be closely monitored during clonidine therapy. Other medications (nonopioid analgesics, antiemetics, antidiarrheals) are often required to treat other symptoms.

## Use in Special Populations

### Use in Opioid-Tolerant Patients

Whether opioid tolerance results from the use of prescribed therapeutic drugs or the abuse of street drugs, there are two main considerations in using opioid analgesics in this population. First, larger-than-usual doses are required to treat pain. Second, signs and symptoms of withdrawal occur if adequate dosage is not maintained or if opioid antagonists are given.

### Use in Children

In general, there is little understanding of the physiology, pathology, assessment, and management of pain in children. Many authorities indicate that children's pain is often ignored or under treated, including children having surgical and other painful procedures for which adults routinely receive an anesthetic, a strong analgesic, or both. This is especially true in preterm and full-term neonates. One reason for inadequate prevention and management of pain in newborns was a common belief that they did not experience pain because of immature nervous systems. However, research indicates that neonates have abundant C fibers and that A-delta fibers are developing during the first few months of life. These are the nerve fibers that carry pain signals from peripheral tissues to the spinal cord. In addition, brain pain centers and the endogenous analgesia system are developed and functional. Endogenous opioids are released at birth and in response to fetal and neonatal distress such as asphyxia or other difficulty associated with the birth process.

Older infants and children may experience pain even when analgesics are readily available. For example, children may fear injections or may be unable to communicate their discomfort. Health care providers or parents may fear adverse effects of opioid analgesics, including excessive sedation, respiratory depression, and addiction.

Other than reduced dosage, there have been few guidelines about the use of opioids in children. With increased knowledge about pain mechanisms, nurses who work with children should be able to manage pain effectively. Specific considerations include the following:

- Opioids administered during labor and delivery may depress fetal and neonatal respiration. The drugs cross the blood-brain barrier of the infant more readily than that of the mother. Therefore, doses that do not depress maternal respiration may profoundly depress the infant's respiration. Respiration should be monitored closely in neonates, and the opioid antagonist naloxone should be readily available.
- Expressions of pain may differ according to age and developmental level. Infants may cry and have muscular rigidity and

thrashing behavior. Preschoolers may behave aggressively or complain verbally of discomfort. Young school-aged children may express pain verbally or behaviorally, often with regression to behaviors used at younger ages. Adolescents may be reluctant to admit they are uncomfortable or need help. With chronic pain, children of all ages tend to withdraw and regress to an earlier stage of development.

- It is recommended that opioids be given by routes (e.g., PO, IV, epidurally) other than IM injections, because IM injections are painful and frightening for children. For any child receiving parenteral opioids, vital signs and level of consciousness must be assessed regularly.
- Opioid formulations for children are not generally available. When children's doses are calculated based on adult doses, the fractions and decimals that often result greatly increase the risk of a dosage error. It is advisable to have two people do the calculations independently and compare results.
- Opioid rectal suppositories are used more often in children than in adults. Although useful when oral or parenteral routes are not indicated, the dose of medication received by the child is unknown because drug absorption is erratic and because adult suppositories are sometimes cut in half or otherwise altered.
- Opioid effects in children may differ from those expected in adults because of physiologic and pharmacokinetic differences. Assess regularly and be alert for unusual signs and symptoms.
- Hydromorphone, methadone, oxycodone, and oxymorphone are not recommended for use in children because safety, efficacy, and dosages have not been established.
- Like adults, children seem more able to cope with pain when they are informed about what is happening to them and are assisted in developing coping strategies. Age-appropriate doll play, a favorite videotape/DVD, diversionary activities, and other techniques can be used effectively. However, such techniques should be used in conjunction with adequate analgesia, not as a substitute for pain medication.

### Use in Older Adults

Opioids should be used cautiously in older adults, especially if they are debilitated; have hepatic, renal, or respiratory impairment; or are receiving other drugs that depress the CNS. Older adults are especially sensitive to respiratory depression, excessive sedation, confusion, and other adverse effects. However, they should receive adequate analgesia, along with vigilant monitoring. Specific recommendations include the following:

- Use nondrug measures (e.g., heat or cold applications, exercise) and nonopioid analgesics to relieve pain, when effective.
- When opioids are needed, use those with short half-lives (e.g., oxycodone, hydromorphone) because they are less likely to accumulate.
- Start with low doses and increase doses gradually, if necessary.

- Give the drugs less often than for younger adults because the duration of action may be longer.
- Monitor carefully for sedation or confusion. Also, monitor voiding and urine output because acute urinary retention is more likely to occur in older adults.
- Assess older adults for ability to self-administer opioids safely. Those with short-term memory loss (common in this population) may require assistance and supervision.

### Use in Clients With Renal Impairment

Most opioids are extensively metabolized in the liver to metabolites that are then excreted in urine. In patients with renal impairment, the drugs should be given in minimal doses, for the shortest effective time, because usual doses may produce profound sedation and a prolonged duration of action. Morphine, for example, produces an active metabolite that may accumulate in patients with renal impairment. Meperidine should not be used because a toxic metabolite, normeperidine, may accumulate. Normeperidine is pharmacologically active and a CNS stimulant that may cause muscle spasms, seizures, and psychosis. These effects are not reversed by an opioid antagonist such as naloxone.

### Use in Clients With Hepatic Impairment

Because opioid analgesics and related drugs are extensively metabolized by the liver, they may accumulate and cause increased adverse effects in the presence of hepatic impairment. Dosages may need to be reduced, especially with chronic use.

### Use in Clients With Critical Illness

Opioids are commonly used to manage pain associated with disease processes and invasive diagnostic and therapeutic procedures. In intensive care units, they are also used concurrently with sedatives and neuromuscular blocking agents, which increases the risks of adverse drug reactions and interactions. In patients with critical illness, opioids are usually given by IV bolus injection or continuous infusion. Guidelines include the following:

- Assume that all critically ill patients are in pain or at high risk for development of pain.
- When pain is thought to be present, identify and treat the underlying cause when possible.
- Assess for pain on a regular schedule around the clock (e.g., every 1 to 2 hours). Use a consistent method for assessing severity, such as a visual analog or numeric scale. If the patient is able to communicate, ask about the location, severity, and so forth. If the patient is unable to communicate needs for pain relief, as is often the case during critical illnesses, the nurse must evaluate posture, body language, risk factors, and other possible indicators of pain.
- Prevent pain when possible. Interventions include being very gentle when performing nursing care to avoid tissue trauma and positioning patients to prevent ischemia, edema, and misalignment. In addition, give analgesics before painful procedures, when indicated.

- When pain occurs, manage it to provide relief and prevent its recurrence. In general, opioids should be given continuously or on a regular schedule of intermittent doses, with supplemental or bolus doses when needed for breakthrough pain. When starting a continuous IV infusion of pain medication, a loading dose should be given to attain therapeutic blood levels quickly.
- Opioids are often given by IV infusion over a prolonged period in patients with trauma and other critical illnesses. They may also be given orally, by transdermal patch, or by epidural infusion, depending on the patient's condition.
- Opioid agonist drugs are preferred; morphine and fentanyl are commonly used. Mixed agonist–antagonist opioids are not recommended for use in critically ill patients. They may cause opioid withdrawal in those who have been receiving chronic opioid therapy and may also cause psychotomimetic effects.
- Consult specialists in pain management (e.g., anesthesiologists, clinical pharmacists, physician) when pain is inadequately controlled with the usual measures.

### Use in Home Care

Opioids are widely used in the home for both acute and chronic pain. With acute pain, such as in postoperative recovery, the use of an opioid is often limited to a short period and patients self-administer their medications. The need for strong pain medication recedes as healing occurs. The home care nurse may teach patients and caregivers safe usage of the drugs (e.g., that the drugs decrease mental alertness and physical agility, so potentially hazardous activities should be avoided), nonpharmacologic methods of managing pain, and ways to prevent adverse effects of opioids (e.g., constipation). Physical dependence is uncommon with short-term use of opioids for acute pain.

With some types of chronic pain, such as those occurring with low back pain or osteoarthritis, opioids are not indicated for long-term use. Treatment involves nonopioid medications, physical therapy, and other measures. The home care nurse may need to explain the reasons for not using opioids on a long-term basis and to help patients and caregivers learn alternative methods of relieving discomfort.

With cancer pain, as previously discussed, the goal of treatment is to prevent or relieve pain and keep patients comfortable, without concern about addiction. Thus, the home care nurse must assist patients and caregivers in understanding the appropriate use of opioids in cancer care, including administration on a regular schedule, storing the drugs to avoid use by persons other than the patient, and avoiding theft and diversion to street use. The nurse also must be proficient in using and teaching various routes of drug administration and in arranging regimens with potentially very large doses and various combinations of drugs. In addition, an active effort is needed to prevent or manage adverse effects, such as a bowel program to prevent constipation.

## Nursing Actions Opioid Analgesics

### NURSING ACTIONS

#### 1. Administer accurately

- Check the rate, depth, and rhythm of respirations before each dose. If the rate is fewer than 12 per minute, delay or omit the dose and report to the physician.
- Have the patient lie down to receive injections of opioid analgesics and for at least a few minutes afterward.
- When injecting opioid analgesics intravenously, give small doses; inject slowly over several minutes; and have opioid antagonist drugs, artificial airways, and equipment for artificial ventilation readily available.
- Put side rails up; instruct the patient not to smoke or try to ambulate without help. Keep the call light within reach.
- When giving controlled-release tablets, do NOT crush them, and instruct the patient not to chew them.
- Follow the manufacturer's instructions re: administration of alternative formulations of fentanyl (e.g., Actiq, Duragesic, Fentora, and Ionsys).

#### 2. Observe for therapeutic effects

- A verbal statement of pain relief
- Decreased behavioral manifestations of pain or discomfort
- Sleeping
- Increased participation in usual activities of daily living, including interactions with other people in the environment
- Fewer and shorter episodes of nonproductive coughing when used for antitussive effects
- Lowered blood pressure, decreased pulse rate, slower and deeper respirations, and less dyspnea when morphine is given for pulmonary edema
- Decreased diarrhea when given for constipating effects

#### 3. Observe for adverse effects

- Respiratory depression—hypoxemia, restlessness, dyspnea, slow, shallow breathing, changes in blood pressure and pulse, decreased ability to cough
- Hypotension
- Excessive sedation—drowsiness, slurred speech, impaired mobility and coordination, stupor, coma
- Nausea and vomiting
- Constipation

### RATIONALE/EXPLANATION

Respiratory depression is a major adverse effect of strong analgesics. Assessing respirations before each dose can help prevent or minimize potentially life-threatening respiratory depression. Prevents or minimizes hypotension, nausea, and vomiting. These effects are more likely to occur in ambulatory patients. Also, patients may be sedated enough to increase risk of falls or other injuries if they try to ambulate. Large doses or rapid intravenous injection may cause severe respiratory depression and hypotension.

To prevent falls or other injuries

Crushing or chewing causes immediate release of the drug, with a high risk of overdose and toxicity. These formulations have specific indications and require special techniques and precautions. Actiq and Fentora are given orally for transmucosal absorption; Duragesic and Ionsys are applied to the skin for transdermal absorption.

Therapeutic effects depend on the reason for use, usually for analgesic effects but sometimes for antitussive or antidiarrheal effects.

Opioids relieve cough by depressing the cough center in the medulla oblongata.

Morphine may relieve pulmonary edema by causing vasodilation, which in turn decreases venous return to the heart and decreases cardiac work.

These drugs slow secretions and motility of the GI tract. Constipation is usually an adverse effect. However, in severe diarrhea or with ileostomy, the drugs decrease the number of bowel movements and make the consistency more paste-like than liquid.

Respiratory depression is a major adverse effect of opioids and results from depression of the respiratory center in the medulla oblongata. It occurs with usual therapeutic doses and increases in incidence and severity with large doses or frequent administration. *It is especially likely to occur when an opioid is first started and when dosage is increased.*

Hypotension stems from drug effects on the vasomotor center in the medulla oblongata that cause peripheral vasodilation and lowering of blood pressure. This is a therapeutic effect with pulmonary edema.

This is caused by depression of the central nervous system (CNS) and is potentially life threatening.

Opioids stimulate the chemoreceptor trigger zone in the brain. Thus, nausea and vomiting may occur with various routes of administration. They are more likely to occur with ambulation than with recumbency.

This is caused by the drug's slowing effects on the GI tract. Constipation may be prevented or treated by increased activity, adequate intake of fluid and fiber, and regular administration of stool softeners (e.g., docusate) and stimulant laxatives (e.g., bisacodyl).

## NURSING ACTIONS

## 4. Observe for drug interactions

- a. Drugs that increase effects of opioids:
- (1) CNS depressants—alcohol, general anesthetics, benzodiazepine antianxiety and hypnotic agents, tricyclic antidepressants, sedating antihistamines, antipsychotic agents, barbiturates, and other drugs that cause sedation
  - (2) Anticholinergics—atropine and other drugs with anticholinergic effects (e.g., antihistamines, tricyclic antidepressants, phenothiazine antipsychotic drugs)
  - (3) Antihypertensive drugs
  - (4) Monoamine oxidase (MAO) inhibitors
  - (5) Protease inhibitors—ritonavir, saquinavir, others
  - (6) Cimetidine (Tagamet)
- b. Drugs that decrease effects of opioids:
- (1) Opioid antagonist (Narcan)
  - (2) Butorphanol, nalbuphine

## RATIONALE/EXPLANATION

All these drugs alone, as well as the opioids, produce CNS depression. When combined, additive CNS depression results. If dosage of one or more interacting drugs is high, severe respiratory depression, coma, and death may ensue.

Increased constipation and urinary retention

Orthostatic hypotension, an adverse effect of both strong analgesics and antihypertensive drugs, may be increased if the two drug groups are given concurrently. These drugs interfere with detoxification of some opioid analgesics, especially meperidine. They may cause additive CNS depression with hypotension and respiratory depression or CNS stimulation with hyperexcitability and convulsions. If an MAO inhibitor is necessary, dosage should be reduced because the combination is potentially life threatening. May increase CNS and respiratory depression. May increase CNS and respiratory depression by inhibiting the cytochrome P450 enzymes that normally metabolize opioids.

Narcan reverses respiratory depression produced by opioids; it does not reverse respiratory depression caused by other CNS depressants.

These analgesics are weak antagonists of opioid analgesics, and they may cause withdrawal symptoms in people who have been receiving opiates or who are physically dependent on opioids.

## Key Concepts

- All patients should be assessed for pain. Acute pain may be manifested verbally or by behavior that indicates discomfort; chronic pain may not be characterized by visible signs and is often accompanied by anxiety and depression. If present, pain should be managed effectively, often with a combination of strategies that may include nonpharmacologic treatments, nonopioid analgesics, opioid analgesics, and adjuvant drugs.
- Pain occurs when tissue damage activates free nerve endings (nociceptors) of peripheral nerves. Pain signals are carried from the site of tissue damage to the spinal cord by A-delta and C nerve fibers, then are relayed to the brain where they are perceived as pain.
- Endorphins and enkephalins react with opioid receptors in the CNS to inhibit transmission of pain signals.
- Opioid analgesics react with opioid receptors in the CNS and peripheral tissues to inhibit transmission of pain signals, to reduce the perception of pain, and to reduce the emotional upsets often associated with pain.
- Most opioid analgesics are Schedule II controlled drugs and may cause serious adverse effects (respiratory depression, sedation) and physical dependence. As a result, they all have **BLACK BOX WARNINGS** regarding safe and appropriate use.
- Opioid agonist drugs stimulate opioid receptors; agonists/antagonists have agonist activity at some receptors and antagonist activity at others; antagonists reverse or block the effects of agonists.
- Opioid selection, dosage, and route of administration should be individualized according to the patient's condition.
- For most acute and chronic pain, analgesics are more effective if given on a regular schedule around the clock. When acute pain has subsided or occurs at irregular intervals and when breakthrough pain occurs in patients receiving long-term analgesic therapy for chronic pain, analgesics can be given as needed.

- For patients who require large doses of opioids to relieve their pain, additional medications and interventions are often needed to manage adverse effects (e.g., nausea, constipation).
- Pain-relieving interventions must be documented in patient's records and patients must be assessed to determine whether the interventions were effective.

## Review and Application Exercises

### Short Answer Exercises

1. When assessing a patient for pain, what are the major considerations?
2. What are some nonpharmacologic interventions for pain, and why should they be used instead of or along with analgesics?
3. What are the major adverse effects of opioid analgesics? How do opioid antagonists counteract adverse effects?
4. For a patient who has had major surgery during the previous 24 to 72 hours, what type of analgesic is indicated? Why?
5. What are the potential differences in dosage between short-term (a few days) and long-term (weeks or months) administration of morphine?
6. Explain the rationale for using both opioid analgesics and nonopioid analgesics in the treatment of pain.
7. For a patient with chronic cancer pain, what are the advantages and disadvantages of using opioid analgesics?
8. For a patient with chronic cancer pain, should opioid analgesics be given as needed or on a regular schedule? Why?
9. For a patient who is receiving large doses of an opioid analgesic, what signs and symptoms may indicate drug toxicity or overdose? What interventions are needed for suspected toxicity?
10. For a patient who has been taking an opioid analgesic for a long time, what signs and symptoms would make you suspect opioid withdrawal? What interventions are needed for suspected withdrawal?
11. When caring for a patient who is receiving morphine, it is most important that the nurse regularly assess for which of the following?
  - a. respiratory depression
  - b. hyperactive bowel sounds
  - c. frequent urination
  - d. insomnia
12. The nurse is caring for a patient with terminal cancer, who requires significant pain relief. Her family is concerned about addiction. The nurse is most correct in explaining that long-term administration of an opioid under medical supervision does not result in addiction but does result in
  - a. tolerance
  - b. overdose
  - c. withdrawal
  - d. hepatotoxicity
13. A postoperative surgical patient is prescribed patient-controlled analgesia, but his family questions why his pain medication is being given in this manner. The nurse is most correct in explaining that the main advantage of patient-controlled analgesia systems is that they
  - a. require less nursing time
  - b. cause fewer adverse effects
  - c. relieve pain more effectively
  - d. can be used long term
14. The nurse is caring for a patient with severe cancer pain. The family is questioning when analgesics should be given. The nurse is correct in explaining that in cases of severe pain, analgesics should be given
  - a. when the patient asks for them
  - b. if a family member or friend asks that they be given
  - c. when a patient is restless
  - d. on a regular schedule, around-the-clock

### NCLEX-Style Questions

11. In administering opioid analgesics to a patient, it is most important that the nurse know that opioid analgesics act mainly by
  - a. causing sleep
  - b. binding with opioid receptors in the brain and spinal cord
  - c. increasing transmission of pain impulses between nerve cells
  - d. decreasing the amount of norepinephrine and serotonin in synapses in the brain

# Analgesic–Antipyretic– Anti-Inflammatory and Related Drugs

## KEY TERMS

- Anti-inflammatory
- Antiprostaglandin drugs
- Antipyretic
- Arachidonic acid
- Cyclooxygenase (COX)
- Disease-modifying antirheumatic drugs (DMARDs)
- Dysmenorrhea
- Hyperuricemia
- Nonsteroidal anti-inflammatory drugs (NSAIDs)
- Prostaglandins
- Pyrogens
- Reye's syndrome
- Salicylism
- Tophi
- Uricosuric

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Discuss the role of prostaglandins in the etiology of pain, fever, and inflammation.
2. Discuss aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) in terms of mechanism of action, indications for use, contraindications to use, nursing process, and principles of therapy.
3. Compare and contrast aspirin, other NSAIDs, and acetaminophen in terms of indications for use and adverse effects.
4. Differentiate among antiplatelet, analgesic, and anti-inflammatory doses of aspirin.
5. Differentiate between nonselective NSAIDs and the cyclooxygenase-2 inhibitor, celecoxib.
6. Teach patients interventions to prevent or decrease adverse effects of aspirin, other NSAIDs, and acetaminophen.
7. Identify factors influencing the use of aspirin, NSAIDs, and acetaminophen in special populations.
8. Discuss recognition and management of acetaminophen toxicity.
9. Discuss the use of NSAIDs and antigout drugs.
10. Discuss the use of NSAIDs, triptans, and ergot antimigraine drugs.

## Applying Your Knowledge

Julie McKay is a 32-year-old woman who has chronic headache pain. Her first headaches began at age 18 as a combination of migraine type and tension headaches. For acute pain, she uses a combination of Excedrin Migraine (acetaminophen 250 mg, ASA 250 mg, and caffeine 65 mg per tablet), extra-strength acetaminophen (500 mg per tablet), and naproxen sodium (550 mg per tablet). For a typical headache, Julie takes two naproxen sodium tablets at the onset of her pain, followed by two tablets of the acetaminophen every 4 hours and two Excedrin Migraine tablets every 4 hours, starting 2 hours after the acetaminophen. If the pain is not relieved, she takes one naproxen sodium tablet in 12 hours and continues with the Excedrin Migraine and acetaminophen. The headache may last from 3 to 5 days.

## Introduction

The analgesic–antipyretic–anti-inflammatory drug group includes chemically and pharmacologically diverse drugs that share the ability to relieve pain, fever, and/or inflammation, symptoms associated with many injuries and illnesses. Drugs discussed in this chapter include

- **P Aspirin** (acetylsalicylic acid [ASA]) (the prototype NSAID)
- Other *nonsteroidal anti-inflammatory drugs (NSAIDs)*
- Acetaminophen
- Drugs used to prevent or treat gout and migraine

Aspirin, NSAIDs, and acetaminophen can also be called *antiprostaglandin drugs*, because they inhibit the synthesis of *prostaglandins*. Prostaglandins are chemical mediators found in most body tissues; they help regulate many cell functions and participate in the inflammatory response. They are formed when cellular injury occurs and phospholipids in cell membranes release *arachidonic acid*. Arachidonic acid is then metabolized by *cyclooxygenase (COX)* enzymes to produce prostaglandins, which act briefly in the area where they are produced and are then inactivated. Prostaglandins exert various and opposing effects in different body tissues (Table 7-1). The role of prostaglandins in mediating pain, fever, and inflammation are described in the following sections.

### Pain

Pain is the sensation of discomfort, hurt, or distress. It is a common human ailment and may occur with tissue injury and inflammation. Prostaglandins sensitize pain receptors and increase the pain associated with other chemical mediators of inflammation and immunity, such as bradykinin, histamine, and leukotrienes (Box 7-1).

### Fever

Fever is an elevation of body temperature above the normal range. Body temperature is controlled by a regulating center in the hypothalamus. Normally, there is a balance between heat

production and heat loss so that a constant body temperature is maintained. When there is excessive heat production, mechanisms to increase heat loss are activated. As a result, blood vessels dilate, more blood flows through the skin, sweating occurs, and body temperature usually stays within normal range.

Fever occurs when the set point of the hypothalamus is raised in response to the presence of *pyrogens* (fever-producing agents). Endogenous pyrogens include cytokines such as interleukin-1, interleukin-6, and tumor necrosis factor (Box 7-1). Exogenous pyrogens include bacteria and their toxins or other byproducts. The upward adjustment of the hypothalamic set point in response to the presence of a pyrogen is mediated by prostaglandin E<sub>2</sub> (see Table 7-1). The body responds to the higher hypothalamic set point by vasoconstriction of blood vessels and shivering, raising the core body temperature to the higher set point. Fever may accompany conditions such as dehydration, inflammation, infectious processes, some drugs, brain injury, or diseases involving the hypothalamus.

### Inflammation

Inflammation is the normal body response to tissue damage from any source, and it may occur in any tissue or organ. It is an attempt by the body to remove the damaging agent and repair the damaged tissue. The signs and symptoms of inflammation are the work of a variety of chemical mediators (Box 7-1). Prostaglandin E<sub>2</sub> and others induce inflammation and also enhance the effects of other mediators of the inflammatory response. Local manifestations are redness, heat, edema, and pain. Redness and heat result from vasodilation and increased blood supply. Edema results from leakage of blood plasma into the area. Pain occurs when pain receptors on nerve endings are stimulated by heat, edema, and pressure; chemicals released by

Table 7-1

GI, gastrointestinal.

## Box 7-1

## Chemical Mediators of Inflammation and Immunity

*Bradykinin* is a kinin in body fluids that becomes physiologically active with tissue injury. When tissue cells are damaged, white blood cells (WBCs) increase in the area and ingest damaged cells to remove them from the area. When the WBCs die, they release enzymes that activate kinins. The activated kinins increase and prolong the vasodilation and increased vascular permeability caused by histamine. They also cause pain by stimulating nerve endings for pain in the area. Thus, bradykinin may aggravate and prolong the erythema, heat, and pain of local inflammatory reactions. It also increases mucous gland secretion.

*Complement* is a group of plasma proteins essential to normal inflammatory and immunologic processes. More specifically, complement destroys cell membranes of body cells (e.g., red blood cells, lymphocytes, platelets) and pathogenic microorganisms (e.g., bacteria, viruses). The system is initiated by an antigen–antibody reaction or by tissue injury. Components of the system (called C1 through C9) are activated in a cascade type of reaction in which each component becomes a proteolytic enzyme that splits the next component in the series. Activation yields products with profound inflammatory effects. C3a and C5a, also called *anaphylatoxins*, act mainly by liberating histamine from mast cells and platelets, and their effects are therefore similar to those of histamine. C3a causes or increases smooth muscle contraction, vasodilation, vascular permeability, degranulation of mast cells and basophils, and secretion of lysosomal enzymes by leukocytes. C5a performs the same functions as C3a and also promotes movement of WBCs into the injured area (chemotaxis). In addition, it activates the lipoxygenase pathway of arachidonic acid metabolism in neutrophils and macrophages, thereby inducing formation of leukotrienes and other substances that increase vascular permeability and chemotaxis.

In the immune response, the complement system breaks down antigen–antibody complexes, especially those in which the antigen is a microbial agent. It enables the body to produce inflammation and localize an infective agent. More specific reactions include increased vascular permeability, chemotaxis, and opsonization (coating a microbe or other antigen so it can be more readily phagocytized).

*Cytokines* may act on the cells that produce them, on surrounding cells, or on distant cells if sufficient amounts reach the bloodstream. Thus, cytokines act locally and systemically to produce inflammatory and immune responses, including increased vascular permeability and chemotaxis of macrophages, neutrophils, and basophils. Two major types of cytokines are interleukins (produced by leukocytes) and interferons (produced by T lymphocytes or fibroblasts). Interleukin-1 (IL-1) mediates several inflammatory responses, including fever; and IL-2 (also called T-cell growth factor) is required for the growth and function of T lymphocytes. Interferons are cytokines that protect nearby cells from invasion by intracellular microorganisms, such as viruses and rickettsiae. They also limit the growth of some cancer cells.

*Histamine* is formed (from the amino acid histidine) and stored in most body tissue, with high concentrations in mast

cells, basophils, and platelets. Mast cells, which are abundant in skin and connective tissue, release histamine into the vascular system in response to stimuli (e.g., antigen–antibody reaction, tissue injury, and some drugs). After it is released, histamine is highly vasoactive, causing vasodilation (increasing blood flow to the area and producing hypotension) and increasing permeability of capillaries and venules (producing edema). Other effects include contracting smooth muscles in the bronchi (producing bronchoconstriction and respiratory distress), gastrointestinal (GI) tract, and uterus; stimulating salivary, gastric, bronchial, and intestinal secretions; stimulating sensory nerve endings to cause pain and itching; and stimulating movement of eosinophils into injured tissue. Histamine is the first chemical mediator released in the inflammatory response and immediate hypersensitivity reactions (anaphylaxis).

When histamine is released from mast cells and basophils, it diffuses rapidly into other tissues. It then acts on target tissues through both histamine-1 ( $H_1$ ) and histamine-2 ( $H_2$ ) receptors.  $H_1$  receptors are located mainly on smooth muscle cells in blood vessels and the respiratory and GI tracts. When histamine binds with these receptors, resulting events include contraction of smooth muscle, increased vascular permeability, production of nasal mucus, stimulation of sensory nerves, pruritus, and dilation of capillaries in the skin.  $H_2$  receptors are also located in the airways, GI tract, and other tissues. When histamine binds to these receptors, there is increased secretion of gastric acid by parietal cells in the stomach mucosal lining, increased mucus secretion and bronchodilation in the airways, contraction of esophageal muscles, tachycardia, inhibition of lymphocyte function, and degranulation of basophils (with additional release of histamine and other mediators) in the bloodstream. In allergic reactions, both types of receptors mediate hypotension (in anaphylaxis), skin flushing, and headache. The peak effects of histamine occur within 1 to 2 minutes of its release and may last as long as 10 minutes, after which it is inactivated by histaminase (produced by eosinophils) or *N*-methyltransferase.

*Leukotrienes*, like prostaglandins, are derived from arachidonic acid metabolism. Leukotrienes, identified as  $LTB_4$ ,  $LTC_4$ ,  $LTD_4$ , and  $LTE_4$ , mediate inflammation and immune responses.  $LTB_4$  plays a role in chemotaxis, mediating the aggregation of leukocytes at sites of injury.  $LTC_4$ ,  $LTD_4$ , and  $LTE_4$  produce smooth muscle contractility, bronchospasm, and increased vascular permeability.

Nitric oxide (NO) is synthesized by a variety of cells by the enzyme NO synthase from the amino acid arginine. It readily diffuses across cell membranes, where it reacts with a wide variety of molecules and is inactivated. NO inhibits aggregation of platelets, preventing formation of blood clots. NO relaxes smooth muscles in blood vessels, producing vasodilation. It inhibits inflammation in the walls of blood vessels. NO also plays a role in protecting against invading microbes. Helper T lymphocytes, active in the inflammatory response, secrete NO. NO also enhances the killing of phagocytized microbes within the lysosomes of cells.

*Platelet-activating factor (PAF)*, like prostaglandins and leukotrienes, is derived from arachidonic acid metabolism and has multiple inflammatory activities. It is produced by mast cells, neutrophils, monocytes, and platelets. Because these cells are widely distributed, PAF effects can occur in virtually every

organ and tissue. Besides causing platelet aggregation, PAF activates neutrophils, attracts eosinophils, increases vascular permeability, causes vasodilation, and causes IL-1 and tumor necrosis factor–alpha (TNF-alpha) to be released. PAF, IL-1, and TNF-alpha can induce each other's release.

the damaged cells; and prostaglandins. Systemic manifestations include leukocytosis, increased erythrocyte sedimentation rate, fever, headache, loss of appetite, lethargy or malaise, and weakness. Both local and systemic manifestations vary according to the cause and extent of tissue damage. In addition, inflammation may be acute or chronic.

Inflammation may be a component of virtually any illness. Inflammatory conditions affecting organs or systems are often named by adding the suffix “itis” to the involved organ or system (e.g., hepatitis). Current research findings suggest that inflammation may be important in the pathology of disorders (not previously identified as inflammatory conditions) such as heart disease and Alzheimer's disease. *Anti-inflammatory* drugs are indicated when the inflammatory response is inappropriate, abnormal or persistent, or destroys tissue.

## General Characteristics of Analgesic–Antipyretic–Anti-Inflammatory and Related Drugs

### Mechanism of Action

Aspirin and other NSAIDs inhibit prostaglandin synthesis in both the central nervous system (CNS) and the peripheral nervous system. The action of acetaminophen on prostaglandin inhibition is limited to the CNS. This selective action may explain the inability of acetaminophen to reduce inflammation and the absence of adverse effects in the gastrointestinal (GI) tract, kidneys, and platelets. Aspirin, other NSAIDs, and acetaminophen inhibit the COX enzymes, which are required for prostaglandin formation (Fig. 7-1). Two forms of cyclooxygenase, COX-1 and COX-2, have been identified. Aspirin and other nonselective NSAIDs inhibit both COX-1 and COX-2. The COX-2 inhibitor, celecoxib, is more selective for the COX-2 enzyme. The exact mechanism of action of acetaminophen is unclear.

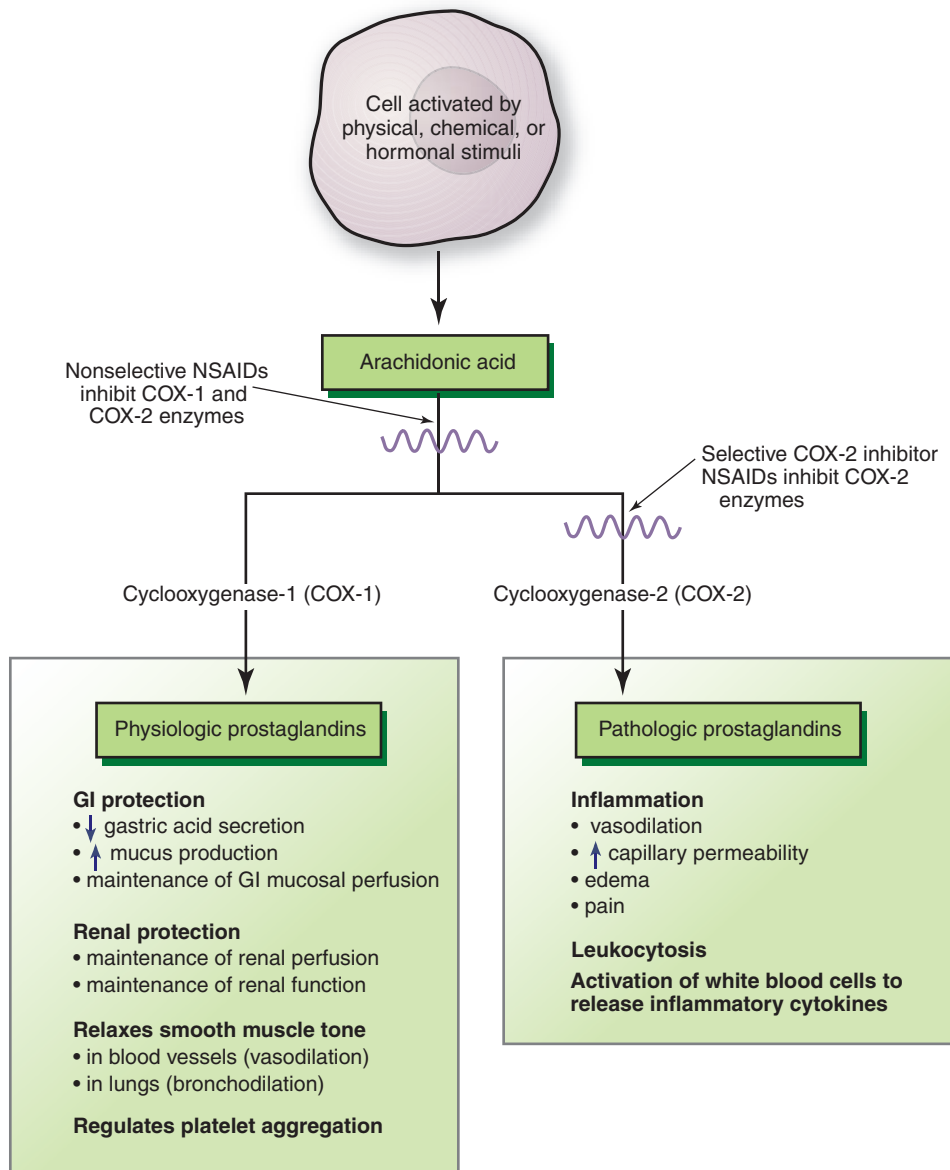

COX-1 is normally synthesized continuously and is present in all tissues and cell types, especially platelets, endothelial cells, the GI tract, and the kidneys. Prostaglandins produced by COX-1 are important in numerous homeostatic functions and are associated with protective effects on the stomach and kidneys. In the stomach, prostaglandins decrease gastric acid secretion, increase mucus secretion, and regulate blood circulation. In the kidneys, they help maintain adequate blood flow and function. In the cardiovascular system, they help regulate vascular tone (i.e., vasoconstriction and vasodilation) and

platelet function. Drug-induced inhibition of these prostaglandins results in the adverse effects associated with aspirin and related nonselective NSAIDs, especially gastric irritation, ulceration, and bleeding. Inhibition of COX-1 activity in platelets may be more responsible for GI bleeding than inhibition in gastric mucosa.

COX-2 is also normally present in several tissues (e.g., brain, bone, kidneys, GI tract, female reproductive system). However, it is thought to occur in small amounts or to be inactive until stimulated by pain and inflammation. In inflamed tissues, COX-2 is induced by inflammatory chemical mediators such as interleukin-1 and tumor necrosis factor–alpha. In the GI tract, COX-2 is also induced by trauma and *Helicobacter pylori* infection, a common cause of peptic ulcer disease. Overall, prostaglandins produced by COX-2 are associated with pain and other signs of inflammation. Inhibition of COX-2 results in the therapeutic effects of analgesia and anti-inflammatory activity. The COX-2 inhibitor drugs are NSAIDs designed to selectively inhibit COX-2 and relieve pain and inflammation with fewer adverse effects, especially stomach damage; however, with long-term use, adverse effects still occur in the GI, renal, and cardiovascular systems.

Aspirin relieves pain by acting both centrally and peripherally to block the transmission of pain impulses. Related drugs act peripherally to prevent sensitization of pain receptors to various chemical substances released by damaged cells. To relieve fever, the drugs act on the hypothalamus to decrease its response to pyrogens and reset the “thermostat” at a lower level. For inflammation, the drugs prevent prostaglandins from increasing the pain and edema produced by other substances released by damaged cells. Although these drugs relieve symptoms and contribute greatly to the patient's comfort and quality of life, they do not cure the underlying disorders that cause the symptoms.

Aspirin and nonselective NSAIDs also have antiplatelet effects that differ in mechanism and extent. When aspirin is absorbed into the bloodstream, the acetyl portion dissociates and then binds irreversibly to platelet COX-1. This action prevents synthesis of thromboxane A<sub>2</sub>, a prostaglandin derivative, thereby inhibiting platelet aggregation. A small single dose (325 mg) irreversibly acetylates circulating platelets within a few minutes, and effects last for the lifespan of the platelets (7 to 10 days). Most other NSAIDs bind reversibly with platelet COX-1 so that antiplatelet effects occur only while the drug is present in the blood. Thus, aspirin has greater effects, but all the drugs except acetaminophen and the COX-2 inhibitors inhibit platelet aggregation, interfere with blood coagulation, and increase the risk of bleeding.

**Figure 7-1** ■ Arachidonic acid metabolic pathways result in production of physiologic and pathologic (i.e., inflammatory) prostaglandins. Nonselective and selective NSAIDs inhibit production of prostaglandins by inhibiting steps in the arachidonic acid pathway.

## Indications for Use

Despite many similarities, aspirin, other NSAIDs, and acetaminophen differ in their approved uses.

### To Treat Inflammatory Disorders

Aspirin and other NSAIDs are widely used to prevent and treat mild to moderate pain and inflammation associated with musculoskeletal disorders (e.g., degenerative joint disease, rheumatoid arthritis, bursitis). Acetaminophen lacks anti-inflammatory effects but may be useful as an analgesic.

Degenerative joint disease (DJD), also known as osteoarthritis (OA), is a disease that affects the articular cartilage, subchondral bone, and synovium of weight-bearing joints. The joints of the fingers may also be affected by OA. Signs and symptoms of OA include pain, stiffness, and functional impairment. As joint cartilage deteriorates, over time there is less padding and lubricating fluid, underlying bone is exposed, and

friction and abrasion lead to inflammation of the synovial membrane lining of the joint. Deformity of the joint occurs as the disease advances.

Rheumatoid arthritis (RA) is a chronic, painful, inflammatory disorder that affects the synovial tissue of hinge-like joints, tissues around these joints, and eventually other body organs are involved (systemic effects). It is an autoimmune disorder characterized by an inflammatory and immune reaction against the body's own tissues. Juvenile rheumatoid arthritis is a chronic, inflammatory, systemic disease that may cause joint or connective tissue damage and visceral lesions throughout the body. Onset may occur before 16 years of age.

Bursitis is an inflammation of the bursa (a cavity in connective tissue that contains synovial fluid; the fluid reduces friction between tendons and bones or ligaments). Common forms include acute painful shoulder, "tennis elbow," "housemaid's knee," and bunions.

### To Relieve Pain

Aspirin, other NSAIDs, and acetaminophen are effective in treating mild to moderate pain associated with conditions such as headache, minor trauma (e.g., athletic injuries such as sprains), minor surgery (e.g., dental extraction, episiotomy), and other acute and chronic conditions. These drugs are not recommended to treat pain arising from a visceral origin. Ketorolac (Toradol) is a nonselective NSAID that is used only as an analgesic. Aspirin and other NSAIDs are also effective in relieving *dysmenorrhea* (pain associated with menstruation) since these drugs inhibit prostaglandin-mediated uterine contractions.

### To Reduce Fever

Aspirin, other NSAIDs (i.e., ibuprofen), and acetaminophen are all effective in reducing fever in adults. Due to the risk of Reye's syndrome (see contraindications below), aspirin should not be used to treat fever in children.

### To Suppress Platelet Aggregation

Low-dose aspirin is indicated for patients that have experienced an ischemic stroke, transient ischemic attack, angina, acute MI, or previous MI, reducing the risk of death and/or recurrent event (Level A). This indication stems from its antiplatelet activity and resultant effects on blood coagulation (i.e., decreased clot formation). Low-dose aspirin can also be used for primary prevention of MI or stroke in healthy adults. Studies such as the Women's Health Study (Ridker, 2005) reveal benefits of this application vary by age, gender, and condition. In this study, aspirin was effective in reducing risk of first MI in men of all ages and women older than 65 years. Aspirin did not afford protection from first MI in women from 40 to 60 years of age. Aspirin reduced risk of first stroke in women of all ages, but no reduction in risk was observed in men. Aspirin was effective in reducing second MI or stroke in both genders, and this effect was not age dependent. In some individuals, aspirin may fail to reduce platelet aggregation, resulting in increased risk for adverse vascular events. Aspirin resistance is described further in Evidence-Based Practice Box 7-1.

Low-dose aspirin (150 mg/day preoperatively and continued for 35 days), unless contraindicated, is also effective for prophylaxis of asymptomatic and symptomatic venous thromboembolism (VTE) in surgical patients (Level A). Additional guidelines for thromboembolism prophylaxis include use of a single dose of aspirin (150 mg) before long distance travel for individuals at high risk for VTE if not contraindicated by other conditions (Level D)

### Other Indications

Several studies suggest that use of aspirin and other NSAIDs may protect against development of Alzheimer's disease and a variety of cancers (e.g., colorectal, breast, ovarian, and prostate). These possible benefits are only evident with long-term use and at high doses. The benefits versus risk of side effects such as GI bleeding are unclear at this time. No studies demonstrated any protective benefits from low-dose aspirin therapy. Celecoxib (Celebrex), a COX-2 inhibitor, is used to

## Evidence-Based Practice

### 7-1 Aspirin Resistance

Aspirin resistance can be operationally defined as the failure of aspirin to reduce platelet aggregation resulting in an adverse vascular event such as an MI or stroke. The reported frequency of aspirin resistance is highly variable, ranging from 5.2% up to 60%. Measuring the frequency of aspirin resistance with accuracy is difficult due to the lack of a reliable test to measure the effect of aspirin on platelets. The etiology of aspirin resistance, and even its existence, is hotly debated in the literature; the mechanism of aspirin resistance is unclear. Proposed reasons for aspirin resistance include increased sensitivity of the platelets to the platelet-aggregating effects of collagen; genetic variations in glycoprotein IIA (part of the fibrinogen receptor on platelets); altered drug targets such as a COX-1 polymorphism; poor patient compliance; interactions with nonselective NSAIDs such as ibuprofen, which may compete for COX-1 binding sites; and poor gastrointestinal absorption. Some studies have suggested that aspirin resistance may actually be a dose-related phenomenon, proposing that aspirin-resistant patients might have achieved inhibition of platelet aggregation at higher aspirin doses. Studies have also suggested that aspirin resistance changes over time and may be related to daily variations in platelet activity.

Low-dose aspirin therapy is a Level A recommendation in the evidence-based practice guidelines for prevention of serious vascular events in healthy individuals as well as those at high risk for thrombotic events. An estimated 26 million patients in the United States take ASA therapy to prevent myocardial infarctions and strokes. An aspirin resistance rate of 15% would translate into almost 4 million individuals at risk of a serious vascular event due to treatment failure. The clinical impact of this issue is immense.

treat familial adenomatous polyposis, in which the drug reduces the number of polyps and may decrease risks of colon cancer. Several NSAIDs are formulated as eye drops for use in treating eye disorders (see Chap. 63).

### Contraindications to Use

The Food and Drug Administration (FDA) has issued a **BLACK BOX WARNING** regarding increased risk of serious GI adverse events including bleeding, ulceration, and perforation of the stomach and intestines with use of nonselective NSAIDs as well as the selective COX-2 inhibitor, celecoxib. Although celecoxib was formulated to have fewer adverse effects in the GI tract and renal system, long-term use and/or high dosages can result in GI bleeding and renal impairment. Consequently, all NSAIDs and aspirin are contraindicated in the presence of peptic ulcer disease, GI or other bleeding disorders, and impaired renal function. In addition, celecoxib is contraindicated in patients who are allergic to sulfonamides.

In people who have demonstrated hypersensitivity to aspirin, all nonaspirin NSAIDs are also contraindicated because cross-hypersensitivity reactions may occur with any drugs that inhibit prostaglandin synthesis. Over-the-counter (OTC) products containing acetaminophen or aspirin/NSAIDs are contraindicated for chronic alcohol abusers because of possible liver damage (acetaminophen) or stomach bleeding (aspirin and other NSAIDs). The FDA requires an alcohol warning label on all OTC pain relievers and fever reducers. This warning states that people who drink three or more alcoholic drinks daily should ask their health care provider before taking the products.

In children and adolescents, aspirin is contraindicated in the presence of viral infections such as influenza or chickenpox because of its association with *Reye's syndrome*. In pregnancy, aspirin is categorized as Pregnancy Risk Category D. Risks to the pregnant woman include anemia from GI blood loss and postpartum hemorrhage. Potential risks to the fetus include low birth weight, premature closure of the ductus arteriosus, renal toxicity, intracranial hemorrhage, and stillbirth. Furthermore, the safety of most nonselective NSAIDs during pregnancy has not been established.

Ketorolac, an injectable NSAID often used for pain, is contraindicated in patients at risk of excessive bleeding. Thus, ketorolac should not be administered during labor and delivery, before or during any major surgery, with suspected or confirmed cerebrovascular bleeding, or to patients who are currently taking aspirin or other NSAIDs.

The FDA has issued a **BLACK BOX WARNING** regarding increased risk of serious cardiovascular thrombotic events, myocardial infarction, and stroke with use of selective and nonselective NSAIDs. This risk may be increased with long-term use or in patients with history of cardiovascular disease or risk factors for cardiovascular disease. Three COX-2 inhibitors have been marketed in the United States: celecoxib (Celebrex), rofecoxib (Vioxx), and valdecoxib (Bextra). Only celecoxib remains available for prescription at this time. Rofecoxib was voluntarily withdrawn from the market amid concerns resulting from evidence gathered in the Adenomatous Polyp Prevention on Vioxx (APPROVe) study, which showed a significant increase in myocardial infarctions and strokes in subjects receiving rofecoxib versus a placebo. Subsequent review of data from prevention studies involving celecoxib (National Cancer Institute's Adenoma Prevention with Celecoxib trial, or APC trial) and short-term studies of valdecoxib after coronary artery bypass grafting (CABG) surgery indicated that these drugs may also be associated with an increased risk of myocardial infarctions and strokes when used for long periods of time or in high-risk clinical situations such as immediately after heart surgery. In April 2005, valdecoxib was withdrawn from the U.S. market based on data suggesting increased potential for adverse cardiovascular events as well as an increased risk of serious skin reactions such as toxic epidermal necrolysis, Stevens-Johnson syndrome, and erythema multiforme. Although data from long-term clinical trials suggest that nonselective NSAIDs may also be associated with

increased cardiovascular risk, short-term use of low doses of NSAIDs for pain relief does not appear to increase the risk of adverse cardiovascular events (with the exception of valdecoxib in post-CABG patients).

A closer look at the function of two contrasting prostaglandin products of the COX enzymes (in vitro) may suggest a possible mechanism for the occurrence of adverse cardiovascular events with long-term use of COX-2 inhibitors. Prostaglandin I<sub>2</sub>, a prostaglandin product of COX-2, has been shown to be responsible for inhibition of platelet aggregation, vasodilation, and prevention of proliferation of vascular smooth muscle cells. Thromboxane A<sub>2</sub>, a prostaglandin product of COX-1, causes platelet aggregation, vasoconstriction, and vascular proliferation. Aspirin and older nonselective NSAIDs inhibit both prostaglandin I<sub>2</sub> and thromboxane A<sub>2</sub> formation, though the COX-2 inhibitor medications inhibit only prostaglandin I<sub>2</sub> formation, leaving thromboxane A<sub>2</sub> unopposed. It has been proposed that this imbalance may lead to an increased risk of thrombotic events, elevated blood pressure, and accelerated atherogenesis and ultimately an increased risk of cardiovascular events such as myocardial infarction and thrombotic stroke. Although this proposed mechanism is possible, the increased risk of adverse cardiovascular events with long-term use of some nonselective NSAIDs, which inhibit both COX-1 and COX-2 enzymes, cannot be fully explained by this mechanism. Research is ongoing to identify the mechanisms underlying cardiovascular risks associated with selective COX-2 inhibitors.

COX-2 inhibitors may be appropriate for patients at high risk of GI bleeding or for those individuals with intolerance to the nonselective NSAIDs; however, prescribers should carefully evaluate the patient's risk for cardiovascular events before prescribing these drugs. Further FDA review of studies involving NSAIDs and cardiovascular risk is ongoing and may result in additional recommendations in the future.

## Classifications and Individual Drugs

Subgroups and selected individual drugs are described below. Indications for use, trade names, and dosage ranges of individual drugs are listed in Table 7-2.

### Aspirin and Other Salicylates

**P** **Aspirin** is the prototype of the analgesic–antipyretic–anti-inflammatory drugs and the most commonly used salicylate. Because it is a nonprescription drug and is widely available, people tend to underestimate its usefulness. It can be purchased in plain, chewable, enteric-coated, and effervescent tablets and rectal suppositories. It is not marketed in liquid form because it is unstable in solution.

Regular aspirin tablets are well absorbed after oral administration; their action starts within 15 to 30 minutes, peaks in 1 to 2 hours, and lasts 4 to 6 hours. Taking aspirin with food

Table 7-2

**Drugs at a Glance: Analgesic, Antipyretic, Anti-Inflammatory Drugs**

Generic/Trade Name	Indications for Use	ROUTES AND DOSAGE RANGES		
		Adults	Children	Comments
<b>Acetaminophen</b> (Tylenol, others)	Pain Fever	PO 325–650 mg q4–6h, or 1000 mg three or four times per day; maximum 4 g/d  Rectal suppository 650 mg q4–6h, maximum of 6 in 24 h	PO 10 mg/kg or according to age as follows: 0–3 mo, 40 mg; 4–11 mo, 80 mg; 1–2 y, 120 mg; 2–3 y, 160 mg; 4–5 y, 240 mg; 6–8 y, 320 mg; 9–10 y, 400 mg; 11 y, 480 mg. Doses may be given q4–6h to a maximum of 5 doses in 24 h.  Rectal suppository: age under 3 y, consult physician; age 3–6 y, 120 mg q4–6h, maximum, 720 mg in 24 h; age 6–12 y, 325 mg q4–6h, maximum 2.6 g in 24 h	<b>Warning:</b> Overdoses may cause fatal liver damage. Maximum recommended dose for adults is 4 g/d, from all sources. Parents and caregivers should ask pediatricians about the amounts of acetaminophen children may take safely.
<b>P Aspirin</b>	Pain, fever Osteoarthritis (OA), Rheumatoid Arthritis (RA) Prophylaxis of myocardial infarction (MI), transient ischemic attacks (TIAs), and stroke in men Rheumatic fever	<i>Pain, fever:</i> PO 325– 650 mg q4h PRN; usual single dose, 650 mg  <i>OA, RA:</i> PO 2–6 g/d in divided doses <i>Prophylaxis of MI, TIA, and stroke:</i> PO 81–325 mg/d  <i>Acute rheumatic fever:</i> PO 5–8 g/d, in divided doses <i>TIAs;</i> PO 1300 mg/d in divided doses (650 mg twice a day or 325 mg four times a day)	<i>Pain, fever:</i> PO 10–15 mg/kg q4h, up to 60–80 mg/kg/d  <i>Recommended doses for weight:</i> 24–35 lb (10.6–15.9 kg), 162 mg; 36–47 lb (16–21.4 kg), 243 mg; 48–59 lb (21.5–26.8 kg), 324 mg; 60–71 lb (26.9–32.3 kg), 405 mg; 72–95 lb (32.4–43.2 kg), 486 mg; 96 lb or above (43.3 kg or above), 648 mg  <i>Juvenile RA:</i> PO 60–110 mg/kg/d in divided doses q6–8h  <i>Acute rheumatic fever:</i> PO 100 mg/kg/d, in divided doses, for 2 wk, then 75 mg/kg/d for 4–6 wk	Therapeutic serum level of salicylate is 100–300 mcg/mL for treatment of arthritis and rheumatic fever; toxicity occurs at levels above 300 mcg/mL.
<b>Celecoxib</b> (Celebrex)	OA RA Familial adenomatous polyposis (FAP)	OA: PO 100 mg twice daily or 200 mg once daily RA: PO 100–200 mg twice daily FAP: PO 200 mg twice daily	Dosage not established	200-mg doses should be taken with food.

## Drugs at a Glance: Analgesic, Antipyretic, Anti-Inflammatory Drugs (continued)

Generic/Trade Name	Indications for Use	ROUTES AND DOSAGE RANGES		
		Adults	Children	Comments
<b>Diclofenac potassium</b> (Cataflam)  <b>Diclofenac sodium</b> (Voltaren, Voltaren XR)	OA RA Ankylosing spondylitis (AS) Pain, dysmenorrhea	OA: PO 100–150 mg/d in divided doses (e.g., 50 mg two or three times or 75 mg twice or 100 mg once daily) RA: PO 150–200 mg/d in two, three, or four divided doses AS: PO 100–125 mg/d in four or five divided doses (e.g., 25 mg four or five times daily) Pain, dysmenorrhea: (diclofenac potassium only) PO 50 mg three times daily	Dosage not established	Diclofenac potassium is available only in 50-mg, <i>immediate-release</i> tablets. It may be used for all indications. Diclofenac sodium is available in 25-, 50-, and 75-mg <i>delayed-release</i> tablets and a 100-mg <i>extended-release</i> (XR) tablet. It is not recommended for acute pain or dysmenorrhea.
<b>Diflunisal</b>	OA RA Pain	OA, RA: PO 500–1000 mg/d, in two divided doses, increased to a maximum of 1500 mg/d if necessary Pain: PO 500–1000 mg initially, then 250–500 mg q8–12h	Not recommended for use in children <12 years of age	
<b>Etodolac</b>	OA RA Pain	OA, RA: PO 600–1200 mg/d in two to four divided doses Pain: PO 200–400 mg q6–8h <i>Maximum according to weight:</i> 1200 mg/d for 60 kg (132 lbs) or more; 20 mg/kg/d for <60 kg	Dosage not established	Available in <i>immediate-release</i> and <i>extended-release</i> (XR) tablets of various strengths. The immediate-release forms should be used to treat acute pain.
<b>Flurbiprofen</b> (Ansaid)	OA RA	OA, RA: PO 200–300 mg/d in two, three, or four divided doses	Dosage not established	
<b>Ibuprofen</b> (Advil, Motrin, PediaCare Fever)	OA RA Pain, dysmenorrhea Fever	OA, RA: PO 300–600 mg 3 or 4 times per day; maximum, 2400 mg/d Pain, dysmenorrhea: PO 400 mg q4–6h PRN; maximum, 3200 mg/d	1–12 y: Fever, initial temperature 39.2°C (102.5°F) or less, PO 5 mg/kg q6–8h; initial temperature above 39.2°C (102.5°F), PO 10 mg/kg q6–8h; maximum dose, 40 mg/kg/d Juvenile arthritis; PO 20–40 mg/kg/d, in three or four divided doses	Available in numerous dosage forms and concentrations, including regular tablets; chewable tablets; capsules; oral suspensions (of 100 mg/5 mL); and oral drops (of 40 mg/mL, for infants)

Generic/Trade Name	Indications for Use	ROUTES AND DOSAGE RANGES		
		Adults	Children	Comments
<b>Indomethacin</b> (Indocin, Indocin SR)	OA RA AS Tendinitis Bursitis Acute painful shoulder Acute gout Closure of patent ductus arteriosus (IV only)	PO, rectal suppository; 75 mg/d initially, increased by 25 mg/d at weekly intervals to a maximum of 150–200 mg/d, if necessary  <i>Acute gouty arthritis, acute painful shoulder;</i> PO 75–150 mg/d in three or four divided doses until pain and inflammation are controlled (e.g., 3–5 d for gout; 7–14 d for painful shoulder), then discontinued	<i>Premature infants with patent ductus arteriosus;</i> IV 0.2–0.3 mg/kg q12h for a total of three doses	The sustained-release form is not recommended for acute gouty arthritis.
<b>Ketoprofen</b> (Oruvail)	Pain Dysmenorrhea OA RA	<i>Pain, dysmenorrhea:</i> PO 25–50 mg q6–8h PRN OA, RA: PO 150–300 mg/d in three or four divided doses Extended-release; 200 mg once daily Maximum; 300 mg/d for regular formulation; 200 mg/d for extended release; 100–150 mg/d for clients with impaired renal function	Do not give to children <16 years unless directed by a physician.	Extended-release capsules are available as generic ketoprofen and Oruvail. Note that the names do not contain any letters (e.g., SR, XL) that indicate long-acting dosage forms.
<b>Ketorolac</b> (Toradol)	Moderately severe, acute pain, for short-term (up to 5 days) treatment	IV, IM 30 mg q6h PRN to a maximum of 120 mg/d PO 10 mg q4–6h to a maximum of 40 mg/d Older adults (>65 y), those with renal impairment, those with weight < 50 kg (110 lbs); IV, IM 15 mg q6h to a maximum of 60 mg/d	Dosage not established	Treatment is started with one or more injected doses, followed by oral doses when the client is able to take them.  Maximum duration of both injected and oral doses, 5 days
<b>Meloxicam</b> (Mobic)	OA	PO 7.5 mg once daily; increased to 15 mg once daily if necessary	Dosage not established	May be taken without regard to meals
<b>Nabumetone</b>	OA RA	PO 1000–2000 mg/day in one or two doses	Dosage not established	Available in 500-mg and 750-mg tablets

(continued on page 110)

<b>Naproxen</b> (Naprosyn)	OA RA	<i>Naproxen</i> : PO 250–500 mg twice daily	<i>Juvenile arthritis (naproxen only)</i> : PO 10 mg/kg/d in two divided doses. Oral suspension (125 mg/5 mL) twice daily according to weight: 13 kg (29 lb), 2.5 mL; 25 kg (55 lb), 5 mL; 39 kg (84 lb), 7.5 mL	Available in several dosage strength tablets, in a suspension, and in immediate- and delayed-release formulations	
<b>Naproxen sodium</b> (Aleve, Anaprox, Napreelan)	Juvenile arthritis AS Pain Dysmenorrhea Bursitis Tendinitis Acute gout	<i>Gout</i> : PO 750 mg initially, then 250 mg q8h until symptoms subside Maximum, 1250 mg/d <i>Naproxen sodium: Pain, dysmenorrhea, acute tendinitis, bursitis</i> : PO 550 mg q12h or 275 mg q6–8h Maximum, 1375 mg/d OA, RA, AS: PO 275–550 mg twice a day <i>Acute gout</i> : PO 825 mg initially, then 275 mg q8h until symptoms subside Controlled-release (Napreelan); 750–1000 mg once daily	OTC preparation not recommended for children < 12 y		
<b>Oxaprozin</b> (Daypro)	OA RA	PO 600–1200 mg once daily Maximum; 1800 mg/d or 26 mg/kg/d, whichever is lower, in divided doses	Dosage not established		
<b>Piroxicam</b> (Feldene)	OA RA	PO 20 mg/d or 10 mg twice daily	Dosage not established		
<b>Salsalate</b> (Disalcid, others)	Pain, fever Rheumatic fever OA RA	PO 3000 mg/d in divided doses	Dosage not established		May be taken with food to decrease GI effects. Administer with full glass of water to prevent tablet or capsule from lodging in esophagus
<b>Sulindac</b> (Clinoril)	OA RA Ankylosing spondylitis Bursitis Tendinitis Acute painful shoulder Acute gout	PO 150–200 mg twice a day; maximum, 400 mg/d <i>Acute gout, acute painful shoulder</i> : PO 200 mg twice a day until pain and inflammation subside (e.g., 7–14 d), then reduce dosage or discontinue	Dosage not established		

GI, gastrointestinal; PRN, as needed.

slows absorption but also decreases gastric irritation. Absorption of enteric-coated aspirin and rectal suppositories is slower and less complete.

Aspirin is distributed to all body tissues and fluids, including fetal tissues, breast milk, and the CNS. The highest concentrations are found in the plasma, liver, heart, and lungs. In

plasma, aspirin binds to albumin (75% to 90%). Aspirin has a short half-life of 15 to 20 minutes because it is rapidly converted to salicylic acid, an active metabolite. Salicylic acid has a half-life of 2 to 3 hours at low doses and 6 to 12 hours at therapeutic anti-inflammatory doses. It undergoes oxidation and conjugation in the liver, and its metabolites are excreted

through the kidneys. In alkaline urine (e.g., pH of 8), renal excretion of salicylate is greatly increased.

**Diflunisal** is a salicylic acid derivative that differs chemically from aspirin. It is reportedly equal or superior to aspirin in mild to moderate pain, RA, and OA. Compared with aspirin, it has less *antipyretic* effect, causes less gastric irritation, and has a longer duration of action.

**Salsalate** (Disalcid) is a salicylate with antipyretic, analgesic, antirheumatic, and anti-inflammatory properties. It is indicated for relief of pain and fever as well as treatment of rheumatic fever, RA, and OA. It is absorbed in the small intestine rather than in the stomach and is reported to cause fewer GI adverse effects than aspirin. Onset, peak, and duration of action are similar to aspirin. The drug is metabolized in the liver and excreted in the urine.

## NSAIDs

**Propionic acid derivatives** include flurbiprofen (Ansaid), ibuprofen (Motrin, Advil), ketoprofen (Oruvail), naproxen (Naprosyn), and oxaprozin (Daypro). In addition to their use as anti-inflammatory agents, some are used as analgesics and antipyretics. Ibuprofen, ketoprofen, and naproxen are available OTC, with recommended doses smaller and durations of use shorter than those for prescription formulations. Although these drugs are usually better tolerated than aspirin, they are much more expensive and may cause all the adverse effects associated with aspirin and other prostaglandin inhibitors.

**Ibuprofen**, a commonly used drug, is well absorbed with oral administration. Its action starts in about 30 minutes, peaks in 1 to 2 hours, and lasts 4 to 6 hours. The drug is highly bound (about 99%) to plasma proteins and has a half-life of about 2 hours. It is metabolized in the liver and excreted by the kidneys. It is available by prescription and OTC; in tablets, chewable tablets, capsules, oral suspension, and oral drops; and for use by adults and children.

**Acetic acid derivatives** include indomethacin (Indocin) and sulindac (Clinoril). These drugs have strong anti-inflammatory effects and more severe adverse effects than the propionic acid derivatives. Potentially serious adverse effects include GI ulceration, bone marrow depression, hemolytic anemia, mental confusion, depression, and psychosis. These effects are especially associated with indomethacin; sulindac was developed in an effort to find equally effective but less toxic derivatives. Adverse reactions occur less often with sulindac but are still common.

In addition to other uses, intravenous (IV) indomethacin is approved for treatment of patent ductus arteriosus in premature infants. The ductus arteriosus joins the pulmonary artery to the aorta in the fetal circulation. When it fails to close at time of birth (i.e., patent ductus arteriosus), blood is shunted from the aorta to the pulmonary artery, causing severe cardiopulmonary problems.

Related drugs are **etodolac**, **ketorolac** (Toradol), and **nabumetone** (Relafen). Etodolac reportedly causes less gastric irritation, especially in older adults at high risk of GI bleeding. Ketorolac is used only for pain, and although it can be given

orally, its unique characteristic is that it can be given by injection. Parenteral ketorolac reportedly compares with morphine and other opioids in analgesic effectiveness for moderate or severe pain. However, its use is limited to 5 days because it increases the risk of bleeding. Hematomas and wound bleeding have been reported with postoperative use. An intranasal form of ketorolac is currently in phase III drug testing trials and shows promise in relieving postsurgical pain and in reducing the amount of other analgesics (e.g., morphine) required in the postoperative period.

**Oxicam** drugs include meloxicam (Mobic) and piroxicam (Feldene). Meloxicam has a serum half-life of 15 to 20 hours and is excreted about equally in urine and feces. Piroxicam has a half-life of about 50 hours. The long half-lives allow the drugs to be given once daily, but optimal efficacy may not occur for 1 to 2 weeks.

**Diclofenac** sodium (Voltaren) is chemically different from but pharmacologically similar to other NSAIDs. Formulations are delayed or extended-release and onset of action is therefore delayed. Peak action occurs in about 2 hours and effects last 12 to 15 hours. The formulation of diclofenac potassium (Cataflam) is immediate-release; action starts quickly, peaks in about 20 minutes to 2 hours, and also lasts 12 to 15 hours. As a result, the potassium salt may be given for rapid relief of pain and primary dysmenorrhea. Diclofenac has a serum half-life of about 2 hours and is excreted mainly in the urine.

Only one COX-2 inhibitor, **celecoxib**, is currently marketed in the United States; however, several other COX-2 inhibitors (e.g., lumiracoxib, parecoxib, and etoricoxib) are currently under review by the FDA. COX-2 inhibitors were designed to selectively block production of prostaglandins associated with pain and inflammation without blocking those associated with protective effects on gastric mucosa, renal function, and platelet aggregation. Thus, they produce less gastric irritation and renal impairment than aspirin and other NSAIDs. However, with prolonged use or high dosages, GI bleeding, renal impairment, and associated hypertension and edema are still risks. COX-2 inhibitors are not associated with increased risk of bleeding because they do not have the antiplatelet effects of aspirin and other NSAIDs.

Celecoxib (Celebrex) is well absorbed with oral administration; peak plasma levels and peak action occur approximately 3 hours after an oral dose. It is highly protein bound (97%) and its serum half-life is about 11 hours. It is metabolized by the cytochrome P450 enzymes in the liver to inactive metabolites that are then excreted in the urine. A small amount is excreted unchanged in the urine.

## Applying Your Knowledge 7-1

Review Julie's medications. What would be the most likely adverse reaction to this medication regimen, considering the total amount of medication that Julie may take for her headaches?

.....

## Acetaminophen

**Acetaminophen** (also called APAP, an abbreviation of *N*-acetyl-*p*-aminophenol) is a nonprescription drug commonly used as an aspirin substitute because it does not cause nausea, vomiting, or GI bleeding, and it does not interfere with blood clotting. It is equal to aspirin in analgesic and antipyretic effects, but it lacks anti-inflammatory activity.

Acetaminophen is well absorbed with oral administration, and peak plasma concentrations are reached within 30 to 120 minutes. Duration of action is 3 to 4 hours.

Acetaminophen is metabolized in the liver (Fig. 7-2); approximately 94% is excreted in the urine as nontoxic glucuronate and sulfate conjugates and 2% is excreted unchanged. The remaining 4% is metabolized by cytochrome P450 enzymes to a toxic metabolite, which is normally inactivated by conjugation with glutathione and excreted in urine. With usual therapeutic doses, a sufficient amount of glutathione is available in the liver to detoxify acetaminophen. However, in acute or chronic overdose situations, the supply of glutathione may become depleted. In the absence of glutathione, the toxic metabolite combines with liver cells and causes damage or fatal liver necrosis. In people who abuse alcohol, usual therapeutic doses may cause or increase liver damage. The probable mechanism for increased risk of hepatotoxicity in this population is that ethanol induces drug-metabolizing cytochrome P450 enzymes in the liver and reduces the available supply of glutathione. The resulting rapid metabolism of acetaminophen produces enough toxic metabolite to exceed the available glutathione and results in hepatotoxicity.

Acetaminophen is available in tablet, liquid, and rectal suppository forms and is found in numerous combination products marketed as analgesics and cold remedies. It is often prescribed with codeine, hydrocodone, or oxycodone for added analgesic effects.

## Applying Your Knowledge 7-2

### How Can You Avoid This Medication Error?

Julie comes down with a cold and calls the office. You advise her to take Sinutab (acetaminophen 325 mg and pseudoephedrine hydrochloride 30 mg per tablet) for relief of her symptoms in addition to her usual treatment of headache.

## Drugs Used to Treat Gout and Hyperuricemia

Uric acid is a waste product resulting from protein metabolism. Elevated serum levels (*hyperuricemia*) may result from a genetic defect in purine metabolism resulting in an inability to metabolize uric acid (a waste product of protein metabolism). These individuals are sometimes called “overproducers” of uric acid. Hyperuricemia may also result from an inability to excrete uric acid, and these individuals are termed “under-excreters.” Hyperuricemia may be asymptomatic or may lead to urate deposits in various tissues. In the musculoskeletal system, often in the feet, urate deposits produce periodic episodes of severe pain, edema, and inflammation (gouty arthritis). In the kidneys, urate deposits may form renal calculi or cause other damage. Secondary hyperuricemia may occur in conditions characterized by high cell destruction or turnover (e.g., leukemia, multiple myeloma, cancer chemotherapy), producing gout.

Individual drugs used to treat gout and hyperuricemia are described below; dosages are listed in Table 7-3.

**Allopurinol** (Zyloprim) is used to prevent or treat hyperuricemia, which occurs with gout and with antineoplastic drug therapy. Uric acid is formed by purine metabolism and an enzyme called xanthine oxidase. Allopurinol prevents

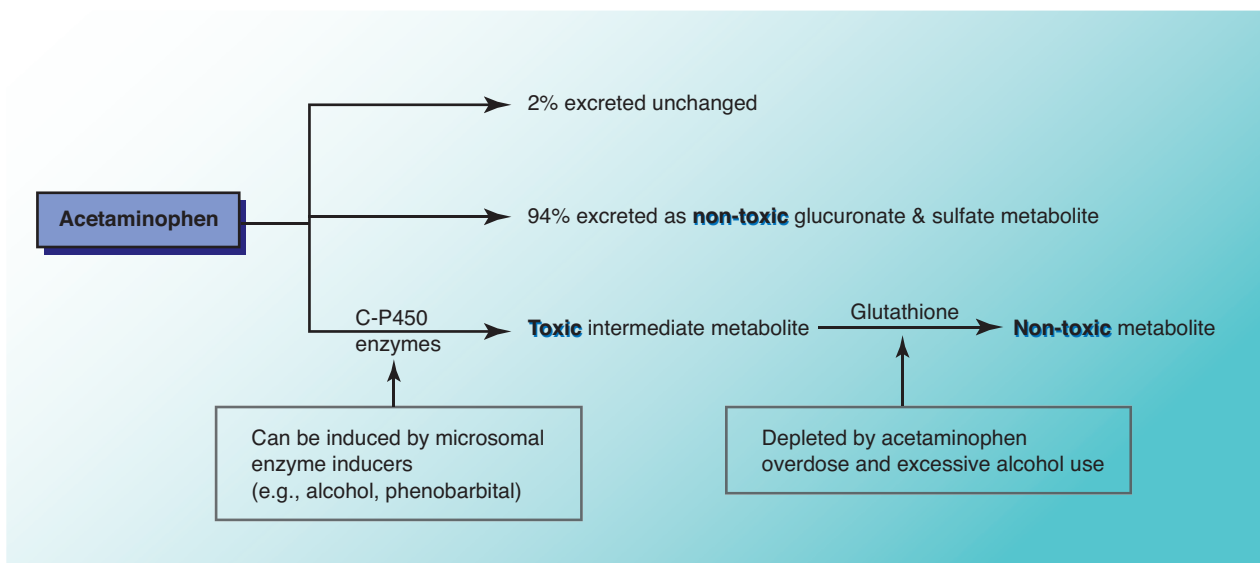

Figure 7-2 ■ Acetaminophen metabolic pathway.

Table 7-3

## Drugs at a Glance: Drugs Used in Gout

Generic/Trade Name	ROUTES AND DOSAGE RANGES	
	Adults	Children
<b>Allopurinol</b> (Zyloprim)	Mild gout, PO 200–400 mg/d Severe gout, PO 400–600 mg/d Hyperuricemia in clients with renal insufficiency, PO 100–200 mg/d Secondary hyperuricemia from anticancer drugs, PO 100–200 mg/d; maximum 800 mg/d	Secondary hyperuricemia from anticancer drugs: <6 y, PO 150 mg/d; 6–10 y, PO 300 mg/d
<b>Colchicine</b>	Acute attacks, PO 1.2 mg initially followed by 0.6 mg q1h or 1.2 mg q2 h until pain is relieved or diarrhea ensues.*The total amount to control pain and inflammation is usually 4–8 mg. IV 1–2 mg initially, then 0.5 mg q3–6h until response is obtained; maximum total dose 4 mg Prophylaxis, PO 0.6–1.2 mg/d	Dosage not established
<b>Probenecid</b> (Benemid)	PO 250 mg twice a day for 1 wk, then 500 mg twice a day	>2 y, PO 40 mg/kg/d in divided doses
<b>Sulfinpyrazone</b> (Anturane)	PO 100–200 mg twice a day, gradually increased over 1 wk to a maximum of 400–800 mg/d	Dosage not established

\*Recommended dosage varies, and some authorities do not recommend dosing until diarrhea occurs.

formation of uric acid by inhibiting xanthine oxidase. It is especially useful in treating chronic gout characterized by *tophi* (deposits of uric acid crystals in the joints, kidneys, and soft tissues) and impaired renal function. The drug promotes resorption of urate deposits and prevents their further development. Acute attacks of gout may result when urate deposits are mobilized. These may be prevented by concomitant administration of colchicine until serum uric acid levels are lowered.

**Colchicine** is an anti-inflammatory drug used to prevent or treat acute attacks of gout. In acute attacks, colchicine may be used for relieving inflammation, joint pain, and edema. Colchicine is no longer considered a first line medication to treat gout due to drug toxicities, and an NSAID (e.g., indomethacin) that is equally effective in treating gout is often preferentially prescribed. Colchicine decreases inflammation by decreasing the movement of leukocytes into body tissues containing urate crystals. It has no direct analgesic or antipyretic effects. In patients unable to tolerate the severe GI side effects of oral colchicine (i.e., nausea, vomiting, severe diarrhea, and abdominal pain) colchicine may be given intravenously; however, it is important to note that oral and intravenous dosages of colchicine are not the same to avoid making a dangerous drug error. Colchicine causes severe local irritation to tissues and therefore should never be administered intramuscularly or subcutaneously. Because colchicine is toxic to the bone marrow, it is limited to only 7 days of therapy. Reduced dosages are required in the presence of diminished renal or liver function, and colchicine should not be used in individuals with combined renal and hepatic insufficiency.

**Probenecid** (Benemid) increases the urinary excretion of uric acid. This *uricosuric* action is used therapeutically to treat hyperuricemia and gout. It is not effective in acute attacks of gouty arthritis but prevents hyperuricemia and tophi associated with chronic gout. Probenecid may cause acute gout until serum uric acid levels are within the normal range; concomitant administration of colchicine prevents this effect. (Probenecid also is used with penicillin, most often in treating sexually transmitted diseases. It increases blood levels and prolongs the action of penicillin by decreasing the rate of urinary excretion.)

**Sulfinpyrazone** (Anturane) is a uricosuric agent similar to probenecid. It is not effective in acute gout but prevents or decreases tissue changes of chronic gout. Colchicine is usually given during initial sulfinpyrazone therapy to prevent acute gout.

### Drugs Used to Treat Migraine

Migraine headaches are characterized by periodic attacks of pain, nausea, and increased sensitivity to light and sound. Migraines demonstrate a familial pattern and are thought to be inherited as an autosomal dominant trait with incomplete penetrance. During childhood, migraine headaches are evenly distributed between genders; however, in adulthood migraines affect females three times more often than males. Migraine headaches are believed to result from periods of neural hyperexcitability, resulting in vasodilation. Vasodilation leads to pain and further neural hyperexcitability, specifically activation of the trigeminal nerve. Activation of the trigeminal nerve results in release of neuropeptides that trigger an

inflammatory response within the meningeal blood vessels. Hormones, especially estrogen, are also thought to play a role in the pattern of migraine headaches. This is supported by the observation that many women experience migraine headaches at the time of their menstrual cycle. Finally, “trigger chemicals” found in foods such as monosodium glutamate (MSG), chocolate, aged cheese, and wine are associated with migraine headaches.

Drugs used to treat migraine headaches can be divided into two categories: medications used to treat acute pain and medications used to prevent migraine headaches from occurring. Drugs used for migraine prophylaxis are different in their classification and mechanism of action from medications useful in treating the acute pain of a migraine headache. Prophylactic drugs include beta blockers such as propranolol (see Chap. 18), calcium channel blockers such as nifedipine (see Chap. 50), tricyclic antidepressants such as imipramine (see Chap. 10), and anticonvulsants such as valproic acid (see Chap. 11).

Drugs used for relieving the acute pain of migraine headaches include aspirin, other NSAIDs, and acetaminophen. In most studies, aspirin, ibuprofen, naproxen, tolfenamic acid, and the combination of aspirin, acetaminophen, and caffeine seem to be the most effective in treating migraine pain. Aspirin may be combined with metoclopramide to enhance absorption and treat migraine associated nausea. Aspirin may also be combined with caffeine to speed absorption. Acetaminophen is usually combined with another analgesic such as aspirin or an opioid, rather than taken alone, when used to treat migraine pain. For severe migraine pain, opioid analgesics (see Chap. 6) may be prescribed.

Serotonin receptor (5-HT<sub>1B</sub> and 5-HT<sub>1D</sub>) agonists (also known as triptans) and ergot alkaloids are prescription medications indicated for aborting acute migraine headaches. The triptans and ergot alkaloids are discussed in this section. Individual drugs are described below. Dosages are given in Table 7-4.

**Almotriptan** (Axert), **eletriptan** (Relpax), **frovatriptan** (Frova), **naratriptan** (Amerge), **rizatriptan** (Maxalt), **sumatriptan** (Imitrex), and **zolmitriptan** (Zomig), called “triptans,” were developed specifically for the treatment of moderate or severe migraines. They are called selective serotonin 5-HT<sub>1B</sub> and 5-HT<sub>1D</sub> receptor agonists because they act on a specific serotonin (5-hydroxytryptamine, or 5-HT) receptor subtypes in the brain. Binding to serotonin receptors in the intracranial blood vessels results in vasoconstriction. Binding to serotonin receptors within the trigeminal nervous system suppresses the release of inflammatory neuropeptides, reducing inflammation in meningeal blood vessels. By constricting blood vessels and reducing vascular inflammation, triptans are effective in aborting acute migraine headaches. The drugs vary in onset of action, with subcutaneous sumatriptan acting the most rapidly and starting to relieve migraine headache within 10 minutes. Most patients obtain relief within 1 to 2 hours with all of the oral drugs. The drugs are metabolized in the liver by monoamine oxidase or cytochrome P450 enzymes; metabolism of eletriptan, rizatriptan, and zolmitriptan produces active

metabolites. Subcutaneous sumatriptan produces more adverse effects than the oral drugs, which have similar adverse effects (e.g., pain, paresthesias, nausea, dizziness, drowsiness). These drugs are considered safer than ergot alkaloids.

Because of their vasoconstrictive properties, triptans are contraindicated in patients with a history of angina pectoris, myocardial infarction, or uncontrolled hypertension. Use caution with the concurrent use of antidepressants (e.g., SSRIs, SNRIs, and MAOIs), meperidine, and dextromethorphan with triptans since all of these medications have the potential to increase serotonin levels in the brain. Serotonin syndrome, a potentially fatal reaction, may occur when two drugs that raise the serotonin levels in the brain are taken concurrently, resulting in restlessness, hallucinations, loss of coordination, tachycardia, rapid changes in blood pressure, fever, hyperactive reflexes, nausea, vomiting, and diarrhea. Serotonin syndrome occurs most frequently when a medication is initially started or the dosage is increased. Serotonin syndrome is treated by withdrawing the medications that caused this reaction and administering IV fluids and supportive medications such as cyproheptadine (Periactin) to block serotonin production and benzodiazepines to relax muscles and decrease agitation.

**Ergotamine tartrate** (Ergomar) is an ergot alkaloid used only in the treatment of migraine. Ergot preparations relieve migraine by activating 5-HT<sub>1D</sub> receptors on intracranial blood vessels, resulting in vasoconstriction. Ergotamine is most effective when given sublingually or by inhalation at the onset of headache. When given orally, ergotamine is erratically absorbed, and therapeutic effects may be delayed for 20 to 30 minutes. Ergotamine is contraindicated during pregnancy and in the presence of severe hypertension, peripheral vascular disease, coronary artery disease, renal or hepatic disease, and severe infections. **Ergotamine tartrate and caffeine** (Cafegot) is a commonly used antimigraine preparation. Caffeine reportedly increases the absorption and vasoconstrictive effects of ergotamine.

**Dihydroergotamine mesylate** (DHE 45) is a semisynthetic derivative of ergotamine with similar mechanism of action and contraindications. The FDA has issued a **BLACK BOX WARNING** advising against concurrent therapy of dihydroergotamine with CYP 3A4 inhibitors (e.g., protease inhibitors, macrolide antibiotics, ketoconazole, grapefruit juice, and others) because the resulting increased serum levels of dihydroergotamine have been reported to result in serious or life-threatening peripheral and cerebral ischemia.

## Herbal and Dietary Supplements

In addition to the drugs described above, many herbal medicines are used to relieve pain and/or inflammation. For most of these (e.g., comfrey, marigold, peppermint, primrose, ginger), such usage is anecdotal and unsupported by clinical studies. For a few supplements, there is some evidence of effectiveness with few adverse effects.

Table 7-4

## Drugs at a Glance: Drugs Used in Migraine

GENERIC/TRADE NAME	ROUTES AND DOSAGE RANGES
<b>Serotonin Agonists (Triptans)</b>	
<b>Almotriptan</b> (Axert)	PO 6.25 mg, repeat after 2 h if necessary. Maximum, 12.5 mg/24h
<b>Eletriptan</b> (Relpax)	PO 20–40 mg as a single dose, repeat after 2 h if necessary. Maximum dose, 80 mg/d
<b>Frovatriptan</b> (Frova)	PO 2.5 mg; repeat after 2 h if necessary. Maximum dose, 7.5 mg
<b>Naratriptan</b> (Amerge)	PO 1–2.5 mg as a single dose; repeat in 4 h if necessary. Maximum, 5 mg/d
<b>Rizatriptan</b> (Maxalt)	PO 5–10 mg as a single dose; repeat after 2 h if necessary. Maximum dose, 30 mg/d
<b>Sumatriptan</b> (Imitrex)	PO 25–100 mg as a single dose. Maximum dose, 300 mg/d Sub-Q 6 mg as a single dose. Maximum, 12 mg/d Nasal spray 5, 10, or 20 mg by unit-dose spray device. Maximum, 40 mg/d
<b>Zolmitriptan</b> (Zomig)	PO 1.25–2.5 mg as a single dose; may repeat after 2 h if necessary. Maximum dose, 10 mg/d Nasal spray 0.5, 1, 2.5, or 5 mg by unit-dose spray device. Maximum, 10 mg/d Orally disintegrating tablets (Zomig-ZMT) 2.5–5 mg as a single dose; may repeat after 2 h if necessary. Maximum dose, 10 mg/d
<b>Ergot Preparations</b>	
<b>Dihydroergotamine mesylate</b> (DHE 45)	IM 1 mg at onset of migraine, may be repeated hourly, if necessary, to a total of 3 mg IV 1 mg, repeated, if necessary, after 1 h; maximum dose 2 mg. Do not exceed 6 mg/wk.
<b>Ergotamine tartrate</b> (Ergomar)	PO, sublingually, 1–2 mg at onset of migraine, then 2 mg q30 min, if necessary, to a maximum of 6 mg/24 h or 10 mg/wk Inhalation, 0.36 mg (one inhalation) at onset of migraine, repeat in 5 min, if necessary, to a maximum of 6 inhalations/24 h
<b>Ergotamine tartrate and caffeine</b> (Cafergot)	<i>Adults:</i> PO 2 tablets at onset of migraine, then 1 tablet q30 min, if necessary, up to 6 tablets per attack or 10 tablets/wk Rectal suppository 0.5–1 suppository at onset of migraine, repeat in 1 h, if necessary, up to two suppositories per attack or five suppositories/wk <i>Children:</i> PO 0.5–1 tablet initially, then 0.5 tablet q30 min, if necessary, to a maximum of three tablets

**Feverfew** is a herbal medicine with some evidence of effectiveness in migraine, especially in reducing incidence and severity. Its main active ingredient is thought to be parthenolide. Feverfew is thought to inhibit platelet aggregation, prostaglandin synthesis, and the release of inflammatory mediators such as histamine, but its exact mechanism in migraine prophylaxis is unknown. It is contraindicated in pregnant and lactating women.

In general, patients should be encouraged to try standard methods of preventing and treating migraine before taking products with uncertain benefits and risks. For example, commercial preparations of feverfew are not standardized and may contain different amounts of parthenolide. The usual recommended dose is 25 to 50 milligrams daily with food, but more studies are needed.

Adverse effects include hypersensitivity reactions in people who are allergic to ragweed, asters, chrysanthemums, or daisies, and stopping the preparation abruptly can result in withdrawal symptoms of pain and stiffness. No interactions with OTC or prescription drugs have been reported, but there is a potential for increasing risks of bleeding in patients taking an antiplatelet drug (e.g., aspirin) or an anticoagulant (e.g., warfarin).

**Chondroitin and glucosamine** can each be used alone but are more often taken in combination to relieve the pain of osteoarthritis. Chondroitin sulfate (CS), a supplement extracted from animal cartilage or manufactured synthetically and used to treat arthritis, is thought to delay the breakdown of joint cartilage (by inhibiting elastase, a proteolytic enzyme found in synovial membranes), to stimulate synthesis of new

cartilage (by stimulating chondrocytes to produce collagen and proteoglycan), and to promote the “shock-absorbing” quality of cartilage (by retaining water).

Chondroitin is a normal component of joint cartilage, which also contains water (65% to 80%), collagen, proteoglycans, and chondrocytes that produce new collagen and proteoglycans. CS was first used as a dietary supplement because studies suggested that it would promote healing of cartilage damaged by inflammation or injury. The daily dose of CS is based on weight: less than 120 pounds, 800 milligrams; 120 to 200 pounds, 1200 milligrams; more than 200 pounds, 1600 milligrams. CS is usually taken with food, in two to four divided doses.

Proponents of CS cite clinical trials that indicate beneficial effects and low incidence of adverse effects. In 2003, a meta-analysis of 15 high-quality, randomized, double-blind controlled trials comparing chondroitin and glucosamine to placebo or active control concluded that oral CS significantly improved symptoms, including joint mobility, in patients with OA. Adverse effects were found to be statistically similar to placebo in all studies. The main adverse effect of CS is reportedly minor stomach upset. In addition, there is a theoretical risk of bleeding because of the drug’s structural similarity to heparin, but there have been no reports of bleeding from the use of CS.

Opponents question whether CS is absorbed systemically, because of its large molecular size, and whether it is able to reach cartilage cells. They also state that little is known about long-term toxicity of the compound.

**Glucosamine**, a synthetic supplement, is also taken for arthritis. Glucosamine is an essential structural component of joint connective tissue. With OA, glucosamine production is decreased, synovial fluid becomes thin and less effective in lubricating the joint, and joint cartilage deteriorates. The rationale for taking supplementary glucosamine is to reduce cartilage breakdown and improve cartilage production and repair.

Some studies indicate that glucosamine may decrease mild to moderate pain caused by OA in some patients, possibly as well as NSAIDs. Other studies indicate little or no benefit when glucosamine is compared with placebo. There is controversy about the ability of glucosamine to affect cartilage structure and delay joint deterioration. Most studies are criticized as being too small, of too short a duration, and of having flawed designs. A study of 212 patients with knee OA indicated that long-term use of glucosamine improves symptoms and prevents changes in joint structure. These patients took 1500 milligrams of glucosamine sulfate or placebo once a day for 3 years. Radiographs of the knees were taken before starting glucosamine and after 1 and 3 years of treatment. The researchers concluded that significant improvement of symptoms and less joint deterioration occurred in patients receiving glucosamine. Critics of this study said the pain relief was minor and the radiographic changes were insignificant and did not indicate improvement in disease progression.

The previously mentioned 2003 meta-analysis, which compared chondroitin and glucosamine with placebo or con-

trols, concluded that structural improvement as measured by joint space narrowing was significantly demonstrated in patients receiving glucosamine. Glucosamine significantly improved joint structure and symptoms in patients with OA of the knee.

Glucosamine is available as a hydrochloride salt and as a sulfate salt. Most studies have been performed with glucosamine sulfate (GS), which is the preferred form. Dosage of GS is based on weight: less than 120 pounds, 1000 milligrams; 120 to 200 pounds, 1500 milligrams; more than 200 pounds, 2000 milligrams. GS is usually taken with food, in two to four divided doses.

There are no known contraindications to the use of glucosamine, but it should be avoided during pregnancy and lactation and in children, because effects are unknown. Adverse effects include GI upset (e.g., epigastric pain, heartburn, nausea, constipation, diarrhea), drowsiness, headache, and skin rash. No interactions with OTC or prescription drugs have been reported.

In an effort to clarify the efficacy of glucosamine and chondroitin, the Glucosamine/Chondroitin Arthritis Intervention Trial (GAIT), funded by the National Institutes of Health, was conducted at 16 rheumatology centers around the United States. The results of this study, published in 2006, suggest the benefit of glucosamine and chondroitin depends on pain severity. In people with moderate-to-severe knee OA pain, glucosamine was more effective in relieving pain than celecoxib, either supplement alone, or a placebo. In subjects with mild OA knee pain, glucosamine and chondroitin did not show effectiveness over a placebo. Based on the GAIT results, the Arthritis Foundation issued a statement supportive of the potential benefits of using glucosamine and chondroitin as part of the overall treatment plan in individuals with moderate to severe knee OA (Level A). Because benefits of glucosamine and chondroitin may be delayed, some physicians suggest taking the supplements for 3 months (glucosamine 500 mg and chondroitin 400 mg three times a day) and then evaluating for clinical improvement (e.g., less pain, improved ability to walk).

A Cochrane review of studies including 13 herbal medicines proposed for relief of back pain was completed in 2006. Three herbal medicines seemed to reduce low back pain more than a placebo. The review reported moderate evidence that 50 to 100 milligrams of *Harpagophytum procumbens* (Devil’s claw) and 120 to 240 milligrams of *Salix alba* (White willow bark) are useful in the short-term treatment of acute nonspecific low back pain and limited evidence that the topical application of *Capsicum frutescens* (Cayenne) is beneficial. Devil’s claw is proposed to have anti-inflammatory actions; however, this effect is not due to arachidonic acid metabolism. Devil’s claw is contraindicated in patients with ulcers or in pregnant women because the drug may stimulate uterine contractions. Chemical components of Devil’s claw are reported to affect chronotropic (heart rate) and inotropic (force of contraction) cardiac function and lower blood glucose. Consequently, individuals with cardiac disorders, dysrhythmias, and diabetes

should exercise caution in using Devil’s claw. White willow bark contains salicylate-like chemical compounds and shares similar adverse reactions, contraindications, and drug interactions with other salicylates (i.e., aspirin). Capsicum is thought to reduce pain by depleting substance P, a mediator in the transmission of pain impulses from peripheral receptors to the central nervous system. Capsicum should not be used by pregnant women. Simultaneous use of heat treatments with capsicum should be avoided to prevent possible skin irritation.

Many herbal medications have the potential to interact with aspirin, other NSAIDs, and acetaminophen. Ginkgo, garlic, ginger, bilberry, dong quai, feverfew, ginseng, tumeric, meadowsweet, and willow possess antiplatelet actions and may interact with aspirin and other NSAIDs, increasing the risk of bleeding. Camomile, motherwort, horse chestnut, fenugreek, and red clover possess coumarin-like activity and may increase the risk of bleeding when taken with ASA or other NSAIDs. Ginkgo (and possibly some of the previously mentioned herbs) may also increase the risk of bleeding when used with acetaminophen. Echinacea and kava are potentially hepatotoxic and may increase the risk of liver damage when used concurrently with acetaminophen. Willow and meadowsweet may increase the risk of nephrotoxicity when taken concurrently with acetaminophen.

## Nursing Process

### Assessment

- Assess for signs and symptoms of pain, such as location, severity, duration, and factors that cause or relieve the pain (see Chap. 6).
- Assess for fever (thermometer readings above 99.6°F [37.3°C] are usually considered fever). Hot, dry skin; flushed face; reduced urine output; and concentrated urine may accompany fever if the person also is dehydrated.
- Assess for inflammation. Local signs are redness, heat, edema, and pain or tenderness; systemic signs include fever, elevated white blood cell count (leukocytosis), and weakness.
- With arthritis or other musculoskeletal disorders, assess for pain and limitations in activity and mobility.
- Ask about use of OTC analgesic, antipyretic, or anti-inflammatory drugs and herbal or dietary supplements.
- Ask about allergic reactions to aspirin or NSAIDs.
- Assess for history of peptic ulcer disease, GI bleeding, liver, or kidney disorders.
- With migraine, assess severity and patterns of occurrences.

### Nursing Diagnoses

- Acute Pain
- Chronic Pain

- Activity Intolerance related to pain
- Risk for Poisoning: Acetaminophen overdose
- Risk for Injury related to adverse drug effects (GI bleeding, renal insufficiency, liver damage)
- Deficient Knowledge: Therapeutic and adverse effects of commonly used drugs
- Deficient Knowledge: Correct use of OTC drugs for pain, fever, and inflammation

## Planning/Goals

### The patient will

- Experience relief of discomfort with minimal adverse drug effects
- Experience increased mobility and activity tolerance
- Inform health care providers if taking aspirin, an NSAID or acetaminophen regularly.
- Self-administer the drugs safely
- Avoid overuse of the drugs
- Use measures to prevent accidental ingestion or overdose, especially in children
- Experience fewer and less severe attacks of migraine

## Interventions

Implement measures to prevent or minimize pain, fever, and inflammation.

- Treat the disease processes (e.g., infection, arthritis) or circumstances (e.g., impaired blood supply, lack of physical activity, poor positioning or body alignment) thought to be causing pain, fever, or inflammation.
- Treat pain as soon as possible; early treatment may prevent severe pain and anxiety and allow the use of milder analgesic drugs. Use distraction, relaxation techniques, or other nonpharmacologic techniques along with drug therapy, when appropriate.
- With acute musculoskeletal injuries (e.g., sprains) think RICE: Rest, Ice, Compression, Elevation to decrease pain, swelling, and inflammation. Cold therapy should be applied for 20 minutes every 3 to 4 hours for 48 hours.
- Assist patients with migraine to identify and avoid “triggers.”
- Assist patients to drink 2 to 3 liters of fluid daily when taking an NSAID regularly. This strategy decreases gastric irritation and helps to maintain good kidney function. With long-term use of aspirin, fluids help to prevent precipitation of salicylate crystals in the urinary tract. With antigout drugs, fluids help to prevent precipitation of urate crystals and formation of urate kidney stones. Fluid intake is especially important initially when serum uric acid levels are high and large amounts of uric acid are being excreted.
- Provide appropriate teaching for any drug therapy (see accompanying displays).

## Evaluation

- Interview and observe regarding relief of symptoms.
- Interview and observe regarding mobility and activity levels.
- Interview and observe regarding safe, effective use of the drugs.
- Select drugs appropriately.

## Applying Your Knowledge 7-3

Given Julie's medication regimen, what nursing measures should be implemented to decrease the probability of GI bleeding?

## Principles of Therapy

### Use of Aspirin

When pain, fever, or inflammation is present, aspirin is effective across a wide range of clinical conditions. Like any other drug, aspirin must be used appropriately to maximize therapeutic benefits and minimize adverse reactions.

For pain, aspirin is useful alone when the discomfort is of low to moderate intensity. For more severe pain, aspirin may be combined with an oral opioid (e.g., codeine) or given between opioid doses. Aspirin and opioid analgesics act by different mechanisms, so such use is rational. For acute pain, aspirin is taken when the pain occurs and is often effective within a few minutes. For chronic pain, a regular schedule of administration, such as every 4 to 6 hours, is more effective.

For fever, aspirin is effective if drug therapy is indicated. However, aspirin is contraindicated in children because of its association with Reye's syndrome.

For inflammation, aspirin is useful in both short- and long-term therapy of conditions characterized by pain and inflammation, such as RA or OA. Although effective, the high doses and frequent administration required for anti-inflammatory effects increase the risks of GI upset, ulceration, and bleeding.

For acute pain or fever, plain aspirin tablets are preferred. For chronic pain, long-term use in arthritis, and daily use for antiplatelet effects, enteric-coated tablets may be better tolerated. Rectal suppositories are sometimes used when oral administration is contraindicated.

### Drug Dosage

The dose of aspirin given depends mainly on the condition being treated. Low doses (325 mg initially and 80 mg daily) are used for antiplatelet effects in preventing arterial thrombotic disorders such as myocardial infarction or stroke. Because aspirin is highly protein bound, lower-than-average doses are needed for patients with low serum albumin levels, because a

larger proportion of each dose is free to exert pharmacologic activity. Larger doses are needed for anti-inflammatory effects (maximum daily dosage of 8000 mg) than for analgesic and antipyretic effects (325 to 650 mg every 4 hours). In general, patients taking low-dose aspirin to prevent myocardial infarction or stroke should continue to take the aspirin if prescribed a COX-2 inhibitor NSAID because the COX-2 inhibitors have little effect on platelet function.

### Toxicity: Recognition and Management

Salicylate intoxication (*salicylism*) may occur with an acute overdose or with chronic use of therapeutic doses, especially the higher doses taken for anti-inflammatory effects. Chronic ingestion of large doses saturates a major metabolic pathway, thereby slowing drug elimination, prolonging the serum half-life, and causing drug accumulation.

#### Prevention

To decrease risks of toxicity, plasma salicylate levels should be measured when an acute overdose is suspected and periodically when large doses of aspirin are taken long term. Therapeutic levels are 150 to 300 micrograms per milliliter. Signs of salicylate toxicity occur at serum levels greater than 200; severe toxic effects may occur at levels greater than 400.

#### Signs and Symptoms

Manifestations of salicylism include nausea, vomiting, fever, fluid and electrolyte deficiencies, tinnitus, decreased hearing, visual changes, drowsiness, confusion, hyperventilation, and others. Severe CNS dysfunction (e.g., delirium, stupor, coma, seizures) indicates life-threatening toxicity.

#### Treatment

In mild salicylism, stopping the drug or reducing the dose is usually sufficient. In severe salicylate overdose, treatment is symptomatic and aimed at preventing further absorption from the GI tract; increasing urinary excretion; and correcting fluid, electrolyte, and acid-base imbalances. When the drug may still be in the GI tract, gastric lavage and activated charcoal help reduce absorption. IV sodium bicarbonate produces an alkaline urine in which salicylates are more rapidly excreted, and hemodialysis effectively removes salicylates from the blood. IV fluids are indicated when high fever or dehydration is present. The specific content of IV fluids depends on the serum electrolyte and acid-base status.

### Use of NSAIDs

Nonaspirin NSAIDs are widely used and preferred by many people because of less gastric irritation and GI upset compared with aspirin. Many NSAIDs are prescription drugs used primarily for analgesia and anti-inflammatory effects in arthritis and other musculoskeletal disorders. However, several are approved for more general use as an analgesic or antipyretic. Ibuprofen, ketoprofen, and naproxen are available by prescription and OTC. Patients must be instructed to avoid combined use of prescription and nonprescription NSAIDs because of the high risk of adverse effects. NSAIDs commonly cause gastric mucosal damage, and prolonged use may lead to gastric ulceration and

## Patient Teaching Guidelines

### Drugs Used in Migraine

#### General Considerations

- Try to identify and avoid situations known to precipitate acute attacks of migraine.
- For mild or infrequent migraine attacks, acetaminophen, aspirin, or another nonsteroidal anti-inflammatory drug may be effective.
- For moderate-to-severe migraine attacks, the drug of first choice is probably sumatriptan (Imitrex) or a related drug, if not contraindicated (e.g., by heart disease or hypertension). However, one of these drugs should not be taken if an ergot preparation has been taken within the previous 24 hours.
- If you have frequent or severe migraine attacks, consult a physician about medications to prevent or reduce the frequency of acute attacks.
- Never take an antimigraine medication prescribed for someone else or allow someone else to take yours. The medications used to relieve acute migraine can constrict blood vessels, raise blood pressure, and cause serious adverse effects.
- Chronic overuse of analgesics, preparations containing sedatives or caffeine, triptans, opioids, or ergotamine may play a role in causing rebound headaches.

#### Self-Administration

- Take medication at onset of pain, when possible, to prevent development of more severe symptoms.
- With triptans, take oral drugs (except for rizatriptan and zolmitriptan orally disintegrating tablets) with fluids. If symptoms recur, a second dose may be taken. However, do not take a second dose of almotriptan, eletriptan, frovatriptan, rizatriptan, or zolmitriptan sooner than 2 hours after the first dose, or a second dose of naratriptan sooner

than 4 hours after the first dose. Do not take more than 12.5 mg of almotriptan, 80 mg of eletriptan, 7.5 mg of frovatriptan, 5 mg of naratriptan, 30 mg of rizatriptan, or 10 mg of zolmitriptan in any 24-hour period.

- Rizatriptan and zolmitriptan are available in a regular tablet, which can be taken with fluids, and in an orally disintegrating tablet, which can be dissolved on the tongue and swallowed without fluids. The tablet should be removed from its package with dry hands and placed on the tongue immediately. Zolmitriptan is also available as a nasal spray. The usual dose is one spray into one nostril, not to exceed 10 mg/d (2 doses).
- Sumatriptan can be taken by mouth, injection, or nasal spray. Instructions should be strictly followed for the prescribed method of administration. For the nasal spray, the usual dose is one spray into one nostril. If symptoms return, a second spray may be taken 2 hours or longer after the first spray. Do not take more than 40 mg of nasal spray or 200 mg orally or by injection in any 24-hour period. If self-administering injectable sumatriptan, be sure to give in fatty tissue under the skin. This drug must not be taken intravenously; serious, potentially fatal reactions may occur.
- If symptoms of an allergic reaction (e.g., shortness of breath, wheezing, heart pounding, swelling of eyelids, face or lips, skin rash, or hives) occur after taking a triptan drug, tell your prescribing physician immediately and do not take any additional doses without specific instructions to do so.
- With ergot preparations, report signs of poor blood circulation, such as tingling sensations or coldness, numbness, or weakness of the arms and legs. These are symptoms of ergot toxicity. To avoid potentially serious adverse effects, do not exceed recommended doses.

## Patient Teaching Guidelines

### Acetaminophen, Aspirin, and Other NSAIDs

#### General Considerations

- Aspirin and other anti-inflammatory drugs such as ibuprofen are used to relieve pain, fever, and inflammation. Aspirin is as effective as the more costly medications but at typical doses is more likely to cause stomach irritation and bleeding problems.
- Many prescription and OTC medications for pain, fever, and colds/flu/sinusitis contain acetaminophen, aspirin, or other NSAIDs. There is a risk of overdosing when taking different products containing the same or similar medications. Read all drug labels carefully and do not exceed the total recommended dosage for any medication.
- It is generally safe to take an occasional dose of aspirin or an NSAID for pain or fever if taking low-dose aspirin to prevent heart attack or stroke.
- Improvement of symptoms with NSAIDs depends on the reason for use. When taken for pain, the drugs usually act within 30 to 60 minutes; when taken for inflammatory disorders, improvement may occur within 24 to 48 hours with aspirin and 1 to 2 weeks with other NSAIDs.

- Taking a medication for fever is not usually recommended unless the fever is high or is accompanied by other symptoms. Fever is one way the body fights infection.
- Do not take OTC ibuprofen more than 3 days for fever or 10 days for pain. If these symptoms persist or worsen, or if new symptoms develop, contact a health care provider.
- Avoid aspirin for approximately 2 weeks before and after major surgery or dental work to decrease the risk of excessive bleeding. If pregnant, do not take aspirin for approximately 2 weeks before the estimated delivery date.
- Inform any health care provider if taking acetaminophen, aspirin, ibuprofen, or any other NSAID regularly.
- Inform health care providers if you have ever had an allergic reaction (e.g., asthma, difficulty in breathing, hives), severe GI symptoms (e.g., ulcer, bleeding), or rash or other skin disorder after taking aspirin, ibuprofen, or similar drugs.
- Avoid or minimize alcoholic beverages because alcohol increases gastric irritation and risks of bleeding. The Food and Drug Administration requires an alcohol warning on

## Patient Teaching Guidelines

## Acetaminophen, Aspirin, and Other NSAIDs (continued)

the labels of OTC pain and fever relievers and urges people who drink three or more alcoholic drinks every day to ask their doctors before using the products.

- To avoid accidental ingestion and aspirin poisoning, store aspirin in a closed childproof container and keep out of children's reach.

### Self-Administration

- Take aspirin and other NSAIDs with a full glass of liquid and food to decrease stomach irritation. Meloxicam (Mobic) may be taken without regard to food.
- Swallow enteric-coated aspirin whole; do not chew or crush. The coating is applied to decrease stomach irritation by making the tablet dissolve in the intestine. Also do not take with an antacid, which can cause the tablet to dissolve in the stomach.
- Swallow any long-acting pills or capsules whole; do not chew or crush. If you are unsure whether the medication you are taking is long acting, ask your health care provider.
- Drink 2 to 3 quarts of fluid daily when taking an NSAID regularly. This decreases gastric irritation and helps to maintain good kidney function.
- Report signs of bleeding (e.g., nose bleed, vomiting blood, bruising, blood in urine or stools), difficulty breathing, skin rash or hives, ringing in ears, dizziness, severe stomach upset, or swelling and weight gain.

### Acetaminophen

- Acetaminophen is often the initial drug of choice for relieving mild to moderate pain and fever because it

does not cause gastric irritation or bleeding. It may be taken on an empty stomach.

- Acetaminophen is an effective aspirin substitute for pain or fever but not for inflammation or prevention of heart attack or stroke.
- Do not exceed recommended doses of acetaminophen due to risk of life-threatening liver damage. People with liver disorders such as hepatitis or those who ingest alcoholic beverages frequently should use extreme caution.
- Do not exceed recommended duration of use (longer than 5 days in children, 10 days in adults, or 3 days for fever in adults and children) without consulting a physician.
- Avoid or minimize alcoholic beverages because alcohol increases risk of liver damage. People who ingest three or more alcoholic drinks every day should ask their doctors before taking products containing acetaminophen.

### Antigout Drugs

- When colchicine is taken for acute gout, pain is usually relieved in 4 to 12 hours with IV administration and in 24 to 48 hours with oral administration. Inflammation and edema may not decrease for several days.
- With colchicine for chronic gout, carry the drug and take as directed when pain begins until relief is obtained or nausea, vomiting, and diarrhea occur.
- Drink 2 to 3 quarts of fluid daily with antigout drugs. An adequate fluid intake helps prevent formation of uric acid kidney stones. Fluid intake is especially important initially, when uric acid levels in the blood are high and large amounts of uric acid are being excreted in the urine.
- When allopurinol is taken, blood levels of uric acid usually decrease to normal range within 1 to 3 weeks.

bleeding even in the absence of prior warning signs. Because NSAIDs lead to renal impairment in some patients, blood urea nitrogen and serum creatinine should be checked approximately 2 weeks after starting any of the agents.

NSAIDs inhibit platelet activity only while drug molecules are in the bloodstream, not for the life of the platelet (approximately 1 week) as aspirin does. Thus, they are not prescribed therapeutically for antiplatelet effects.

### Effects of NSAIDs on Other Drugs

NSAIDs decrease effects of certain drugs. With angiotensin-converting enzyme (ACE) inhibitors, decreased antihypertensive effects are probably caused by sodium and water retention. With beta blockers, decreased antihypertensive effects are attributed to NSAID inhibition of renal prostaglandin synthesis, which allows unopposed pressor systems to produce hypertension. With diuretics, decreased effects on hypertension and edema are attributed to retention of sodium and water. Chronic use of NSAIDs, particularly ibuprofen, has been shown to inhibit the cardioprotective effects of low-dose aspirin by competing with aspirin for COX-1 inhibition.

NSAIDs increase effects of other drugs. With anticoagulants, prothrombin time may be prolonged, and risks of bleed-

ing are increased by NSAID-induced gastric irritation and antiplatelet effects. With cyclosporine, nephrotoxicity associated with both drugs may be increased. With digoxin, ibuprofen and indomethacin may increase serum levels. With phenytoin, serum drug levels and pharmacologic effects, including adverse or toxic effects, may be increased. With lithium, serum drug levels and risk of toxicity may be increased (except with sulindac, which has no effect or may decrease serum lithium levels). With methotrexate (MTX), risks of toxicity (e.g., stomatitis, bone marrow suppression, nephrotoxicity) may be increased. Celecoxib and meloxicam apparently do not increase MTX toxicity.

### Use of Acetaminophen

Acetaminophen is effective and widely used for the treatment of pain and fever. It has two major advantages over aspirin: acetaminophen does not cause gastric irritation or increase the risk of bleeding. It is the drug of choice for children with febrile illness (because of the association of aspirin with Reye's syndrome), elderly adults with impaired renal function (because aspirin and NSAIDs may cause further impairment), and pregnant women (because aspirin is associated with several maternal and fetal disorders, including bleeding).

Despite the high degree of safety of acetaminophen when used appropriately, it is not the drug of choice for people with hepatitis or other liver disorders or for those who drink substantial amounts of alcoholic beverages. The major drawback to acetaminophen use is potentially fatal liver damage with overdose. The kidneys and myocardium may also be damaged.

### Toxicity: Recognition and Management

Acetaminophen poisoning may occur with a single large dose (possibly as little as 6 g, but usually 10–15 g) or with chronic ingestion of excessive doses (5–8 g/day for several weeks or 3–4 g/day for 1 year). Potentially fatal hepatotoxicity is the main concern and is most likely to occur with doses of 20 grams or more. Metabolism of acetaminophen produces a toxic metabolite that is normally inactivated by combining with glutathione. In overdose situations, the supply of glutathione is depleted and the toxic metabolite accumulates and directly damages liver cells (see Fig. 7-2). Acute renal failure may also occur.

### Prevention

The recommended maximum daily dose is 4 grams for adults; additional amounts constitute an overdose. Ingestion of an overdose may be accidental or intentional. One contributing factor may be that some people think the drug is so safe that they can take any amount without harm. Another may be that people take the drug in several formulations without calculating or realizing that they are taking potentially harmful amounts. For example, numerous brand names of acetaminophen are available OTC, and acetaminophen is an ingredient in many prescription and OTC combination products (e.g., Percocet; OTC cold, flu, headache, and sinus remedies). For chronic alcohol abusers, short-term ingestion of usual therapeutic doses may cause hepatotoxicity, and it is recommended that these persons ingest no more than 2 grams daily. The FDA has issued a warning advising individuals who ingest three or more alcoholic drinks daily to avoid acetaminophen or to ask a physician before using even small doses. Another recommendation is to limit duration of use (5 days or less in children, 10 days or less in adults, and 3 days in both adults and children when used to reduce fever) unless directed by a physician.

Because of multiple reports of liver damage from acetaminophen poisoning, the FDA has strengthened the warning on products containing acetaminophen and emphasized that the maximum adult dose of 4 grams daily, from all sources, should not be exceeded.

### Signs and Symptoms

Early symptoms (12–24 hours after ingestion) are nonspecific (e.g., anorexia, nausea, vomiting, diaphoresis) and may not be considered serious or important enough to report or seek treatment. At 24 to 48 hours symptoms may subside, but tests of liver function (e.g., aspartate aminotransferase, alanine aminotransferase, bilirubin, prothrombin time) begin to show increased levels. Later manifestations may include jaundice, vomiting, and CNS stimulation with excitement and delirium, followed by vascular collapse, coma, and death. Peak hepato-

toxicity occurs in 3 to 4 days; recovery in nonfatal overdoses occurs in 7 to 8 days.

Plasma acetaminophen levels should be obtained when an overdose is known or suspected, preferably within 4 hours after ingestion and every 24 hours for several days. Minimal hepatotoxicity is associated with plasma levels of less than 120 micrograms per milliliter at 4 hours after ingestion or less than 30 micrograms per milliliter at 12 hours after ingestion. With blood levels greater than 300 micrograms per milliliter at 4 hours after ingestion, about 90% of patients develop liver damage.

### Treatment

Gastric lavage is recommended if overdose is detected within 4 hours after ingestion, and activated charcoal can be given to inhibit absorption. In addition, the specific antidote is acetylcysteine (Mucomyst), a mucolytic agent given by inhalation in respiratory disorders. For acetaminophen poisoning, acetylcysteine (Mucomyst) may be given orally or intravenously (Acetadote) (dosages are listed with other antidotes in Chap. 2). The drug provides cysteine, a precursor substance required for the synthesis of glutathione. The synthesized glutathione combines with a toxic metabolite and decreases hepatotoxicity. Acetylcysteine is most beneficial if given within 8 to 10 hours of acetaminophen ingestion but may be helpful within 36 hours. It does not reverse damage that has already occurred.

## Applying Your Knowledge 7-4

How much acetaminophen is Julie possibly consuming in a 24-hour time period, and what danger does this present?

.....

## Treatment of Specific Disorders

### Arthritis

The primary goals of treatment are to control pain and inflammation and to minimize immobilization and disability. Rest, exercise, physical therapy, and drugs are used to attain these goals. Few of these measures prevent or slow joint destruction.

### Osteoarthritis (OA)

The main goal of drug therapy is relief of pain. Acetaminophen (4 g/day) is the initial drug of choice unless contraindicated by liver disease or hypersensitivity (Level A). Aspirin and other NSAIDs are also effective in reducing pain and inflammation (Level A); an antacid, H<sub>2</sub> blocker, or proton pump inhibitor may be added to the treatment regime for gastroprotection (Level A). Ibuprofen and other propionic acid derivatives are often used, although available NSAIDs have comparable effectiveness. A drug may be given for 2 or 3 weeks on a trial basis. If therapeutic benefits occur, the drug may be continued; if no benefits seem evident or toxicity occurs, another drug may be tried. A COX-2 inhibitor may be preferred for patients at high risk of GI ulceration and bleeding; however, caution must be used for individuals with cardiovascular risk factors or renal

dysfunction (Level B). NSAIDs are usually given in analgesic doses for OA, rather than the larger anti-inflammatory doses given for RA.

Additional treatments for knee OA include topical capsaicin, oral chondroitin and glucosamine, and intra-articular injections of corticosteroids (see Chap. 23) or hyaluronic acid (e.g., Synvisc, a product that helps restore the “shock-absorbing” ability of joint structures). Patients who continue to have severe pain and functional impairment despite medical treatment may need knee replacement surgery.

### Rheumatoid Arthritis (RA)

Acetaminophen may be useful to relieve pain (Level A); however, aspirin or another NSAID may be preferred because these drugs offer relieve pain as well as anti-inflammatory effects (Level B). Aspirin is effective, but many people are unable to tolerate the adverse effects associated with anti-inflammatory doses. When aspirin is used, dosage usually ranges between 2 and 6 grams daily but should be individualized to relieve symptoms, maintain therapeutic salicylate blood levels, and minimize adverse effects. For people who cannot take aspirin, another NSAID may be given. For those who cannot take aspirin or a nonselective NSAID because of GI irritation, peptic ulcer disease, bleeding disorders, or other contraindications, the selective COX-2 inhibitor NSAID, celecoxib, may be preferred. NSAIDs are usually given in larger, anti-inflammatory doses for RA, rather than the smaller, analgesic doses given for OA. Corticosteroids such as prednisone are also useful in slowing joint damage due to inflammation.

*Disease-modifying antirheumatic drugs (DMARDs)* include a variety of medications used to relieve symptoms and slow joint destruction (so called disease-modifying effects). DMARDs are the drugs of choice to treat active rheumatoid arthritis (Level B-C). DMARDs, as well as corticosteroids, may cause serious adverse effects, including greatly increased susceptibility to infection. Methotrexate (MTX), which is also used in cancer chemotherapy, is an example of a DMARD given in smaller doses for RA. About 75% of patients have a beneficial response, with improvement usually evident within 4 to 8 weeks (i.e., less morning stiffness, pain, joint edema, and fatigue). Biologic response modifiers, a type of DMARD, include drugs such as adalimumab (Humira), etanercept (Enbrel), infliximab (Remicade), and leflunomide (Arava), which modify the immune system by inhibiting cytokines, which mediate inflammation (see Chap. 41). Clinical improvement usually occurs within a few weeks. According to the Arthritis Foundation, a biologic response modifier given along with MTX may be the most effective and aggressive treatment for individuals with severe RA.

### Hyperuricemia and Gout

Opinions differ regarding treatment of asymptomatic hyperuricemia. Some authorities do not believe that drug therapy is indicated, and others believe that lowering serum uric acid levels may prevent joint inflammation and renal calculi. Allopurinol, probenecid, or sulfapyrazone may be given for this purpose. Colchicine also should be given for several weeks to prevent acute attacks of gout while serum uric acid levels are

being lowered. During initial administration of these drugs, a high fluid intake (to produce approximately 2000 mL of urine per day) and alkaline urine are recommended to prevent renal calculi. Urate crystals are more likely to precipitate in acid urine.

### Acute Migraine

Evidence-based guidelines for treating acute migraine headache as reported by the American Academy of Neurology include the following recommendations for adults: aspirin and other oral NSAIDs including combination products containing caffeine are effective first line treatment for mild to moderate migraine headaches (Level A). Acetaminophen is not usually used as monotherapy for migraine pain (Level B). Preparations containing sedatives such as butalbital should be limited due to the possibility of overuse headaches and withdrawal issues (Level C). Because nausea and vomiting often accompany migraine pain, oral or parenteral antiemetics may be prescribed (Level B-C depending on the antiemetic drug). Parenteral metoclopramide may also be used as monotherapy to treat migraine headaches (Level B). For moderate to severe migraine attacks, sumatriptan and related drugs are effective (Level A). They cause fewer adverse effects than ergot preparations and are usually well tolerated. However, because they are strong vasoconstrictors, they should not be taken by people with coronary artery disease or hypertension. They are also expensive compared with other antimigraine drugs. When nausea and vomiting accompany migraine headache and a triptan is indicated, sumatriptan may be given intranasal or subcutaneously (Level C).

Ergot alkaloids such as ergotamine and ergotamine-caffeine combination are effective treatment for moderate to severe migraine headaches (Level B). Dihydroergotamine (DHE 45) IM/Sub-Q may be used for patients with moderate to severe migraine pain (Level B). DHE 45 nasal spray is safe and effective for treating acute migraines (Grade A) and may be considered when migraine pain is accompanied by nausea and vomiting (Level C). If an ergot preparation is used, it should be given at the onset of headache, and the patient should lie down in a quiet, darkened room. For further information regarding best migraine practices for adults, the student is referred to the American Academy of Neurology Web site, [www.neurology.org](http://www.neurology.org).

Evidence-based guidelines for acute treatment of migraine headache as reported by the American Academy of Neurology (endorsed by the Academy of Pediatrics and the American Headache Society) include the following recommendations for children. Ibuprofen is effective for treating acute migraine headaches in children (Level A), and acetaminophen is probably effective and also can be considered for treating migraine pain (Level B). Aspirin is not recommended for children under the age of 15 due to the risk of Reye's syndrome. Several triptans were evaluated for acute migraine pain in children and adolescents. Rizatriptan and zolmitriptan were not superior to placebos for treating acute migraine pain in children, but sumatriptan nasal spray is effective for the treatment of acute migraine pain in adolescents (Level A). There are no data for

the use of oral sumatriptan in children or adolescents and limited data on the efficacy of subcutaneous sumatriptan (Level U). For further evidence-based practice guidelines for treating and preventing migraine headaches in children and adolescents, the student is referred to the American Academy of Neurology Web site, [www.neurology.org](http://www.neurology.org)

Both categories of migraine abortive drugs (e.g., ergot alkaloids and serotonin agonists) exert powerful vasoconstrictive effects and have the potential to raise blood pressure. For this reason, ergot alkaloids and serotonin agonists should not be used within 24 hours of each other when treating migraine headaches.

Excessive use of simple analgesics, analgesics containing sedatives (e.g., butalbital) or caffeine, triptans, opioids, or ergotamine are believed to play a role in triggering overuse headaches, also called “rebound headaches.” The most common clinical approach to management of overuse headaches involves tapering and/or cessation of the overused medication accompanied by temporary treatment of the rebound headache. Patients must be educated about the risks of chronic use of analgesics and encouraged to limit use of abortive and prophylactic migraine drugs appropriately. Use of nonpharmacologic therapies such as psychotherapy, biofeedback, and relaxation training may also be useful.

### Perioperative

Aspirin should generally be avoided for 1 to 2 weeks before and after surgery because it increases the risk of bleeding. Most other NSAIDs should be discontinued approximately 3 days before surgery; nabumetone and piroxicam have long half-lives and must be discontinued approximately 1 week before surgery. NSAIDs, administered intraoperatively, have been shown to reduce postoperative pain and use of opioids after abdominal surgery. After surgery, especially after relatively minor procedures, such as dental extractions and episiotomies, an NSAID may be used to relieve pain. Caution is needed because of increased risk of bleeding, and the drug should not be given if there are other risk factors for bleeding. In addition, ketorolac, the only injectable NSAID, has been used to relieve postoperative pain. This drug has several advantages over opioid analgesics, but bleeding and hematomas may occur.

### Cancer

Cancer often produces chronic pain from tumor invasion of tissues or complications of treatment (chemotherapy, surgery, or radiation). As with acute pain, acetaminophen, aspirin, or other NSAIDs prevent sensitization of peripheral pain receptors by inhibiting prostaglandin formation. NSAIDs are especially effective for pain associated with bone metastases. For mild pain, acetaminophen or an NSAID may be used alone; for moderate to severe pain, these drugs may be continued and an opioid analgesic added. Nonopioid and opioid analgesics may be given together or alternated; a combination of analgesics is often needed to provide optimal pain relief. Aspirin is contraindicated for the patient receiving chemotherapy that depresses the bone marrow because of the high risk of thrombocytopenia and bleeding.

## Use in Special Populations

### Use in Children

Acetaminophen is usually the drug of choice for pain or fever in children. Children seem less susceptible to liver toxicity than adults, apparently because they form less of the toxic metabolite during metabolism of acetaminophen. However, there is a risk of overdose and hepatotoxicity because acetaminophen is a very common ingredient in OTC cold, flu, fever, and pain remedies. An overdose can occur with large doses of one product or smaller amounts of several different products. In addition, toxicity has occurred when parents or caregivers have given the liquid concentration intended for children to infants. The concentrations are different and cannot be given interchangeably. Infants' doses are measured with a dropper, and children's doses are measured by teaspoon. Caution parents and caregivers to ask pediatricians for written instructions on giving acetaminophen to their children, to read the labels of all drug products very carefully, and to avoid giving children acetaminophen from multiple sources. Ibuprofen also may be given for fever. Alternating acetaminophen and ibuprofen every 4 hours over a 3-day period to control fever in young children (ages 6–36 months) has been shown to be more effective than monotherapy with either agent. Ibuprofen is preferred over acetaminophen when treating acute migraine headache pain in children and adolescents.

Aspirin is not recommended because of its association with Reye's syndrome, a life-threatening illness characterized by encephalopathy, hepatic damage, and other serious problems. Reye's syndrome usually occurs after a viral infection, such as influenza or chickenpox, during which aspirin was given for fever. A rare, but serious, adverse effect of ibuprofen and NSAIDs in children is the occurrence of severe skin reactions, such as Stevens-Johnson syndrome or toxic epidermal necrolysis. For children with juvenile RA, aspirin, ibuprofen, or naproxen may be given. Pediatric indications for use and dosages have not been established for most of the other drugs.

When an NSAID is given during late pregnancy to prevent premature labor, it may adversely affect the kidneys of the fetus. When an NSAID is given shortly after birth to close a patent ductus arteriosus, it may adversely affect the kidneys of the neonate.

### Use in Older Adults

The American Geriatric Society recommends acetaminophen be the initial consideration for treatment of middle to moderate pain of musculoskeletal origin (Level B). Acetaminophen is usually safe in recommended doses unless liver damage is present or the person is a chronic alcohol abuser. Aspirin is usually safe in the low doses prescribed for prevention of myocardial infarction and stroke (antiplatelet effects). Aspirin and other NSAIDs are probably safe in therapeutic doses for occasional use as an analgesic or antipyretic. The incidence of musculoskeletal disorders (e.g., OA) is higher in older adults, and aspirin or another NSAID is often prescribed. Older patients on long-term NSAIDs should be evaluated for GI blood loss, renal dysfunction, edema, hypertension, and drug–

drug or drug–disease interactions (Level A). Use of gastroprotective agents is recommended for individuals at risk of upper GI bleeding events (Level B). A COX-2 inhibitor may be preferred in older adults because they are less likely to cause gastric ulceration and bleeding; however, this benefit must be weighed against the increased risk of cardiovascular events.

### **Use in Patients With Renal Impairment**

Acetaminophen, aspirin, and other NSAIDs can cause or aggravate renal impairment even though they are eliminated mainly by hepatic metabolism. Acetaminophen is normally metabolized in the liver to metabolites that are excreted through the kidneys; these metabolites may accumulate in patients with renal failure. In addition, acetaminophen is nephrotoxic in overdose because it forms a metabolite that attacks kidney cells and may cause necrosis. Aspirin is nephrotoxic in high doses, and protein binding of aspirin is reduced in patients with renal failure so that blood levels of active drug are higher. In addition, aspirin and other NSAIDs can decrease blood flow in the kidneys by inhibiting synthesis of prostaglandins that dilate renal blood vessels. When renal blood flow is normal, these prostaglandins have limited activity. However, when renal blood flow is decreased, synthesis of these prostaglandins is increased, and they protect the kidneys from ischemia and hypoxia by antagonizing the vasoconstrictive effects of angiotensin II, norepinephrine, and other substances. Thus, in patients who depend on prostaglandins to maintain an adequate renal blood flow, the prostaglandin-blocking effects of aspirin and NSAIDs result in constriction of renal arteries and arterioles, decreased renal blood flow, decreased glomerular filtration rate, and retention of salt and water. NSAIDs can also cause kidney damage by other mechanisms, including a hypersensitivity reaction that leads to acute renal failure, manifested by proteinuria, hematuria, or pyuria. Biopsy reports usually indicate inflammatory reactions such as glomerulonephritis or interstitial nephritis.

People at highest risk from the use of these drugs are those with pre-existing renal impairment; those older than 50 years of age; those taking diuretics; and those with hypertension, diabetes, or heart failure. Measures to prevent or minimize renal damage include avoiding nephrotoxic drugs when possible, treating the disorders that increase risk of renal damage, stopping the NSAID if renal impairment occurs, monitoring renal function, reducing dosage, and maintaining hydration.

The role of COX-2 inhibitor NSAIDs in renal impairment is not clear. Although it was hoped that these drugs would have protective effects on the kidneys, studies indicate that their effects on the kidneys are similar to those of the older nonselective NSAIDs.

### **Use in Patients With Hepatic Impairment**

Except for acetaminophen, the effects of NSAIDs on liver function and the effects of hepatic impairment on most NSAIDs are largely unknown. Because the drugs are metabolized in the liver, they should be used with caution and in lower doses in people with impaired hepatic function or a history of liver disease. For example, some authorities recommend a maximum daily dose of 2 grams for people with hepatitis (compared

with a maximum daily dose of 4 grams for people who do not have impaired liver function).

Acetaminophen can cause fatal liver necrosis in overdose because it forms a metabolite that can destroy liver cells. The hepatotoxic metabolite is formed more rapidly when drug-metabolizing enzymes in the liver have been stimulated by ingestion of alcohol, cigarette smoking, and drugs such as anti-convulsants and others. Thus, alcoholics are at high risk of hepatotoxicity with usual therapeutic doses.

In cirrhotic liver disease, naproxen and sulindac may be metabolized more slowly and aggravate hepatic impairment if dosage is not reduced. In liver impairment, blood levels of oral sumatriptan and related antimigraine drugs may be high because less of the drug is metabolized on its first pass through the liver and a higher proportion of a dose reaches the systemic circulation. Thus, the drugs should be used cautiously, possibly in reduced dosage.

### **Use in Patients With Critical Illness**

Acetaminophen, aspirin, and other NSAIDs are infrequently used during critical illness, partly because they are usually given orally and many patients are unable to take oral medications. Pain is more likely to be treated with injectable opioid analgesics in this population. Acetaminophen may be given by rectal suppository for pain or fever in patients who are unable to take oral drugs.

These drugs may be risk factors for renal or hepatic impairment or bleeding disorders. For example, if a patient has a history of taking aspirin, including the low doses prescribed for antithrombotic effects, there is a risk of bleeding from common therapeutic (e.g., intramuscular injections, venipuncture, inserting urinary catheters or GI tubes) or diagnostic (e.g., drawing blood, angiography) procedures. If a patient has been taking an NSAID regularly, he or she may be more likely to experience renal failure if the critical illness causes dehydration or requires treatment with one or more nephrotoxic drugs. If a patient presents with acute renal failure, NSAID ingestion must be considered as a possible cause. If a patient is known to drink alcoholic beverages and take acetaminophen, he or she may be more likely to experience impaired liver function.

### **Use in Home Care**

Home use of acetaminophen, NSAIDs, and other analgesic drugs is extremely widespread. Many people are aware of the beneficial effects of these drugs in relieving pain, but they may not be adequately informed about potential problems associated with use of the drugs. Thus, the home care nurse may need to assist patients in perceiving a need for additional information and provide that information. Specific suggestions include reading and following instructions on labels of OTC analgesics, not exceeding recommended dosages without consulting a health care provider, and avoiding multiple sources of acetaminophen or NSAIDs (e.g., multiple OTC NSAIDs or an OTC and a prescription NSAID). In addition, adverse drug effects should be reviewed with patients, and patients should be assessed for characteristics (e.g., older age group, renal impairment, overuse of the drugs) that increase the risks of adverse effects.

## Nursing Actions

## Analgesic–Antipyretic–Anti-Inflammatory, and Related Drugs

## NURSING ACTIONS

## RATIONALE/EXPLANATION

## 1. Administer accurately

- a. Give aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) with a full glass of water or other fluid and with or just after food.
- b. Do not crush tablets or open capsules of long-acting dosage forms and instruct patients not to crush or chew the products. Examples include:
  - (1) Enteric-coated aspirin (e.g., Ecotrin)
  - (2) Diclofenac sodium (Voltaren or Voltaren XR)
  - (3) Diflunisal (Dolobid)
  - (4) Etodolac (Lodine XL)
  - (5) Indomethacin or Indocin SR
  - (6) Ketoprofen or Oruvail extended-release capsules
  - (7) Naproxen delayed-release (EC-Naprosyn) or naproxen sodium controlled-release (Napreelan)
- c. Give antimigraine preparations at the onset of headache.
- d. Give rapidly disintegrating tablets for migraine relief by placing tablet on the tongue. Do not give with water.

To decrease gastric irritation. Even though food delays absorption and decreases peak plasma levels of some of the drugs, it is probably safer to give them with food. Meloxicam may be given without regard to food.  
Breaking the tablets or capsules allows faster absorption, destroys the long-acting feature, and increases risks of adverse effects and toxicity from overdose.

To prevent development of more severe symptoms

Allows drug to dissolve and be absorbed

## 2. Observe for therapeutic effects

- a. When drugs are given for pain, observe for decreased or absent manifestations of pain.
- b. When drugs are given for fever, record temperature every 2–4 hours, and observe for a decrease.
- c. When drugs are given for arthritis and other inflammatory disorders, observe for decreased pain, edema, redness, heat, and stiffness of joints. Also observe for increased joint mobility and exercise tolerance.
- d. When colchicine is given for acute gouty arthritis, observe for decreased pain and inflammation in involved joints.
- e. When allopurinol, probenecid, or sulfipyrazone is given for hyperuricemia, observe for normal serum uric acid level (approximately 2–8 mg/100 mL).
- f. When allopurinol, probenecid, or sulfipyrazone is given for chronic gout, observe for decreased size of tophi, absence of new tophi, decreased joint pain and increased joint mobility, and normal serum uric acid levels.
- g. When triptans or ergot preparations are given to treat migraine headache, observe for relief of symptoms.

Pain relief is usually evident within 30–60 minutes.

With aspirin, improvement is usually noted within 24–48 hours. With most of the NSAIDs, 1–2 weeks may be required before beneficial effects become evident.

Therapeutic effects occur within 4–12 hours after intravenous colchicine administration and 24–48 hours after oral administration. Edema may not decrease for several days. Serum uric acid levels usually decrease to normal range within 1–3 weeks.

Therapeutic effects are usually evident within 15–30 minutes.

## 3. Observe for adverse effects

- a. With analgesic–antipyretic–anti-inflammatory and antigout agents, observe for:
  - (1) Gastrointestinal problems—anoxia, nausea, vomiting, diarrhea, bleeding, ulceration
  - (2) Hematologic problems—petechiae, bruises, hematuria, melena, epistaxis, and bone marrow depression (leukopenia, thrombocytopenia, anemia)
  - (3) Central nervous system effects—headache, dizziness, fainting, ataxia, insomnia, confusion, drowsiness
  - (4) Skin rashes, dermatitis
  - (5) Hypersensitivity reactions with dyspnea, bronchospasm, skin rashes

These are common reactions, more likely with aspirin, indomethacin, piroxicam, sulindac, colchicine, and sulfipyrazone and less likely with acetaminophen, celecoxib, diflunisal, etodolac, ibuprofen, and naproxen.

Bone marrow depression is more likely to occur with colchicine.

These effects are relatively common with indomethacin and may occur with most of the other drugs, especially with high dosages.

Rare but serious skin reactions, such as Stevens-Johnson syndrome or toxic epidermal necrolysis, are possible. These effects may simulate asthma in people who are allergic to aspirin and aspirin-like drugs; most likely to occur in patients with a history of nasal polyps.

---	--

NURSING ACTIONS	RATIONALE/EXPLANATION
(3) Salicylates (4) Heparin	Increase ulcerogenic effect Increases risk of bleeding. These drugs should not be used concurrently.
e. Drugs that <i>decrease</i> effects of indomethacin:	Delay absorption from the gastrointestinal tract
(1) Antacids	Decrease risks of renal calculi from precipitation of uric acid crystals. Alkalinizing agents are recommended until serum uric acid levels return to normal.
f. Drugs that <i>decrease</i> effects of allopurinol, probenecid, and sulfinpyrazone:	Decreases attacks of acute gout. Recommended for concurrent use until serum uric acid levels return to normal.
(1) Alkalinizing agents (e.g., sodium bicarbonate)	Decrease uricosuric effects
(2) Colchicine	Mainly at salicylate doses of less than 2 grams per day, decrease uricosuric effects of probenecid and sulfinpyrazone but do not interfere with the action of allopurinol. Salicylates are uricosuric at doses greater than 5 grams per day.
(3) Diuretics	
(4) Salicylates	
g. Drugs that <i>increase</i> effects of ergot preparations:	Additive vasoconstriction with risks of severe, persistent hypertension and intracranial hemorrhage CYP3A4 enzyme inhibition increases the amount of ergot preparation that remains in the body, resulting in life-threatening peripheral and cerebral vasoconstriction and ischemia.
(1) Vasoconstrictors (e.g., ephedrine, epinephrine, phenylephrine)	
(2) Any drug that inhibits CYP3A4 enzyme metabolism (protease inhibitors, macrolide antibiotics, ketoconazole, grapefruit juice, others)	
h. Drugs that <i>increase</i> effects of triptan antimigraine drugs:	Serotonin syndrome, a potentially life-threatening reaction, may occur when two drugs that affect serotonin levels in the body are taken concurrently. Symptoms of serotonin syndrome include restlessness, hallucinations, fever, loss of coordination, tachycardia, rapid changes in blood pressure, hyperactive reflexes, nausea, vomiting, and diarrhea.
(1) Antidepressants (SSRIs, SNRIs, MAOIs)	Increase serum levels of triptans and may cause serious adverse effects, including cardiac dysrhythmias and myocardial infarction
(2) MAOIs	<b>Triptans and MAOIs must not be taken concurrently; a triptan should be taken for at least 2 weeks after an MAOI is discontinued.</b>
(3) Ergot preparations	<b>Triptans and ergot preparations should not be taken concurrently or within 24 hours of each other, because severe hypertension and stroke may occur.</b>
i. Drugs that <i>increase</i> effects of eletriptan (Relplax)	Inhibition of CYP3A4 enzymes increases the amount of eletriptan that remains in the body, resulting in toxicity.
(1) Any drug that inhibits CYP3A4 enzyme metabolism. Examples include protease inhibitors, macrolide antibiotics, ketoconazole, grapefruit juice, others.	

## Key Concepts

- Aspirin, other NSAIDs, and acetaminophen inhibit COX enzymes, which are required for prostaglandin formation.
- Aspirin and other nonselective NSAIDs inhibit both COX-1 and COX-2. The COX-2 inhibitor, celecoxib, is more selective for the COX-2 enzyme. The exact mechanism of action of acetaminophen is unclear.
- Prostaglandins produced by COX-1 are important in regulating homeostasis and are associated with platelet aggregation and protective effects on the stomach and kidneys.
- Drug-induced inhibition results in gastric ulceration, renal dysfunction, and diminished blood clotting.
- Prostaglandins produced by COX-2 are associated with pain and inflammation. Drug-induced inhibition results in therapeutic effects of analgesia and anti-inflammatory activity.
- Individuals with hypersensitivity to aspirin should not take NSAIDs due to the risk of cross-sensitivity to other antiprostaglandin drugs.

- The use of gastroprotective drugs such as antacids, H<sub>2</sub> blockers, and proton pump inhibitors may be indicated to prevent upper gastrointestinal bleeding with chronic use of aspirin and other nonselective NSAIDs.
- In children and adolescents, aspirin is contraindicated in the presence of viral infections due to the risk of Reye's syndrome. Acetaminophen is the drug of choice for fever in children. Acetaminophen and ibuprofen may be alternated in the treatment of children with fever.
- The major drawback of acetaminophen use is the potentially fatal liver damage with overdose. Acetylcysteine is the specific antidote to acetaminophen overdose.
- Allopurinol, which inhibits the synthesis of uric acid, is the drug of choice for individuals with gout due to "overproduction" of uric acid.
- Colchicine is the only antigout drug with anti-inflammatory effects; it is useful for treating acute attacks.
- Probenecid and sulfinpyrazone are uricosuric drugs effective in treating individuals with gout who "under-excrete" uric acid.
- During treatment for gout, encourage individuals to increase fluid intake to 2000 milliliters per day to prevent renal calculi.
- Aspirin, other NSAIDs, and acetaminophen may be useful in the treatment of mild infrequent migraine pain.
- Serotonin receptor agonists and ergot alkaloids are effective in aborting acute migraine headaches. These medicines are powerful vasoconstrictors and may raise blood pressure. They should not be used within 24 hours of each other when treating migraine headaches.
- Overuse of all types of analgesics may lead to overuse or rebound headaches.

## Review and Application Exercises

### Short Answer Exercises

1. How do aspirin and other NSAIDs produce analgesic, antipyretic, anti-inflammatory, and antiplatelet effects?
2. What adverse effects occur with aspirin and other NSAIDs, especially with daily ingestion?
3. Compare and contrast the uses and effects of aspirin, ibuprofen, and acetaminophen.
4. For a 6-year-old child with fever, would aspirin or acetaminophen be preferred? Why?
5. For a 50-year-old adult with RA, would aspirin, another NSAID, or acetaminophen be preferred? Why?
6. For a 75-year-old adult with OA and a long history of "stomach trouble," would aspirin, another NSAID, or acetaminophen be preferred? Why?
7. What are some nursing interventions to decrease the adverse effects of aspirin, other NSAIDs, and acetaminophen?
8. When teaching a patient about home use of aspirin, other NSAIDs, and acetaminophen, what information must be included?
9. What is the rationale for using acetylcysteine in the treatment of acetaminophen toxicity?
10. What is the rationale for combining opioid and nonopioid analgesics in the treatment of moderate pain?
11. If you were a patient, what information do you think would be most helpful in home management of migraine?

### NCLEX-Style Questions

12. The nurse would question the pain medication order for which of the following patients?
  - a. acetaminophen for OA in a 60-year-old man with peptic ulcer disease
  - b. celecoxib for RA in a 48-year-old woman taking warfarin
  - c. acetaminophen for a headache in a 55-year-old man scheduled for surgery in the morning
  - d. aspirin for a feverish 12-year-old child with influenza
13. The most important laboratory tests the nurse should evaluate for a patient who takes an overdose of acetaminophen are
  - a. plasma salicylate
  - b. aspartate aminotransferase and alanine aminotransferase, bilirubin, and prothrombin time
  - c. blood urea nitrogen and creatinine
  - d. hemoglobin, hematocrit, and complete blood count
14. Which of the following nursing interventions is most important when allopurinol is prescribed for the treatment of gout?
  - a. Monitor stools for occult blood.
  - b. Encourage an acid ash diet to acidify the urine.
  - c. Encourage fluid intake of at least 3000 mL of fluid per day.
  - d. Encourage the use of aspirin when an OTC analgesic is necessary.
15. Prior to administering sumatriptan for migraine headaches, the nurse should assess for
  - a. bradycardia
  - b. elevated blood glucose level
  - c. adequate urine output
  - d. use of ergot preparations in past 24 hours

# Antianxiety and Sedative-Hypnotic Drugs

## KEY TERMS

- Anterograde amnesia
- Anxiety
- Anxiety disorder
- Anxiolytics
- Hypnotics
- Insomnia
- Sedatives

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Discuss characteristics, sources, and signs and symptoms of anxiety.
2. Discuss functions of sleep and consequences of sleep deprivation.
3. Describe nondrug interventions to decrease anxiety and insomnia.
4. List characteristics of benzodiazepine antianxiety and hypnotic drugs in terms of mechanism of action, indications for use, nursing process implications, and potential for abuse and dependence.
5. Describe strategies for preventing, recognizing, or treating benzodiazepine withdrawal reactions.
6. Contrast characteristics of selected nonbenzodiazepines and benzodiazepines.
7. Teach patients guidelines for rational, safe use of antianxiety and sedative-hypnotic drugs.
8. Discuss the use of flumazenil and other treatment measures for overdose of benzodiazepines.

## Applying Your Knowledge

Gertrude Portman is an 88-year-old woman who has been admitted for observation due to a syncopal episode. She is in the early stages of Alzheimer's disease and appears very anxious and agitated. Mrs. Portman has the following medical orders for sedation:

Alprazolam (Xanax) 0.25–0.5 mg 2–4 times daily for anxiety; Venlafaxine (Effexor XR) 75 mg daily; and Zolpidem (Ambien) 5 mg PO at half strength (HS) for sleep.

## Introduction

Antianxiety and sedative-hypnotic agents are central nervous system (CNS) depressants that have similar effects. Antianxiety drugs (also known as *anxiolytics*) and *sedatives* promote relaxation, and hypnotics produce sleep. The difference between the effects depends largely on dosage. Large doses of antianxiety and sedative agents produce sleep, and small doses of *hypnotics* produce antianxiety or sedative effects. In addition, therapeutic doses of hypnotics taken at bedtime may have residual sedative effects (“morning hangover”) the following day. Because these drugs produce varying degrees of CNS depression, some are also used as anticonvulsants and anesthetics.

The main drugs used to treat insomnia are the benzodiazepines and the nonbenzodiazepine hypnotics. Benzodiazepines are also used to treat short-term symptoms of acute anxiety in response to stressful situations. Antidepressants (i.e., selective serotonin reuptake inhibitors [SSRIs],

tricyclics [TCAs], and newer miscellaneous drugs) are preferred as first line drugs for long-term treatment of most chronic anxiety disorders, with benzodiazepines considered second line drugs (see Evidence-Based Practice Box 8-1). Antidepressant medications are discussed in more detail in Chapter 10. The barbiturates, a historically important group of CNS depressants, are obsolete for most uses, including treatment of anxiety and insomnia. A few may be used as intravenous general anesthetics (see Appendix C), phenobarbital may be used to treat seizure disorders (see Chap. 11), and some are abused (see Chap. 14).

To promote understanding of the uses and effects of both benzodiazepines and nonbenzodiazepines, anxiety and insomnia are described in the following sections. The clinical manifestations of these disorders are similar and overlapping; that is, daytime anxiety may be manifested as nighttime difficulty in sleeping because the person cannot “turn off” worries, and difficulty in sleeping may be manifested as anxiety, fatigue, and decreased ability to function during usual waking hours.

## Evidence-Based Practice

### 8-1 Treatment of Generalized Anxiety Disorder: Antidepressants Versus Anxiolytics

Historically, the benzodiazepine and nonbenzodiazepine antianxiety drugs have been the drugs of choice for treatment of generalized anxiety disorder. More recently, the antidepressants have been increasingly prescribed to treat generalized anxiety disorder.

A Cochrane Review (2002) of 15 clinical trials was conducted to determine the efficacy of antidepressants for treating generalized anxiety disorder. Antidepressants (i.e., imipramine, venlafaxine, and paroxetine) were found to be effective in the treatment of generalized anxiety disorder and were generally well tolerated by patients with anxiety. There was no evidence to determine that one class of antidepressants is more effective than another in treating adults with generalized anxiety disorder. In children with generalized anxiety disorder, one study showed Sertraline to be efficacious.

For the purposes of this review, only studies including subjects with generalized depression as a sole diagnosis were included; however, anxiety disorders are often comorbid with depression. The comorbidity rate for general anxiety disorder and depression is estimated to be as high as 62%. Studies of twins suggest a shared genetic basis for generalized anxiety disorder and depression. This comorbidity often results in worse treatment outcomes, increased risk for suicidality, greater recurrence of symptoms, and greater utilization of health care resources.

When generalized anxiety disorder is comorbid with depression, antidepressants may have a therapeutic advantage in that one drug can be beneficial for treating both conditions. However, antidepressants may result in an initial increase in agitation and anxiety resulting in just enough clinical improvement to allow the depressed and suicidal patient the energy to carry out suicidal plans. The nurse must be vigilant in monitoring patients with comorbid anxiety and depression for treatment-induced suicidality.

Kapczinski, F., Lima, M. S., Souza, J. S., Cunha, A., & Schmitt, R. (2002). Antidepressants for generalized anxiety disorder. *Cochrane Database Systematic Reviews*, 2, CD003592.

## Anxiety

Anxiety is a common disorder that may be referred to as nervousness, tension, worry, or other terms that denote an unpleasant feeling. It occurs when a person perceives a situation as threatening to physical, emotional, social, or economic well-being. Anxiety may occur in association with everyday events related to home, work, school, social activities, and chronic illness, or it may occur episodically, in association with acute illness, death, divorce, losing a job, starting a new job, or taking a test. Situational anxiety is a normal response to a stressful situation. It may be beneficial when it motivates the person toward constructive, problem-solving, coping activities. Symptoms may be quite severe, but they usually last only 2 to 3 weeks.

Although there is no clear boundary between normal and abnormal anxiety, when anxiety is severe or prolonged and impairs the ability to function in usual activities of daily living, it is called an *anxiety disorder*. The American Psychiatric Association delineates anxiety disorders as medical diagnoses in the *Diagnostic and Statistical Manual of Mental Disorders, 4th edition, Text Revision (DSM-IV-TR)*. This classification includes several types of anxiety disorders (Box 8-1). Generalized anxiety disorder (GAD) is emphasized in this chapter.

The pathophysiology of anxiety disorders is unknown, but there is evidence of a biologic basis and possible imbalances among several neurotransmission systems. A simplistic view involves an excess of excitatory neurotransmitters (e.g., norepinephrine) or a deficiency of inhibitory neurotransmitters (e.g., gamma-aminobutyric acid [GABA]).

The noradrenergic system is associated with the hyperarousal state experienced by patients with anxiety (i.e., feelings of panic, restlessness, tremulousness, palpitations, hyperventilation), which is attributed to excessive norepinephrine. Norepinephrine is released from the locus ceruleus (LC) in response to an actual or a perceived threat. The LC is a brain stem nucleus that contains many noradrenergic neurons and has extensive projections to the limbic system, cerebral cortex, and cerebellum. The involvement of the noradrenergic system in anxiety is supported by the observations that drugs that stimulate activity in the LC (e.g., caffeine) may cause symptoms of anxiety, and drugs used to treat anxiety (e.g., benzodiazepines) decrease neuronal firing and norepinephrine release in the LC.

Neuroendocrine factors also play a role in anxiety disorders. Perceived threat or stress activates the hypothalamic–pituitary–adrenal axis and corticotropin-releasing factor (CRF), one of its components. CRF activates the LC, which then releases norepinephrine and generates anxiety. Overall, CRF is considered important in integrating the endocrine, autonomic, and behavioral responses to stress.

GABA is the major inhibitory neurotransmitter in the brain and spinal cord. GABA<sub>A</sub> receptors are attached to chloride channels in nerve cell membranes. When GABA interacts with GABA<sub>A</sub> receptors, chloride channels open, chloride ions move into the neuron, and the nerve cell is less able to be excited (i.e., generate an electrical impulse).

## Box 8-1

## Anxiety Disorders

**Generalized Anxiety Disorder (GAD)**

Major diagnostic criteria for GAD include worry about two or more circumstances and multiple symptoms for 6 months or longer, and elimination of disease processes or drugs as possible causes. The frequency, duration, or intensity of the worry is exaggerated or out of proportion to the actual situation. Symptoms are related to motor tension (e.g., muscle tension, restlessness, trembling, fatigue), overactivity of the autonomic nervous system (e.g., dyspnea, palpitations, tachycardia, sweating, dry mouth, dizziness, nausea, diarrhea), and increased vigilance (feeling fearful, nervous, or keyed up; difficulty concentrating; irritability; insomnia).

Symptoms of anxiety occur with numerous disease processes, including medical disorders (e.g., hyperthyroidism, cardiovascular disease, cancer) and psychiatric disorders (e.g., mood disorders, schizophrenia, substance use disorders). They also frequently occur with drugs that affect the central nervous system (CNS). With CNS stimulants (e.g., nasal decongestants, antiasthma drugs, nicotine, caffeine), symptoms occur with drug administration; with CNS depressants (e.g., alcohol, benzodiazepines), symptoms are more likely to occur when the drug is stopped, especially if stopped abruptly.

When the symptoms are secondary to medical illness, they may decrease as the illness improves. However, most persons with GAD experience little relief when one stressful situation or problem is resolved. Instead, they quickly move on to another worry. Additional characteristics of GAD include its chronicity, although the severity of symptoms fluctuates over time; its frequent association with somatic symptoms (e.g., headache, gastrointestinal complaints, including irritable bowel syndrome); and its frequent coexistence with depression, other anxiety disorders, and substance abuse or dependence.

**Obsessive-Compulsive Disorder (OCD)**

An obsession involves an uncontrollable desire to dwell on a thought or a feeling; a compulsion involves repeated performance of some act to relieve the fear and anxiety associated with an obsession. OCD is characterized by obsessions or compulsions that are severe enough to be time consuming (e.g., take more than an hour per day), cause marked distress, or impair the person's ability to function in usual activities or relationships. The compulsive behavior provides some relief from anxiety but is not pleasurable. The person recognizes that the obsessions or compulsions are excessive or unreasonable and attempts to resist them. When patients resist or are prevented from performing the compulsive behavior, they experience increasing anxiety and often abuse alcohol or anti-anxiety, sedative-type drugs in the attempt to relieve anxiety.

**Panic Disorder**

Panic disorder involves acute, sudden, recurrent attacks of anxiety, with feelings of intense fear, terror, or impending doom. It may be accompanied by such symptoms as palpitations, sweating, trembling, shortness of breath or a feeling of

smothering, chest pain, nausea, or dizziness. Symptoms usually build to a peak over about 10 minutes and may require medication to be relieved. Afterward, the person is usually preoccupied and worried about future attacks.

A significant number (50–65%) of patients with panic disorder are thought to also have major depression. In addition, some patients with panic disorder also develop agoraphobia, a fear of having a panic attack in a place or situation where one cannot escape or get help. Combined panic disorder and agoraphobia often involves a chronic, relapsing pattern of significant functional impairment and may require lifetime treatment.

**Post-Traumatic Stress Disorder (PTSD)**

PTSD develops after seeing or being involved in highly stressful events that involve actual or threatened death or serious injury (e.g., natural disasters, military combat, violent acts such as rape or murder, explosions or bombings, serious automobile accidents). The person responds to such an event with thoughts and feelings of intense fear, helplessness, or horror and develops symptoms such as hyperarousal, irritability, outbursts of anger, difficulty sleeping, difficulty concentrating, and an exaggerated startle response. These thoughts, feelings, and symptoms persist as the traumatic event is relived through recurring thoughts, images, nightmares, or flashbacks in which the actual event seems to be occurring. The intense psychic discomfort leads people to avoid situations that remind them of the event; become detached from other people; have less interest in activities they formerly enjoyed; and develop other disorders (e.g., anxiety disorders, major depression, alcohol or other substance abuse).

The response to stress is highly individualized and the same event or type of event might precipitate PTSD in one person and have little effect in another. Thus, most people experience major stresses and traumatic events during their lifetimes, but many do not develop PTSD. This point needs emphasis because many people seem to assume that PTSD is the normal response to a tragic event and that intensive counseling is needed. For example, counselors converge upon schools in response to events that are perceived to be tragic or stressful. Some authorities take the opposing view, however, that talking about and reliving a traumatic event may increase anxiety in some people and thereby increase the likelihood that PTSD will occur.

**Social Anxiety Disorder (SAD)**

This disorder involves excessive concern about scrutiny by others, which may start in childhood and be lifelong. Affected persons are afraid they will say or do something that will embarrass or humiliate them. As a result, they try to avoid certain situations (e.g., public speaking) or experience considerable distress if they cannot avoid them. They are often uncomfortable around other people or experience anxiety in many social situations. SAD may be inherited; there is a threefold increase in the occurrence of SAD in related family members.

The serotonin system, although not as well understood, is also thought to play a role in anxiety. Both serotonin reuptake inhibitors and serotonin receptor agonists are now used to treat anxiety disorders. Research has suggested two possible roles for the serotonin receptor  $HT_{1A}$ . During embryonic development, stimulation of  $HT_{1A}$  receptors by serotonin is thought to play a role in development of normal brain circuitry necessary for normal anxiety responses. However, during adulthood, SSRIs act through  $HT_{1A}$  receptors to reduce anxiety responses.

Additional causes of anxiety disorders include medical conditions (anxiety disorder due to a general medical condition according to the *DSM-IV-TR*), psychiatric disorders, and substance abuse. Almost all major psychiatric illnesses may be associated with symptoms of anxiety (e.g., dementia, major depression, mania, schizophrenia). Anxiety related to substance abuse is categorized in the *DSM-IV-TR* as substance-induced anxiety disorder.

## Sleep and Insomnia

Sleep is a recurrent period of decreased mental and physical activity during which a person is relatively unresponsive to sensory and environmental stimuli. Normal sleep allows rest, renewal of energy for performing activities of daily living, and alertness on awakening.

When a person retires for sleep, there is an initial period of drowsiness or sleep latency, which lasts about 30 minutes. After the person is asleep, cycles occur approximately every 90 minutes during the sleep period. During each cycle, the sleeper progresses from drowsiness (stage I) to deep sleep (stages III and IV). These stages are characterized by depressed body functions, non-rapid eye movement (non-REM), and non-dreaming, and they are thought to be physically restorative. Activities that occur during these stages include increased tissue repair, synthesis of skeletal muscle protein, and secretion of growth hormone. At the same time, there is decreased body temperature, metabolic rate, glucose consumption, and production of catabolic hormones. Stage IV is followed by a period of 5 to 20 minutes of REM, dreaming, and increased physiologic activity.

REM sleep is thought to be mentally and emotionally restorative; REM deprivation can lead to serious psychological problems, including psychosis. It is estimated that a person spends about 75% of sleeping hours in non-REM sleep and about 25% in REM sleep. However, older adults often have a different pattern, with less deep sleep, more light sleep, more frequent awakenings, and generally more disruptions.

*Insomnia*, prolonged difficulty in going to sleep or staying asleep long enough to feel rested, is the most common sleep disorder. Insomnia has many causes, including such stressors as pain, anxiety, illness, changes in lifestyle or environment, and various drugs. Occasional sleeplessness is a normal response to many stimuli and is not usually harmful. Insomnia is said to be chronic when it lasts longer than 1 month. As in anxiety, several neurotransmission systems are apparently involved in regulating sleep-wake cycles and producing insomnia.

## General Characteristics of Benzodiazepines

Benzodiazepines are widely used for anxiety and insomnia and are also used for several other indications. They have a wide margin of safety between therapeutic and toxic doses and are rarely fatal, even in overdose, unless combined with other CNS depressant drugs, such as alcohol. They are Schedule IV drugs under the Controlled Substances Act. They are drugs of abuse and may cause physiologic dependence; therefore, withdrawal symptoms occur if the drugs are stopped abruptly. To avoid withdrawal symptoms, benzodiazepines should be gradually tapered and discontinued. They do not induce drug-metabolizing enzymes or suppress REM sleep. They may cause characteristic effects of CNS depression, including excessive sedation, impairment of physical and mental activities, and respiratory depression. They are not recommended for long-term use.

Benzodiazepines differ mainly in their plasma half-lives, production of active metabolites, and clinical uses. Drugs with half-lives longer than 24 hours (e.g., chlordiazepoxide, diazepam, clorazepate, flurazepam) form active metabolites that also have long half-lives and tend to accumulate, especially in older adults and people with impaired liver function. These drugs require 5 to 7 days to reach steady-state serum levels. Therapeutic effects (e.g., decreased anxiety or insomnia) and adverse effects (e.g., sedation, ataxia) are more likely to occur after 2 or 3 days of therapy than initially. Such effects accumulate with chronic usage and persist for several days after the drugs are discontinued. Drugs with half-lives shorter than 24 hours (e.g., alprazolam, lorazepam, midazolam, oxazepam, temazepam, triazolam) do not have active metabolites and do not accumulate. Although the drugs produce similar effects, they differ in clinical uses mainly because their manufacturers developed and promoted them for particular purposes. All benzodiazepines are effective sedative-hypnotics, but only flurazepam, temazepam, and triazolam are marketed for the treatment of insomnia.

## Mechanism of Action

Benzodiazepines bind with benzodiazepine receptors in nerve cells of the brain; this receptor complex also has binding sites for GABA, an inhibitory neurotransmitter. This GABA-benzodiazepine receptor complex regulates the entry of chloride ions into the cell. When GABA binds to the receptor complex, chloride ions enter the cell and hyperpolarize the cell membrane, making the cell membrane more stable and less responsive to excitatory neurotransmitters, such as norepinephrine. Benzodiazepines bind at a different site on the receptor complex and enhance the inhibitory effect of GABA to relieve anxiety, tension, and nervousness and to produce sleep. The decreased neuronal excitability also accounts for the usefulness of benzodiazepines as muscle relaxants, hypnotics, and anticonvulsants.

At least two benzodiazepine receptors, called BZ1 and BZ2, have been identified in the brain. BZ1 is thought to be

Table 8-1

## Pharmacokinetics of Benzodiazepines

Generic Name	Protein Binding (%)	Half-Life (H)	Metabolite(S)	ACTION		
				Onset	Peak	Duration
Alprazolam	80	7–15	Inactive	30 min	1–2 h	4–6 h
Chlordiazepoxide	96	5–30	Active	10–15 min	1–4 h	2–3 d
Clonazepam	97	20–50	Inactive	varies	1–4 h	weeks
Clorazepate	97	40–50	Active	rapid	1–2 h	days
Diazepam	98	20–80	Active	PO 30–60 min IV 1–5 min	1–2 h 30 min	3 h 15–60 min
Flurazepam	97	2–3	Active	15–45 min	30–60 min	6–8 h
Lorazepam	85	10–20	Inactive	PO 1–30 min IM 15–30 min IV 5–20 min	2–4 h 60–90 min 30 min	12–24 h 12–24 h 4 h
Midazolam		1–2	Active	15 min		30–60 min
Oxazepam	87	5–20	Inactive	slow	2–4 h	2–4 h
Temazepam	96	9–12	Inactive	30–60 min	2–3 h	6–8 h
Triazolam	78–89	2–5	Inactive	15–30 min	1–2 h	4–6 h

concerned with sleep mechanisms. BZ2 is associated with memory, motor, sensory, and cognitive functions.

## Pharmacokinetics

Benzodiazepines are well absorbed with oral administration, and most are given orally. A few (e.g., diazepam, lorazepam) are given both orally and parenterally. They are highly lipid soluble, widely distributed in body tissues, and highly bound to plasma proteins (85% to 98%). The high lipid solubility allows the drugs to easily enter the CNS and perform their actions. Then, the drugs are redistributed to peripheral tissues, from which they are slowly eliminated. Diazepam, for example, is an extremely lipid-soluble drug that enters the CNS and acts within 1 to 5 minutes after intravenous (IV) injection. However, the duration of action of a single IV dose is short (30 to 100 minutes) because the drug rapidly leaves the CNS and distributes peripherally. Thus, the pharmacodynamic effects (e.g., sedation) do not correlate with plasma drug levels because the drugs move in and out of the CNS rapidly. This redistribution allows a patient to awaken even though the drug may remain in the blood and other peripheral tissues for days or weeks before it is completely eliminated. The pharmacokinetic profile of some benzodiazepines is given in Table 8-1.

Benzodiazepines are mainly metabolized in the liver by the cytochrome P450 enzymes (3A4 subgroup) and glucuronide conjugation. Some (e.g., midazolam) are also metabolized by CYP3A4 enzymes in the intestine. Most benzodiazepines are oxidized by the enzymes to metabolites that are then conjugated. For example, diazepam is converted to *N*-desmethyl-diazepam (*N*-DMDZ), an active metabolite with a

long elimination half-life (up to 200 hours). *N*-DMDZ is further oxidized to oxazepam and then conjugated and excreted. With repeated drug doses, *N*-DMDZ accumulates and may contribute to both long-lasting antianxiety effects and to adverse effects. If oxidation is impaired (e.g., in older adults, in individuals with liver disease, with concurrent use of drugs that inhibit oxidation), higher blood levels of both the parent drugs and metabolites increase the risks of adverse drug effects. In contrast, lorazepam, oxazepam, and temazepam are conjugated only, so their elimination is not impaired by the above factors. Drug metabolites are excreted through the kidneys.

## Indications for Use

Major clinical uses of the benzodiazepines are as antianxiety, hypnotic, and anticonvulsant agents. They also are given for preoperative sedation, prevention of agitation and delirium tremens in acute alcohol withdrawal, and treatment of anxiety symptoms associated with depression, acute psychosis, or mania. Thus, they are often given concurrently with antidepressants, antipsychotics, and mood stabilizers.

Not all benzodiazepines are approved for all uses; Table 8-2 lists indications for the individual benzodiazepines. Diazepam has been extensively studied and has more approved uses than others.

## Contraindications to Use

Contraindications to benzodiazepines include severe respiratory disorders, severe liver or kidney disease, hypersensitivity reactions, and a history of alcohol or other drug abuse. The drugs must be used very cautiously when taken concurrently with any other CNS depressant drugs.

## Individual Drugs

### Benzodiazepines

**P Diazepam** (Valium) is the prototype benzodiazepine. High-potency benzodiazepines such as **alprazolam** (Xanax), **lorazepam** (Ativan), and **clonazepam** (Klonopin) may be more commonly prescribed due to their greater therapeutic effects and rapid onset of action. The trade names, indications for use,

and dosage ranges of individual benzodiazepines are listed in Table 8-2.

### Other Antianxiety and Sedative-Hypnotic Drugs

Several nonbenzodiazepine drugs of varied characteristics are also used as antianxiety and sedative-hypnotic agents. These include many antidepressants, buspirone, clomipramine, and hydroxyzine as antianxiety agents and chloral hydrate,

Table 8-2

Drugs at a Glance: Benzodiazepines

Generic/Trade Name	Clinical Indications	ROUTES AND DOSAGE RANGES	
		Adults	Children
<b>Alprazolam</b> (Xanax, Xanax XR)	Anxiety Panic disorder	Anxiety: PO 0.25–0.5 mg 3 times daily; maximum, 4 mg daily in divided doses <i>Older or debilitated adults</i> : PO 0.25 mg 2–3 times daily, increased gradually if necessary <i>Panic disorder</i> : PO 0.5 mg 3 times daily initially, gradually increase to 4–10 mg daily Xanax XR: PO 0.5–1 mg daily; gradually increase PRN to maximum dose of 3–6 mg daily	Dosage not established
<b>Chlordiazepoxide</b> (Librium)	Anxiety Acute alcohol withdrawal	PO 15–100 mg daily, once at bedtime or in 3–4 divided doses IM, IV 50–100 mg; maximum, 300 mg daily <i>Older or debilitated adults</i> : PO 5 mg 2–4 times daily; IM, IV 25–50 mg	>6 y: PO 5–10 mg 2–4 times daily <6 y: Not recommended
<b>Clonazepam</b> (Klonopin, Klonopin wafers)	Seizure disorders Panic disorder	<i>Seizure disorders</i> : PO 0.5 mg 3 times daily, increased by 0.5–1 mg every 3 days until seizures are controlled or adverse effects occur; maximum, 20 mg daily <i>Panic disorder</i> : PO 0.25 mg 2 times daily, increasing to 1 mg daily after 3 days	<i>Up to 10 y or 30 kg</i> : 0.01–0.03 mg/kg/d initially; not to exceed 0.05 mg/kg/d, in 2 or 3 divided doses; increase by 0.25–0.5 mg every third day until a daily dose of 0.1–0.2 mg/kg is reached
<b>Clorazepate</b> (Tranxene)	Anxiety Seizure disorders	PO 7.5 mg 3 times daily, increased by no more than 7.5 mg/wk; maximum, 90 mg daily	9–12 y: PO 7.5 mg 2 times daily, increased by no more than 7.5 mg/wk; maximum, 60 mg daily <9 y: Not recommended
<b>P Diazepam</b> (Valium)	Anxiety Seizure disorders Acute alcohol withdrawal Muscle spasm Preoperative sedation	PO 2–10 mg 2–4 times daily IM, IV 5–10 mg, repeated in 3–4 hours if necessary; give IV slowly, no faster than 5 mg (1 mL) per minute <i>Older or debilitated adults</i> : PO 2–5 mg once or twice daily, increased gradually if needed and tolerated	PO 1–2.5 mg 3–4 times daily, increased gradually if needed and tolerated >30 d and <5 y of age: Seizures, IM, IV 0.2–0.5 mg/2–5 min to a maximum of 5 mg 5 y or older: Seizures, IM, IV 1 mg/2–5 min to a maximum of 10 mg

(continued on page 136)

Table 8-2

## Drugs at a Glance: Benzodiazepines (continued)

Generic/Trade Name	Clinical Indications	ROUTES AND DOSAGE RANGES	
		Adults	Children
<b>Flurazepam</b> (Dalmane)	Insomnia	PO 15–30 mg	Not for use in children <15 years of age
<b>Lorazepam</b> (Ativan)	Anxiety Preoperative sedation	PO 2–6 mg/d in 2–3 divided doses IM 0.05 mg/kg to a maximum of 4 mg IV 2 mg, diluted with 2 mL of sterile water, sodium chloride, or 5% dextrose injection; do not exceed 2 mg/min <i>Older or debilitated adults:</i> PO 1–2 mg/d in divided doses	
<b>Midazolam</b> (Versed)	Preoperative sedation Sedation before short diagnostic tests and endoscopic examinations Induction of general anesthesia Supplementation of nitrous oxide/oxygen anesthesia for short surgical procedures	<i>Preoperative sedation:</i> IM 0.05–0.08 mg/kg approximately 1 h before surgery <i>Prediagnostic test sedation:</i> IV 0.1–0.15 mg/kg or up to 0.2 mg/kg initially; maintenance dose, approximately 25% of initial dose; reduce dose by 25%–30% if an opioid analgesic is also given <i>Induction of anesthesia:</i> IV 0.3–0.35 mg/kg initially, then reduce dose as above for maintenance; reduce initial dose to 0.15–0.3 mg/kg if a narcotic is also given	Preoperative or preprocedure sedation, induction of anesthesia: PO syrup 0.25–1 mg/kg (maximum dose, 20 mg) as a single dose
<b>Oxazepam</b> (Serax)	Anxiety Acute alcohol withdrawal	PO 10–30 mg 3–4 times daily <i>Older or debilitated adults:</i> PO 10 mg 3 times daily, gradually increased to 15 mg 3 times daily if necessary	
<b>Temazepam</b> (Restoril)	Insomnia	PO 15–30 mg	Not for use in children <18 years of age
<b>Triazolam</b> (Halcion)	Insomnia	PO 0.125–0.25 mg	Not for use in children <18 years of age

eszopiclone, ramelteon, zaleplon, and zolpidem as sedative-hypnotics. Miscellaneous nonbenzodiazepines are listed in Table 8-3.

**Buspirone** (BuSpar) differs chemically and pharmacologically from other anti-anxiety drugs. Its mechanism of action is unclear, but it apparently interacts with serotonin and dopamine receptors in the brain. Compared with the benzodiazepines, buspirone lacks muscle relaxant and anticonvulsant effects, does not cause sedation or physical or psychological dependence, does not increase the CNS depression of alcohol and other drugs, and is not a controlled substance. Adverse effects include nervousness and excitement. Thus, patients wanting and accustomed to sedative effects may not like the drug or comply with instructions for its use. Its only clinical indication for use is the short-term treatment of anxiety. Although some beneficial effects may occur within 7 to 10 days, optimal effects may require 3 to 4 weeks. Because therapeutic effects may be delayed, buspirone is not considered

beneficial for immediate effects or occasional (as needed, or PRN) use. Buspirone is rapidly absorbed after oral administration. Peak plasma levels occur within 45 to 90 minutes. It is metabolized by the liver to inactive metabolites, which are then excreted in the urine and feces. Its elimination half-life is 2 to 3 hours.

**Chloral hydrate** (Noctec, Aquachloral), the oldest sedative-hypnotic drug, is relatively safe, effective, and inexpensive in usual therapeutic doses. It reportedly does not suppress REM sleep. Tolerance develops after approximately 2 weeks of continual use. It is a drug of abuse and may cause physical dependence.

**Clomipramine** (Anafranil), **escitalopram** (Lexapro), **fluoxetine** (Prozac, Sarafem), **paroxetine** (Paxil), **sertraline** (Zoloft), and **venlafaxine** (Effexor, extended release only) are antidepressants generally prescribed for depression (see Chap. 10); however, they are also considered to be first line treatment for anxiety disorders. The Food and Drug Administration

### Drugs at a Glance: Miscellaneous Antianxiety and Sedative-Hypnotic Agents

Generic/ Trade Name	Major Clinical Use	ROUTES AND DOSAGE RANGES	
		Adults	Children
<b>Antianxiety Agents</b>			
<b>Buspirone</b> (BuSpar)	Anxiety	PO 5 mg 3 times daily, increased by 5 mg/d at 2- to 3-day intervals if necessary. Usual maintenance dose 20–30 mg/d in divided doses; maximum dose 60 mg/d.	Not recommended
<b>Clomipramine</b> (Anafranil)	Obsessive-compulsive disorder (OCD)	PO 25 mg/d initially; increase to 100 mg/d during the first 2 wk and to a maximum dose of 250 mg/d over several weeks if necessary.	PO 25 mg/d initially, gradually increased over 2 wk to a maximum of 3 mg/kg/d or 100 mg, whichever is smaller. Then increase to 3 mg/kg/d or 200 mg per day if necessary.
<b>Escitalopram</b> (Lexapro)	Generalized anxiety disorder (GAD)	PO 10 mg once daily, may increase after 1 wk, maximum dose 20 mg/d	Not recommended
<b>Hydroxyzine</b> (Vistaril)	Anxiety, sedative, pruritus	PO 75–400 mg/d in 3 or 4 divided doses Pre- and postoperative and pre- and postpartum sedation, IM 25–100 mg in a single dose	PO 2 mg/kg per day in 4 divided doses. Pre- and postoperative sedation, IM 1 mg/kg in a single dose.
<b>Paroxetine</b> (Paxil, Paxil CR)	Generalized anxiety disorder (GAD)	PO 20 mg/d, may increase by 10 mg/d every week to maximum dose 50 mg/d. In elderly, 10 mg/d, may increase to maximum dose 40 mg/d.	FOR OCD: 10–60 mg/d Not recommended for GAD or PTSD
	Obsessive-compulsive disorder (OCD)		
	Post-traumatic stress disorder (PTSD)		
	Panic disorders	PO 10 mg/d, increase by 10 mg/d every week to maximum dose 60 mg/d; maximum dose in elderly 40 mg/d.	Not recommended
	Social anxiety disorder (SAD)	PO 20 mg/d, may increase by 10 mg/d every week to maximum dose of 60 mg/d. In elderly, PO 10 mg/d may increase to maximum dose of 40 mg/d	Not recommended
<b>Sertraline</b> (Zoloft)	Obsessive-compulsive disorder (OCD)	OCD, PO 50 mg once daily	OCD, 6–12 y: PO 25 mg once daily; 13–17 y, PO 50 mg once daily
	Panic disorder	Panic disorder and PTSD, PO 25 mg once daily initially, increased after 1 wk to 50 mg once daily	
	Post-traumatic stress disorder (PTSD)		
	Social anxiety disorder (SAD)	SAD: PO 25 mg daily initially, increasing after 1 week to 50 mg; maximum dose 200 mg daily	
<b>Venlafaxine</b> extended release (Effexor XR)	Generalized anxiety disorder (GAD)	PO 37.5–75 mg once daily initially, increased up to 225 mg daily if necessary	Dosage not established
	Panic disorder	PO 75 mg once daily	
	Social anxiety disorder (SAD)		
<b>Sedative-Hypnotic Agents</b>			
<b>Chloral hydrate</b> (Aquachloral, Noctec)	Sedative, hypnotic	Sedative: PO, rectal suppository 250 mg 3 times per day  Hypnotic: PO, rectal suppository 500–1000 mg at bedtime; maximum dose, 2 g/d	Sedative: PO, rectal suppository 25 mg/kg per day, in 3 or 4 divided doses  Hypnotic: PO, rectal suppository 50 mg/kg at bedtime; maximum single dose, 1 g

(continued on page 138)

Table 8-3

**Drugs at a Glance: Miscellaneous Antianxiety and Sedative-Hypnotic Agents** (continued)

Generic/ Trade Name	Major Clinical Use	ROUTES AND DOSAGE RANGES	
		Adults	Children
<b>Sedative Hypnotic Agents</b>			
<b>Eszopiclone</b> (Lunesta)	Hypnotic	PO 2 mg at bedtime; may be increased to 3 mg if needed. For elderly, debilitated patients, and those with hepatic impairment, 1 mg PO at bedtime; may be increased to 2 mg if needed.	Not recommended
<b>Ramelteon</b> (Rozerem)	Hypnotic	PO 8 mg at bedtime	Not recommended
<b>Zaleplon</b> (Sonata)	Hypnotic	PO 10 mg at bedtime; 5 mg for adults who are elderly, of low weight, or have mild to moderate hepatic impairment	Dosage not established
<b>Zolpidem</b> (Ambien)	Hypnotic	PO 10 mg at bedtime; 5 mg for older adults and those with hepatic impairment	Not recommended

(FDA) has issued a **BLACK BOX WARNING** about the risk of suicidality (suicidal thinking or behavior) in young adults being treated with antidepressant medications. The nurse should observe the patient carefully for signs of clinical worsening, unusual behavior changes, or suicidality when administering antidepressant medications to adults.

**Eszopiclone** (Lunesta) is the first oral nonbenzodiazepine hypnotic to be approved for long-term use ( $\leq 12$  months). During drug testing, tolerance to the hypnotic benefits of eszopiclone was not observed over a 6-month period. Eszopiclone increases total sleep time and reduces the amount of time needed to fall asleep. Studies show the drug does not reduce nighttime awakenings. Eszopiclone is classified as a Schedule IV controlled substance by the Controlled Substance Act.

The hypnotic effect of eszopiclone is believed to be due to interaction with the GABA<sub>A</sub> receptor at location close to or coupled with the benzodiazepine receptors. Eszopiclone is rapidly absorbed after oral administration, reaching peak plasma levels 1 hour after administration. Onset of action may be delayed by approximately 1 hour if the drug is taken with a high-fat or heavy meal. Eszopiclone has a half-life of 6 hours. It is metabolized in the liver by CYP3A4 and CYP2E1 enzyme systems via oxidation and demethylation processes, producing metabolites that are much less reactive with GABA<sub>A</sub> receptors than the parent drug. Eszopiclone is eliminated primarily by the renal system.

The drug is contraindicated in patients with hypersensitivity reactions, and it should be used cautiously during pregnancy and lactation and in people who are depressed or have impaired hepatic or respiratory function. Adverse reactions include behavior changes such as reduced inhibition,

aggression or bizarre behavior, worsening depression and suicidal ideation, hallucinations, and *anterograde amnesia* (short-term memory loss). A commonly reported reaction to eszopiclone is an unpleasant taste. Elderly patients, those with hepatic impairment or debilitating conditions, and those taking drugs that inhibit CYP3A4 enzymes (e.g., antidepressants, antifungals, erythromycin, grapefruit, protease inhibitors, others) require lower dosages to reduce adverse effects. Eszopiclone should not be taken with alcohol or other CNS depressants to avoid additive effects.

**Hydroxyzine** (Vistaril) is an antihistamine with sedative and antiemetic properties. Clinical indications for use include anxiety, preoperative sedation, nausea and vomiting associated with surgery or motion sickness, and pruritus and urticaria associated with allergic dermatoses.

**Ramelteon** (Rozerem) is the newest oral nonbenzodiazepine hypnotic, approved for the long-term treatment of insomnia characterized by difficulty with sleep onset. Unlike other nonbenzodiazepine hypnotics, which bind to GABA<sub>A</sub> receptors, ramelteon binds to melatonin receptors in the central nervous system. Stimulation of melatonin receptors by ramelteon, like endogenous melatonin, is thought to play a role in the maintenance of the circadian rhythm, which helps regulate the normal sleep-wake cycle. Ramelteon does not appear to cause rebound insomnia post-treatment. Because it does not produce physical dependence, ramelteon is not classified as a controlled substance.

Ramelteon is rapidly absorbed orally, reaching peak plasma levels in about 45 minutes. Ramelteon is moderately protein bound (82%) and undergoes rapid hepatic first pass metabolism by CYP1A2 and to a lesser degree CYP2C and CYP3A4 enzyme systems. Ramelteon is excreted primarily

in the urine and does not accumulate in the body with daily dosing due to the short half-life of the drug (1 to 2.6 hours). Patients should avoid taking ramelteon with a high fatty meal because onset of action may be delayed by the presence of food.

Ramelteon is contraindicated in patients with severe hepatic impairment or in those patients taking fluvoxamine, a strong CYP1A2 inhibitor. The drug should be used with caution in those with depression or impaired respiratory function. Ramelteon may affect the endocrine hormones, resulting in decreased testosterone levels, increased prolactin levels, and decreased cortisol levels. Common adverse reactions to ramelteon include headache, fatigue, dizziness, nausea, diarrhea, arthralgia/myalgia, and taste changes. Like other hypnotics, ramelteon should not be taken with alcohol because of excessive sedation and respiratory depression.

**Zaleplon** (Sonata) is an oral, nonbenzodiazepine hypnotic approved for the short-term treatment (7 to 10 days) of insomnia. It binds to the benzodiazepine BZ1 receptor and apparently enhances the inhibitory effects of GABA, as do the benzodiazepines. It is a Schedule IV controlled substance; a few studies indicate abuse potential similar to that associated with benzodiazepines.

Zaleplon is well absorbed, but bioavailability is only about 30% because of extensive presystemic or “first-pass” hepatic metabolism. Action onset is rapid and peaks in 1 hour. A high-fat, heavy meal slows absorption and may reduce the drug’s effectiveness in inducing sleep. It is 60% bound to plasma proteins, and its half-life is 1 hour. The drug is metabolized mainly by aldehyde oxidase and slightly by the cytochrome P450 3A4 enzymes to inactive metabolites. The metabolites and a small amount of unchanged drug are excreted in the urine.

The drug is contraindicated in patients with hypersensitivity reactions and during lactation, and it should be used cautiously during pregnancy and in people who are depressed or have impaired hepatic or respiratory function. Adverse effects include depression, drowsiness, nausea, dizziness, headache, hypersensitivity, impaired coordination, and short-term memory impairment. To decrease risks of adverse effects, dosage should be reduced in patients with mild to moderate hepatic impairment and should be avoided in those with severe hepatic impairment. No dosage adjustment is needed with mild to moderate renal impairment; drug effects with severe renal impairment have not been studied. Dosage should also be reduced in older adults. Drug safety and effectiveness in children have not been established. Japanese patients may be at higher-than-average risk of adverse effects because these subjects had higher peak plasma levels and longer durations of action in clinical trials. These effects were attributed to differences in body weight or drug-metabolizing enzymes resulting from dietary, environmental, or other factors.

Zaleplon should not be taken concurrently with alcohol or other CNS depressant drugs because of the increased risk of excessive sedation and respiratory depression. There is also a risk of increased serum zaleplon levels if the drug is taken

concurrently with cimetidine (see Chap. 59). Cimetidine inhibits both the aldehyde oxidase and cytochrome P450 3A4 enzymes that metabolize zaleplon. If cimetidine is taken, zaleplon dosage should be reduced to 5 milligrams. It is very important that patients taking zaleplon be taught about this interaction because cimetidine is available without prescription, and the patient may not inform the health care provider who prescribes zaleplon about taking cimetidine.

Overall, zaleplon is effective in helping a person get to sleep and has several advantages as a hypnotic, including the rapid onset, absence of active metabolites, absence of clinically significant cytochrome P450 drug interactions, rapid clearance from the body, and absence of major memory impairments. However, it may not increase total sleep time or decrease the number of awakenings during sleeping hours.

**Zolpidem** (Ambien and Ambien CR), like zaleplon and eszopiclone, is a nonbenzodiazepine hypnotic. It differs structurally from the benzodiazepines but produces similar effects. Zolpidem is a Schedule IV drug approved for short-term treatment (7 to 10 days) of insomnia. Zolpidem should be given with caution to patients with signs and symptoms of major depression because of increased risk of intentional overdose.

Zolpidem is well absorbed with oral administration and has a rapid onset of action, usually within 20 to 30 minutes. Its half-life is 2.5 hours, and its hypnotic effects last 6 to 8 hours. A newer controlled release form of zolpidem (Ambien CR) contains a rapid releasing layer of medication which aids a person in falling asleep and a second layer which is released more slowly to promote sleep all night. Zolpidem is 90% bound to plasma proteins. Bioavailability, peak plasma concentration, and half-life are increased in older adults and in patients with impaired hepatic function. Dosage should be reduced for these groups. Zolpidem is metabolized to inactive metabolites that are then eliminated by renal excretion. Dosage reductions are not required for patients with renal impairment, but these patients should be closely monitored.

Adverse effects include daytime drowsiness, dizziness, nausea, diarrhea, and anterograde amnesia. Rebound insomnia may occur for a night or two after stopping the drug, and withdrawal symptoms may occur if it is stopped abruptly after approximately a week of regular use. Zolpidem should not be taken concurrently with alcohol or other CNS depressant drugs because of the increased risk of excessive sedation and respiratory depression.

## Herbal and Dietary Supplements

Numerous preparations have been used to relieve anxiety and insomnia. None has been adequately studied regarding dosage; effects; or interactions with prescribed drugs, over-the-counter drugs, or other supplements. Three products are commonly used.

**Kava** is derived from a shrub found in many South Pacific islands. It is claimed to be useful in numerous disorders,

including anxiety, depression, insomnia, asthma, pain, rheumatism, muscle spasms, and seizures. It suppresses emotional excitability and may produce a mild euphoria. Effects include analgesia, sedation, diminished reflexes, impaired gait, and pupil dilation. Kava has been used or studied most often for treatment of anxiety, stress, and restlessness. It is thought to act similarly to the benzodiazepines by interacting with GABA<sub>A</sub> receptors on nerve cell membranes. This action and limited evidence from a few small clinical trials may support use of the herb in the treatment of anxiety, insomnia, and seizure disorders. However, additional studies are needed to delineate therapeutic and adverse effects, dosing recommendations, and drug interactions when used for these conditions.

Adverse effects include impaired thinking, judgment, motor reflexes, and vision. Serious adverse effects may occur with long-term, heavy use, including decreased plasma proteins, decreased platelet and lymphocyte counts, dyspnea, and pulmonary hypertension. Kava should not be taken concurrently with other CNS depressant drugs (e.g., benzodiazepines, ethanol), antiplatelet drugs, or levodopa (increases Parkinson symptoms). In addition, it should not be taken by women who are pregnant or lactating or by children under 12 years of age. Finally, it should be used cautiously by patients with renal disease, thrombocytopenia, or neutropenia. In 2002, the Food and Drug Administration (FDA) issued a warning that products containing kava have been implicated in at least 25 cases of severe liver toxicity (e.g., hepatitis, cirrhosis, liver failure).

**Melatonin** is a hormone produced by the pineal gland, an endocrine gland in the brain. Endogenous melatonin is derived from the amino acid tryptophan, which is converted to serotonin, which is then enzymatically converted to melatonin in the pineal gland. Exogenous preparations are produced synthetically and may contain other ingredients. Melatonin products are widely available. Recommended doses on product labels usually range from 0.3 to 5 milligrams.

Melatonin influences sleep–wake cycles; it is released during sleep, and serum levels are very low during waking hours. Prolonged intake of exogenous melatonin can reset the sleep–wake cycle. As a result, it is widely promoted for prevention and treatment of jet lag (considered a circadian rhythm disorder) and treatment of insomnia. It is thought to act similarly to the benzodiazepines in inducing sleep. In several studies of patients with sleep disturbances, those taking melatonin experienced modest improvement compared with those taking a placebo. Other studies suggest that melatonin supplements improve sleep in older adults with melatonin deficiency and decrease weight loss in people with cancer. Large, controlled studies are needed to determine the effects of long-term use and the most effective regimen when used for jet lag.

Melatonin supplements are contraindicated in patients with hepatic insufficiency because of reduced clearance. They are also contraindicated in people with a history of cerebrovascular disease, depression, or neurologic disorders. They should be used cautiously by people with renal impairment and those taking benzodiazepines or other CNS depressant

drugs. Adverse effects include altered sleep patterns, confusion, headache, hypothermia, pruritus, sedation, and tachycardia.

**Valerian** is an herb used mainly as a sedative-hypnotic. It apparently increases the amount of GABA in the brain, probably by inhibiting the transaminase enzyme that normally metabolizes GABA. Increasing GABA, an inhibitory neurotransmitter, results in calming, sedative effects.

There are differences of opinion about the clinical usefulness of valerian; some practitioners say that studies indicate the herb's effectiveness as a sleep aid and mild antianxiety agent, whereas other practitioners say that these studies were flawed by small samples, short durations, and poor definitions of patient populations. An expert panel convened by the U.S. Pharmacopeia and a recent Cochrane Review (2006) concluded that there is insufficient evidence to support the use of valerian for treating insomnia (Level U).

Adverse effects with acute overdose or chronic use include blurred vision, cardiac disturbance, excitability, headache, hypersensitivity reactions, insomnia, and nausea. There is a risk of hepatotoxicity from overdosage and from using combination herbal products containing valerian. Valerian should not be taken by people with hepatic impairment (risk of increased liver damage) or by pregnant or breast-feeding women (effects are unknown). The herb should not be taken concurrently with any other sedatives, hypnotics, alcohol, or CNS depressants because of the potential for additive CNS depression.

## Applying Your Knowledge 8-1

### Legal/Ethical Dilemma

Mrs. Portman's daughter questions you about the medication her mother is receiving. She feels that her mother is too sedated and does not want her to receive any more medication. Without the medications, Mrs. Portman wanders away and is at risk to hurt herself. What would you do?

## Nursing Process

### Assessment

Assess the patient's need for antianxiety or sedative-hypnotic drugs, including intensity and duration of symptoms. Manifestations are more obvious with moderate to severe anxiety or insomnia. Some guidelines for assessment include the following:

- What is the patient's statement of the problem? Does the problem interfere with usual activities of daily living? If so, how much and for how long?
- Try to identify factors that precipitate anxiety or insomnia in the patient. Some common precursors are physical symptoms; feeling worried, tense, or nervous; factors such as illness, death of a friend or family member, divorce, or job stress; and excessive CNS stimulation from caffeine-

containing beverages or drugs such as bronchodilators and nasal decongestants. In addition, excessive daytime sleep and too little exercise and activity may cause insomnia, especially in older patients.

- Observe for behavioral manifestations of anxiety, such as psychomotor agitation, facial grimaces, tense posture, and others.
- Observe for physiologic manifestations of anxiety. These signs may include increased blood pressure and pulse rate, increased rate and depth of respiration, increased muscle tension, and pale, cool skin.
- If behavioral or physiologic manifestations seem to indicate anxiety, try to determine whether this is actually the case. Because similar manifestations may indicate pain or other problems rather than anxiety, the observer's perceptions must be validated by the patient before appropriate action can be taken.
- If insomnia is reported, observe for signs of sleep deprivation such as drowsiness, slow movements or speech, and difficulty concentrating or focusing attention.
- Obtain a careful drug history, including the use of alcohol and sedative-hypnotic drugs, and assess the likelihood of drug abuse and dependence. People who abuse other drugs, including alcohol, are likely to abuse antianxiety and sedative-hypnotic drugs. Also, assess for use of CNS stimulant drugs (e.g., appetite suppressants, bronchodilators, nasal decongestants, caffeine, cocaine) and herbs (e.g., ephedra).
- Identify coping mechanisms used in managing previous situations of stress, anxiety, and insomnia. These are very individualized. Reading, watching television, listening to music, or talking to a friend are examples. Some people are quiet and inactive; others participate in strenuous activity. Some prefer to be alone; others prefer being with a friend, family member, or group.
- After drug therapy for anxiety or insomnia is begun, assess the patient's level of consciousness and functional ability before each dose so that excessive sedation can be avoided.

### Nursing Diagnoses

- Ineffective Individual Coping related to need for antianxiety or sedative-hypnotic drug
- Deficient Knowledge: Appropriate uses and effects of antianxiety or sedative-hypnotic drugs
- Deficient Knowledge: Nondrug measures for relieving anxiety and insomnia
- Noncompliance: Overuse
- Risk for Injury related to sedation, respiratory depression, impaired mobility, and other adverse effects
- Sleep Pattern Disturbance: Insomnia related to one or more causes (e.g., anxiety, daytime sleep)

### Planning/Goals

#### The patient will

- Feel more calm, relaxed, and comfortable with anxiety; experience improved quantity and quality of sleep with insomnia
- Be monitored for excessive sedation and impaired mobility to prevent falls or other injuries (in health care settings)
- Verbalize and demonstrate nondrug activities to reduce or manage anxiety or insomnia
- Demonstrate safe, accurate drug usage
- Notify a health care provider if he or she wants to stop taking a benzodiazepine; agree to not stop taking a benzodiazepine abruptly
- Avoid preventable adverse effects, including abuse and dependence

### Interventions

Use nondrug measures to relieve anxiety or to enhance the effectiveness of antianxiety drugs.

- Assist patients to identify and avoid or decrease situations that cause anxiety and insomnia, when possible. In addition, help them to understand that medications do not solve underlying problems.
- Support the patient's usual coping mechanisms when feasible. Provide the opportunity for reading, exercising, listening to music, or watching television; promote contact with significant others; or simply allow the patient to be alone and uninterrupted for a while.
- Use interpersonal and communication techniques to help the patient manage anxiety. The degree of anxiety and the clinical situation largely determine which techniques are appropriate. For example, staying with the patient, showing interest, listening, and allowing him or her to verbalize concerns may be beneficial.
- Providing information may be a therapeutic technique when anxiety is related to medical conditions. People vary in the amount and kind of information they want, but usually the following topics should be included:
  - The overall treatment plan, including medical or surgical treatment, choice of outpatient care or hospitalization, expected length of treatment, and expected outcomes in terms of health and ability to function in activities of daily living
  - Specific diagnostic tests, including preparation; aftereffects, if any; and how the patient will be informed of results
  - Specific medication and treatment measures, including expected therapeutic results
  - What the patient must do to carry out the plan of treatment

- When offering information and explanations, keep in mind that anxiety interferes with intellectual functioning. Thus, communication should be brief, clear, and repeated as necessary, because patients may misunderstand or forget what is said.
- Modify the environment to decrease anxiety-provoking stimuli. Modifications may involve altering temperature, light, and noise levels.
- Use measures to increase physical comfort. These may include a wide variety of activities, such as positioning, helping the patient bathe or ambulate, giving back rubs, or providing fluids of the patient's choice.
- Consult with other services and departments on the patient's behalf. For example, if financial problems were identified as a cause of anxiety, social services may be able to help.
- When a benzodiazepine is used with diagnostic tests or minor surgery, provide instructions for postprocedure care to the patient or to family members, preferably in written form.

Implement measures to decrease the need for or increase the effectiveness of sedative-hypnotic drugs, such as the following:

- Modify the environment to promote rest and sleep (e.g., reduce noise and light).
- Plan care to allow uninterrupted periods of rest and sleep, when possible.
- Relieve symptoms that interfere with rest and sleep. Drugs such as analgesics for pain or antitussives for cough are usually safer and more effective than sedative-hypnotic drugs. Nondrug measures, such as positioning, exercise, and back rubs, may be helpful in relieving muscle tension and other discomforts. Allowing the patient to verbalize concerns, providing information so that he or she knows what to expect, or consulting other personnel (e.g., social worker, chaplain) may be useful in decreasing anxiety.
- Help the patient modify lifestyle habits to promote rest and sleep (e.g., limiting intake of caffeine-containing beverages, limiting intake of fluids during evening hours if nocturia interferes with sleep, avoiding daytime naps, having a regular schedule of rest and sleep periods, increasing physical activity, not trying to sleep unless tired or drowsy).

In addition, patient guidelines for antianxiety and sedative-hypnotic drugs are presented in the accompanying display.

## Evaluation

- Decreased symptoms of anxiety or insomnia and increased rest and sleep are reported or observed.
- Excessive sedation and motor impairment are not observed.
- The patient reports no serious adverse effects.
- Monitoring of prescriptions (e.g., "pill counts") does not indicate excessive use.

## Principles of Therapy

### Drug Dosage

With benzodiazepines, dosage must be individualized and carefully titrated because requirements vary widely among patients. With antianxiety agents, the goal is to find the lowest effective dose that does not cause excessive daytime drowsiness or impaired mobility. In general, start with the smallest dose likely to be effective (e.g., diazepam 2 mg three times daily or equivalent doses of others). Then, according to patient response, doses can be titrated upward to relieve symptoms of anxiety and avoid adverse drug effects. The maximum daily dose of diazepam is 40 milligrams per day or (equivalent doses of other drugs). With hypnotics, the lowest effective doses should be taken on an intermittent basis, not every night. Additional guidelines include the following:

- Smaller-than-usual doses may be indicated in patients receiving cimetidine or other drugs that decrease the hepatic metabolism of benzodiazepines, in older adults, and in debilitated patients. With alprazolam, the most commonly prescribed benzodiazepine, the dose should be reduced by 50% if given concurrently with the antidepressant fluvoxamine.
- In older adults, most benzodiazepines are metabolized more slowly, and half-lives are longer than in younger adults. Exceptions are lorazepam and oxazepam, whose half-lives and dosages are the same for older adults as for younger ones. The recommended initial dose of zaleplon and zolpidem is 5 milligrams, one half of that recommended for younger adults. Dosages of eszopiclone should also be reduced for older adults, beginning with 1 milligram initially, not to exceed 2 milligrams at bedtime.
- Larger-than-usual doses may be needed for patients who are severely anxious or agitated. Also, large doses are usually required to relax skeletal muscle; control muscle spasm; control seizures; and provide sedation before surgery, cardioversion, endoscopy, and angiography.
- When benzodiazepines are used with opioid analgesics, the analgesic dose should be reduced initially and increased gradually to avoid excessive CNS depression.

### Applying Your Knowledge 8-2

Mrs. Portman is given 0.5 mg of alprazolam at 2:00 P.M. You assess her at 6:00 P.M. and prepare her for her dinner. Mrs. Portman is very drowsy and has difficulty feeding herself. After dinner, Mrs. Portman begins to experience mild anxiety and you prepare to administer an appropriate dose of medication. What would you prepare and why?

## Patient Teaching Guidelines Antianxiety and Sedative-Hypnotic Drugs

### General Considerations

- “Nerve pills” and “sleeping pills” can relieve symptoms temporarily, but they do not cure or solve the underlying problems. With rare exceptions, these drugs are recommended only for short-term use. For long-term relief, counseling or psychotherapy may be more beneficial because it can help you learn other ways to decrease your nervousness and difficulty in sleeping.
- Use nondrug measures to promote relaxation, rest, and sleep when possible. Physical exercise, reading, craft work, stress management, and relaxation techniques are safer than any drug.
- Try to identify and avoid factors that cause nervousness or insomnia, such as caffeine-containing beverages and stimulant drugs. This may prevent or decrease the severity of nervousness or insomnia so that sedative-type drugs are not needed. If the drugs are used, these factors can cancel or decrease the drugs’ effects. Stimulant drugs include asthma and cold remedies and appetite suppressants.
- Most “nerve pills” and “sleeping pills” belong to the same chemical group and have similar effects, including the ability to decrease nervousness, cause drowsiness, and cause dependence. Thus, there is no logical reason to take a combination of the drugs for anxiety, or to take one drug for daytime sedation and another for sleep. Ativan, Xanax, Valium, and Restoril are commonly used examples of this group, but there are several others as well.
- Inform all health care providers when taking a sedative-type medication, preferably by the generic and trade names. This helps avoid multiple prescriptions of drugs with similar effects and reduces the risk of serious adverse effects from overdose.
- Do not perform tasks that require alertness if drowsy from medication. The drugs often impair mental and physical functioning, especially during the first several days of use, and thereby make routine activities potentially hazardous. Avoid smoking, ambulating without help, driving a car, operating machinery, and other potentially hazardous tasks. These activities may lead to falls or other injuries if undertaken while alertness is impaired.
- Avoid alcohol and other depressant drugs (e.g., over-the-counter [OTC] antihistamines and sleeping pills, narcotic analgesics, sedating herbs such as kava and valerian, and the dietary supplement melatonin) while taking any antianxiety or sedative-hypnotic drugs (except buspirone). An antihistamine that causes drowsiness is the active ingredient in OTC sleep aids (e.g., Compoz, Nytol, Somnifex, Unisom) and in many pain reliever products with “PM” as part of their names (e.g., Tylenol PM). Because these drugs depress brain functioning when taken alone, combining them produces additive depression and may lead to excessive drowsiness, difficulty breathing, traumatic injuries, and other potentially serious adverse drug effects.
- Store drugs safely, out of reach of children and adults who are confused or less than alert. Accidental or intentional ingestion may lead to serious adverse effects. Also, do not keep the drug container at the bedside, because a person sedated by a previous dose may take additional doses.
- Do not share these drugs with anyone else. These mind-altering, brain-depressant drugs should be taken only by those people for whom they are prescribed.
- Do not stop taking a Valium-related drug abruptly. Withdrawal symptoms can occur. When being discontinued, dosage should be gradually reduced, as directed by and with the supervision of a health care provider.
- Do not take most “sleeping pills” every night. Many sleeping pills lose their effectiveness in 2–4 weeks if taken nightly, and cause sleep disturbances when stopped. If longer drug therapy for insomnia is needed, eszopiclone (Lunesta) and ramelteon (Rozerem) are approved for long-term use.
- Alprazolam (Xanax) is sometimes confused with ranitidine (Zantac), a drug for heartburn and peptic ulcers.

### Self-Administration

- Follow instructions carefully about how much, how often, and how long to take the drugs. These drugs produce more beneficial effects and fewer adverse reactions when used in the smallest effective doses and for the shortest duration feasible in particular circumstances. All of the Valium-related drugs, eszopiclone (Lunesta), zaleplon (Sonata), and zolpidem (Ambien) can cause physical dependence, which may eventually cause worse problems than the original anxiety or insomnia.
- Take sleeping pills just before going to bed so that you are lying down when the expected drowsiness occurs.
- Omit one or more doses if excessive drowsiness occurs to avoid difficulty breathing, falls, and other adverse drug effects.
- Take oral benzodiazepines with a glass of water; they may be taken with food if stomach upset occurs.
- Take buspirone on a daily schedule. It is not fully effective until after 3–4 weeks of regular use; it is ineffective for occasional use.
- Take nonbenzodiazepine hypnotics on an empty stomach, at bedtime, because fatty heavy meals delay onset of action.
- Take Xanax XR once daily, preferably in the morning. Take the tablet intact; do not crush, chew, or break it.
- Take Klonopin wafers (orally disintegrating tablets) by carefully peeling open the foil packaging and placing the tablet in the mouth. Disintegration quickly occurs in saliva, and the tablet can be swallowed with or without water.

## Drug Administration

### Frequency of Administration

The antianxiety benzodiazepines are often given in three or four daily doses. This is necessary for the short-acting agents, but there is no pharmacologic basis for multiple daily doses of the long-acting drugs. Because of their prolonged actions, all or

most of the daily dose can be given at bedtime. This schedule promotes sleep, and there is usually enough residual sedation to maintain antianxiety effects throughout the next day. If necessary, one or two small supplemental doses may be given during the day. Although the hypnotic benzodiazepines vary in their onset of action, they should be taken at bedtime because it is safer for patients to be recumbent when drowsiness occurs.

Eszopiclone, ramelteon, zaleplon, and zolpidem also should be taken at bedtime because of their rapid onset of action.

### Duration of Therapy

Benzodiazepines should be given for the shortest effective period to decrease the likelihood of drug abuse and physiologic and psychological dependence. Few problems develop with short-term use unless an overdose is taken or other CNS depressant drugs (e.g., alcohol) are taken concurrently. Most problems occur with long-term use, especially of larger-than-usual doses. In general, an antianxiety benzodiazepine should not be taken for longer than 4 months and a hypnotic benzodiazepine should not be taken more than three or four nights a week for approximately 3 weeks.

For buspirone, recommendations for duration of therapy have not been established. For zaleplon and zolpidem, the recommended duration is no longer than 10 days. Eszopiclone is approved for long-term treatment of insomnia and may be taken up to 12 months. Ramelteon, the only non-controlled substance scheduled hypnotic, is approved for long-term use.

### Benzodiazepine Withdrawal: Prevention and Management

Physical dependence on benzodiazepines, which is associated with longer use and higher doses, is indicated by withdrawal symptoms when the drugs are stopped. Mild symptoms occur in approximately half the patients taking therapeutic doses for 6 to 12 weeks; severe symptoms are most likely to occur when high doses are taken regularly for more than 4 months and then abruptly discontinued. Although the drugs have not been proven effective for more than 4 months of regular use, this period is probably exceeded quite often in clinical practice.

Withdrawal symptoms may be caused by the abrupt separation of benzodiazepine molecules from their receptor sites and the resulting acute decrease in GABA neurotransmission. Because GABA is an inhibitory neurotransmitter, less GABA may produce a less inhibited CNS and therefore symptoms of hyperarousal or CNS stimulation. Common manifestations include increased anxiety, psychomotor agitation, insomnia, irritability, headache, tremor, and palpitations. Less common but more serious manifestations include confusion, abnormal perception of movement, depersonalization, psychosis, and seizures.

Severe symptoms are most likely to occur with short-acting drugs (e.g., alprazolam, lorazepam, triazolam) unless they are discontinued very gradually. Symptoms may occur within 24 hours of stopping a short-acting drug, but they usually occur 4 to 5 days after stopping a long-acting drug such as diazepam. Symptoms can be relieved by administration of a benzodiazepine.

To prevent withdrawal symptoms, the drug should be tapered in dose and gradually discontinued. Reducing the dose by 10% to 25% every 1 or 2 weeks over 4 to 16 weeks usually is effective. However, the rate may need to be even slower with high doses or long-term use. After the drug is discontinued, the patient should be monitored for a few weeks for symptoms of

withdrawal or recurrence of symptoms for which the drug was originally prescribed.

### Benzodiazepine Toxicity: Recognition and Management

Toxic effects of benzodiazepines include excessive sedation, respiratory depression, and coma. **Flumazenil** (Romazicon) is a specific antidote that competes with benzodiazepines for benzodiazepine receptors and reverses toxicity. Clinical indications for use include benzodiazepine overdose and reversal of sedation after diagnostic or therapeutic procedures. The degree of sedation reversal depends on the plasma concentration of the ingested benzodiazepine and the flumazenil dose and frequency of administration. The drug acts rapidly, with onset within 2 minutes and peak effects within 6 to 10 minutes. However, the duration of action is short (serum half-life is 60 to 90 minutes) compared with that of most benzodiazepines, so repeated doses are usually required. Adverse effects include precipitation of acute benzodiazepine withdrawal symptoms, agitation, confusion, and seizures. Re-sedation and hypoventilation may occur if flumazenil is not given long enough to coincide with the duration of action of the benzodiazepine.

The drug should be injected into a freely flowing IV line in a large vein. Dosage recommendations vary with use. For reversal of conscious sedation or general anesthesia, the initial dose is 0.2 milligrams over 15 seconds, then 0.2 milligrams every 60 seconds, if necessary, to a maximum of 1.0 milligrams (total of five doses). For overdose, the initial dose is 0.2 milligrams over 30 seconds, wait 30 seconds, then 0.3 milligrams over 30 seconds, then 0.5 milligrams every 60 seconds up to a total dose of 3 milligrams, if necessary, for the patient to reach the desired level of consciousness. Slow administration and repeated doses are recommended to awaken the patient gradually and decrease the risks of causing acute withdrawal symptoms. A patient who does not respond within 5 minutes of administering the total recommended dose should be reassessed for other causes of sedation.

### Applying Your Knowledge 8-3

Mrs. Portman continues to receive her medication for a few days and then is no longer given the alprazolam. She begins to experience anxiety, agitation, and irritability. What is the possible explanation for these symptoms?

.....

### Drug Therapy for Anxiety

Antianxiety drugs are not recommended for treating everyday stress and anxiety. Some authorities believe such use promotes reliance on drugs and decreases development of healthier coping mechanisms. For severe anxiety associated with a temporary stressful situation, an anxiolytic drug may be beneficial for short-term use as needed; prolonged therapy is not recommended. These drugs are most clearly indicated when anxiety

causes disability and interferes with job performance, interpersonal relationships, and other activities of daily living. Because anxiety often accompanies pain, antianxiety agents are sometimes used to treat pain. However, in the management of chronic pain, antianxiety drugs have not demonstrated a definite benefit and in some cases may actually heighten the pain awareness. Anxiety about recurrence of pain is better controlled by adequate analgesia than by antianxiety drugs.

Because benzodiazepines are equally effective in relieving acute anxiety, other factors may assist the prescriber in choosing a particular drug for a particular patient. For example, alprazolam, clorazepate, and diazepam decrease anxiety within 30 to 60 minutes. Thus, one of these drugs may be preferred when rapid onset of drug action is desired. Lorazepam and oxazepam have a slower onset of action and thus are not recommended for acute symptoms of anxiety. Because they have short half-lives and their elimination does not depend on the cytochrome P450 oxidizing enzymes in the liver, lorazepam and oxazepam are the drugs of choice for patients who are elderly, have liver disease, or are taking drugs that interfere with hepatic drug-metabolizing enzymes.

For chronic anxiety disorders, prescribers must consider the type of anxiety disorder before prescribing treatment. Antidepressants are considered first line drugs for the treatment of most anxiety disorders; however, benzodiazepines may be prescribed as second line drugs for some anxiety disorders. Although benzodiazepines are effective anxiolytics, long-term use is associated with concerns over tolerance, dependency, withdrawal, lack of efficacy for treating the depression that often accompanies anxiety disorders, and the need for multiple daily dosing with some benzodiazepines. In studies comparing the effects of antidepressants and benzodiazepines for treating generalized anxiety disorder (GAD), it was concluded that benzodiazepines work faster (within a few days) but that antidepressants are more effective after 4 to 6 weeks. Some clinicians prescribe a combination of a benzodiazepine and an antidepressant. The benzodiazepine provides relief during the 2 to 3 weeks required for antidepressant effects, and then it is tapered and discontinued while the antidepressant is continued. Antidepressants do not cause cognitive impairment or dependence, as do benzodiazepines. In addition, patients with GAD often have depression as well. Thus, an antidepressant can relieve both anxiety and depression, but a benzodiazepine is not effective for treating depression.

One factor to consider in the use of antidepressants is that these drugs can increase the agitation and hyperarousal already present in the patient with GAD. To minimize stimulation, initial doses of antidepressants should be about 50% less than the doses for depression. Then, the dose can be increased over 1 to 2 weeks. The optimal maintenance dose of an antidepressant for GAD is usually the same as for depression. Another factor is that patients may not be willing to take antidepressants long term because of the sexual dysfunction and weight gain associated with the drugs.

Bupirone is an alternative antianxiety agent, especially for patients with conditions (e.g., chronic obstructive lung

disease) that may be aggravated by the sedative and respiratory depressant effects of benzodiazepines. A Cochrane Review (2006) found BuSpar to be useful in the treatment of GAD, especially those that had not previously been taking a benzodiazepine; however, it may not be superior to benzodiazepines. Longer term studies are needed to answer this question. BuSpar has a delayed onset of action for up to 2 to 4 weeks. Thus, bupirone is not useful for acute episodes of anxiety, and it may be difficult to persuade some patients to take the drug long enough to be effective. Adverse effects are usually mild and can include nausea and dizziness. Bupirone should not be taken in combination with monoamine oxidase inhibitors; otherwise, bupirone has few drug–drug interactions. When used to treat GAD, some clinicians recommend relatively high doses of 30 to 60 milligrams daily (in two or three divided doses).

Overall, a combination of drug therapy and psychotherapy may be the most effective treatment for GAD. Antidepressants, bupirone, and benzodiazepines are the drugs of choice; cognitive behavioral therapy (CBT) is probably the nonpharmacologic treatment of choice. Drug therapy can relieve the symptoms; CBT can help patients learn to manage their anxiety and decrease their negative thinking. After anxiety is under control, some clinicians recommend continuing drug therapy for at least a year.

Although selective serotonin reuptake inhibitors are preferred for the treatment of panic disorders because they are effective and well tolerated, benzodiazepines continue to be the most commonly prescribed medication for treatment of panic disorders. Longer acting benzodiazepines such as clonazepam and alprazolam XR are useful in treating breakthrough panic symptoms that may occur at the end of therapy with shorter acting medications. Selective serotonin reuptake inhibitors and venlafaxine are first line therapy for social anxiety disorder; however, benzodiazepines may be prescribed in children after failure to respond to all other types of drug therapy. Benzodiazepines are not generally prescribed for obsessive-compulsive disorder; selective serotonin reuptake inhibitors and clomipramine are preferred therapy for this condition. Although benzodiazepines may be useful in reducing acute anxiety associated with post-traumatic stress syndrome (PTSD), they are not considered effective in the long-term management of PTSD.

### Drug Therapy for Insomnia

In general, sedative-hypnotic drugs should be used only when insomnia causes significant distress and resists management by nonpharmacologic means; they should not be used for occasional sleeplessness. The goal of treatment is to relieve anxiety or sleeplessness without permitting sensory perception, responsiveness to the environment, or alertness to drop below safe levels. The drugs of choice for most patients are the benzodiazepines and the nonbenzodiazepine hypnotics, eszopiclone, ramelteon, zaleplon, and zolpidem. However, for patients with insomnia associated with major depression, antidepressants are preferred.

Sedative-hypnotic drugs should not be taken every night unless necessary. Intermittent administration helps maintain drug effectiveness and decreases the risks of drug abuse and dependence. It also decreases disturbances of normal sleep patterns. For chronic insomnia, only eszopiclone is recommended for long-term treatment ( $\leq 12$  months). Most benzodiazepine hypnotics lose their effectiveness in producing sleep after 4 weeks of daily use; triazolam loses effectiveness in 2 weeks. It is not helpful to switch from one drug to another because cross-tolerance develops. To restore the sleep-producing effect, administration of the hypnotic drug must be interrupted for 1 to 2 weeks.

When sedative-hypnotic drugs are prescribed for outpatients, the prescription should limit the number of doses dispensed and the number of refills. This is one way of decreasing the risk of abuse and suicide.

As with the antianxiety benzodiazepines, most hypnotic benzodiazepines are oxidized in the liver by the cytochrome P450 enzymes to metabolites that are then conjugated and excreted through the kidneys. An exception is **temazepam** (Restoril), which is eliminated only by conjugation with glucuronide. Thus, temazepam is the drug of choice for patients who are elderly, have liver disease, or are taking drugs that interfere with hepatic drug-metabolizing enzymes.

## Use in Special Populations

### Use in Children

Anxiety is a common disorder among children and adolescents. When given antianxiety and sedative-hypnotic drugs, they may have unanticipated or variable responses, including paradoxical CNS stimulation and excitement rather than CNS depression and calming. Few studies have been done in children. Thus, much clinical usage of these drugs is empiric, not approved by the FDA, and not supported by data. As with other populations, benzodiazepines should be given to children only when clearly indicated, in the lowest effective dose, and for the shortest effective time.

Drug pharmacodynamics and pharmacokinetics are likely to be different in children than in adults. Pharmacodynamic differences may stem from changes in neurotransmission systems in the brain as the child grows. Pharmacokinetic differences may stem from changes in distribution or metabolism of drugs; absorption seems similar to that in adults. In relation to distribution, children usually have a lesser percentage of body fat than adults. Thus, antianxiety and sedative-hypnotic drugs, which are usually highly lipid soluble, cannot be as readily stored in fat as they are in adults. This often leads to shorter half-lives and the need for more frequent administration. In relation to metabolism, young children (e.g., preschoolers) usually have a faster rate than adults and may therefore require relatively high doses for their size and weight. In relation to excretion, renal function is usually similar to that of adults and most of the drugs are largely inactive. Thus, with normal renal function, excretion probably has little effect on blood levels of active drug or the child's response to the drug.

Oral and parenteral diazepam has been used extensively in children, in all age groups older than 6 months. Other benzodiazepines are not recommended for particular age groups (see Table 8-2). The effects of buspirone, eszopiclone, zaleplon, and zolpidem in children are unknown, and these drugs are not recommended for use in children. Because there are reproductive concerns over the use of ramelteon in children due to decreased testosterone levels and increased prolactin levels, ramelteon is not recommended for use in children and adolescents.

The FDA has issued **BLACK BOX WARNINGS** for the use of most antidepressants (including the SSRIs) in children and adolescents. SSRIs may increase suicidality in children and adolescents with major depressive or other psychiatric disorders, especially during the first months of treatment. Although these drugs are generally prescribed for depression, they are also indicated for treatment of some anxiety disorders in children (see Table 8-3). The benefit versus risk must be carefully weighed before administering these medications to children or adolescents. The nurse should observe the patient carefully for signs of clinical worsening, unusual behavior changes, or suicidality.

### Use in Older Adults

Most antianxiety and sedative-hypnotic drugs are metabolized and excreted more slowly in older adults, so the effects of a given dose last longer. In addition, several of the benzodiazepines produce pharmacologically active metabolites, which prolong drug actions. Thus, the drugs may accumulate and increase adverse effects if dosages are not reduced. The initial dose of any antianxiety or sedative-hypnotic drug should be small, and any incremental increases should be made gradually to decrease the risks of adverse effects. Adverse effects include oversedation, dizziness, confusion, hypotension, and impaired mobility, which may contribute to falls and other injuries unless patients are carefully monitored and safeguarded. Benzodiazepines may produce paradoxical excitement and aggression in adults older than 50 years of age who have a history of psychosis. SSRIs are considered by some clinicians to be first line interventions for anxiety in older patients because of their efficacy and relatively low incidence of side effects.

Benzodiazepines should be tapered rather than discontinued abruptly in older adults, as in other populations. Withdrawal symptoms may occur within 24 hours after abruptly stopping a short-acting drug but may not occur for several days after stopping a long-acting agent.

For anxiety, short-acting benzodiazepines, such as alprazolam or lorazepam, are preferred over long-acting agents, such as diazepam. Buspirone may be preferred over a benzodiazepine because it does not cause sedation, psychomotor impairment, or increased risk of falls. However, it must be taken on a regular schedule and is not effective for PRN use.

For insomnia, sedative-hypnotic drugs should usually be avoided or their use minimized in older adults. Finding and treating the causes and using nondrug measures to aid sleep are much safer. If a sedative-hypnotic is used, shorter-acting benzodiazepines are preferred because they are eliminated more

rapidly and are therefore less likely to accumulate and cause adverse effects. In addition, dosages should be smaller than for younger adults, the drugs should not be used every night or for longer than a few days, and older adults should be monitored closely for adverse effects. If zaleplon or zolpidem is used, the recommended dose for older adults is half that of younger adults (5 mg). With eszopiclone, reduced dosing recommendations begin at 1 milligram with a maximum dosage of 2 milligrams at night. No dosage changes are required for elderly patients using ramelteon.

### Use in Patients With Hypoalbuminemia

Patients with hypoalbuminemia (e.g., from malnutrition or liver disease) are at risk of adverse effects if they take drugs that are highly bound to plasma proteins, such as the benzodiazepines, buspirone, and zolpidem. If a benzodiazepine is given to patients with low serum albumin levels, alprazolam or lorazepam is preferred because these drugs are less extensively bound to plasma proteins and less likely to cause adverse effects. If buspirone or zolpidem is given, dosage may need to be reduced.

### Use in Patients With Renal Impairment

Patients with renal impairment are often given sedatives to relieve anxiety and depression, and excessive sedation is the major adverse effect. It may be difficult to assess the patient for excessive sedation because drowsiness, lethargy, and mental status changes are also common symptoms of uremia.

All benzodiazepines undergo hepatic metabolism and then elimination in urine. Several of the drugs produce active metabolites that are normally excreted by the kidneys. If renal excretion is impaired, the active metabolites may accumulate and cause excessive sedation and respiratory depression.

Buspirone is contraindicated in patients with severe renal impairment. Eszopiclone, ramelteon, zaleplon, and zolpidem may be used by these patients and do not require dosage reduction.

### Use in Patients With Hepatic Impairment

Benzodiazepines undergo hepatic metabolism and then elimination in urine. In the presence of liver disease (e.g., cirrhosis, hepatitis), the metabolism of most benzodiazepines is slowed, with resultant accumulation and increased risk of adverse effects. If a benzodiazepine is needed, lorazepam and oxazepam are preferred antianxiety agents, and temazepam is the preferred hypnotic. These drugs require only conjugation with glucuronide for elimination, and liver disease does not significantly affect this process. If other benzodiazepines are given to patients with advanced liver disease, small initial doses and slow, gradual increases are indicated. Buspirone is metabolized in the liver and should not be used by patients with severe hepatic impairment. Eszopiclone, ramelteon, zaleplon, and zolpidem are metabolized more slowly in patients with liver impairment, and reduced dosages are recommended for patients with mild to moderate liver dysfunction (see Table 8-3). Ramelteon, eszopiclone, and zaleplon should not be used by patients with severe liver impairment.

### Use in Patients With Critical Illness

Antianxiety and sedative-hypnotic drugs are often used in critically ill patients to relieve stress, anxiety, and agitation. By their calming effects, they may also decrease cardiac workload (e.g., heart rate, blood pressure, force of myocardial contraction, myocardial oxygen consumption) and respiratory effort. Additional benefits include improving tolerance of treatment measures (e.g., mechanical ventilation); keeping confused patients from harming themselves by pulling out IV catheters, feeding or drainage tubes, wound drains, and other treatment devices; and allowing more rest or sleep. Dosage of sedative drugs can be titrated to some extent by assessing patients according to a sedation scale. For example, the Ramsay scale rates levels of sedation numerically, with 1 indicating a wide-awake and agitated patient and 6 indicating an unresponsive patient. The desirable level is usually 2 or 3, levels which indicate that the patient is calm, drowsy, but easily aroused and responsive to commands. In addition to sedation, the drugs often induce amnesia, which may be a desirable effect in the critically ill.

Benzodiazepines are commonly used sedatives in critical care units. The drugs may be given orally or by gastrointestinal tube when the patient is able to take medications enterally, needs a fairly stable sedative dose, and is expected to need prolonged sedation (e.g., patients receiving mechanical ventilation). However, most patients receive IV sedatives, often in conjunction with opioid analgesics for pain control. IV drugs are usually given by infusion, sometimes by intermittent bolus injection. The infusions may be given on a short-term (e.g., a few days) or long-term (e.g., weeks) basis. Response to the benzodiazepines is somewhat unpredictable because most drug data were derived from short-term administration of the drugs to non-critically ill adults and may differ significantly with long-term infusions and administration to critically ill patients.

Lorazepam (Ativan) is probably the benzodiazepine of first choice. It has a slow onset of action (5 to 20 minutes) because of delayed brain penetration but an intermediate to prolonged duration. In addition, there is little accumulation and its elimination is not significantly affected by hepatic or renal disease. Because of the slow onset of action of lorazepam, an IV injection of diazepam or midazolam (Versed) is usually given to achieve rapid sedative effects. Midazolam is short acting when given in a single IV injection or for a short time to patients with normal hepatic, renal, and cardiac function. However, in the critical care setting, it is usually given by continuous IV infusion and both midazolam and an active metabolite may accumulate. Overall, drug effects are less predictable in these patients because changes in protein binding, hepatic metabolism, and other factors lead to wide variations in drug elimination and duration of action. Some people (e.g., those being mechanically ventilated, those who have had cardiac surgery, those with septic shock or acute renal failure) have continued to be sedated for days or hours after the drug is discontinued. In patients with renal

failure, active metabolites may accumulate to high levels. For these reasons, plus its high cost, some clinicians recommend using midazolam for IV bolus dosing before starting lorazepam and for short-term periods of less than 48 hours.

Diazepam also may be given to patients who require rapid sedation (e.g., those with extreme agitation). It acts within 1 to 5 minutes after IV injection and lasts about 30 to 100 minutes. However, diazepam should not be given long term because its metabolism forms an active metabolite with an extremely long half-life, which accumulates and may cause excessive sedation and respiratory depression.

Although the risk of adverse effects with a benzodiazepine is high in critically ill patients, routine use of flumazenil, the benzodiazepine antidote, is generally not recommended because it may cause seizures or cardiac arrest. These effects are most likely to occur in people with a history of seizures,

cardiac arrest, head injury, cerebral hypoxia, or chronic benzodiazepine use.

### Use in Home Care

Although antianxiety and sedative-hypnotic drugs are not recommended for long-term use, they are often used at home. Previously described precautions and teaching needs related to safe use of the drugs apply in home care just as they do in other settings. The home care nurse should encourage patients to use nondrug methods of reducing anxiety and insomnia and should review the risks of injuries if mental and physical responses are slowed by the drugs. In addition, assess patients for signs and symptoms of overuse; withdrawal; and use of other sedating drugs, including alcohol, sedating antihistamines, and other prescription drugs. Although the home care nurse is more likely to encounter these drugs as legal prescriptions, they are also commonly abused street drugs.

## Nursing Actions Antianxiety and Sedative-Hypnotic Drugs

### NURSING ACTIONS

#### 1. Administer accurately

- a. If a patient appears excessively sedated when a dose of an antianxiety or sedative-hypnotic drug is due, omit the dose and record the reason.
- b. For oral sedative-hypnotics:
  - (1) Prepare the patient for sleep before giving hypnotic doses of any drug.
  - (2) Give with a glass of water or other fluid. Avoid taking with or immediately after a fatty or heavy meal.
  - (3) Raise bedrails and instruct the patient to stay in bed or to ask for help if necessary to get out of bed.
- c. For benzodiazepines:
  - (1) Give orally, when feasible.
  - (2) Do not mix injectable diazepam with any other drug in a syringe or add to intravenous (IV) fluids.
  - (3) Give IM benzodiazepines undiluted, deeply, into large muscle masses, such as the gluteus muscle of the hip.
  - (4) With IV benzodiazepines, be very careful to avoid intra-arterial injection or extravasation into surrounding tissues. Have equipment available for respiratory assistance.
  - (5) Give IV **diazepam** slowly, over at least 1 minute for 5 mg (1 mL); into large veins (not hand or wrist veins); by direct injection into the vein or into IV infusion tubing as close as possible to the venipuncture site.
  - (6) Give IV **lorazepam** slowly, over at least 1 minute for 2 mg, by direct injection into the vein or into IV infusion tubing. Immediately before injection, dilute with an equal volume of sterile water for injection, 0.9% sodium chloride injection, or 5% dextrose in water.

### RATIONALE/EXPLANATION

To avoid excessive sedation and other adverse effects

Most of the drugs cause drowsiness within 15–30 minutes. The patient should be in bed when he or she becomes drowsy to increase the therapeutic effectiveness of the drug and to decrease the likelihood of falls or other injuries. The fluid enhances dissolution and absorption of the drug for a quicker onset of action. Fatty foods delay onset of action. To avoid falls and other injuries related to sedation and impaired mobility

These drugs are well absorbed from the gastrointestinal (GI) tract, and onset of action occurs within a few minutes. Diazepam is better absorbed orally than intramuscularly (IM). When given IM, the drug crystallizes in tissue and is absorbed very slowly.

Diazepam is physically incompatible with other drugs and solutions.

These drugs are irritating to tissues and may cause pain at injection sites.

These drugs are very irritating to tissues and may cause venous thrombosis, phlebitis, local irritation, edema, and vascular impairment. They may also cause respiratory depression and apnea.

To avoid apnea and tissue irritation

To avoid apnea, hypotension, and tissue irritation

**NURSING ACTIONS**

- (7) Give IV **midazolam** slowly, over approximately 2 minutes, after diluting the dose with 0.9% sodium chloride injection or 5% dextrose in water.
- (8) Midazolam may be mixed in the same syringe with morphine sulfate, and atropine sulfate.
- (9) Do not crush, break, or allow patient to chew extended-release forms of **alprazolam**.
- (10) Carefully peel open packaging of orally disintegrating tablets of **clonazepam** and place in the mouth. Be sure your hands are dry when handling tablets.
- d. Give **hydroxyzine** orally or deep IM only. When given IM for preoperative sedation, it can be mixed in the same syringe with atropine, and most opioid analgesics likely to be ordered at the same time.
- e. Give **clomipramine** in divided doses, with meals, initially; after titration to a stable dose, give the total daily dose at bedtime.

**2. Observe for therapeutic effects**

- a. When a drug is given for antianxiety effects, observe for:

- (1) An appearance of being relaxed, perhaps drowsy, but easily aroused
- (2) Verbal statements such as “less worried,” “more relaxed,” “resting better”
- (3) Decrease in or absence of manifestations of anxiety, such as rigid posture, facial grimaces, crying, elevated blood pressure and heart rate
- (4) Less time spent in worrying or compulsive behaviors

- b. When a drug is given for hypnotic effects, drowsiness should be evident within approximately 30 minutes, and the patient usually sleeps for several hours.
- c. When diazepam or lorazepam is given IV for control of acute convulsive disorders, seizure activity should decrease or stop almost immediately. When a drug is given for chronic anticonvulsant effects, lack of seizure activity is a therapeutic effect.
- d. When hydroxyzine is given for nausea and vomiting, absence of vomiting and verbal statements of relief indicate therapeutic effects.
- e. When hydroxyzine is given for antihistaminic effects in skin disorders, observe for decreased itching and fewer statements of discomfort.

**3. Observe for adverse effects**

- a. Excessive sedation—drowsiness, stupor, difficult to arouse, impaired mental processes, impaired mobility, respiratory depression, confusion
- b. Hypotension
- c. Pain and induration at injection sites
- d. Paradoxical excitement, anger, aggression, and hallucinations

**RATIONALE/EXPLANATION**

Rapid IV injection may cause severe respiratory depression and apnea; dilution facilitates slow injection.

No apparent chemical or physical incompatibilities occur with these substances.

Increased drug absorption may lead to toxicity.

Tablets rapidly dissolve when moistened and can be swallowed with or without water.

IM hydroxyzine is very irritating to tissues.

Giving with meals decreases adverse effects on the GI tract; giving the total dose once daily at bedtime decreases daytime sedation.

Therapeutic effects depend largely on the reason for use. With benzodiazepines, decreased anxiety and drowsiness may appear within a few minutes.

With buspirone, antianxiety effects may occur within 7–10 days of regular use, with optimal effects in 3–4 weeks.

Most adverse effects are caused by central nervous system (CNS) depression.

These effects are more likely to occur with large doses or if the recipient is elderly, debilitated, or has liver disease that slows drug metabolism. Respiratory depression and apnea stem from depression of the respiratory center in the medulla oblongata; they are most likely to occur with large doses or rapid IV administration of diazepam, lorazepam, or midazolam. Excessive drowsiness is more likely to occur when drug therapy is begun, and it usually decreases within a week. Hypotension probably results from depression of the vasomotor center in the brain and is more likely to occur with large doses or rapid IV administration of diazepam, lorazepam, or midazolam.

Parenteral solutions are irritating to tissues.

## Nursing Actions Antianxiety and Sedative-Hypnotic Drugs (continued)

### NURSING ACTIONS

- e. Chronic intoxication—sedation, confusion, emotional lability, muscular incoordination, impaired mental processes including anterograde amnesia, mental depression, GI problems, weight loss
- f. Withdrawal or abstinence syndrome—anxiety, insomnia, restlessness, irritability, tremors, postural hypotension, seizures
- g. With buspirone, the most common adverse effects are headache, dizziness, nausea, nervousness, fatigue, and excitement. Less frequent effects include dry mouth, chest pain, tachycardia, palpitations, drowsiness, confusion, and depression.
- h. With nonbenzodiazepine hypnotics, common adverse effects include daytime drowsiness, dizziness, headache, nausea and diarrhea. Less frequent effects include ataxia, confusion, paradoxical excitation.

#### 4. Observe for drug interactions

- a. Drugs that *increase* effects of antianxiety and sedative-hypnotic drugs:
  - (1) CNS depressants—alcohol, opioid analgesics, tricyclic antidepressants, sedating antihistamines, phenothiazine and other antipsychotic agents
  - (2) Amprenavir, clarithromycin, cimetidine, diltiazem, erythromycin, fluoxetine, fluvoxamine, itraconazole, ketoconazole, metoprolol, nefazodone, omeprazole, oral contraceptives, propranolol, ritonavir, valproic acid
- b. Drugs that *decrease* effects of antianxiety and sedative-hypnotic agents:
  - (1) CNS stimulants—antiasthma drugs, appetite suppressants, bronchodilators (e.g., albuterol, theophylline), nasal decongestants (e.g., phenylephrine, pseudoephedrine), and lifestyle drugs (e.g., caffeine, nicotine)
  - (2) Enzyme inducers (e.g., carbamazepine, isoniazid, phenytoin, rifampin)
- c. Drug that *increases* effects of zaleplon:
  - (1) Cimetidine
- d. Drug that *increases* effects of zolpidem:
  - (1) Ritonavir

### RATIONALE/EXPLANATION

These signs and symptoms may occur with benzodiazepines and are similar to those occurring with chronic alcohol abuse (see Chap. 14).

These signs and symptoms may occur when benzodiazepines are discontinued abruptly, especially after high doses or long-term use.

All these drugs produce CNS depression when given alone. Any combination increases CNS depression, sedation, and respiratory depression. Combinations of these drugs are hazardous and should be avoided. Ingesting alcohol with antianxiety or sedative-hypnotic drugs may cause respiratory depression, coma, and convulsions. Although buspirone does not appear to cause additive CNS depression, concurrent use with other CNS depressants is best avoided.

These drugs inhibit cytochrome P450 3A4 enzymes that metabolize most benzodiazepines and many nonbenzodiazepine sedative hypnotics. Midazolam should be avoided in patients receiving a CYP3A4 inhibitor drug; lorazepam or propofol may be used for sedation.

These drugs do not affect elimination of lorazepam or temazepam.

Phenylephrine and pseudoephedrine are available alone or in multisymptom cold remedies.

With chronic use, these drugs antagonize their own actions and the actions of other drugs metabolized by the same enzymes in the liver. They increase the rate of drug metabolism and elimination from the body.

Inhibits both aldehyde oxidase and CYP3A4 enzymes that metabolize zaleplon, thereby greatly increasing serum levels and risks of toxicity

Inhibits hepatic metabolism of zolpidem and may cause severe sedation and respiratory depression. These drugs should not be given concurrently.

## Key Concepts

- Anxiety is a common disorder that occurs when a person perceives a situation as threatening to physical, emotional, social, or economic well-being.
- When anxiety is severe or prolonged and impairs the ability to function in usual activities of daily living, it is called an anxiety disorder. The American Psychiatric Association delineates anxiety disorders as medical diagnosis in the *Diagnostic and Statistical Manual of Mental Disorders, 4th edition, Text Revision*.
- Examples of anxiety disorders include generalized anxiety disorder, obsessive-compulsive disorder, panic disorder, post-traumatic stress disorder, and social anxiety disorder.
- Insomnia is a prolonged difficulty in going to sleep or staying asleep long enough to feel rested.
- Benzodiazepines are indicated as sedatives-hypnotics, antianxiety agents, muscle relaxants, and anticonvulsants.
- Benzodiazepines and some nonbenzodiazepine hypnotics are Schedule IV drugs under the Controlled Substance Act and can cause physical dependence and withdrawal syndromes.
- The choice of benzodiazepine for a particular purpose and patient depends on the pharmacokinetics of the drug. Benzodiazepines differ in their plasma half-life, production of active metabolites, and metabolism.
- Benzodiazepine and most nonbenzodiazepine hypnotics are indicated for short-term use only; tolerance develops after approximately 2 weeks. Eszopiclone, a nonbenzodiazepine hypnotic, is approved for use up to 12 months.
- Contraindications to most antianxiety and sedative-hypnotics include severe respiratory disorders, severe liver or kidney disease, hypersensitivity reaction, and a history of drug or alcohol abuse.
- Concurrent use of antianxiety or sedative-hypnotic drugs with other CNS depressants should be avoided to prevent respiratory depression and excessive sedation.
- The specific antidote to benzodiazepine overdose is flumazenil. Flumazenil has a shorter half-life than many benzodiazepines, and repeated dosages may be needed to avoid re-sedation and hypoventilation.
- Ramelteon binds to melatonin receptors to produce sleep. It is not a controlled substance and is approved for long-term use.
- Antidepressants, such as the selective serotonin reuptake inhibitors, are considered first line treatment for anxiety; benzodiazepines are considered second line drugs.
- There is an increased risk for suicidality in children, adolescents, and adults treated with antidepressant medications.
- Buspirone is indicated for short-term treatment of anxiety; however, it may take up to 3 to 4 weeks to achieve optimal effects.
- Generally, in older adults dosages of antianxiety and sedative-hypnotic drugs should be decreased.

## Review and Application Exercises

### Short Answer Exercises

1. What is anxiety, and how may it be manifested?
2. How do benzodiazepines act to relieve anxiety?
3. What are some nonpharmacologic interventions to decrease anxiety?
4. When assessing a patient before giving an antianxiety benzodiazepine, what assessment data would cause the nurse to omit the dose?
5. Why is sleep necessary? What functions does sleep fulfill?
6. Why are nonpharmacologic interventions to promote relaxation and sleep usually preferred over the use of sedative-hypnotic drugs?
7. What is the main difference between sedatives and hypnotics?
8. In terms of nursing care, what difference does it make whether a benzodiazepine is metabolized to active or inactive metabolites?
9. What are drug dependence, tolerance, and withdrawal symptoms in relation to the benzodiazepines?
10. What are some special precautions for using sedatives and hypnotics in older adults and those with renal or hepatic impairment or critical illness?
11. For an ambulatory patient beginning a prescription for a benzodiazepine antianxiety or hypnotic agent, what instructions must be emphasized for safe, effective, and rational drug use?
12. When assisting in home care of a patient taking a benzodiazepine, what kinds of data would the nurse collect to evaluate whether the patient is using the drug appropriately or abusing it?

### NCLEX-Style Questions

13. When using flumazenil (Romazicon) as an antidote for benzodiazepine overdose, the nurse should
  - a. Administer the antidote IM into a large muscle.
  - b. Inject the antidote IV push over 5 seconds.
  - c. Observe for re-sedation after administration of the antidote.
  - d. Administer the antidote one time only.
14. When administering benzodiazepines to patients with malnutrition or liver disease, the nurse should monitor carefully for
  - a. toxicity
  - b. withdrawal
  - c. paradoxical excitation
  - d. seizures
15. Which statement would indicate to the nurse the need for further patient teaching?
  - a. "I only use my medication when I really need it."
  - b. "I avoid smoking after taking my sleeping pill."
  - c. "I skip my evening glass of wine when I take my sleeping pill."
  - d. "My sister often has a sleep problem similar to mine."

# Antipsychotic Drugs

## KEY TERMS

- Akathisia
- Anhedonia
- Choreoathetoid
- Delusions
- Dystonia
- Extrapyrimal effects
- Hallucinations
- Neuroleptic
- Neuroleptic malignant syndrome
- Paranoia
- Psychosis
- Schizophrenia
- Tardive dyskinesia

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Discuss common manifestations of psychotic disorders, including schizophrenia.
2. Discuss characteristics of phenothiazines and related antipsychotics.
3. Compare characteristics of “atypical” antipsychotic drugs with those of “typical” phenothiazines and related antipsychotic drugs.
4. Describe the main elements of acute and long-term treatment of psychotic disorders.
5. State interventions to decrease adverse effects of antipsychotic drugs.
6. State interventions to promote compliance with outpatient use of antipsychotic drugs.

## Applying Your Knowledge

Caroline Jones is brought to the mental health clinic by a friend. The friend says that Caroline has been seeing things that are not there and has become more withdrawn. Caroline has not taken care of her personal hygiene for some time. She is diagnosed with acute psychosis and is treated with psychotherapy and the medications haloperidol and risperidone.

.....

## Introduction

### Psychosis

Antipsychotic drugs are used mainly for the treatment of *psychosis*, a severe mental disorder characterized by disordered thought processes (disorganized and often bizarre thinking); blunted or inappropriate emotional responses; bizarre behavior ranging from hypoactivity to hyperactivity with agitation, aggressiveness, hostility, and combativeness; social withdrawal in which a person pays less-than-normal attention to the environment and other people; deterioration from previous levels of occupational and social functioning (poor self-care and interpersonal skills); hallucinations; and paranoid delusions. *Hallucinations* are sensory perceptions of people or objects that are not present in the external environment. More specifically, people see, hear, or feel stimuli that are not visible to external observers, and they cannot distinguish between these false perceptions and reality. Hallucinations occur in delirium, dementias, schizophrenia, and other psychotic states. In schizophrenia or bipolar affective disorder, they are usually auditory; in delirium, they are usually visual or tactile; and in dementia, they are usually visual. *Delusions* are false beliefs that persist in the absence of reason or evidence. Deluded people often believe that other people control their thoughts, feelings, and behaviors or seek to harm them (*paranoia*). Delusions indicate severe

mental illness. Although they are commonly associated with schizophrenia, delusions also occur with delirium, dementias, and other psychotic disorders.

Psychosis may be acute or chronic. Acute episodes, also called confusion or delirium, have a sudden onset over hours to days and may be precipitated by physical disorders (e.g., brain damage related to cerebrovascular disease or head injury, metabolic disorders, infections); drug intoxication with adrenergics, antidepressants, some anticonvulsants, amphetamines, cocaine, and others; and drug withdrawal after chronic use (e.g., alcohol, benzodiazepine antianxiety or sedative-hypnotic agents). In addition, acute psychotic episodes may be superimposed on chronic dementias and psychoses, such as schizophrenia. This chapter focuses primarily on schizophrenia as a chronic psychosis.

## Schizophrenia

Although *schizophrenia* is often referred to as a single disease, it includes a variety of related disorders. The lifetime prevalence of schizophrenia in the United States is approximately 1%. Males and females are equally affected; however, the disorder manifests itself earlier in males (early twenties for males as compared with late twenties to early thirties for females).

The etiology of schizophrenia is unknown. The neurodevelopmental model proposes that schizophrenia results when abnormal brain synapses are formed in response to an intrauterine insult during the second trimester of pregnancy when neuronal migration is normally taking place. Intrauterine events such as upper respiratory infection, obstetric complications, and neonatal hypoxia have been associated with schizophrenia. The emergence of psychosis in response to the formation of these abnormal circuits in adolescence or early adulthood corresponds to the time period of neuronal maturation. Some studies of patients with schizophrenia have shown early neurologic abnormalities in infancy and early childhood, such as abnormal movements or motor developmental delays in infancy and psychological abnormalities as early as 4 years of age. This early onset of abnormalities coupled with emergence of schizophrenia in young adulthood suggests a neurodegenerative etiology for schizophrenia as well.

Genetics is strongly suspected to play a role in the development of schizophrenia. Family studies identify increased risk if a first degree relative has the illness (10%), if a second degree relative has the illness (3%), if both parents have the illness (40%), and if a monozygotic twin has the illness (48%). Adoption studies of twins suggest that heredity rather than environment is a key factor in the development of schizophrenia.

Many genetic studies are underway to identify the gene or genes responsible for schizophrenia. Possible genes linked to schizophrenia include mutations in *WKL1* on chromosome 22, which is thought to play a role in catatonic schizophrenia; mutations in *DISC1*, which causes delays in migration of brain neurons in mouse models; and mutation in the gene responsible for the glutamate receptor, which regulates the amount of glutamine in synapses.

Symptoms may begin gradually or suddenly, usually during adolescence or early adulthood. According to the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders, 4th edition, Text Revision (DSM-IV-TR)* characteristic psychotic symptoms must have been present during a 1-month period with presence of some overt psychotic symptoms for at least 6 months before schizophrenia can be diagnosed. Behavioral manifestations of schizophrenia are categorized as positive and negative symptoms. Positive symptoms are characterized by central nervous system (CNS) stimulation and include agitation, behavioral disturbances, delusions, disorganized speech, hallucinations, insomnia, and paranoia. Negative symptoms are characterized by lack of pleasure (*anhedonia*), lack of motivation, blunted affect, poor grooming and hygiene, poor social skills, poverty of speech, and social withdrawal. Antipsychotic drugs are generally more effective in treating positive symptoms than negative symptoms. A recent Cochrane Review looked at the efficacy of antidepressants for treating the negative symptoms of schizophrenia (see Evidence-Based Practice Box 9-1).

### Evidence-Based Practice

#### 9-1 Are Antidepressant Medications Effective for the Treatment of Negative Symptoms of Schizophrenia?

Traditional antipsychotic medications are more efficacious for the treatment of positive symptoms of schizophrenia than negative symptoms. Newer atypical antipsychotics are reported to be marginally more efficacious; however, they often do not usually achieve satisfactory reduction of negative symptoms, resulting in a condition known as residual schizophrenia. Antidepressants are sometimes added to the therapeutic regime for patients with residual schizophrenia due to their stimulating or activating effect on symptoms of depression such as mood and affect. Only five studies were available for the Cochrane Review (2007) to determine the safety and efficacy of the addition of an antidepressant to antipsychotic drug therapy for treatment of negative symptoms of schizophrenia. In these studies, patients treated with an antidepressant plus an antipsychotic drug showed more clinically significant improvement in negative symptoms of schizophrenia compared with those given an antipsychotic plus a placebo. There were no statistically significant differences in adverse effects between the two groups. The review concluded that the combination of antidepressants and antipsychotics may be effective in treating negative symptoms of schizophrenia; however, more studies are needed to provide information about long-term outcomes of this treatment such as compliance rates, relapse rates, recurrence of negative symptoms, and ability to function cognitively and socially.

An important nursing implication to consider: Some antidepressants can inhibit the metabolism of antipsychotic drugs, increasing the risk of toxicity and adverse effects.

Rummel, C., Kissling, W., & Leucht, S. (2006). Antidepressants for the negative symptoms of schizophrenia (*Cochrane Database of Systematic Reviews*, 6, CD005581.)

There is evidence of abnormal neurotransmission systems in the schizophrenic brain, especially in the dopaminergic, serotonergic, and glutamatergic systems. There is also evidence of extensive interactions among neurotransmission systems. In addition, illnesses or drugs that alter neurotransmission in one system are likely to alter neurotransmission in other systems. The dopaminergic, serotonergic, and glutamatergic systems have been studied most.

The dopaminergic system has been more extensively studied than other systems, because schizophrenia has historically been attributed to increased dopamine activity in the brain. Stimulation of dopamine can initiate psychotic symptoms or exacerbate an existing psychotic disorder. The importance of dopamine is further supported by two findings: (1) antipsychotic drugs exert their therapeutic effects by decreasing dopamine activity (i.e., blocking dopamine receptors), and (2) drugs that increase dopamine levels in the brain (e.g., bromocriptine, cocaine, levodopa) can cause signs and symptoms of psychosis.

In addition to the increased amount of dopamine, dopamine receptor subtypes and their location are also involved. In general, over-activity of dopamine<sub>2</sub> (D<sub>2</sub>) receptors in the basal ganglia, hypothalamus, limbic system, brain stem, and medulla is thought to account for the positive symptoms of schizophrenia, and under-activity of dopamine<sub>1</sub> (D<sub>1</sub>) receptors in the prefrontal cortex is thought to account for the negative symptoms.

The serotonergic system, which is widespread in the brain, is mainly inhibitory in nature. In schizophrenia, serotonin apparently decreases dopamine activity in the part of the brain associated with negative symptoms, causing or aggravating these symptoms.

The glutamatergic neurotransmission system involves glutamate, the major excitatory neurotransmitter in the CNS. Glutamate receptors are widespread and possibly located on every neuron in the brain. They are also diverse, and their functions may vary according to subtypes and their locations in particular parts of the brain. When glutamate binds to its receptors, the resulting neuronal depolarization activates signaling molecules (e.g., calcium, nitric oxide) within and between brain cells. Thus, glutamatergic transmission may affect every CNS neuron and is considered essential for all mental, sensory, motor, and affective functions. Dysfunction of glutamatergic neurotransmission has been implicated in the development of psychosis.

In addition, the glutamatergic system interacts with the dopaminergic and gamma-aminobutyric acid (GABA) systems and possibly other neurotransmission systems. In people with schizophrenia, evidence indicates the presence of abnormalities in the number, density, composition, and function of glutamate receptors. In addition, glutamate receptors are genetically encoded and can interact with environmental factors (e.g., stress, alcohol and other drugs) during brain development. Thus, glutamatergic dysfunction may account for the roles of genetic and environmental risk factors in the development of schizophrenia as well as the cognitive impairments and negative symptoms associated with the disorder.

## General Characteristics of Antipsychotic Drugs

Antipsychotic drugs (neuroleptics) are derived from several chemical groups. These drugs may be broadly categorized as first-generation or “typical” agents and second-generation or “atypical” agents. First-generation drugs include the phenothiazines and *older* nonphenothiazines, such as haloperidol (Haldol) and thiothixene (Navane), which share similar pharmacologic actions, clinical uses, and adverse effects. Second-generation agents or *newer* nonphenothiazines include clozapine, risperidone, paliperidone, olanzapine, quetiapine, ziprasidone, and aripiprazole.

### Mechanism of Action

Most antipsychotic drugs bind to D<sub>2</sub> dopamine receptors and block the action of dopamine (Fig. 9-1). However, drug binding to the receptors does not account for antipsychotic effects because binding occurs within a few hours after a drug dose, and antipsychotic effects may not occur until the drugs have been given for a few weeks. Manifestations of hyperarousal (e.g., anxiety, agitation, hyperactivity, insomnia, aggressive or combative behavior) are relieved more quickly than hallucinations, delusions, and thought disorders. One view of the delayed effects is that the blockade of dopamine receptors leads to changes in the receptors and postreceptor effects on cell

**Figure 9-1** ■ Antipsychotic drugs prevent dopamine and serotonin from occupying receptor sites on neuronal cell membranes and exerting their effects on cellular functions. This action leads to changes in receptors and cell functions that account for therapeutic effects (i.e., relief of psychotic symptoms). Other neurotransmitters and receptors may also be involved.

metabolism and function. With chronic drug administration (i.e., chronic blockade of dopamine receptors), dopamine receptors up-regulate, increasing the number of receptors on postsynaptic and possibly presynaptic nerve cell membranes. Clozapine (Clozaril) and other atypical agents block dopamine receptors as well as serotonin and glutamate receptors. Overall, the drugs “re-regulate” the abnormal neurotransmission systems associated with psychosis.

## Indications for Use

The major clinical indication for use of antipsychotic drugs is schizophrenia. The drugs also are used to treat psychotic symptoms associated with brain impairment induced by head injury, tumor, stroke, alcohol withdrawal, overdoses of CNS stimulant drugs, and other disorders. They may be useful in the manic phase of bipolar affective disorder to control manic behavior until lithium, the drug of choice, becomes effective.

The phenothiazines are also used for clinical indications not associated with psychiatric illness. These include treatment of nausea, vomiting, and intractable hiccups. The drugs relieve nausea and vomiting by blocking dopamine receptors in the chemoreceptor trigger zone, a group of neurons in the medulla oblongata that causes nausea and vomiting when activated by physical or psychological stimuli. The mechanism by which the drugs relieve hiccups is unclear. **Promethazine** (Phenergan) is not used for antipsychotic effects but is often used for antiemetic, sedative, and antihistaminic effects.

## Contraindications to Use

Because of their wide-ranging adverse effects, antipsychotic drugs may cause or aggravate a number of conditions. They are contraindicated in patients with liver damage, coronary artery disease, cerebrovascular disease, parkinsonism, bone marrow

depression, severe hypotension or hypertension, coma, or severely depressed states. They should be used cautiously in people with seizure disorders, diabetes mellitus, glaucoma, prostatic hypertrophy, peptic ulcer disease, and chronic respiratory disorders.

## Individual Drugs

Phenothiazines and first-generation “typical” nonphenothiazines are similar in ability to relieve symptoms of psychosis; however, they differ in potency and adverse effects produced. Second-generation “atypical” nonphenothiazines are equally effective in relieving symptoms of psychosis; however, they have a more favorable adverse effect profile. For this reason they are considered first-line therapy for schizophrenia.

### Phenothiazines

These drugs are historically important because **P chlorpromazine** (Thorazine), the first drug to effectively treat psychotic disorders, belongs to this group. These drugs have been used since the 1950s, but their usage and clinical importance have waned in recent years.

The phenothiazines are well absorbed after oral and parenteral administration. They are distributed to most body tissues and reach high concentrations in the brain. They are metabolized in the liver by the cytochrome P450 enzyme system; several produce pharmacologically active metabolites. Metabolites are excreted in urine. These drugs do not cause psychological dependence, but they may cause physical dependence manifested by withdrawal symptoms (e.g., lethargy, difficulty sleeping) if they are abruptly discontinued. Pharmacokinetics of various antipsychotics are presented in Table 9-1.

Table 9-1

Pharmacokinetics of Antipsychotic Drugs

Generic Name	Route	ACTION			
		Onset	Peak	Duration	Half-Life (Hours)
<b>Aripiprazole</b>	PO	Varies	3–5 h	24 h	75–146
<b>Chlorpromazine</b>	PO	30–60 min	2–4 h	4–6 h (10–12 h for extended release)	3–40
	IM	Unknown	2–3 h	4–18 h	3–40
<b>Clozapine</b>	PO	Unknown	1–6 h	4–12 h	9–17
<b>Fluphenazine decanoate</b>	IM	24–72 h	24 h	1–3 wks	7–10 days
<b>Fluphenazine hydrochloride</b>	PO	60 min	3–5 h	6–8 h	5–15
<b>Haloperidol</b>	PO	2 h	2–6 h	8–12 h	21–24
	IM	20–30 min	30–45 min	4–8 h	
<b>Haloperidol decanoate</b>	IM	3–9 days	Unknown	1 month	3 wk

Generic Name	Route	ACTION			
		Onset	Peak	Duration	Half-Life (Hours)
Olanzapine	PO	Varies	4–5 h	weeks	20–27
Paliperidone	PO	Varies	24 h	Unknown	23 h
Perphenazine	PO	Varies	Unknown	Unknown	Unknown
	IM/IV	5–10 min	1–2 h	6 h	
Quetiapine	PO	Varies	2–4 h	8–10 h	6
Risperidone	PO	1–2 h	3–17 h	weeks	20–30
Thiothixene	PO	Slow	1–3 h	12 h	3–4
Trifluoperazine	PO	Varies	2–4 h	<12 h	3–40
	IM	Rapid	1–2 h	<12 h	3–40
Ziprasidone	PO	Varies	1 h	6–8 h	3
Ziprasidone mesylate	IM	Unknown	1 h	Unknown	2–5

Phenothiazines have many effects, including CNS depression, autonomic nervous system depression (antiadrenergic and anticholinergic effects), antiemetic effects, lowering of body temperature, and hypersensitivity reactions. Additional adverse effects include increased prolactin levels, producing gynecomastia and galactorrhea; sexual dysfunction, including decreased libido, impaired ability to reach orgasm, and erectile/ejaculatory dysfunction; reduced seizure threshold, especially in those with seizure disorders; dysrhythmias due to prolongation of the QT interval; and weight gain. *Neuroleptic malignant syndrome*, a rare but potentially fatal adverse effect, is characterized by rigidity, severe hyperthermia, agitation, confusion, delirium, dyspnea, tachycardia, respiratory failure, and acute renal failure. Supportive treatments for neuroleptic malignant syndrome include hydration, cooling measures and antipyretics to reduce fever, benzodiazepines to reduce agitation, dantrolene to directly relax muscles, and bromocriptine or amantadine (dopamine agonists) to reduce CNS depression.

Phenothiazines differ mainly in potency and adverse effects. Low-potency phenothiazines include chlorpromazine and thioridazine. Perphenazine is an example of a medium-potency phenothiazine. High-potency phenothiazines include trifluoperazine and fluphenazine. With low-potency drugs, higher dosages are required to achieve the same antipsychotic effect as smaller dosages of high-potency drugs. High-potency antipsychotic drugs are more likely to produce early extrapyramidal side effects (e.g., acute dystonia, parkinsonism, and akathisia) than low-potency drugs; however, the risk for late extrapyramidal effects (e.g., tardive dyskinesia) occurs with all phenothiazines. High-potency drugs also carry increased risk for neuroleptic malignant syndrome when compared with lower potency drugs. Anticholinergic side effects (e.g., blurred vision, constipation, dry mouth, photophobia, tachycardia, and urinary hesitancy), antiadrenergic effects such as orthostatic hypotension, and CNS depression (sedation) occur more frequently with low-potency drugs than with high-potency drugs.

Information about administration, dosage, and other characteristics of individual phenothiazine drugs are listed in Table 9-2.

## Nonphenothiazines

Nonphenothiazines include first-generation “typical” antipsychotics, which share many similarities to phenothiazines, and second-generation “atypical” antipsychotics, which vary in relation to typical drugs and to each other. Details about administration, dosage, and other characteristics of selected nonphenothiazines are listed in Table 9-3.

### First-Generation “Typical” Antipsychotics

**Haloperidol** (Haldol) is a butyrophenone used in psychiatric disorders. A related drug, droperidol, is used in anesthesia and as an antiemetic. Haloperidol is a frequently used, long-acting drug. It is well absorbed after oral or intramuscular (IM) administration, is metabolized in the liver, and is excreted in urine and bile. It may cause adverse effects similar to those of the phenothiazines. Haloperidol is a high-potency drug, producing a relatively low incidence of orthostatic hypotension and sedation and a high incidence of extrapyramidal effects.

Haloperidol may be used as the initial drug for treating psychotic disorders or as a substitute in patients who are hypersensitive or refractory to the phenothiazines. It also is used to treat some conditions in which other antipsychotic drugs are not used, including mental retardation with hyperkinesia (abnormally increased motor activity), Tourette’s syndrome (a rare disorder characterized by involuntary movements and vocalizations), and Huntington’s disease (a rare genetic disorder that involves progressive psychiatric symptoms and involuntary movements). For patients who are unable or unwilling to take the oral drug as prescribed, a slowly absorbed, long-acting formulation (haloperidol decanoate) may be given IM, once monthly.

**Thiothixene** (Navane), another high-potency drug, is used only for antipsychotic effects. Compared with haloperi-

Table 9-2

## Drugs at a Glance: Phenthiazine Antipsychotic Drugs

Generic/Trade Name	Routes of Administration and Dosage Ranges	MAJOR SIDE EFFECTS (INCIDENCE)		
		Sedation	Extrapyramidal Reactions	Hypotension
<b>P Chlorpromazine</b> (Thorazine)	<p>Adults: PO 200–600 mg daily in divided doses. Dose may be increased by 100 mg daily q2–3 days until symptoms are controlled, adverse effects occur, or a maximum daily dose of 2 g is reached. IM 25–100 mg initially for acute psychotic symptoms, repeated in 1–4 hours PRN until control is achieved.</p> <p>Elderly or debilitated adults: PO one third to one half usual adult dose, increased by 25 mg daily q2–3 days if necessary. IM 10 mg q6–8h until acute symptoms are controlled.</p> <p>Children: PO, IM 0.5 mg/kg q4–8h. Maximum IM dose, 40 mg daily in children under 5 y of age and 75 mg for older children.</p>	High	Moderate	Moderate to high
<b>Fluphenazine decanoate</b> (Prolixin Decanoate)	<p>Adults under 50 y: IM; Sub-Q 12.5 mg initially followed by 25 mg every 2 weeks. Dosage requirements rarely exceed 100 mg q2–6 wk.</p> <p>Adults over 50 y, debilitated clients, or clients with a history of extrapyramidal reactions: 2.5 mg initially followed by 2.5–5 mg q10–14 days</p> <p>Children: No dosage established</p>	Low to moderate	High	Low
<b>Fluphenazine hydrochloride</b> (Prolixin, Permitil)	<p>Adults: PO 2.5–10 mg initially, gradually reduced to maintenance dose of 1–5 mg (doses above 3 mg are rarely necessary). Acute psychosis: 1.25 mg initially, increased gradually to 2.5–10 mg daily in 3–4 divided doses.</p> <p>Elderly or debilitated adults: PO 1–2.5 mg daily; IM one third to one half the usual adult dose</p> <p>Children: PO 0.75–10 mg daily in children 5 to 12 y. IM no dosage established.</p>	Low to moderate	High	Low
<b>Perphenazine</b> (Trilafon)	<p>Adults: PO 16–64 mg daily in divided doses. Acute psychoses: IM 5–10 mg initially, then 5 mg q6h if necessary. Maximum daily dose, 15 mg for ambulatory clients and 30 mg for hospitalized clients.</p> <p>Elderly or debilitated adults: PO, IM one third to one half usual adult dose</p> <p>Children: PO dosages not established, but the following amounts have been given in divided doses: ages 1–6 y, 4–6 mg daily; 6–12 y, 6 mg daily; over 12 y, 6–12 mg daily</p>	Low to moderate	High	Low

Generic/Trade Name	Routes of Administration and Dosage Ranges	MAJOR SIDE EFFECTS (INCIDENCE)		
		Sedation	Extrapyramidal Reactions	Hypotension
<b>Prochlorperazine</b> (Compazine)	Adults: PO 10 mg 3–4 times daily, increased gradually (usual daily dose, 100–150 mg). IM 10–20 mg; may be repeated in 2–4 h. Switch to oral form as soon as possible. Children over 2 y: PO, rectal 2.5 mg 2–3 times daily; IM 0.06 mg/lb	Moderate	High	Low
<b>Trifluoperazine</b> (Stelazine)	Adults: Outpatients PO 2–4 mg daily in divided doses. Hospitalized clients, PO 4–10 mg daily in divided doses. Acute psychoses: IM 1–2 mg q4–5h, maximum of 10 mg daily. Elderly or debilitated adults: PO, IM one third to one half usual adult dose. If given IM, give at less frequent intervals than above. Children 6 y and over: PO, IM 1–2 mg daily, maximum daily dose 15 mg Children under 6 y: no dosage established	Moderate	High	Low

dol, thiothixene is more likely to produce orthostatic hypotension. Thiothixene can be given orally or parenterally.

### Second-Generation “Atypical” Antipsychotics

In recent years, the “atypical” or newer nonphenothiazines have become the drugs of first choice. They have virtually replaced phenothiazines and related drugs except in patients doing well on older drugs and in the treatment of acute psychotic episodes. The atypical drugs have both similarities and differences when compared with other antipsychotic drugs and with each other. The main similarity is their effectiveness in treating the positive symptoms of psychosis; the main differences are greater effectiveness in relieving negative symptoms of schizophrenia and fewer resulting movement disorders (i.e., extrapyramidal symptoms such as acute dystonia, parkinsonism, akathisia, and tardive dyskinesia). Although adverse effects are generally milder and more tolerable than with older drugs, clozapine may cause life-threatening agranulocytosis, and some of these drugs have been associated with weight gain, hyperglycemia, diabetes, and neuroleptic malignant syndrome.

All second-generation or atypical antipsychotics share a **BLACK BOX WARNING** for elderly patients with dementia-related psychosis. For these patients, the second-generation antipsychotics are associated with increased mortality risk primarily due to cardiovascular disorders or infections.

**P Clozapine** (Clozaril), the prototype of the atypical agents, is chemically different from the older antipsychotic drugs. It blocks both dopamine and serotonin receptors in the brain. Clozapine is restricted to patients with treatment-

resistant schizophrenia and those patients who have exhibited recurrent suicidal behavior.

Advantages of clozapine include improvement of negative symptoms, without causing the extrapyramidal effects associated with older antipsychotic drugs. However, despite these advantages, it is a second-line drug, recommended only for patients who have not responded to treatment with at least two other antipsychotic drugs or who exhibit recurrent suicidal behavior. The reason for the second-line status of clozapine is its association with agranulocytosis, a life-threatening decrease in white blood cells (WBCs), which usually occurs during the first 3 months of therapy. A **BLACK BOX WARNING** alerts health practitioners to this dangerous side effect. Weekly WBC counts are required during the first 6 months of therapy; if acceptable WBC counts are maintained, then WBC counts can be monitored every 2 weeks. Nurses should also be aware of a **BLACK BOX WARNING** for dose-related increased risk for seizures in individuals with prior history or predisposing factors. Additional **BLACK BOX WARNINGS** for clozapine (especially in the first months of treatment) include increased risk for fatal myocarditis, orthostatic hypotension with or without syncope, and rarely cardiopulmonary arrest. Clozapine is also more likely to cause constipation, drowsiness, and weight gain than other atypical drugs. Clozapine is metabolized primarily by CYP1A2 enzymes and to a lesser degree by CYP2D6 and CYP3A4 enzymes.

**Olanzapine** (Zyprexa) is indicated for treatment of schizophrenia and the acute phase of bipolar disorder. It has therapeutic effects similar to those of clozapine, but adverse effects may differ. Compared with clozapine, olanzapine is more likely

Table 9-3

## Drugs at a Glance: Nonphenothiazine Antipsychotic Drugs

Generic/Trade Name	ROUTES AND DOSAGE RANGES	
	Adults	Children
<b>First-Generation, “Typical” Drugs</b>		
<b>Haloperidol</b> (Haldol)	<p>Acute psychosis, PO 1–15 mg/d initially in divided doses, gradually increased to 100 mg/d, if necessary; usual maintenance dose, 2–8 mg daily; IM 2–10 mg q1–8h until symptoms are controlled (usually within 72 h)</p> <p>Chronic schizophrenia, PO 6–15 mg/d; maximum 100 mg/d; dosage is reduced for maintenance, usually 15–20 mg/d</p> <p>Haloperidol decanoate IM, initial dose up to 100 mg, depending on the previous dose of oral drug, then titrated according to response. Usually given every 4 weeks.</p> <p>Tourette’s syndrome, PO 6–15 mg/d; maximum 100 mg/d; usual maintenance dose, 9 mg/d</p> <p>Mental retardation with hyperkinesia, PO 80–120 mg/d, gradually reduced to a maintenance dose of approximately 60 mg/d; IM 20 mg/d in divided doses, gradually increased to 60 mg/d if necessary. Oral administration should be substituted after symptoms are controlled.</p> <p><i>Elderly or debilitated adults:</i> Same as for children &lt;12 y</p>	<p>12 y and older: Acute psychosis, chronic refractory schizophrenia, Tourette’s syndrome, mental retardation with hyperkinesia: same as for adults</p> <p>&lt;12 y: Acute psychosis, PO 0.5–1.5 mg/d initially, gradually increased in increments of 0.5 mg; usual maintenance dose, 2–4 mg/d. IM dosage not established.</p> <p>Chronic refractory schizophrenia, dosage not established</p> <p>Tourette’s syndrome, PO 1.5–6 mg/d initially in divided doses; usual maintenance dose, 1.5 mg/d</p> <p>Mental retardation with hyperkinesia, PO 1.5 mg/d initially, in divided doses, gradually increased to a maximum of 15 mg/d, if necessary. When symptoms are controlled, dosage is gradually reduced to the minimum effective level. IM dosage not established.</p>
<b>Thiothixene</b> (Navane)	<p>PO 6–10 mg/d in divided doses; maximum 60 mg/d</p> <p>Acute psychosis, IM 8–16 mg/d in divided doses; maximum 30 mg/d</p> <p><i>Elderly or debilitated adults:</i> PO, IM one third to one half the usual adult dosage</p>	<p>12 y and older: Same as adults</p> <p>&lt;12 y: Dosage not established</p>
<b>Second-Generation, “Atypical” Drugs</b>		
<b>Aripiprazole</b> (Abilify) (Abilify Discmelt)	PO 10–15 mg once daily; maximum dose 30 mg/d	Dosage not established
<b>Olanzapine</b> (Zyprexa) (Zyprexa ODT)	PO 5–10 mg/d initially; given once daily at bedtime; increased over several weeks to 20 mg/d, if necessary	Dosage not established
<b>Paliperidone</b> (Invega)	PO 6 mg daily in the morning, may be increased over several weeks to maximum of 12 mg/d	Dosage not established
<b>P Clozapine</b> (Clozaril) (FazoClo ODT)	PO 12.5 mg once or twice daily. Increase by 25–50 mg/d every 3–7 days up to a maximum dose of 900 mg/d	Dosage not established
<b>Quetiapine</b> (Seroquel)	PO 25 mg bid initially; increased by 25–50 mg two or three times daily on second and third days, as tolerated, to 300–400 mg, in two or three divided doses on the fourth day	Dosage not established

Generic/Trade Name	ROUTES AND DOSAGE RANGES	
	Adults	Children
	<p>Additional increments or decrements can be made at 2-day intervals; maximum dose 800 mg/d</p> <p><i>Elderly or debilitated adults:</i> Use lower initial doses and increase more gradually, to a lower target dose than for other adults.</p> <p><i>Hepatic impairment:</i> PO, same as for elderly or debilitated adults</p>	
<b>Risperidone</b> (Risperdal)	<p>PO, initially 1 mg twice daily (2 mg/d); increase to 2 mg twice daily on the second day (4 mg/d); increase to 3 mg twice daily on the third day (6 mg/d), if necessary. Usual maintenance dose, 4 to 8 mg/d. After initial titration, dosage increases or decreases should be made at a rate of 1 mg/wk.</p> <p><i>Elderly or debilitated adults:</i> PO, initially 0.5 mg twice daily (1 mg/d); increase in 0.5-mg increments to 1.5 mg twice daily (3 mg/d)</p> <p><i>Renal or hepatic impairment:</i> PO, same as for elderly or debilitated adults</p>	<p>13–17 y: PO, initially 0.5 mg/d. Increase 1–2 mg/d for a target dose of 3 mg/d. Dosage range is 1–6 mg/d.</p>
(Risperdal Consta)	<p>IM 25 mg every 2 wk; maximum dose not to exceed 50 mg/2 wk. Oral Risperdal should be continued for first 3 weeks of therapy to ensure adequate blood levels are maintained.</p>	<p>&lt; 18 y: Dosage not established</p>
<b>Ziprasidone</b> (Geodon)	<p>PO 20 mg twice daily with food, initially; gradually increased up to 80 mg twice daily, if necessary</p>	
<b>Ziprasidone mesylate</b>	<p>IM 10–20 mg every 4 h up to a maximum of 40 mg/d, not to exceed 3 days for treatment of acute agitation in schizophrenia</p>	<p>Not recommended</p>

to cause extrapyramidal effects and less likely to cause agranulocytosis. Compared with the typical antipsychotics, olanzapine reportedly causes less sedation, extrapyramidal symptoms, anticholinergic effects, and orthostatic hypotension. However, it has been associated with weight gain, hyperglycemia, and initiation or aggravation of diabetes mellitus.

The drug is well absorbed after oral administration; its absorption is not affected by food. A steady-state concentration is reached after approximately 1 week of once-daily administration. Olanzapine is metabolized in the liver by the CYP1A2 and to a lesser degree CYP2D6 and CYP2C19 enzymes. It is excreted in urine and feces.

**Quetiapine** (Seroquel), like the other atypical agents, blocks both dopamine and serotonin receptors and relieves both positive and negative symptoms of psychosis and is also indicated for the acute manic phase of bipolar disorder. After oral administration, quetiapine is well absorbed and may be taken without regard to meals. It is extensively metabolized in the liver by CYP3A4 enzymes. Clinically significant drug interactions may occur with drugs that induce or inhibit the liver enzymes, and dosage of quetiapine may need to be

increased in patients taking enzyme inducers (e.g., carbamazepine, phenytoin, rifampin) or decreased in patients taking enzyme inhibitors (e.g., cimetidine, erythromycin). Common adverse effects include drowsiness, headache, orthostatic hypotension, and weight gain.

**Risperidone** (Risperdal) also blocks both dopamine and serotonin receptors and relieves both positive and negative symptoms of psychosis as well as the acute manic phase of bipolar disorder. It is a frequently prescribed, first-choice agent that is usually well tolerated. A Cochrane Review (2005) compared risperidone and olanzapine and concluded that both drugs were effective in treating schizophrenia. The main difference noted between the two drugs was in adverse effects; patients taking risperidone experienced significantly less weight gain than with olanzapine.

Risperidone is well absorbed with oral administration. Peak blood levels occur in 1 to 2 hours, but therapeutic effects are delayed for 1 to 2 weeks. Risperidone is metabolized mainly in the liver by the CYP2D6 enzymes and produces an active metabolite. Effects are attributed approximately equally to risperidone and the metabolite. Slow metabolizers of risperi-

done require lower doses to avoid toxicity. Most (70%) of the drug is excreted in urine and some (14%) in feces. Adverse effects include agitation, anxiety, headache, insomnia, dizziness, and hypotension. Risperidone may also cause parkinsonism and other movement disorders, especially at higher doses, but is less likely to do so than the typical antipsychotic drugs.

**Paliperidone** (Invega), an active metabolite of risperidone, blocks both dopamine and serotonin receptors. It is effective in treating both positive and negative symptoms. Paliperidone is administered orally in an extended-release tablet and reaches peak blood levels 24 hours after administration. The half-life of paliperidone is 23 hours. The cytochrome P450 system plays a very limited role in the metabolism of paliperidone, resulting in fewer drug interactions with other antipsychotics. The drug is eliminated by the renal system. Adverse effects include akathisia, extrapyramidal effects, QT prolongation, orthostatic hypotension, syncope, hyperprolactinemia, and hyperglycemia.

**Ziprasidone** (Geodon) is another atypical agent used to treat schizophrenia and the acute manic phase of bipolar disorder. It may be given orally or intramuscularly. It is effective in suppressing many of the negative symptoms such as blunted affect, lack of motivation, and social withdrawal. Additional benefits include a decrease in weight and improvement in cholesterol and triglyceride levels. Ziprasidone is contraindicated in people who are allergic to the drug, who are pregnant or lactating, who have a prolonged QT interval on electrocardiogram (ECG), or who have a history of severe heart disease. It must be used cautiously in people with impaired renal or hepatic function and cardiovascular disease. Because it may prolong the QT interval and cause torsades de pointes, a potentially fatal type of ventricular tachycardia, ziprasidone is probably not a drug of first choice.

Ziprasidone is metabolized in the liver by CYP3A4 enzymes and excreted in urine. Adverse effects include cardiac dysrhythmias, drowsiness, headache, and nausea; weight gain is less likely than with other antipsychotic drugs.

**Aripiprazole** (Abilify) is approved for the treatment of schizophrenia and acute mania associated with bipolar disorder. It is the first in a new category of drugs called partial dopamine agonists. A partial agonist is a drug that has the ability to block a receptor if it is overstimulated and to stimulate a receptor if it is understimulated. The beneficial effect of aripiprazole in patients with schizophrenia is proposed to involve a combination of partial agonist activity at D<sub>2</sub> and serotonin 5-HT<sub>1A</sub> receptors and antagonist activity at serotonin 5-HT<sub>2A</sub> receptors. Aripiprazole also blocks alpha<sub>1</sub> adrenergic receptors, increasing the risk for orthostatic hypotension, and exerts an antihistamine effect by H<sub>1</sub> blockade. Aripiprazole may also cause neuroleptic malignant syndrome, tardive dyskinesia, weight gain, hyperglycemia, and diabetes mellitus.

Aripiprazole is well absorbed orally, with or without food. It is 99% protein bound. It is metabolized in the liver by the CYP3A4 and CYP2D6 enzyme systems and has an active metabolite. Generally, no dosage adjustment for aripiprazole is

required on the basis of hepatic or renal impairment. Slow metabolizers of aripiprazole require significantly lower doses to avoid drug toxicity.

### Applying Your Knowledge 9-1

After 6 weeks of therapy, Ms. Jones has far fewer symptoms; however, she has been observed to have a gradual loss of muscle movement. What adverse reaction is likely to be occurring?

.....

## Nursing Process

### Assessment

Assess the patient's mental health status, need for antipsychotic drugs, and response to drug therapy. There is a wide variation in response to drug therapy. Close observation of physical and behavioral reactions is necessary to evaluate effectiveness and to individualize dosage schedules. Accurate assessment is especially important when starting drug therapy and when increasing or decreasing dosage. Some assessment factors include the following:

- Interview the patient and family members. Attempts to interview an acutely psychotic person yield little useful information because of the patient's distorted perception of reality. The nurse may be able to assess the patient's level of orientation and delusional and hallucinatory activity. If possible, try to determine from family members or others what the patient was doing or experiencing when the acute episode began (i.e., predisposing factors, such as increased environmental stress or alcohol or drug ingestion); whether this is a first or a repeated episode of psychotic behavior; whether the person has physical illnesses, takes any drugs, or uses alcohol; whether the patient seems to be a hazard to self or others; and some description of pre-illness personality traits, level of social interaction, and ability to function in usual activities of daily living.
- Observe the patient for the presence or absence of psychotic symptoms such as agitation, hyperactivity, combativeness, and bizarre behavior.
- Obtain baseline data to help monitor the patient's response to drug therapy. Some authorities advocate initial and periodic laboratory tests of liver, kidney, and blood functions, as well as electrocardiograms. Such tests may assist in early detection and treatment of adverse drug effects. Baseline blood pressure readings also may be helpful.
- Continue assessing the patient's response to drug therapy and his or her ability to function in activities of daily living, whether the patient is hospitalized or receiving outpatient treatment.

## Nursing Diagnoses

- Altered Thought Processes related to psychosis
- Self-Care Deficit related to the disease process or drug-induced sedation
- Impaired Physical Mobility related to sedation
- Altered Tissue Perfusion related to hypotension
- Risk for Injury related to excessive sedation and movement disorders (extrapyramidal effects)
- Risk for Violence: Self-Directed or Directed at Others
- Noncompliance related to underuse of prescribed drugs

## Planing/Goals

### The patient will

- Become less agitated within a few hours of the start of drug therapy, and less psychotic within 1–3 weeks
- Be kept safe while sedated from drug therapy
- Be cared for by staff in areas of nutrition, hygiene, exercise, and social interactions when unable to provide self-care
- Improve in ability to participate in self-care activities
- Avoid preventable adverse drug effects, especially those that impair safety
- Be helped to take medications as prescribed and return for follow-up appointments with health care providers

## Interventions

Use nondrug measures when appropriate to increase the effectiveness of drug therapy and to decrease adverse reactions.

- Drug therapy is ineffective if the patient does not receive sufficient medication; many people are unable or unwilling to take medications as prescribed. Any nursing action aimed toward more accurate drug administration increases the effectiveness of drug therapy.
 

Specific nursing actions must be individualized to the patient and/or caregiver. Some general nursing actions that may be helpful include emphasizing the therapeutic benefits expected from drug therapy; answering questions or providing information about drug therapy and other aspects of the treatment plan; devising a schedule of administration times that is as convenient as possible for the patient; and assisting the patient or caregiver in preventing or managing adverse drug effects (see accompanying patient teaching guidelines). Most adverse effects are less likely to occur or be severe with the newer atypical drugs than with phenothiazines and other older drugs.
- Supervise ambulation to prevent falls or other injuries if the patient is drowsy or elderly or has postural hypotension.
- Several measures can help prevent or minimize hypotension, such as having the patient lie down for approximately an hour after a large oral dose or an injection of antipsy-

chotic medication; applying elastic stockings; and instructing the patient to change positions gradually, elevate legs when sitting, avoid standing for prolonged periods, and avoid hot baths (hot baths cause vasodilation and increase the incidence of hypotension). In addition, the daily dose can be decreased or divided into smaller amounts.

- Dry mouth and oral infections can be decreased by frequently brushing the teeth; rinsing the mouth with water; chewing sugarless gum or candy; and ensuring an adequate fluid intake. Excessive water intake should be discouraged because it may lead to serum electrolyte deficiencies.
- The usual measures of increasing fluid intake, dietary fiber, and exercise can help prevent constipation.
- Support caregivers in efforts to maintain contact with inpatients and provide care for outpatients. One way is to provide caregivers with telephone numbers of health care providers and to make periodic telephone calls to caregivers.
- Provide patient teaching regarding drug therapy (see accompanying display).

## Evaluation

- Interview the patient to determine the presence and extent of hallucinations and delusions.
- Observe the patient for decreased signs and symptoms.
- Document abilities and limitations in self-care.
- Note whether any injuries have occurred during drug therapy.
- Interview the caregiver about the patient's behavior and medication response (i.e., during a home visit or telephone call).

## Applying Your Knowledge 9-2

Ms. Jones says she is dizzy when she gets up. What nursing measures can be implemented to prevent injury?

.....

## Principles of Therapy

### Goals of Therapy

Overall, the goal of treatment is to relieve symptoms with minimal or tolerable adverse drug effects. In patients with acute psychosis, the goal during the first week of treatment is to decrease symptoms (e.g., aggression, agitation, combativeness, hostility) and normalize patterns of sleeping and eating. The next goals may be increased ability for self-care and increased socialization. Therapeutic effects usually occur gradually, over 1 to 2 months. Long-term goals include increasing the patient's ability to cope with the environment, promoting optimal functioning in self-care and activities of daily living, and preventing acute episodes and hospitalizations. With drug therapy,

## Patient Teaching Guidelines Antipsychotic Drugs

Antipsychotic drugs are given to patients with schizophrenia, a chronic mental illness. Because of the nature of the disease, a responsible adult caregiver is needed to prompt a patient about taking particular doses and to manage other aspects of the drug therapy regimen, as follows.

### General Considerations

- Ask about the planned drug therapy regimen, including the desired results, when results can be expected, and the tentative length of drug therapy.
- Maintain an adequate supply of medication to ensure regular administration. Consistent blood levels are necessary to control symptoms and to prevent recurring episodes of acute illness and hospitalization.
- Do not allow the patient to drive a car, operate machinery, or perform activities that require alertness when drowsy from medication. Drowsiness, slowed thinking, and impaired muscle coordination are especially likely during the first 2 weeks of drug therapy but tend to decrease with time.
- Report unusual side effects and all physical illnesses, because changes in drug therapy may be indicated.
- Try to prevent the patient from taking unprescribed medications, including those available without prescription or those prescribed for another person, to prevent undesirable drug interactions. Alcohol and sleeping pills should be avoided because they may cause excessive drowsiness and decreased awareness of safety hazards in the environment.
- Keep all physicians informed about all the medications being taken by the patient, to decrease risks of undesirable drug interactions.

- These drugs should be tapered in dosage and discontinued gradually; they should not be stopped abruptly.
- Notify your physician if you become pregnant or intend to become pregnant

### Medication Administration

Assist or prompt the patient to:

- Take medications in the correct doses and at the correct times, to maintain blood levels and beneficial effects.
- Avoid taking these medications with antacids. If an antacid is needed (e.g., for heartburn), it should be taken 1 hour before or 2 hours after the antipsychotic drug. Antacids decrease absorption of these drugs from the intestine.
- Lie down for approximately an hour after receiving medication, if dizziness and faintness occur.
- Take the medication at bedtime, if able, so that drowsiness aids sleep and is minimized during waking hours.
- Practice good oral hygiene, including dental checkups, thorough and frequent toothbrushing, drinking fluids, and frequent mouth rinsing. Mouth dryness is a common side effect of the drugs. Although it is usually not serious, dry mouth can lead to mouth infections and dental cavities.
- Minimize exposure to sunlight, wear protective clothing, and use sunscreen lotions. Sensitivity to sunlight occurs with some of the drugs and may produce a sunburn type of skin reaction.
- Avoid exposure to excessive heat. Some of these medications may cause fever and heat prostration with high environmental temperatures. In hot weather or climates, keep the client indoors and use air conditioning or fans during the hours of highest heat levels.

patients often can participate in psychotherapy, group therapy, or other treatment modalities; return to community settings; and return to their pre-illness level of functioning.

## Drug Selection

The physician caring for a patient with psychosis has a greater choice of drugs than ever before. Some general factors to consider include the patient's age and physical condition, the severity and duration of illness, the frequency and severity of adverse effects produced by each drug, the patient's use of and response to antipsychotic drugs in the past, the supervision available, and the physician's experience with a particular drug.

The atypical drugs are the drugs of choice, especially for patients who are newly diagnosed with schizophrenia, because these drugs may be more effective in relieving some symptoms, they usually produce milder adverse effects, and patients seem to take them more consistently. The ability of the atypical antipsychotics to reduce adverse effects is seen as a significant advantage, because patients are more likely to take the drugs. Better compliance with drug therapy helps prevent acute episodes of psychosis and repeated hospitalizations, thereby reducing the overall cost of care, according to studies. A major drawback is the high cost of these drugs, which may preclude their use in some patients.

An additional drawback and concern is weight gain and abnormal glucose metabolism. Most of the drugs in the atypical group have been associated with weight gain, especially with the chronic use required for treatment of schizophrenia. Recent reports also associate clozapine, olanzapine, paliperidone, risperidone, quetiapine, and aripiprazole with changes in blood glucose levels, including hyperglycemia and diabetes mellitus. In some extreme cases, ketoacidosis, hyperosmolar coma, and death have been reported. A causal relationship between use of these drugs and onset of diabetes has not been established. However, before starting one of the drugs, patients should be assessed for diabetes or risk factors related to the development of diabetes (e.g., obesity; personal or family history of diabetes; symptoms of diabetes such as polyuria, polydipsia, or polyphagia). If symptoms or risk factors are identified, blood glucose levels should be checked before starting the drug and periodically during treatment.

When compared with atypical antipsychotic drugs, traditional or typical antipsychotic drugs are apparently equally effective, but some patients who do not respond well to one of them may respond to another. Because the typical drugs are similarly effective, some physicians base their choice on a drug's adverse effects. In addition, some physicians use a phenothiazine first and prescribe a nonphenothiazine as a second-line

drug for patients with chronic schizophrenia whose symptoms have not been controlled by the phenothiazines and for patients with hypersensitivity reactions to the phenothiazines. Thioridazine (Mellaril), formerly a commonly used drug, is now indicated only when other drugs are ineffective because of its association with serious cardiac dysrhythmias.

Patients who are unable or unwilling to take daily doses of a maintenance antipsychotic drug may be given periodic injections of a long-acting form of fluphenazine, haloperidol, or risperidone. Extrapyramidal symptoms may be more problematic with depot injections of antipsychotic drugs.

Any person who has had an allergic or hypersensitivity reaction to an antipsychotic drug usually should not be given that drug (or any drug in the same chemical group) again. Cross-sensitivity occurs, and the likelihood of another allergic reaction is high.

There is no logical basis for giving more than one antipsychotic drug at a time. There is no therapeutic advantage, and the risk of serious adverse reactions is increased.

## Dosage and Administration

Dosage and route of administration must be individualized according to the patient's condition and response; in some cases prescribers may exceed the recommended maximum dosage approved by the Food and Drug Administration (FDA). Oral drugs undergo extensive first-pass metabolism in the liver so that a significant portion of a dose does not reach the systemic circulation and low serum drug levels are produced. In contrast, IM doses avoid first-pass metabolism and produce serum drug levels approximately double those of oral doses. Thus, usual IM doses are approximately half the oral doses.

Initial drug therapy for acute psychotic episodes may require IM administration and hospitalization; symptoms are usually controlled within 48 to 72 hours, after which oral drugs can be given. When treatment is initiated with oral drugs, divided daily doses are recommended. Oral concentrates are better absorbed than pills and can be similar to IM administration in the time to reach peak serum concentrations. For maintenance therapy, once-daily dosing is usually preferred. A single bedtime dose is effective for most patients. This schedule increases compliance with prescribed drug therapy, allows better nighttime sleep, and decreases hypotension and daytime sedation. Effective maintenance therapy requires close supervision and contact with the patient and family members.

## Duration of Therapy

In schizophrenia, antipsychotic drugs are usually given for years because there is a high rate of relapse (acute psychotic episodes) when drug therapy is discontinued, most often by patients who become unwilling or unable to continue their medication regimen. Drug therapy usually is indicated for at least 1 year after an initial psychotic episode and for at least 5 years, perhaps for life, after multiple episodes. Several studies indicate that low-dose, continuous maintenance therapy is effective in long-term prevention of recurrent psychosis. With wider use of maintenance therapy and the newer, better-

tolerated antipsychotic drugs, patients may experience fewer psychotic episodes and hospitalizations.

## Drug Withdrawal: Recognition and Treatment

Antipsychotic drugs can cause symptoms of withdrawal when suddenly or rapidly discontinued. Specific symptoms are related to drug potency, extent of dopaminergic blockade, and anticholinergic effects. Low-potency drugs (e.g., chlorpromazine), for example, have strong anticholinergic effects, and sudden withdrawal can cause cholinergic effects such as diarrhea, drooling, and insomnia. To prevent withdrawal symptoms, drugs should be tapered in dosage and gradually discontinued over several weeks.

## Treatment of Extrapyramidal Symptoms

*Extrapyramidal effects* (i.e., abnormal movements) are more likely to occur with usage of older high-potency antipsychotic drugs than with the newer atypical agents. Such neuromuscular symptoms appear in fewer than half of the patients taking traditional antipsychotic drugs and are better handled by reducing dosage, if this does not cause recurrence of psychotic symptoms. Acute *dystonia* (manifested by severe spasms of muscles of the face, neck, tongue, or back) typically occurs early in treatment and constitutes an emergency. Severe manifestations of acute dystonia include oculogyric crisis (severe involuntary upward rotation of the eyes) and opisthotonus (severe spasm of back muscles, causing head, and heels to bend backward and the body to bow forward). Acute dystonia is treated with intramuscular or intravenous administration of anticholinergic medications such as benztropine or diphenhydramine. *Akathisia* (manifested by motor restlessness and inability to be still) usually occurs in the first few months of treatment with antipsychotics. Switching to a second-generation atypical medication may be indicated to treat akathisia.

Anticholinergics, benzodiazepines, and beta blockers may also be prescribed to control the urge to move. Parkinsonism (manifested by resting tremor, bradykinesia, rigidity, and postural instability) may occur in the first month of therapy with antipsychotics due to dopamine receptor blockade. Centrally acting anticholinergic drugs such as benztropine, diphenhydramine, and amantadine are useful in treating drug-induced parkinsonism. Levodopa and direct dopamine agonists (e.g., bromocriptine) should not be used to treat antipsychotic-induced parkinsonism because these drugs can counteract the effectiveness of the antipsychotic drug and may result in a recurrence of psychotic symptoms. *Tardive dyskinesia* (*choreoathetoid* or twisting worm-like movements of the face and tongue) is an irreversible late extrapyramidal effect of antipsychotic drugs. Often, the slow worm-like tongue movements are the earliest sign that tardive dyskinesia is developing. These abnormal movements of the face and tongue may interfere with eating and speech. Over time, abnormal movements may appear in other parts of the body. There is no curative

treatment for tardive dyskinesia; anticholinergic drugs, dosage reduction, or use of an alternative second-generation drug may be helpful. Because prevention is the best treatment for tardive dyskinesia, the nurse should be alert to early signs of this movement disorder.

## Perioperative Use

A major concern about giving traditional antipsychotic drugs perioperatively is their potential for adverse interactions with other drugs. For example, the drugs potentiate the effects of general anesthetics and other CNS depressants that are often used before, during, and after surgery. As a result, risks of hypotension and excessive sedation are increased unless doses of other drugs are reduced. If hypotension occurs and requires vasopressor drugs, phenylephrine or norepinephrine should be used rather than epinephrine because antipsychotic drugs inhibit the vasoconstrictive (blood pressure-raising) effects of epinephrine. Guidelines for perioperative use of the newer, atypical drugs have not been developed. Cautious use is indicated because they may also cause hypotension, sedation, and other adverse effects.

## Use in Special Populations

### Use in Children

Antipsychotic drugs are used mainly for childhood schizophrenia, which is often characterized by more severe symptoms and a more chronic course than adult schizophrenia. Drug therapy is largely empiric, because few studies have been conducted in children and adolescents. Guidelines for the use of antipsychotic drugs have been published by the American Academy of Child and Adolescent Psychiatry. Major recommendations are listed in Box 9-1.

It is not clear which antipsychotics are safest and most effective in children and adolescents. Drug pharmacodynamics and pharmacokinetics are likely to be different in children compared with adults. Pharmacodynamic differences may stem from changes in neurotransmission systems in the brain as children grow. Pharmacokinetic differences may stem from changes in distribution or metabolism of drugs; absorption seems similar to that of adults. In relation to distribution, children usually have a lesser percentage of body fat than adults. Thus, antipsychotic drugs, which are highly lipid soluble, cannot be as readily stored in fat as they are in adults. This often leads to shorter half-lives and the need for more frequent administration. In relation to metabolism, children usually have a faster rate than adults and may therefore require relatively high doses for their size and weight. In relation to excretion, children's renal function is usually similar to that of adults, and most of the drugs are largely inactivated by liver metabolism. Thus, with normal renal function, excretion probably has little effect on blood levels of active drug or a child's response to the drug.

Although the newer drugs are being used, children's dosages have not been established for most of these drugs, and long-term effects are unknown. Risperdal has recently been approved by the FDA as the first atypical antipsychotic drug for the treatment of schizophrenia in adolescents, ages 13 to

### Box 9-1

## Guidelines for the Use of Antipsychotic Drugs by the American Academy of Child and Adolescent Psychiatry

- Give a thorough psychiatric and physical examination before starting drug therapy.
- Choose a medication based on potency, adverse effects, and the client's medication response history, if available. A newer, atypical drug is probably the drug of first choice.
- Give the chosen drug at least 4–6 weeks before evaluating its effectiveness. If an inadequate response is then evident, a new antipsychotic drug should be tried.
- After an adequate response is obtained, continue drug therapy for at least several months. For newly diagnosed children who are symptom free for 6–12 months, it may be feasible to stop the drug for a trial period to reassess condition and drug dosage. In general, the lowest effective dose is recommended.
- Use psychosocial and psychotherapeutic interventions along with antipsychotic drugs.
- Have the physician or another health care provider maintain contact with the child and his or her parents or guardian and monitor responses to the medication. For example, weight charts and calculations of body mass index should be maintained with the atypical drugs because most are associated with weight gain and some are associated with the development of diabetes.
- Conduct more controlled studies of drug effects in children and adolescents.

*From the American Academy of Child and Adolescent Psychiatry's Practice Parameter for the Assessment and Treatment of Children and Adolescents with Schizophrenia.*

17. Quetiapine, although not recommended for use in children, has a **BLACK BOX WARNING** for increased risk of suicidality in children and adolescents with major depressive or other psychiatric disorder, especially in the first months of treatment. Traditional drugs are not usually recommended for children younger than 12 years of age. However, prochlorperazine (Compazine), trifluoperazine (Stelazine), and haloperidol (Haldol) may be used in children aged 2 to 12 years.

Dosage regulation is difficult because children may require lower plasma levels for therapeutic effects, but they also metabolize antipsychotic drugs more rapidly than adults. A conservative approach is to begin with a low dose and increase it gradually (no more than once or twice a week), if necessary. Divided doses may be useful initially, with later conversion to once daily at bedtime. Older adolescents may require doses comparable with those of adults.

Adverse effects may be different in children. For example, extrapyramidal symptoms with conventional drugs are more likely to occur in children than in adults. If they do occur, dosage reduction is more effective in alleviating them than are

## Box 9-2

## Considerations Regarding Use of Antipsychotic Drugs in Older Adults

**Drug Selection**

With traditional antipsychotic drugs, haloperidol and fluphenazine may be better tolerated, but they cause a high incidence of extrapyramidal symptoms. With atypical drugs, clozapine is a second-line agent because it produces many adverse effects. Olanzapine, quetiapine, risperidone, ziprasidone, or aripiprazole may be useful, but little information is available about their use in older adults. Ziprasidone should not be used in older adults with cardiac dysrhythmias or severe cardiovascular disease. All second-generation atypical antipsychotics carry a **BLACK BOX WARNING** for elderly patients with dementia-related psychosis due to increased mortality associated with cardiovascular events and infections.

**Dosage**

When the drugs are required, the recommended starting dosage is 25%–33% of the dosage recommended for younger adults. Dosage should also be increased more gradually, if necessary, and according to clinical response. The basic principle of “start low, go slow” is especially applicable. After symptoms are controlled, dosage should be reduced to the lowest effective level. Some specific drugs and dosage ranges include haloperidol 0.25–1.5 mg qd to qid; clozapine 6.25 mg qd, initially; risperidone 0.5 mg qd, initially; quetiapine, a lower initial dose, slower dose titration, and a lower target dose in older

adults. No reduction of dosage is required based on age for aripiprazole.

As in other populations, antipsychotic drugs should be tapered in dosage and discontinued gradually rather than discontinued abruptly.

**Adverse Effects**

Older adults are at high risk of adverse effects because metabolism and excretion are usually slower or more likely to be impaired than in younger adults. With traditional antipsychotic drugs, anticholinergic effects (e.g., confusion, memory impairment, hallucinations, urinary retention, constipation, heat stroke) may be especially problematic. In addition, cardiovascular effects (e.g., hypotension, dysrhythmias) may be especially dangerous in older adults, who often have underlying cardiovascular diseases. Tardive dyskinesia, which may occur with long-term use of the typical antipsychotic drugs, may develop more rapidly and at lower drug dosages in older adults than in younger clients. There is also a risk of neuroleptic malignant syndrome, a rare but serious disorder characterized by confusion, dizziness, fever, and rigidity. Other adverse effects include oversedation, dizziness, confusion, and impaired mobility, which may contribute to falls and other injuries unless clients are carefully monitored and safeguarded. With atypical drugs, many of these adverse effects are less likely to occur, especially at the reduced dosages recommended for older adults.

the anticholinergic antiparkinson drugs commonly used in adults. In addition, hypotension is more likely to develop in children. Blood pressure should be closely monitored during initial dosage titration.

**Use in Older Adults**

Antipsychotic drugs should be used cautiously in older adults. Before they are started, a thorough assessment is necessary, because psychiatric symptoms are often caused by organic disease or other drugs. If this is the case, treating the disease or stopping the offending drug may eliminate the need for an antipsychotic drug. In addition, older adults are more likely to have problems for which the drugs are contraindicated (e.g., severe cardiovascular disease, liver damage, Parkinson's disease) or must be used very cautiously (diabetes mellitus, glaucoma, prostatic hypertrophy, peptic ulcer disease, chronic respiratory disorders).

If antipsychotic drugs are used to control acute agitation in older adults, they should be used in the lowest effective dose for the shortest effective duration. If the drugs are used to treat dementia, they may relieve some symptoms (e.g., agitation, hallucinations, hostility, suspiciousness, uncooperativeness), but they do not improve memory loss and may further impair cognitive functioning. All second-generation or atypical antipsychotics share a **BLACK BOX WARNING** for elderly patients with dementia-related psychosis. For these patients, the second-

generation antipsychotics are associated with increased mortality risk primarily due to cardiovascular disorders or infections.

For older adults in long-term care facilities, there is concern that antipsychotic drugs may be overused to control agitated or disruptive behavior caused by nonpsychotic disorders and for which other treatments are preferable. For example, patients with dementia may become agitated because of environmental or medical problems. Alleviating such causes, when possible, is safer and more effective than administering antipsychotic drugs. Inappropriate use of antipsychotic drugs exposes patients to adverse drug effects and does not resolve underlying problems.

Because of the many implications for patient safety and welfare, federal regulations have been established for the use of antipsychotics in facilities receiving Medicare and Medicaid funds. These regulations include appropriate (e.g., psychotic disorders, delusions, schizophrenia, dementia and delirium that meet certain criteria) and inappropriate (e.g., agitation not thought to indicate potential harm to the resident or others, anxiety, depression, uncooperativeness, wandering) indications. When antipsychotics are required in older adults, several issues should be considered (Box 9-2).

**Use in Various Ethnic Groups**

Most antipsychotic drugs are metabolized in the liver by enzymes in the cytochrome P450 system. The ability of an

individual to produce these enzymes and metabolize drugs efficiently is dependent on genetics, which is influenced by ethnic/racial makeup; however, subgroups within a racial or ethnic category often exhibit genetic variations and therefore different clinical responses to medications. Individuals with strong enzyme activity are known as fast metabolizers, whereas those with slower rates of enzyme activity are slow metabolizers. Fast metabolizers eliminate drugs rapidly and may need a larger-than-usual dose to achieve therapeutic effects, and slow metabolizers eliminate drugs slowly and therefore are at risk of drug accumulation and adverse effects. For example, in fast metabolizers, risperidone has a half-life of 3 hours and its active metabolite has a half-life of 21 hours. In slow metabolizers, risperidone has a half-life of 20 hours and its active metabolite has a half-life of 30 hours. About 6% to 8% of Caucasians are thought to be slow metabolizers. Furthermore, due to the possibility of genetic variation in one enzyme in the cytochrome P450 system and not another, it is possible for a person to be a fast metabolizer of one antipsychotic drug and a slow metabolizer of another. Although much more research is needed, especially with the atypical drugs and with other factors that may be involved, several studies documented differences in antipsychotic drug effects in non-Caucasian populations. Some studies have suggested that atypical antipsychotics may be preferable for treating ethnic minorities because they have fewer extrapyramidal and other adverse effects.

African Americans tend to respond more rapidly; experience a higher incidence of adverse effects, including tardive dyskinesia; and metabolize antipsychotic drugs more slowly than whites. When compared with haloperidol, olanzapine has been associated with fewer extrapyramidal reactions in African Americans.

In addition, compared with Caucasians with psychotic disorders, African Americans may be given higher doses and more frequent injections of long-acting antipsychotic drugs, both of which may increase the incidence and severity of adverse effects.

Asians generally metabolize antipsychotic drugs slowly and therefore have higher plasma drug levels for a given dose than Caucasians. Most studies have been done with haloperidol and in a limited number of Asian subgroups. Thus, it cannot be assumed that all antipsychotic drugs and all people of Asian heritage respond in the same way. To avoid drug toxicity, initial doses should be approximately half the usual doses given to Caucasians and later doses should be titrated according to clinical response and serum drug levels.

A few studies have noted that Hispanics metabolize antipsychotic drugs slowly, requiring lower doses than Caucasians.

### Use in Patients With Renal Impairment

Because most antipsychotic drugs are extensively metabolized in the liver and the metabolites are excreted through the kidneys, the drugs should be used cautiously in patients with impaired renal function. Renal function should be monitored periodically during long-term therapy. If renal function test results (e.g., blood urea nitrogen) become abnormal, the drug

may need to be lowered in dosage or discontinued. Because risperidone is metabolized to an active metabolite, recommended dosage reductions and titrations for patients with renal impairment are the same as those for older adults.

With highly sedating antipsychotic drugs, it may be difficult to assess the patient for excessive sedation because drowsiness, lethargy, and mental status changes may also occur with renal impairment.

### Use in Patients With Hepatic Impairment

Antipsychotic drugs undergo extensive hepatic metabolism and then elimination in urine. In the presence of liver disease (e.g., cirrhosis, hepatitis), metabolism may be slowed and drug elimination half-lives prolonged, with resultant accumulation and increased risk of adverse effects. Thus, the drugs should be used cautiously in patients with hepatic impairment.

Jaundice has been associated with phenothiazines, usually after 2 to 4 weeks of therapy. It is considered a hypersensitivity reaction, and patients should not be re-exposed to a phenothiazine. If antipsychotic drug therapy is required in these patients, a drug from a different chemical group should be given. Overall, there is no conclusive evidence that pre-existing liver impairment increases the risk of jaundice, and patients with alcoholic cirrhosis have been treated without complications. With risperidone, recommended dosage reductions and titrations for patients with hepatic impairment are the same as those for older adults. With quetiapine, higher plasma levels occur in patients with hepatic impairment and a slower rate of dose titration and a lower target dose are recommended.

Periodic liver function tests (e.g., gamma-glutamyl transpeptidase, alkaline phosphatase, bilirubin) are probably indicated, especially with long-term therapy or the use of clozapine, haloperidol, thiothixene, or a phenothiazine.

### Use in Patients With Critical Illness

Antipsychotic drugs are infrequently used in patients who are critically ill. Some patients become acutely agitated or delirious and need sedation to prevent injuring themselves by thrashing about, removing tubes and intravenous (IV) catheters, and so forth. Some physicians prefer a benzodiazepine-type of sedative, whereas others may use haloperidol. Before giving either drug, causes of delirium (e.g., drug intoxication or withdrawal) should be identified and eliminated if possible.

If haloperidol is used, it is usually given IV, by bolus injection. The initial dose is 0.5 to 10 milligrams, depending on the severity of the agitation. It should be injected at a rate no faster than 5 milligrams per minute; the dose can be repeated every 30 to 60 minutes, up to a total amount of 30 milligrams, if necessary. Haloperidol has relatively weak sedative effects and does not cause respiratory depression. However, it can cause hypotension in patients who are volume depleted or receiving antihypertensive drugs. It can also cause cardiac dysrhythmias, including life-threatening torsades de pointes, in patients who are receiving large doses (>50 mg/day) or who have abnormal serum electrolyte levels (e.g., calcium, potassium, magnesium). Patients should be on a cardiac monitor and the ECG should be checked for a prolonged QT interval.

For patients with chronic schizophrenia who are stabilized on an antipsychotic drug when they experience a critical illness, either continuing or stopping the drug may cause difficulties. Continuing the drug may worsen signs and symptoms of the critical illness (e.g., hypotension). Stopping it may cause symptoms of withdrawal.

Little information is available about the newer drugs. If quetiapine is used, very low doses are recommended in older adults, patients with hepatic impairment, debilitated patients, and those predisposed to hypotension. A critically ill patient could have all of these conditions.

**Use in Home Care**

Chronically mentally ill patients, such as those with schizophrenia, are among the most challenging in the caseload of the home care nurse. Major recurring problems include failure to take antipsychotic medications as prescribed and the concur-

rent use of alcohol and other drugs of abuse. Either problem is likely to lead to acute psychotic episodes and hospitalizations. The home care nurse must assist and support caregivers' efforts to maintain medications and manage adverse drug effects, other aspects of daily care, and follow-up psychiatric care. In addition, the home care nurse may need to coordinate the efforts of several health and social service agencies or providers.

**Applying Your Knowledge 9-3**

When making a home visit to Ms. Jones, the nurse observes that the patient is confused, is experiencing muscle twitching, and has a fever. What is the most likely explanation for these symptoms?

.....

**Nursing Actions**

**Antipsychotic Drugs**

**NURSING ACTIONS**

**RATIONALE/EXPLANATION**

**1. Administer accurately**

- a. Check doses carefully, especially when starting or stopping an antipsychotic drug, or substituting one for another.
- b. With older, typical drugs:
  - (1) Give once daily, 1–2 hours before bedtime, when feasible.
  - (2) When preparing solutions, try to avoid skin contact. If contact is made, wash the area immediately.
  - (3) Mix liquid concentrates with at least 60 mL of fruit juice or water just before administration.
  - (4) For intramuscular injections, give only those preparations labeled for IM use; do not mix with any other drugs in a syringe; change the needle after filling the syringe; inject slowly and deeply into gluteal muscles; and have the patients lie down for 30–60 minutes after the injection.
  - (5) With parenteral fluphenazine, give the hydrochloride salt IM only; give the decanoate and enanthate salts IM or subcutaneously (Sub-Q).
- c. With newer, atypical drugs:
  - (1) Give aripiprazole and paliperidone once daily, without regard to meals.
  - (2) Give olanzapine once daily, without regard to meals; with oral disintegrating tablets, peel back foil covering, transfer tablet to dry cup or fingers, and place the tablet into the mouth.
  - (3) Give quetiapine in 2 or 3 daily doses.
  - (4) Give risperidone twice daily; mix the oral solution with 3–4 oz of water, coffee, orange juice, or low-fat milk; do not mix with cola drinks or tea.
  - (5) Give Risperdal Consta deep IM into gluteal muscles.
  - (6) Give ziprasidone twice daily with food.

Doses are often changed. When a drug is started, initial doses are usually titrated upward over days or weeks, then reduced for maintenance; when the drug is stopped, doses are gradually reduced; when substituting, dosage of one may be increased while dosage of the other is decreased.

Peak sedation occurs in about 2 hours and aids sleep. Also, adverse effects such as dry mouth and hypotension are less bothersome.

These solutions are irritating to the skin and many cause contact dermatitis.

To mask the taste. If the patient does not like juice or water, check the package insert for other diluents. Some of the drugs may be mixed with coffee, tea, milk, or carbonated beverages. These drugs are physically incompatible with many other drugs, and a precipitate may occur; parenteral solutions are irritating to body tissues and changing needles helps protect the tissues of the injection tract from unnecessary contact with the drug; injecting into a large muscle mass decreases tissue irritation; lying down helps to prevent orthostatic hypotension.

To decrease tissue irritation

Manufacturer's recommendation

Manufacturer's recommendation. The disintegrating tablet does not require fluid.

## Nursing Actions Antipsychotic Drugs (continued)

### NURSING ACTIONS

#### 2. Observe for therapeutic effects

- a. When the drug is given for acute psychotic episodes, observe for decreased agitation, combativeness, and psychomotor activity.
- b. When the drug is given for acute or chronic psychosis, observe for decreased psychotic behavior, such as:
  - (1) Decreased auditory and visual hallucinations
  - (2) Decreased delusions
  - (3) Continued decrease in or absence of agitation, hostility, hyperactivity, and other behavior associated with acute psychosis
  - (4) Increased socialization
  - (5) Increased ability in self-care activities
  - (6) Increased ability to participate in other therapeutic modalities along with drug therapy.
- c. When the drug is given for antiemetic effects, observe for decreased or absent nausea or vomiting.

#### 3. Observe for adverse effects

- a. With phenothiazines and related drugs, observe for:
  - (1) Excessive sedation—drowsiness, lethargy, fatigue, slurred speech, impaired mobility, and impaired mental processes
  - (2) Extrapyramidal reactions
    - Akathisia*—compulsive, involuntary restlessness and body movements
    - Parkinsonism*—loss of muscle movement (akinesia), muscular rigidity and tremors, shuffling gait, postural abnormalities, mask-like facial expression, hypersalivation, and drooling
    - Dyskinesias* (involuntary, rhythmic body movements) and *dystonias* (uncoordinated, bizarre movements of the neck, face, eyes, tongue, trunk, or extremities)
    - Tardive dyskinesia*—hyperkinetic movements of the face (sucking and smacking of lips, tongue protrusion, and facial grimaces) and choreiform movements of the trunk and limbs

### RATIONALE/EXPLANATION

The sedative effects of antipsychotic drugs are exerted within 48–72 hours. Sedation that occurs with treatment of acute psychotic episodes is a therapeutic effect. Sedation that occurs with treatment of nonacute psychotic disorders, or excessive sedation at any time, is an adverse reaction. These therapeutic effects may not be evident for 3–6 weeks after drug therapy is begun.

Excessive sedation is most likely to occur during the first few days of treatment of an acute psychotic episode, when large doses are usually given. Psychotic clients also seem sedated because the drug lets them catch up on psychosis-induced sleep deprivation. Sedation is more likely to occur in elderly or debilitated people. Tolerance to the drugs' sedative effects develops, and sedation tends to decrease with continued drug therapy.

Akathisia is the most common extrapyramidal reaction, and it may occur about 5–60 days after the start of antipsychotic drug therapy. The motor restlessness may be erroneously interpreted as psychotic agitation necessitating increased drug dosage. This condition can sometimes be controlled by substituting an antipsychotic drug that is less likely to cause extrapyramidal effects or by giving an anticholinergic antiparkinson drug. These symptoms are the same as those occurring with idiopathic Parkinson's disease. They can be controlled with anticholinergic antiparkinson drugs, given along with the antipsychotic drug for about 3 months, then discontinued. This reaction may occur about 5–30 days after antipsychotic drug therapy is begun.

These are less common extrapyramidal reactions, but they may occur suddenly, approximately 1–5 days after drug therapy is started, and be very frightening to the patients and health care personnel. The movements are caused by muscle spasms and result in exaggerated posture and facial distortions. These symptoms are sometimes misinterpreted as seizures, hysteria, or other disorders. Antiparkinson drugs are given parenterally during acute dystonic reactions, but continued administration is not usually required. These reactions occur most often in younger people.

This syndrome occurs after months or years of high-dose antipsychotic drug therapy. The drugs may mask the symptoms so that the syndrome is more likely to be diagnosed when dosage is decreased or the drug is discontinued for a few days. It occurs gradually and at any age but is more common in older people, women, and people with organic brain disorders. The condition is usually irreversible, and there is no effective treatment. Symptoms are not controlled and may be worsened by antiparkinson drugs. Low dosage and short-term use of antipsychotic drugs help prevent tardive dyskinesia; drug-free periods may aid early detection.

## NURSING ACTIONS

- (3) Antiadrenergic effects—hypotension, tachycardia, dizziness, faintness, fatigue
  - (4) Anticholinergic effects—dry mouth, dental caries, blurred vision, constipation, paralytic ileus, urinary retention
  - (5) Respiratory depression—slow, shallow breathing and decreased ability to breathe deeply, cough, and remove secretions from the respiratory tract
  - (6) Endocrine effects—menstrual irregularities, possibly impotence and decreased libido in the male client, weight gain
  - (7) Hypothermia or hyperthermia
  - (8) Hypersensitivity reactions:
    - Cholestatic hepatitis*—may begin with fever and influenza-like symptoms followed in approximately 1 week by jaundice
    - Blood dyscrasias*—leukopenia, agranulocytosis (fever, sore throat, weakness)
    - Skin reactions*—photosensitivity, dermatoses
  - (9) Electrocardiogram (ECG) changes, cardiac dysrhythmias
  - (10) Neuroleptic malignant syndrome—fever (may be confused with heat stroke), muscle rigidity, agitation, confusion, delirium, dyspnea, tachycardia, respiratory failure, acute renal failure
- b. With aripiprazole, observe for:
- (1) CNS effects—anxiety, headache, somnolence, blurred vision, akathisia, tardive dyskinesia, neuroleptic malignant syndrome
  - (2) GI effects—nausea, vomiting, constipation, dysphagia
  - (3) Cardiovascular effects—orthostatic hypotension
  - (4) Other—weight gain, hyperglycemia
- c. With clozapine, observe for:
- (1) CNS effects—drowsiness, dizziness, headache, seizures
  - (2) Gastrointestinal (GI) effects—nausea, vomiting, constipation
  - (3) Cardiovascular effects—hypotension, tachycardia

## RATIONALE/EXPLANATION

Hypotension is potentially one of the most serious adverse reactions to the antipsychotic drugs. It is most likely to occur when the patient assumes an upright position after sitting or lying down (orthostatic or postural hypotension), but it does occur in the recumbent position. It is caused by peripheral vasodilation. Orthostatic hypotension can be assessed by comparing blood pressure readings taken with the patient in supine and standing positions.

Tachycardia occurs as a compensatory mechanism in response to hypotension and as an anticholinergic effect in which the normal vagus nerve action of slowing the heart rate is blocked.

These atropine-like effects are common with therapeutic doses and are increased with large doses of phenothiazines.

This stems from general central nervous system (CNS) depression, which causes drowsiness and decreased movement. It may cause pneumonia or other respiratory problems, especially in people with hypercarbia and chronic lung disease. These apparently result from drug-induced changes in pituitary and hypothalamic functions.

Antipsychotic drugs may impair the temperature-regulating center in the hypothalamus. Hypothermia is more likely to occur. Hyperthermia occurs with high doses and warm environmental temperatures.

Cholestatic hepatitis results from drug-induced edema of the bile ducts and obstruction of the bile flow. It occurs most often in women and after 2–4 weeks of receiving the drug. It is usually reversible if the drug is discontinued.

Some degree of leukopenia occurs rather often and does not seem to be serious. Agranulocytosis, on the other hand, occurs rarely but is life threatening. Agranulocytosis is most likely to occur during the first 4–10 weeks of drug therapy, in women, and in older people.

Skin pigmentation and discoloration may occur with exposure to sunlight.

ECG changes may portend dysrhythmias, especially in people with underlying heart disease. Ziprasidone may prolong the QT/QTc interval, an ECG change associated with torsades de pointes, a life-threatening dysrhythmia.

A rare but potentially fatal reaction that may occur hours to months after initial drug use. Symptoms usually develop rapidly over 24–72 hours. Treatment includes stopping the antipsychotic drug, giving supportive care related to fever and other symptoms, and drug therapy (dantrolene, a skeletal muscle relaxant, and amantadine or bromocriptine, dopamine-stimulating drugs).

## Nursing Actions Antipsychotic Drugs (continued)

### NURSING ACTIONS

(4) Hematologic effects—agranulocytosis

d. With olanzapine, observe for:

- (1) CNS effects—drowsiness, dizziness, akathisia, tardive dyskinesia, neuroleptic malignant syndrome
- (2) GI effects—constipation
- (3) Cardiovascular effects—hypotension, tachycardia
- (4) Other—weight gain, hyperglycemia, diabetes, hyperlipidemia

e. With quetiapine, observe for:

- (1) CNS effects—drowsiness, dizziness, headache, tardive dyskinesia, neuroleptic malignant syndrome
- (2) GI effects—anorexia, nausea, vomiting
- (3) Cardiovascular effects—orthostatic hypotension, tachycardia
- (4) Other—weight gain, hyperglycemia, diabetes

f. With paliperidone, observe for:

- (1) CNS effects — akathisia, extrapyramidal effects, syncope
- (2) GI effects — possible obstruction in patients with known GI narrowing
- (3) Cardiovascular effects — QT prolongation, arrhythmias, orthostatic hypotension
- (4) Other — hyperglycemia, hyperprolactinemia

g. With risperidone, observe for:

- (1) CNS effects—agitation, anxiety, drowsiness, dizziness, headache, insomnia, tardive dyskinesia, neuroleptic malignant syndrome
- (2) GI effects—nausea, vomiting, constipation
- (3) Cardiovascular effects—orthostatic hypotension, dysrhythmias
- (4) Other—photosensitivity

h. With ziprasidone, observe for:

- (1) CNS effects—drowsiness, headache, extrapyramidal reactions
- (2) GI effects—nausea, constipation
- (3) Cardiovascular effects—dysrhythmias, hypotension, ECG changes
- (4) Other—fever

### 4. Observe for drug interactions

a. Drugs that increase effects of antipsychotic drugs:

- (1) Anticholinergics (e.g., atropine)
- (2) Antidepressants, tricyclic
- (3) Antihistamines
- (4) CNS depressants—alcohol, opioid analgesics, anti-anxiety agents, sedative-hypnotics
- (5) Propranolol
- (6) Thiazide diuretics, such as hydrochlorothiazide
- (7) Lithium

### RATIONALE/EXPLANATION

This is the most life-threatening adverse effect of clozapine. Patients' white blood cell (WBC) counts must be checked before starting clozapine, every 2 weeks during the first six months of therapy, then every 2 weeks as long as WBC counts are satisfactory. WBC levels should be monitored weekly for 4 weeks after the drug is discontinued.

Additive anticholinergic effects

Potential of sedative and anticholinergic effects. Additive CNS depression, sedation, orthostatic hypotension, urinary retention, and glaucoma may occur unless dosages are decreased. Apparently these two drug groups inhibit the metabolism of each other, thus prolonging the actions of both groups if they are given concurrently.

Additive CNS depression and sedation

Additive CNS depression. Also, severe hypotension, urinary retention, seizures, severe atropine-like reactions, and other adverse effects may occur, depending on which group of CNS depressant drugs is given.

Additive hypotensive and ECG effects

Additive hypotension

Acute encephalopathy, including irreversible brain damage and dyskinesias, has been reported.

## NURSING ACTIONS

- b. Drugs that decrease effects of antipsychotic drugs:
- (1) Antacids
  - (2) Norepinephrine, phenylephrine
- c. Drugs that alter effects of antipsychotics by altering hepatic metabolism:
- (1) Cimetidine, ketaconazole, nefazodone, grapefruit juice, erythromycin, fluoxetine increase the effects of clozapine, quetiapine, and ziprasidone.
  - (2) Carbamazepine, phenytoin, rifampin, and St. John's wort may decrease the effects of clozapine, quetiapine, and ziprasidone.
  - (3) Cimetidine, fluvoxamine, and fluoroquinolone antibiotics increase the effects of clozapine, haloperidol, olanzapine, thioridazine, and thiothixene.
  - (4) Carbamazepine and cigarette smoke may decrease effects of clozapine, haloperidol, olanzapine, thioridazine, and thiothixene.
  - (5) Fluoxetine, paroxetine, and quinidine may increase the effects of phenothiazines, risperidone, and aripiprazole.
  - (6) Carbamazepine may decrease the effects of phenothiazines, risperidone, and aripiprazole.

## RATIONALE/EXPLANATION

Oral antacids, especially aluminum hydroxide and magnesium trisilicate, may inhibit gastrointestinal absorption of antipsychotic drugs.

Antagonize the hypotensive effects of antipsychotic drugs

CYP3A4 enzyme inhibition slows the metabolism of drugs dependent on this enzyme system.

CYP3A4 enzyme induction speeds the metabolism of drugs dependent on this enzyme system.

CYP1A2 enzyme inhibition slows the metabolism of drugs dependent on this enzyme system.

CYP1A2 enzyme induction speeds the metabolism of drugs dependent on this enzyme system.

CYP2D6 enzyme inhibition slows the metabolism of drugs dependent on this enzyme system.

CYP2D6 enzyme induction speeds the metabolism of drugs dependent on this enzyme system.

## Key Concepts

- First-generation antipsychotics, or “typical antipsychotics,” include the phenothiazines and older nonphenothiazines such as haloperidol and thiothixene.
- Second-generation antipsychotics, or “atypical antipsychotics,” include newer nonphenothiazine drugs. They are also considered first choice therapy for schizophrenia because they have a more favorable side effect profile, producing fewer extrapyramidal movement disorders.
- The mechanism of action of first-generation antipsychotic drugs is blockade of D<sub>2</sub> receptors.
- The mechanism of action of second-generation antipsychotics is blockade of dopamine and serotonin receptors.
- Antipsychotic drugs are indicated to treat psychosis, including disorders such as schizophrenia and the manic phase of bipolar disorder.
- Positive symptoms of schizophrenia respond to drug therapy more readily than negative symptoms. The second-generation “atypical” nonphenothiazine drugs may be slightly more effective in treating negative symptoms of schizophrenia.
- Therapeutic effects to antipsychotics may take several weeks to achieve maximum therapeutic effect.
- All first-generation antipsychotics are considered equal in ability to relieve symptoms of psychosis; however, they differ in potency and side effects.
- Adverse effects occurring more frequently in low-potency drugs as compared with high-potency drugs include anticholinergic effects, antiadrenergic effects (orthostatic hypotension), and CNS depression (sedation).
- Adverse effects more common to high-potency drugs as compared with low-potency drugs include early extrapyramidal effects (acute dystonia, akathisia, parkinsonism).
- Early extrapyramidal effects are treated by reducing dosage, changing to a second-generation antipsychotic, or use of anticholinergic medications. Akathisia may also be treated with benzodiazepines and beta blockers to reduce the urge to move.
- Tardive dyskinesia, a late extrapyramidal effect, may occur with all phenothiazine and typical nonphenothiazine drugs and is generally considered to be irreversible. It may be treated by reducing dosages or switching to a second-generation antipsychotic. Prevention through early detection is key.
- Neuroleptic malignant syndrome (a potentially fatal adverse effect characterized by rigidity, severe hyperthermia, agitation, confusion, delirium, dyspnea, tachycardia, respiratory failure, and acute renal failure) is treated with hydration, cooling measures and antipyretics to reduce fever, benzodiazepines to reduce agitation, dantrolene to directly relax muscles, and bromocriptine or amantadine (dopamine agonists) to reduce CNS depression.

## Review and Application Exercises

### Short Answer Exercises

- How do antipsychotic drugs act to relieve psychotic symptoms?
- What are some uses of antipsychotic drugs other than the treatment of schizophrenia?
- What are major adverse effects of older antipsychotic drugs?
- When instructing a patient to rise slowly from a sitting or lying position, which adverse effect of an antipsychotic drug is the nurse trying to prevent?
- In a patient receiving an antipsychotic drug, what appearances or behaviors would lead the nurse to suspect an extrapyramidal reaction?
- Are antipsychotic drugs likely to be overused and abused? Why or why not?
- In an older patient taking an antipsychotic drug, what special safety measures are needed? Why?
- How do clozapine, olanzapine, quetiapine, risperidone, ziprasidone, and aripiprazole compare with older antipsychotic drugs in terms of therapeutic and adverse effects?
- What can the home care nurse do to prevent acute psychotic episodes and hospitalization of chronically mentally ill patients?
- Patients taking ziprasidone (Geodon) may have prolonged QT intervals, placing them at risk for which of the following?
  - atrial fibrillation
  - torsades de pointes
  - complete heart block
  - atrial tachycardia
- The nurse should administer long-acting injections of antipsychotic drugs in which of the following ways?
  - intramuscularly into the deltoid muscle
  - subcutaneously into the abdomen
  - intramuscularly into the gluteal muscle
  - intravenously into a large vein
- When administering atypical antipsychotics, the nurse should be alert to possible
  - renal failure
  - liver failure
  - diabetes mellitus
  - hypertension
- In monitoring the status of a patient on a long-term course of a phenothiazine antipsychotic, the nurse needs to be most aware that an adverse effect of long-term use of phenothiazine antipsychotics is the development of which of the following?
  - glaucoma
  - tardive dyskinesia
  - hypertension
  - diabetes

### NCLEX-Style Questions

- For patients taking clozapine, the nurse should assess which of the following laboratory values weekly?
  - complete blood count (CBC)
  - hemoglobin and hematocrit
  - blood urea nitrogen and creatinine
  - liver enzyme studies

# Antidepressants and Mood Stabilizers

## KEY TERMS

- Antidepressant discontinuation syndrome
- Bipolar disorder
- Cyclothymia
- Depression
- Dysthymia
- Hypomania
- Mania
- Monoamine oxidase (MAO) inhibitors
- Neonatal withdrawal syndrome
- Postnatal depression
- Selective serotonin reuptake inhibitors (SSRIs)
- Serotonin syndrome

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Describe major features of depression and bipolar disorder.
2. Discuss characteristics of antidepressants in terms of mechanism of action, indications for use, adverse effects, principles of therapy, and nursing process implications.
3. Compare and contrast the different categories of antidepressants: selective serotonin reuptake inhibitors (SSRIs), tricyclic antidepressants (TCAs), mixed serotonin-norepinephrine reuptake inhibitors (SNRIs), monoamine oxidase (MAO) inhibitors, and other atypical antidepressants.
4. Discuss selected characteristics of atypical antidepressants.
5. Describe the use of lithium in bipolar disorder.
6. Describe the use of atypical antipsychotics in the manic phase of bipolar disorder.
7. Discuss interventions to increase safety of lithium therapy.
8. Describe the nursing role in preventing, recognizing, and treating overdoses of antidepressant drugs and lithium.
9. Analyze important factors in using antidepressant drugs and lithium in special populations.

## Applying Your Knowledge

While in the hospital, Carl Mehring, age 70, is diagnosed with chronic depression secondary to his chronic heart failure, hypertension, diabetes mellitus, and renal insufficiency. As Mr. Mehring's health has declined, so has his interest in his family, friends, and hobbies. His physician prescribes sertraline 50 mg PO at bedtime.

## Introduction

Mood disorders include depression, *dysthymia*, bipolar disorder, and *cyclothymia* (Box 10-1). It is difficult to determine the prevalence of depression in the United States; however, major depressive disorder is relatively common in adults and is increasingly being diagnosed in children and adolescents. The National Comorbidity Survey Replication Study (2003) revealed that 16.2% of study participants had experienced a major depressive disorder in their lifetime. Major depression occurs more often in women than in men and shows familial tendencies with increased risk for depression in individuals with an affected twin or first degree relative. *Postnatal depression* is a major depressive episode occurring after the birth of a child (see Evidence-Based Practice Box 10-1). Major

## Box 10-1

## Types of Mood Disorders

**Depression**

Depression, often described as the most common mental illness, is characterized by depressed mood, feelings of sadness, or emotional upset, and it occurs in all age groups. Mild depression occurs in everyone as a normal response to life stresses and losses and usually does not require treatment; severe or major depression is a psychiatric illness and requires treatment. Major depression also is categorized as unipolar, in which people of usually normal moods experience recurrent episodes of depression.

**Major Depression**

The American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, lists criteria for a major depressive episode as a depressed mood plus at least five of the following symptoms for at least 2 weeks:

- Loss of energy, fatigue
- Indecisiveness
- Difficulty thinking and concentrating
- Loss of interest in appearance, work, and leisure and sexual activities
- Inappropriate feelings of guilt and worthlessness
- Loss of appetite and weight loss, or excessive eating and weight gain
- Sleep disorders (hypersomnia or insomnia)
- Somatic symptoms (e.g., constipation, headache, atypical pain)
- Obsession with death, thoughts of suicide
- Psychotic symptoms, such as hallucinations and delusions

**Dysthymia**

*Dysthymia* involves a chronically depressed mood and at least two other symptoms (e.g., anorexia, overeating, insomnia, hypersomnia, low energy, low self-esteem, poor concentration, feelings of hopelessness) for 2 years. Although the symptoms may cause significant social and work-related impairments, they are not severe enough to meet the criteria for major depression.

**Bipolar Disorder**

Bipolar disorder involves episodes of depression alternating with episodes of mania. *Mania* is characterized by excessive CNS stimulation with physical and mental hyperactivity (e.g., agitation, constant talking, constant movement, grandiose ideas, impulsiveness, inflated self-esteem, little need for sleep, poor concentration, racing thoughts, short attention span) for at least 1 week. Symptoms are similar to those of acute psychosis or schizophrenia. *Hypomania* involves the same symptoms, but they are less severe, indicate less CNS stimulation and hyperactivity, and last 3 or 4 days.

**Cyclothymia**

*Cyclothymia* is a mild type of bipolar disorder that involves periods of hypomania and depression that do not meet the criteria for mania and major depression. Symptoms must be present for at least 2 years. It does not usually require drug therapy.

depression is associated with impaired ability to function in usual activities and relationships. The average depressive episode lasts about 5 months, and having one episode is a risk factor for developing another episode.

*Bipolar disorder* is divided into subtypes that are defined by the presentation of the mood disorder. Bipolar disorder type I is characterized by a episodes of major depression plus mania and occurs equally in men and women. Bipolar disorder type II is characterized by episodes of major depression plus hypomanic episodes and occurs more frequently in women. Bipolar spectrum disorder broadens the definition of bipolar disorder to include conditions such as cyclothymia and dysthymia. The prevalence of bipolar disorders is estimated to range up to 5% of the adult population.

Depression and antidepressant drug therapy are emphasized in this chapter. Bipolar disorder and mood-stabilizing drugs are also discussed.

**Etiology of Depression**

Despite extensive study and identification of numerous potential contributory factors, the etiology of depression is unclear. It is likely that depression results from interactions among sev-

eral complex factors. Two of the major theories of depression pathogenesis are described in the following sections.

**Monoamine Neurotransmitter Dysfunction**

*Depression* is thought to result from a deficiency of norepinephrine and/or serotonin. Recent studies suggest that deficiencies of dopamine may also play a role in depression. This hypothesis stemmed from studies demonstrating that antidepressant drugs increase the amounts of norepinephrine and/or serotonin in the central nervous system (CNS) synapse by inhibiting their reuptake into the presynaptic neuron. Serotonin received increased attention after the selective serotonin reuptake inhibitor (SSRI) antidepressants were marketed. Serotonin helps regulate several behaviors that are disturbed in depression, such as mood, sleep, appetite, energy level, and cognitive and psychomotor functions.

Emphasis shifted toward receptors because the neurotransmitter view did not explain why the amounts of neurotransmitter increased within hours after single doses of a drug, but relief of depression occurred only after weeks of drug therapy. Researchers identified changes in norepinephrine and serotonin receptors with chronic antidepressant drug therapy. Studies demonstrated that chronic drug administration results in

## Evidence-Based Practice

### 10-1 Antidepressants and Postnatal Depression

Postnatal depression is defined as a depressive episode that meets the DSM-IV criteria for major depression and occurs within 4 weeks of childbirth. Many clinicians extend this time criteria for the diagnosis of postnatal depression up to 6 months after delivery. The Edinburgh Postnatal Depression Scale, which elicits responses to a series of 10 statements about the mother's feelings during the past week, is commonly used by health care providers to screen for postnatal depression. Postnatal depression is common, affecting 12% to 15% of new mothers. For women with a history of postnatal depression the risk of recurrence is 33%, and suicide is the main cause of maternal death within the first year of childbirth. Postnatal depression may resolve without treatment within 3 to 6 months; however, 25% of affected mothers will still be depressed 1 year after delivery. Treatment generally involves the use of psychotherapy and/or antidepressants; however, there is limited information available to guide the selection of the most efficacious antidepressants for treatment of postnatal depression. One random controlled trial evaluated the use of cognitive behavior therapy and fluoxetine and found that both were effective in treating postnatal depression. Sertraline, paroxetine, venlafaxine, and nortriptyline have been reported to be safe for use by nursing mothers of healthy infants; however, fluoxetine is not recommended because it can cause irritability, sleep disturbances, and poor feeding in exposed breast-feeding infants. Third trimester intrauterine exposure to fluoxetine and other SSRIs may result in a *neonatal withdrawal syndrome*, which shares some similarity to a mild serotonin syndrome. Common symptoms include irritability, prolonged crying, respiratory distress, rigidity, and possibly seizures. Care for neonatal withdrawal syndrome is supportive; symptoms usually abate within a few days.

A Cochrane Review investigated the use of antidepressants in women with a past history of postnatal depression and concluded that there was no clear evidence to recommend antidepressant prophylaxis. Given the limited evidence available on the treatment of postnatal depression, further research is needed.

fewer and less sensitive receptors on the postsynaptic membrane. This down-regulation or desensitization of receptors, first noted with beta-adrenergic receptors and later with norepinephrine and serotonin receptors, corresponds with therapeutic drug effects. All known treatments for depression lead to the down-regulation of beta receptors, which coincides with the behavioral changes associated with antidepressant drug therapy.

Alpha<sub>2</sub>-adrenergic receptors (called autoreceptors), located on presynaptic nerve terminals, may also play a role. When these receptors are stimulated, they inhibit the release of norepinephrine. There is evidence that alpha<sub>2</sub> receptors are also down-regulated by antidepressant drugs, thus allowing increased norepinephrine release. With serotonin receptors, available antidepressants may increase the sensitivity of postsynaptic receptors and decrease the sensitivity of presynaptic receptors.

Physiologically, presynaptic receptors regulate the release and reuptake of neurotransmitters; postsynaptic receptors participate in the transmission of nerve impulses to target tissues.

It seems apparent that long-term administration of antidepressant drugs produces complex changes in the sensitivities of both presynaptic and postsynaptic receptor sites.

Overall, there is increasing awareness that balance, integration, and interactions among norepinephrine, serotonin, and possibly other neurotransmission systems (e.g., dopamine, acetylcholine) are probably more important etiologic factors than single neurotransmitter or receptor alterations. For example, animal studies indicate that serotonin is required for optimal functioning of the neurons that produce norepinephrine. Changes in neurons may also play a major role.

### Neuroendocrine Factors

In addition to monoamine neurotransmission systems, researchers have identified nonmonoamine systems that influence neurotransmission and are significantly altered in depression. A major nonmonoamine is corticotropin-releasing factor or hormone (CRF or CRH), whose secretion is increased in people with depression. CRF-secreting neurons are widespread in the CNS, and CRF apparently functions as a neurotransmitter and mediator of the endocrine, autonomic, immune, and behavioral responses to stress as well as a releasing factor for corticotropin. Hypothalamic CRF is part of the hypothalamic-pituitary-adrenal (HPA) axis, which becomes hyperactive in depression. As a result, there is increased secretion of CRF by the hypothalamus, adrenocorticotropic hormone (ACTH) by the anterior pituitary, and cortisol by the adrenal cortex. The increased cortisol (part of the normal physiologic response to stress) is thought to decrease the numbers or sensitivity of cortisol receptors (down-regulation) and lead to depression. This view is supported by animal studies indicating that antidepressant drugs restore the ability of cortisol receptors to bind with cortisol. This alteration of cortisol receptors takes about 2 weeks, the approximate time interval required for the drugs to improve symptoms of depression. Extrahypothalamic CRF is also increased in depression. Secretion of both hypothalamic and extrahypothalamic CRF apparently returns to normal with recovery from depression.

Other neuroendocrine factors in patients with depression are thought to include abnormalities in the secretion and function of thyroid and growth hormones.

### Additional Factors

Additional factors thought to play a role in the etiology of depression include the immune system, genetic factors, and environmental factors.

Immune cells (e.g., T lymphocytes, B lymphocytes) produce cytokines (e.g., interleukins, interferons, tumor necrosis factor), which affect neurotransmission. Possible mechanisms of cytokine-induced depression include increased CRF and activation of the HPA axis, alteration of monoamine neurotransmitters in several areas of the brain, or cytokines functioning as neurotransmitters and exerting direct effects on brain function.

Genetic factors are considered important mainly because close relatives of a depressed person are more likely to experience depression.

Environmental factors include stressful life events, which apparently change brain structure and function and contribute to the development of depression in some people. Changes have been identified in CRF, the HPA axis, and the noradrenergic neurotransmission system, all of which are activated as part of the stress response. These changes are thought to cause a hypersensitive or exaggerated response to later stressful events, including mild stress or daily life events. Most studies have involved early life trauma such as physical or sexual abuse in childhood.

## Etiology of Bipolar Disorder

Like depression, *mania* and *hypomania* have historically been associated with abnormal functioning of neurotransmitters or receptors, such as a relative excess of excitatory neurotransmitters (e.g., norepinephrine) or a relative deficiency of inhibitory neurotransmitters (e.g., gamma-aminobutyric acid [GABA]). Another more recent proposed etiology for bipolar disorder is alteration in neuronal growth and survival in areas of the brain (e.g., subgenual precortex, hippocampus) involved with mood and memory. Mood-stabilizing drugs such as lithium have been shown to stimulate neuronal growth and reduce brain atrophy in individuals with long-standing mood disorders. Secondary causes of manic and hypomanic behavior include drugs that stimulate the CNS, CNS diseases and infections, and electrolyte or endocrine disorders.

## General Characteristics of Antidepressant Drugs

Drugs used in the pharmacologic management of depressive disorders are derived from several chemical groups. Older antidepressants include the tricyclic antidepressants (TCAs) and the *monoamine oxidase (MAO) inhibitors*. Newer drugs include the *selective serotonin reuptake inhibitors (SSRIs)*, the mixed serotonin-norepinephrine reuptake inhibitors (SNRIs), and several atypical antidepressant drugs that differ from TCAs, MAO inhibitors, SSRIs, and SNRIs. General characteristics of antidepressants include the following:

- All are effective in relieving depression, but they differ in their adverse effects.
- All must be taken for 2 to 4 weeks before depressive symptoms improve.
- They are given orally, absorbed from the small bowel, enter the portal circulation, and circulate through the liver, where they undergo extensive first-pass metabolism before reaching the systemic circulation.
- They are metabolized by the cytochrome P450 enzymes in the liver. Many antidepressants and other drugs are metabolized by the 2D6 or 3A4 subgroup of the enzymes. Thus, antidepressants may interact with each other and with a wide variety of drugs that are normally metabolized by the same subgroups of enzymes.

## Mechanisms of Action

Although the actions of antidepressant drugs are still being studied in relation to newer information about brain function and the etiology of mood disorders, these drugs apparently normalize abnormal neurotransmission systems in the brain by altering the amounts of neurotransmitters and the number or sensitivity of receptors. They may also modify interactions among neurotransmission systems and affect endocrine function (e.g., the HPA axis and cortisol activity).

After neurotransmitters are released from presynaptic nerve endings, the molecules that are not bound to receptors are normally inactivated by reuptake into the presynaptic nerve fibers that released them or metabolized by MAO. Most antidepressants prevent the reuptake of multiple neurotransmitters; SSRIs selectively inhibit the reuptake of serotonin, and MAO inhibitors prevent the metabolism of neurotransmitter molecules. These mechanisms thereby increase the amount of neurotransmitter available to bind to receptors.

With chronic drug administration, receptors adapt to the presence of increased neurotransmitter by decreasing their number or sensitivity to the neurotransmitter. More specifically, norepinephrine receptors, especially postsynaptic beta receptors and presynaptic  $\alpha_2$  receptors, are down-regulated. The serotonin receptor 5-HT<sub>2</sub>, a postsynaptic receptor, and cortisol (glucocorticoid) receptors may also be down-regulated.

Thus, antidepressant effects are attributed to changes in receptors rather than changes in neurotransmitters. Although some of the drugs act more selectively on one neurotransmission system than another initially, this selectivity seems to be lost with chronic administration.

With lithium, the exact mechanism of action is unknown. However, it is known to affect the synthesis, release, and reuptake of several neurotransmitters in the brain, including acetylcholine, dopamine, GABA, and norepinephrine. It also stabilizes postsynaptic receptor sensitivity to neurotransmitters, probably by competing with calcium, magnesium, potassium, and sodium ions for binding sites. Long-term administration of lithium may also stimulate neuronal growth, exerting a neuroprotective effect on areas of the brain involved with mood.

## Indications for Use

Antidepressant therapy may be indicated if depressive symptoms persist at least 2 weeks, impair social relationships or work performance, and occur independently of life events. In addition, antidepressants are increasingly being used for treatment of anxiety disorders. TCAs may be used in children and adolescents in the management of enuresis (bedwetting or involuntary urination resulting from a physical or psychological disorder). In this setting, TCAs may be given after physical causes (e.g., urethral irritation, excessive intake of fluids) have been ruled out. TCAs and duloxetine (an SNRI) are also commonly used in the treatment of neuropathic pain. MAO inhibitors are considered third-line drugs, largely because of their potential for serious interactions with certain foods and other drugs.

## Contraindications to Use

Antidepressants are contraindicated or must be used with caution in patients with acute schizophrenia; mixed mania and depression; suicidal tendencies; severe renal, hepatic, or cardiovascular disease; narrow-angle glaucoma; and seizure disorders. A **BLACK BOX WARNING** alerts health care providers to the increased risk of suicidal ideation in children, adolescents, and young adults 18 to 24 years of age when taking antidepressant medications. Health care providers should be aware that worsening symptoms could be a result of underlying disease or drug therapy. Symptoms of concern include anxiety, agitation, panic attacks, insomnia, irritability, hostility, impulsivity, akathisia, hypomania, and mania. The presence of these symptoms, especially if new (i.e., not part of the patient's presenting symptoms), severe, or abrupt in onset, should prompt evaluation of drug therapy and possible discontinuation of medications. If the decision is made to discontinue antidepressant therapy, it is important that medications be tapered rather than abruptly discontinued.

## Applying Your Knowledge 10-1

### How Can You Avoid This Medication Error?

Mr. Mehring is talking with his pastor when you arrive to administer his medication. He asks you to just leave the medication and he will take it when he finishes his visit. You leave the medication with Mr. Mehring and chart it as given.

## Types of Antidepressants and Individual Drugs

Additional characteristics of antidepressants and lithium are described in the following sections. Names, indications for use, and dosage ranges of individual drugs are listed in Table 10-1.

Table 10-1

Drugs at a Glance: Antidepressant Agents

GENERIC/TRADE NAME	CLINICAL INDICATIONS	ROUTES AND DOSAGE RANGES
<b>Tricyclic Antidepressants</b> <b>Amitriptyline</b> (Elavil)	Depression	PO 50–100 mg once daily at bedtime, gradually increased to 150 mg daily if necessary; IM 80–120 mg daily in 4 divided doses <i>Adolescents and older adults:</i> PO 10 mg 3 times daily and 20 mg at bedtime
<b>Clomipramine</b> (Anafranil)	Obsessive-compulsive disorder (OCD)	PO 25 mg daily, increased to 100 mg daily by end of 2 wk, in divided doses, with meals. Give maintenance dose in a single dose at bedtime. Maximum dose, 250 mg daily. <i>Children and adolescents:</i> PO 25 mg daily, increased to 3 mg/kg or 100 mg, whichever is smaller, over 2 wk. Give maintenance dose in a single dose at bedtime. Maximum dose, 3 mg/kg or 200 mg, whichever is smaller.
<b>Desipramine</b> (Norpramin)	Depression	PO 100–200 mg daily in divided doses or as a single daily dose. Give maintenance dose once daily. Maximum dose, 300 mg/d. <i>Adolescents and older adults:</i> PO 25–100 mg daily in divided doses or as a single daily dose. Maximum dose, 150 mg/d.
<b>Doxepin</b> (Sinequan)	Depression	PO 75–150 mg daily, in divided doses or a single dose at bedtime. Maximum dose, 300 mg/d.
<b>P Imipramine</b> (Tofranil)	Depression Childhood enuresis	PO 75 mg daily in 3 divided doses, gradually increased to 200 mg daily if necessary. Maintenance dose, 75–150 mg daily. <i>Adolescents and older adults:</i> PO 30–40 mg daily in divided doses, increased to 100 mg daily if necessary. <i>Children &gt;6 y:</i> Enuresis, PO 25–50 mg 1 h before bedtime
<b>Nortriptyline</b> (Aventyl, Pamelor)	Depression	PO 25 mg 3 or 4 times daily or in a single dose (75–100 mg) at bedtime. Maximum dose, 150 mg/d. <i>Adolescents and older adults:</i> 30–50 mg/d, in divided doses or a single dose once daily.

(continued on page 180)

Table 10-1

## Drugs at a Glance: Antidepressant Agents (continued)

GENERIC/TRADE NAME	CLINICAL INDICATIONS	ROUTES AND DOSAGE RANGES
<b>Selective Serotonin Reuptake Inhibitors (SSRIs)</b>		
<b>Citalopram</b> (Celexa)	Depression	PO 20 mg once daily, morning or evening, increased to 40 mg daily in 1 wk, if necessary <i>Elderly/hepatic impairment:</i> PO 20 mg daily
<b>Escitalopram</b> (Lexapro)	Depression Generalized anxiety disorder (GAD)	PO 10 mg once daily. May increase to maximum dose of 20 mg after minimum of 1 wk of therapy
<b>Fluoxetine</b> (Prozac, Prozac Weekly, Sarafem)	Depression OCD Bulimia nervosa Premenstrual dysphoric disorder (Sarafem)	PO 20 mg once daily in the morning, increased after several weeks if necessary. Give doses larger than 20 mg once in the morning or in 2 divided doses, morning and noon; maximum daily dose 80 mg. Prozac Weekly (delayed-release capsules), PO 90 mg once each wk, starting 7 days after the last 20-mg dose <i>Children and adolescents 8–17 y for depression:</i> PO 10 mg/d. May increase to 20 mg/d if necessary.
<b>Paroxetine</b> (Paxil, Paxil CR)	Depression GAD OCD Panic disorder Social anxiety disorder	PO 20 mg once daily in the morning, increased at 1 wk or longer intervals, if necessary; usual range, 20–50 mg/d; maximum dose, 60 mg/d. Controlled-release (CR) tablets, PO 25 mg once daily in the morning, increased up to 62.5 mg/d if necessary <i>Elderly or debilitated adults:</i> PO 10 mg once daily, increased if necessary. Maximum dose, 40 mg. <i>Severe renal or hepatic impairment:</i> Same as for older adults
<b>Sertraline</b> (Zoloft)	Depression OCD Panic disorder Post-traumatic stress disorder (PTSD)	Depression, OCD, PO 50 mg once daily morning or evening, increased at 1-wk or longer intervals to a maximum daily dose of 200 mg Panic, PTSD, PO 25 mg once daily, increased after 1 wk to 50 mg once daily <i>Children:</i> OCD, 6–12 y, 25 mg once daily; 13–17 y, 50 mg once daily
<b>Serotonin-Norepinephrine Reuptake Inhibitors (SNRIs)</b>		
<b>Duloxetine</b> (Cymbalta)	Depression GAD	PO 30–60 mg/d, increase by 30-mg increments every week up to a maximum daily dose of 120 mg/d. Contraindicated for hepatic impairment, lower doses for renal impairment.
<b>Venlafaxine</b> (Effexor, Effexor XR)	Depression GAD (XR form)	Immediate-release tablets, PO initially 75 mg/d in 2 or 3 divided doses with food. Increase by 75 mg/d (4 d or longer between increments) up to 225 mg/d if necessary. Extended-release (XR) capsules, PO initially 37.5 or 75 mg/d in a single dose morning or evening. Increase by 75 mg/d (4 d or longer between increments) up to 225 mg/d if necessary. <i>Hepatic or renal impairment:</i> Reduce dose by 50% and increase very slowly.
<b>Monoamine Oxidase (MAO) Inhibitors</b>		
<b>Phenelzine</b> (Nardil)	Depression	PO 15 mg 3 times daily
<b>Tranylcypromine</b> (Parnate)	Depression	PO 30 mg daily in divided doses
<b>Other Atypical Antidepressants</b>		
<b>Bupropion</b> (Wellbutrin, Wellbutrin SR, Wellbutrin XL, Zyban)	Depression (Wellbutrin) Smoking cessation (Zyban)	Immediate-release tablets, PO 100 mg twice daily, increased to 100 mg 3 times daily (at least 6 h apart) if necessary. Maximum single dose, 150 mg.

GENERIC/TRADE NAME	CLINICAL INDICATIONS	ROUTES AND DOSAGE RANGES
		Sustained-release (SR) tablets, PO 150 mg once daily in the morning, increased to 150 mg twice daily (at least 8 h apart). Maximum single dose, 150 mg. Wellbutrin XL: PO 150 mg once daily in the morning. May increase to target dose of 300 mg on or after fourth day of therapy. Maximum single dose, 450 mg.
<b>Mirtazapine</b> (Remeron)	Depression	PO 15 mg/d
<b>Trazodone</b> (Desyrel)	Depression	PO 100–300 mg daily, increased to a maximum dose of 600 mg daily if necessary
<b>Mood-Stabilizing Agents</b>		
<b>Lithium carbonate</b> (Eskalith, Lithobid)	Bipolar disorder (mania)	PO 600 mg 3 times daily or 900 mg twice daily (slow-release forms) Maintenance dose, PO 300 mg 3 or 4 times daily to maintain a serum lithium level of 0.6–1.2 mEq/L
<b>Aripiprazole</b> (Abilify)	Bipolar disorder (acute mania)	PO 30 mg/d
<b>Olanzapine</b> (Zyprexa)	Bipolar disorder (acute mania)	PO 10–15 mg/d initially; may increase by 5 mg qd PRN to maximum dose of 20 mg/d. <i>Elderly or debilitated adults:</i> PO 5 mg/d
<b>Quetiapine</b> (Seroquel)	Bipolar disorder (acute mania)	PO 50 mg twice daily on day 1 PO 100 mg twice daily on day 2 PO 150 mg twice daily on day 3 PO 200 mg twice daily on day 4 If needed, may continue to increase maximum dose 800 mg/d.
	Bipolar disorder (depressive episodes)	PO 50 mg at bedtime. May increase by 50 mg/d to maximum dose 600 mg at bedtime.
<b>Olanzapine/fluoxetine</b> (Symbyax)	Bipolar disorder (depressive episodes)	PO 6/25 mg at bedtime. May increase to maximum 18/75 mg/d.
<b>Risperidone</b> (Risperdal)	Bipolar disorder (acute mania)	PO 2–3 mg/d initially. May increase 1 mg/d to maximum dose of 6 mg/d. <i>Elderly or debilitated adults:</i> PO 0.5mg/d, may increase by 0.5 mg/d to 3 mg/d, then may increase by 1 mg/wk to maximum dose of 6 mg/d. <i>Adolescents 10–17 y:</i> 0.5 mg/d initially. Titrate 0.5–1 daily to a target dose of 2.5 mg/d. Dosage range 0.5–6 mg/d.
<b>Ziprasidone</b> (Goeden)	Bipolar disorder (acute mania)	PO 40 mg twice daily. May increase to maximum dose 80 mg twice daily.
<b>Carbamazepine</b> (Tegretol)	Bipolar disorder	PO 100–200 mg initially. May increase to maximum 1600 mg/d.
<b>Lamotrigine</b> (Lamictal)	Bipolar disorder (maintenance)	PO 50 mg/d initially; may increase to maximum of 200 mg/d.
<b>Valproic acid</b> (Depakene)	Bipolar disorder (acute mania)	PO 250 mg/d; may increase rapidly to lowest effective dose. Maximum dose 60 mg/kg/d.

### Tricyclic Antidepressants

TCAs, of which **P imipramine** is the prototype, are similar drugs that produce a high incidence of adverse effects such as sedation, orthostatic hypotension, cardiac dysrhythmias, anti-

cholinergic effects (e.g., blurred vision, dry mouth, constipation, urinary retention), and weight gain. They are well absorbed after oral administration, but first-pass metabolism by the liver results in blood level variations of 10- to 30-fold among people given identical doses. After they are absorbed,

these drugs are widely distributed in body tissues and metabolized in the liver by CYP2D6 enzymes in the liver to active and inactive metabolites. Because of adverse effects on the heart, especially in overdose, baseline and follow-up electrocardiograms (ECGs) are recommended for all patients. **Amitriptyline** (Elavil) is a commonly used TCA.

## Selective Serotonin Reuptake Inhibitors

SSRIs, of which **P fluoxetine** (Prozac, Sarafem) is the prototype, produce fewer serious adverse effects than the TCAs. They are well absorbed with oral administration, undergo extensive first-pass metabolism in the liver, are highly protein bound (56%–95%), and have a half-life of 24 to 72 hours, which may lead to accumulation with chronic administration. Fluoxetine also forms an active metabolite with a half-life of 7 to 9 days. Thus, steady-state blood levels are achieved slowly, over several weeks, and drug effects decrease slowly (over 2 to 3 months) when fluoxetine is discontinued. Sertraline (Zoloft) and citalopram (Celexa) also have active metabolites, but fluoxetine and paroxetine (Paxil) are more likely to accumulate. Escitalopram (Lexapro), paroxetine, and sertraline reach steady-state concentrations in 1 to 2 weeks. SSRIs are usually given once daily.

Because SSRIs are highly bound to plasma proteins, they compete with endogenous compounds and other medications for binding sites, resulting in drug interactions. Because the drugs are highly lipid soluble, they accumulate in the CNS and other adipose-rich tissue. Metabolism of most SSRIs is accomplished by CYP2D6 enzymes, with the exception of citalopram and escitalopram, which are metabolized by CYP3A4 and CYP2C19.

Adverse effects include a high incidence of gastrointestinal (GI) symptoms (e.g., nausea, diarrhea, and weight loss) and sexual dysfunction (e.g., delayed ejaculation in men, impaired orgasmic ability in women). Most SSRIs also cause some degree of CNS stimulation (e.g., anxiety, nervousness, insomnia), which is most prominent with fluoxetine. Because serotonin release from platelets is essential for hemostasis and psychotropic drugs interfere with serotonin reuptake, these agents are associated with increased risk of GI bleeding. Concomitant use of nonsteroidal anti-inflammatory drugs (NSAIDs), aspirin, or warfarin increases this risk.

*Serotonin syndrome*, a serious and sometimes fatal reaction characterized by hypertensive crisis, hyperpyrexia, extreme agitation progressing to delirium and coma, muscle rigidity, and seizures, may occur due to combined therapy with an SSRI and an MAO inhibitor or other drugs that potentiate serotonin neurotransmission. An SSRI or SNRI and an MAO inhibitor should not be given concurrently or within 2 weeks of each other. In most cases, if a patient taking an SSRI is to be transferred to an MAO inhibitor, the SSRI should be discontinued at least 14 days before starting the MAO inhibitor. However, due to the prolonged half-life, fluoxetine should be discontinued at least 5 weeks before starting an MAO inhibitor.

## Applying Your Knowledge 10-2

On his return visit to the physician 2 weeks later, Mr. Mehring's wife complains that she sees no improvement in her husband's mood and that he is taking too much medication. How would you respond?

.....

## Mixed Serotonin-Norepinephrine Reuptake Inhibitors (SNRIs)

**Venlafaxine** (Effexor) and **duloxetine** (Cymbalta) inhibit the neuronal uptake of serotonin and norepinephrine, increasing the activity of these neurotransmitters in the brain. Venlafaxine is also a weak inhibitor of dopamine neuronal reuptake. These drugs are similar to SSRIs in terms of therapeutic effects but exhibit more anticholinergic, CNS sedation, and cardiac conduction abnormalities than most of the SSRIs.

Venlafaxine crosses the placenta and may enter breast milk. It is metabolized in the liver and excreted in urine. It is contraindicated during pregnancy, and women should use effective birth control methods while taking this drug. Adverse effects include CNS (anxiety, dizziness, dreams, insomnia, nervousness, somnolence, tremors), GI (anorexia, nausea, vomiting, constipation, diarrhea), cardiovascular (hypertension, tachycardia, vasodilation), genitourinary (abnormal ejaculation, impotence, urinary frequency), and dermatologic (sweating, rash, pruritus) symptoms. Venlafaxine does not interact with drugs metabolized by the cytochrome P450 system, but it should not be taken concurrently with MAO inhibitors because of increased serum levels and risks of serotonin syndrome. If a patient taking venlafaxine is to be transferred to an MAO inhibitor, the venlafaxine should be discontinued at least 7 days before starting the MAO inhibitor. If a patient taking an MAO inhibitor is to be transferred to venlafaxine, the MAO inhibitor should be discontinued at least 14 days before starting venlafaxine.

Duloxetine (Cymbalta) is highly protein bound, extensively metabolized by CYP 2D6 and CYP1A2 enzymes in the liver, and excreted by the kidneys. It is not recommended for use in patients with severe renal or any degree of liver impairment. In addition to sharing similar adverse effects as venlafaxine, duloxetine is also associated with hepatic toxicity, leading to increased liver transaminases and bilirubin. Use of alcohol increases the risk of liver damage, and duloxetine is not recommended for patients with significant alcohol use. Duloxetine, like venlafaxine, should not be given concurrently with an MAO inhibitor. Allow at least 5 days after duloxetine is discontinued before switching to therapy with a MAO inhibitor and allow at least 14 days after discontinuation of an MAO inhibitor before initiating treatment with duloxetine.

Duloxetine crosses the placenta and exposed infants, especially in the third trimester, have demonstrated symptoms consistent with drug discontinuation syndrome and serotonin syndrome, requiring prolonged hospitalization. The drug may

be excreted in the breast milk as well. During pregnancy, duloxetine should only be used if benefit outweighs risk, and tapering of the medication during the third trimester may be appropriate.

## Monoamine Oxidase Inhibitors

MAO inhibitors are rarely used in clinical practice today, mainly because they may interact with some foods and drugs to produce severe hypertension and possible heart attack or stroke. Foods that interact contain tyramine, a monoamine precursor of norepinephrine. Normally, tyramine is deactivated in the GI tract and liver so that large amounts do not reach the systemic circulation. When deactivation is blocked by MAO inhibitors, tyramine is absorbed systemically and transported to adrenergic nerve terminals, where it causes a sudden release of large amounts of norepinephrine. Foods that should be avoided include aged cheeses and meats, concentrated yeast extracts, sauerkraut, and fava beans. Drugs that should be avoided include CNS stimulants (e.g., amphetamines, cocaine), adrenergics (e.g., pseudoephedrine), antidepressants (SSRIs, SNRIs), buspirone, levodopa, and meperidine.

## Atypical Antidepressants

**Bupropion** (Wellbutrin, Zyban) inhibits the reuptake of dopamine, norepinephrine, and serotonin. It was marketed with warnings related to seizure activity. Seizures are most likely to occur with doses above 450 milligrams per day and in patients known to have a seizure disorder.

After an oral dose, peak plasma levels are reached in about 2 hours. The average drug half-life is about 14 hours. The drug is metabolized in the liver by CYP2B6 among other enzymes and excreted primarily in the urine. Several metabolites are pharmacologically active. Dosage should be reduced in patients with impaired hepatic or renal function. Acute episodes of depression usually require several months of drug therapy. Bupropion is also effective as a long-term smoking cessation aid.

Bupropion has few adverse effects on cardiac function and does not cause orthostatic hypotension or sexual dysfunction. However, in addition to seizures, the drug has CNS stimulant effects (agitation, anxiety, excitement, increased motor activity, insomnia, restlessness) that may require a sedative during the first few days of administration. These effects may increase the risk of abuse. Other common adverse effects include dry mouth, headache, nausea and vomiting, and constipation.

**Mirtazapine** (Remeron) blocks presynaptic  $\alpha_2$ -adrenergic receptors (which increase the release of norepinephrine), serotonin receptors, and histamine  $H_1$  receptors. Consequently, the drug decreases anxiety, agitation, insomnia, and migraine headaches as well as depression.

Mirtazapine is well absorbed after oral administration, and peak plasma levels occur within 2 hours after an oral dose. It is metabolized in the liver, mainly to inactive metabolites. Common adverse effects include drowsiness (with accompanying

cognitive and motor impairment), increased appetite, weight gain, dizziness, dry mouth, and constipation. It does not cause sexual dysfunction.

Mirtazapine should not be taken concurrently with other CNS depressants (e.g., alcohol, benzodiazepine antianxiety or hypnotic agents) because of additive sedation. In addition, it should not be taken concurrently with an MAO inhibitor or for 14 days after an MAO inhibitor is stopped. An MAO inhibitor should not be started until at least 14 days after mirtazapine is stopped.

**Trazodone** (Desyrel) is used more often for sedation and sleep than for depression because high doses (>300 mg/day) are required for antidepressant effects, and these amounts cause excessive sedation in many patients. The drug is often given concurrently with a stimulating antidepressant, such as bupropion, fluoxetine, sertraline, or venlafaxine.

Trazodone is well absorbed with oral administration, and peak plasma concentrations are obtained within 30 minutes to 2 hours. It is metabolized by CYP3A4 in the liver and excreted primarily by the kidneys. Adverse effects include sedation, dizziness, edema, cardiac dysrhythmias, and priapism (prolonged and painful penile erection).

## Mood-Stabilizing Agents

**Lithium carbonate** (Eskalith) is a naturally occurring metallic salt that is used in patients with bipolar disorder, mainly to treat and prevent manic episodes. It is well absorbed after oral administration, with peak serum levels in 1 to 3 hours after a dose and steady-state concentrations in 5 to 7 days. Serum lithium concentrations should be monitored frequently because they vary widely among patients taking similar doses and because of the narrow range between therapeutic and toxic levels.

Lithium is not metabolized by the body; it is entirely excreted by the kidneys, so adequate renal function is a prerequisite for lithium therapy. Approximately 80% of a lithium dose is reabsorbed in the proximal renal tubules. The amount of reabsorption depends on the concentration of sodium in the proximal renal tubules. A sodium deficit causes more lithium to be reabsorbed and increases the risk of lithium toxicity. A sodium excess causes more lithium to be excreted (i.e., lithium diuresis) and may lower serum lithium levels to nontherapeutic ranges.

Before lithium therapy is begun, baseline studies of renal, cardiac, and thyroid status should be obtained because adverse drug effects involve these organ systems. Baseline electrolyte studies are also necessary.

**Anticonvulsants** (see Chap. 11) are also used as mood-stabilizing agents in bipolar disorder because they modify nerve cell function. Carbamazepine (Tegretol), lamotrigine (Lamictal), and valproate (Depakene) are currently approved by the Food and Drug Administration (FDA) for treating bipolar disorder. Other anticonvulsants (e.g., gabapentin, topiramate, oxcarbazepine) are being used and studied regarding their effects in bipolar disorder but are not approved by the FDA for this purpose.

Both typical and atypical **antipsychotics** (see Chap. 9) are used to decrease dopamine activity in the treatment of the mania phase of bipolar disorder. Both have similar efficacy in reducing acute mania, psychomotor agitation, and psychosis; however, the atypical antipsychotics are associated with fewer adverse effects. Currently, aripiprazole, quetiapine, risperidone, olanzapine (monotherapy or combination with fluoxetine), and ziprasidone are approved by the FDA for this indication.

## Herbal Supplement

**St. John's wort** (*Hypericum perforatum*) is an herb that is widely self-prescribed for depression. Several studies, most of which used about 900 milligrams per day of a standardized extract, indicate its usefulness in mild to moderate depression, with fewer adverse effects than antidepressant drugs. A 3-year, multicenter study by the National Institutes of Health concluded that the herb is not effective in major depression.

Antidepressant effects are attributed mainly to hypericin, although several other active components have also been identified. The mechanism of action is unknown, but the herb is thought to act similarly to antidepressant drugs. Some herbalists refer to St. John's wort as "natural Prozac."

Adverse effects, which are usually infrequent and mild, include constipation, dizziness, dry mouth, fatigue, GI distress, nausea, photosensitivity, restlessness, skin rash, and sleep disturbances. These symptoms are relieved by stopping the herb.

Drug interactions may be extensive. St. John's wort may reduce effectiveness of cyclosporine, HIV protease inhibitors, oral contraceptives, digoxin, warfarin, and theophylline through interactions mediated by CYP3A4, CYP2C9, CYP1A2, and CYP2C19 enzyme systems as well as other mechanisms. St. John's wort should not be combined with alcohol, antidepressant drugs (e.g., MAO inhibitors, SSRIs, TCAs), nasal decongestants or other over-the-counter cold and flu medications, bronchodilators, opioid analgesics, or amino acid supplements containing phenylalanine and tyrosine. All of these interactions may result in hypertension, possibly severe.

Most authorities agree that there is insufficient evidence to support the use of St. John's wort for mild to moderate depression and that more studies are needed to confirm the safety and effectiveness of this herb. Most of the previous studies were considered flawed.

Overall, both consumers and health care professionals seem to underestimate the risks of taking this herbal supplement. For patients who report use of St. John's wort, teach them to purchase products from reputable sources because the amount and type of herbal content may vary among manufacturers; to avoid taking antidepressant drugs, alcohol, and cold and flu medications while taking St. John's wort; to avoid the herb during pregnancy because effects are unknown; and to use sunscreen lotions and clothing to protect themselves from sun exposure.

## Nursing Process

### Assessment

Assess the patient's condition in relation to depressive disorders.

- Identify patients at risk for current or potential depression. Areas to assess include health status, family and social relationship, and work status. Severe or prolonged illness, impaired interpersonal relationships, inability to work, and job dissatisfaction may precipitate depression. Depression also occurs without an identifiable cause.
- Observe for signs and symptoms of depression. Clinical manifestations are nonspecific and vary in severity. For example, fatigue and insomnia may be caused by a variety of disorders and range from mild to severe. When symptoms are present, try to determine their frequency, duration, and severity.
- When a patient appears depressed or has a history of depression, assess for suicidal thoughts and behaviors. Statements indicating a detailed plan, accompanied by the intent, ability, and method for carrying out the plan, place the patient at high risk for suicide.
- Identify the patient's usual coping mechanisms for stressful situations. Coping mechanisms vary widely, and behavior that may be helpful to one patient may not be helpful to another. For example, one person may prefer being alone or having decreased contact with family and friends, whereas another may find increased contact desirable.

### Nursing Diagnoses

- Dysfunctional Grieving related to loss (of health, ability to perform usual tasks, job, significant other, and so forth)
- Self-Care Deficit related to fatigue and self-esteem disturbance with depression or sedation with antidepressant drugs
- Sleep Pattern Disturbance related to mood disorder or drug therapy
- Risk for Injury related to adverse drug effects
- Risk for Violence: Self-Directed or Directed at Others
- Deficient Knowledge: Effects and appropriate use of antidepressant and mood-stabilizing drugs

### Planning/Goals

#### The patient will

- Experience improvement of mood and depressive state
- Receive or self-administer the drugs correctly
- Be kept safe while sedated during therapy with the TCAs and related drugs
- Be assessed regularly for suicidal tendencies. If present, caretakers will implement safety measures.

- Be cared for by staff in areas of nutrition, hygiene, exercise, and social interactions when unable to provide self-care
- Resume self-care and other usual activities
- Avoid preventable adverse drug effects

## Interventions

Use measures to prevent or decrease the severity of depression. General measures include supportive psychotherapy and reduction of environmental stress. Specific measures include the following:

- Support the patient's usual mechanisms for handling stressful situations, when feasible. Helpful actions may involve relieving pain or insomnia, scheduling rest periods, and increasing or decreasing socialization.
- Call the patient by name, encourage self-care activities, allow him or her to participate in setting goals and making decisions, and praise efforts to accomplish tasks. These actions promote a positive self-image.
- When signs and symptoms of depression are observed, initiate treatment before depression becomes severe. Institute suicide precautions for patients at risk. These usually involve close observation, often on a one-to-one basis, and removal of potential weapons from the environment. For patients hospitalized on medical-surgical units, transfer to a psychiatric unit may be needed.
- Provide patient teaching regarding drug therapy (see accompanying display).

## Evaluation

- Observe for behaviors indicating lessened depression.
- Interview regarding feelings and mood.
- Observe and interview regarding adverse drug effects.
- Observe and interview regarding suicidal thoughts and behaviors.

## Principles of Therapy

### Drug Selection

Because the available drugs have similar efficacy in treating depression, the choice of an antidepressant depends on the patient's age; medical conditions; previous history of drug response, if any; and the specific drug's adverse effects. Cost also needs to be considered. Although the newer drugs are much more expensive than the TCAs, they may be more cost effective overall because TCAs are more likely to cause serious adverse effects, they require monitoring of plasma drug levels and ECGs, and patients are more likely to stop taking them. The SSRIs are the drugs of first choice. These drugs are effective and usually produce fewer and milder adverse effects than

other drugs. Guidelines for choosing one SSRI over another have not been established.

TCAs are second-line drugs for the treatment of depression. Initial selection of TCAs may be based on the patient's previous response or susceptibility to adverse effects. For example, if a patient (or a close family member) responded well to a particular drug in the past, that is probably the drug of choice for repeated episodes of depression. The response of family members to individual drugs may be significant because there is a strong genetic component to depression and drug response. If therapeutic effects do not occur within 4 weeks, the TCA probably should be discontinued or changed, because some patients tolerate or respond better to one TCA than to another. For potentially suicidal patients, an SSRI or another newer drug is preferred over a TCA because the TCAs are much more toxic in overdoses.

MAO inhibitors are third-line drugs for the treatment of depression because of their potential interactions with other drugs and certain foods. An MAO inhibitor is most likely to be prescribed when the patient does not respond to other antidepressant drugs or when electroconvulsive therapy is refused or contraindicated.

Criteria for choosing bupropion, mirtazapine, duloxetine, and venlafaxine are not clearly defined. Bupropion does not cause orthostatic hypotension or sexual dysfunction. Mirtazapine decreases anxiety, agitation, migraines, and insomnia, as well as depression. In addition, it does not cause sexual dysfunction or clinically significant drug–drug interactions. Duloxetine relieves painful physical symptoms (overall pain, backache, shoulder pain, etc.) associated with depression, thereby reducing remission rates, and reduces depression-associated anxiety. However, duloxetine has CNS stimulant effects and can produce hepatotoxicity. Venlafaxine has stimulant effects, increases blood pressure, and causes sexual dysfunction, but it does not cause significant drug–drug interactions.

For patients with certain concurrent medical conditions, antidepressants may have adverse effects. For patients with cardiovascular disorders, most antidepressants can cause hypotension, but the SSRIs, bupropion, and venlafaxine are rarely associated with cardiac dysrhythmias. Duloxetine, venlafaxine, and MAO inhibitors can increase blood pressure. For patients with seizure disorders, bupropion, clomipramine, and duloxetine should be avoided. SSRIs, MAO inhibitors, and desipramine are less likely to cause seizures. For patients with diabetes mellitus, SSRIs may have a hypoglycemic effect. Duloxetine may slightly increase fasting glucose levels, and bupropion and venlafaxine have little effect on blood sugar levels. Duloxetine can cause mydriasis, increasing intraocular pressure in patients with narrow-angle glaucoma.

Lithium is the drug of choice for patients with bipolar disorder. When used therapeutically, lithium is effective in controlling mania in 65% to 80% of patients. When used prophylactically, the drug decreases the frequency and intensity of manic cycles. Carbamazepine (Tegretol), lamotrigine (Lamictal), and valproate (Depakene) are anticonvulsants

## Patient Teaching Guidelines

## Antidepressants and Lithium

### General Considerations

- Take antidepressants as directed to maximize therapeutic benefits and minimize adverse effects. Do not alter doses when symptoms subside. Antidepressants are usually given for several months, perhaps years. Lithium therapy may be lifelong.
- Therapeutic effects (relief of symptoms) may not occur for 2–4 weeks after drug therapy is started. As a result, it is very important not to think the drug is ineffective and stop taking it prematurely.
- Do not take other prescription or over-the-counter drugs without consulting a health care provider, including over-the-counter cold remedies. Potentially serious drug interactions may occur.
- Do not take the herbal supplement St. John's wort while taking a prescription antidepressant drug. Serious interactions may occur.
- Inform any physician, surgeon, dentist, or nurse practitioner about the antidepressant drugs being taken. Potentially serious adverse effects or drug interactions may occur if certain other drugs are prescribed.
- Avoid activities that require alertness and physical coordination (e.g., driving a car, operating other machinery) until reasonably sure the medication does not make you drowsy or impair your ability to perform the activities safely.
- Avoid alcohol and other central nervous system depressants (e.g., any drugs that cause drowsiness). Excessive drowsiness, dizziness, difficulty breathing, and low blood pressure may occur, with potentially serious consequences.
- Learn the name and type of a prescribed antidepressant drug to help avoid undesirable interactions with other drugs or a physician prescribing other drugs with similar effects. There are several different types of antidepressant drugs, with different characteristics and precautions for safe and effective usage.
- Escitalopram (Lexapro) is a derivative of citalopram (Celexa), and the two medications should not be taken concomitantly.
- Bupropion is a unique drug prescribed for depression (brand name Wellbutrin) and for smoking cessation (brand name Zyban). It is extremely important not to increase the dose or take the two brand names at the same time (as might happen with different physicians or filling prescriptions at different pharmacies). Overdoses may cause seizures, as well as other adverse effects. When used for smoking cessation, Zyban is recommended for up to 12 weeks if progress is being made. If significant progress is not made by approximately 7 weeks, it is considered unlikely that longer drug use will be helpful.
- Do not stop taking any antidepressant drug without discussing it with a health care provider. If a problem occurs, the type of drug, the dose, or other aspects may be changed to solve the problem and allow continued use of the medication.
- Counseling, support groups, relaxation techniques, and other nonmedication treatments are recommended along with drug therapy.

- Notify your physician if you become pregnant or intend to become pregnant during therapy with antidepressant drugs.

### Self-Administration

- With a selective serotonin reuptake inhibitor (e.g., Celexa, Lexapro, Paxil, Prozac, Zoloft), take in the morning because the drug may interfere with sleep if taken at bedtime. In addition, notify a health care provider if a skin rash or other allergic reaction occurs. Allergic reactions are uncommon but may require that the drug be discontinued.
- With a tricyclic antidepressant (e.g., amitriptyline), take at bedtime to aid sleep and decrease adverse effects. Also, report urinary retention, fainting, irregular heartbeat, seizures, restlessness, and mental confusion. These are potentially serious adverse drug effects.
- With venlafaxine (Effexor), take as directed or ask for instructions. This drug is often taken twice daily. Notify a health care provider if a skin rash or other allergic reaction occurs. An allergic reaction may require that the drug be discontinued.
- With duloxetine (Cymbalta), swallow the medication whole, do not crush, chew, or sprinkle capsule contents on food.
- There are short-, intermediate-, and long-acting forms of bupropion that are taken 3 times, 2 times, or 1 time per day, respectively. Be sure to take your medication as prescribed by your physician.
- With lithium, several precautions are needed for safe use:
  1. Take with food or milk or soon after a meal to decrease stomach upset.
  2. Do not alter dietary salt intake. Decreased salt intake (e.g., low-salt diet) increases risk of adverse effects from lithium. Increased intake may decrease therapeutic effects.
  3. Drink 8–12 glasses of fluids daily; avoid excessive intake of caffeine-containing beverages. Caffeine has a diuretic effect and dehydration increases lithium toxicity.
  4. Do not take diuretic medications without consulting a health care provider. Diuretics cause loss of sodium and water, which increases lithium toxicity.
  5. Minimize activities that cause excessive perspiration, such as sweating during heavy exercise, sauna use, or outdoor activities during hot summer days. Loss of salt in sweat increases the risk of adverse effects from lithium.
  6. Report for measurements of lithium blood levels as instructed, and do not take the morning dose of lithium until the blood sample has been obtained. Regular measurements of blood lithium levels are necessary for safe and effective lithium therapy. Accurate measurement of serum drug levels requires that blood be drawn approximately 12 hours after the previous dose of lithium.
  7. If signs of overdose occur (e.g., vomiting, diarrhea, unsteady walking, tremor, drowsiness, muscle weakness), stop taking lithium and contact the prescribing physician or other health care provider.

with mood-stabilizing properties that may be used for patients who do not respond to lithium.

## Drug Dosage and Administration

Dosage of antidepressant drugs should be individualized according to clinical response. Antidepressant drug therapy is usually initiated with small, divided doses that are gradually increased until therapeutic or adverse effects occur.

With SSRIs and venlafaxine, therapy is begun with once-daily oral administration of the manufacturer's recommended dosage. Dosage may be increased after 3 or 4 weeks if depression is not relieved. As with most other drugs, smaller doses may be indicated in older adults and in patients taking multiple medications. Duloxetine is initiated with twice-a-day oral administration without regard to food.

### Applying Your Knowledge 10-3

Mr. Mehring reports he is having difficulty sleeping. What measures should be initiated?

With TCAs, therapy is begun with small doses, which are increased to the desired dose over 1 to 2 weeks. Minimal effective doses are approximately 150 milligrams per day of imipramine (Tofranil) or its equivalent. TCAs can be administered once or twice daily because they have long elimination half-lives. After dosage is established, TCAs are often given once daily at bedtime. This regimen is effective and well tolerated by most patients. Elderly patients may experience fewer adverse reactions if divided doses are continued. With TCAs, measurement of plasma levels is helpful in adjusting dosages.

With bupropion, seizures are more likely to occur with large single doses, large total doses, and large or abrupt increases in dosage. Recommendations to avoid these risk factors are as follows:

- Give bupropion in equally divided doses, three times daily (at least 6 hours apart) for immediate-release tablets, twice daily for sustained-release tablets, and once a day for extended-release forms of bupropion XL.
- The maximal single dose of immediate-release tablets is 150 milligrams (sustained-release, 200 mg; XL, 450 mg).
- The recommended initial dose is 200 milligrams, gradually increased to 300 milligrams. If no clinical improvement occurs after several weeks of 300 milligrams per day, the dosage may be increased to 450 milligrams, the maximal daily dose for immediate-release tablets (sustained-release, 400 mg; XL, 450 mg).
- The recommended maintenance dose is the lowest amount that maintains remission.

With lithium, dosage should be based on serum lithium levels, control of symptoms, and occurrence of adverse effects. Measurements of serum levels are required because therapeutic doses are only slightly lower than toxic doses and because

patients vary widely in rates of lithium absorption and excretion. Thus, a dose that is therapeutic in one patient may be toxic in another. Lower doses are indicated for older adults and for patients with conditions that impair lithium excretion (e.g., diuretic drug therapy, dehydration, low-salt diet, renal impairment, decreased cardiac output).

When lithium therapy is being initiated, the serum drug concentration should be measured two or three times weekly in the morning, 12 hours after the last dose of lithium. For most patients, the therapeutic range of serum drug levels is 0.5 to 1.2 milliequivalents per liter (SI units, 0.5 to 1.2 mmol/L). Serum lithium levels should not exceed 1.5 milliequivalents per liter, because the risk of serious toxicity is increased at higher levels.

After symptoms of mania are controlled, lithium doses should be lowered. Serum lithium levels should be measured at least every 3 months during long-term maintenance therapy.

## Duration of Drug Therapy

Guidelines for the duration of antidepressant drug therapy are not well established, and there are differences of opinion. Some authorities recommend 9 months of treatment after symptoms subside for a first episode of depression, 5 years after symptoms subside for a second episode, and long-term therapy after a third episode. Recent studies support the use of long-term maintenance therapy for patients at high risk of recurrent depression at antidepressant dosages that helped the patient achieve remission.

With lithium, long-term therapy is the usual practice because of a high recurrence rate if the drug is discontinued. When lithium is discontinued, most often because of adverse effects or the patient's lack of adherence to the prescribed regimen, gradually tapering the dose over 2 to 4 weeks delays recurrence of symptoms.

## Effects of Antidepressants on Other Drugs

The SSRIs are strong inhibitors of the cytochrome P450 enzyme system, which metabolizes many drugs, especially those metabolized by the 1A2, 2D6, and 3A4 groups of enzymes. Inhibiting the enzymes that normally metabolize or inactivate a drug produces the same effect as an excessive dose of the inhibited drug. As a result, serum drug levels and risks of adverse effects are greatly increased. Specific interactions include the following:

- Fluoxetine, paroxetine, and sertraline inhibit 2D6 enzymes and slow metabolism of bupropion, codeine, desipramine, dextromethorphan, flecainide, metoprolol, nortriptyline, phenothiazines, propranolol, risperidone, and timolol.
- TCAs are metabolized by 2D6 enzymes and may inhibit the metabolism of other drugs metabolized by the 2D6 group (other antidepressants, phenothiazines, carbamazepine, flecainide, propafenone). Lower-than-usual doses of both the TCA and the other drug may be needed.

- Mirtazapine and venlafaxine are not thought to have clinically significant effects on cytochrome P450 enzymes, but few studies have been done and effects are unknown.
- Duloxetine competes with other drugs metabolized by the CYP2D6 enzymes (flecainide, phenothiazines, propafenone, TCAs, and thioridazine), increasing risk of toxicity. Because of increased risk of ventricular arrhythmias and sudden death, duloxetine should not be given with thioridazine.

## Toxicity: Recognition and Management

Some antidepressant drugs are highly toxic and potentially lethal when taken in large doses. Toxicity is most likely to occur in depressed patients who intentionally ingest large amounts of drug in suicide attempts and in young children who accidentally gain access to medication containers. Measures to prevent acute poisoning from drug overdose include dispensing only a few days' supply (i.e., 5 to 7 days) to patients with suicidal tendencies and storing the drugs in places inaccessible to young children. General measures to treat acute poisoning include early detection of signs and symptoms, stopping the drug, and instituting treatment if indicated. Specific symptoms and signs of overdose and treatment measures for selected antidepressants are discussed below.

### SSRIs and SNRIs

Symptoms of overdose include nausea, vomiting, agitation, restlessness, hypomania, and other signs of CNS stimulation. Management includes symptomatic and supportive treatment, such as maintaining an adequate airway and ventilation, monitoring cardiac rhythm, and administering activated charcoal.

### TCAs

Overdose symptoms occur 1 to 4 hours after drug ingestion and consist primarily of CNS depression and cardiovascular effects (e.g., nystagmus, tremor, restlessness, seizures, hypotension, dysrhythmias, myocardial depression). Death usually results from cardiac, respiratory, and circulatory failure. Management of TCA toxicity consists of performing gastric lavage and giving activated charcoal to reduce drug absorption, establishing and maintaining a patent airway, performing continuous ECG monitoring of comatose patients or those with respiratory insufficiency or wide QRS intervals, giving intravenous fluids and vasopressors for severe hypotension, and giving intravenous phenytoin (Dilantin) or fosphenytoin (Cerebyx) or a parenteral benzodiazepine (e.g., lorazepam) if seizures occur.

### MAO inhibitors

Symptoms of overdose occur 12 hours or more after drug ingestion and consist primarily of adrenergic effects (e.g., tachycardia, increased rate of respiration, agitation, tremors, convulsive seizures, sweating, heart block, hypotension, delirium, coma). Management consists of diuresis, acidification of urine, or hemodialysis to remove the drug from the body.

## Atypical Antidepressants

Symptoms of bupropion overdose include agitation and other mental status changes, nausea and vomiting, and seizures. General treatment measures include hospitalization, decreasing absorption (e.g., giving activated charcoal to conscious patients), and supporting vital functions. If seizures occur, an intravenous benzodiazepine (e.g., lorazepam) is the drug of first choice.

## Mood-Stabilizing Agents

Toxic manifestations of lithium overdosage occur at serum lithium levels greater than 2.5 milliequivalents per liter and include nystagmus, tremors, oliguria, confusion, impaired consciousness, visual or tactile hallucinations, choreiform movements, convulsions, coma, and death. Treatment involves supportive care to maintain vital functions, including correction of fluid and electrolyte imbalances. With severe overdoses, hemodialysis is preferred because it removes lithium from the body.

## Antidepressant Discontinuation Syndrome: Prevention and Management

*Antidepressant discontinuation syndrome* has been reported with sudden termination of most antidepressant drugs. In general, symptoms occur more rapidly and may be more intense with drugs that have a short half-life and/or with long-term antidepressant therapy. As with other psychotropic drugs, these antidepressant drugs should be tapered in dosage and discontinued gradually unless severe drug toxicity, anaphylactic reactions, or other life-threatening conditions are present. Tapering of most antidepressants may take 6 to 8 weeks to avoid antidepressant discontinuation syndrome. Lower dosages may require less tapering time, and more tapering time may be needed to discontinue long-term maintenance therapy. The occurrence of withdrawal symptoms may indicate that the patient has omitted doses or stopped taking the drug.

The most clearly defined withdrawal syndromes are associated with SSRIs and TCAs. With SSRIs, withdrawal symptoms include dizziness, gastrointestinal upset, lethargy or anxiety/hyperarousal, dysphoria, sleep problems, and headache which can last from several days to several weeks. More serious symptoms may include aggression, hypomania, mood disturbances, and suicidal tendencies. Fluoxetine has a long half-life and has not been associated with withdrawal symptoms. Other SSRIs and SNRIs have short half-lives and may cause withdrawal reactions if stopped abruptly. Paroxetine, which has a half-life of approximately 24 hours and does not produce active metabolites, may be associated with relatively severe withdrawal symptoms even when discontinued gradually, over 7 to 10 days. Symptoms may include a flu-like syndrome with nausea, vomiting, fatigue, muscle aches, dizziness, headache, and insomnia. The short-acting SSRIs and SNRIs should be tapered in dosage and gradually discontinued to prevent or minimize withdrawal reactions.

TCAAs have strong anticholinergic effects. When TCAAs are abruptly discontinued cholinergic rebound may occur. Symptoms of excessive cholinergic activity include hypersalivation, diarrhea, urinary urgency, abdominal cramping, and sweating. The patient may benefit from short-term use of an anticholinergic agent such as atropine or benztropine to alleviate symptoms of cholinergic rebound. TCA tapering should be gradual and may take up to 3 months.

## Perioperative Use

Antidepressants must be used very cautiously, if at all, perioperatively because of the risk of serious adverse effects and adverse interactions with anesthetics and other commonly used drugs. It is usually recommended that antidepressants be tapered in dosage and gradually discontinued. MAO inhibitors are contraindicated and should be discontinued at least 10 days before elective surgery. TCAAs should be discontinued several days before elective surgery and resumed several days after surgery. SSRIs and other antidepressants have not been studied in relation to perioperative use; however, it seems reasonable to discontinue the drugs when feasible because of potential adverse effects, especially on the cardiovascular system and CNS.

Lithium should be stopped 1 to 2 days before surgery and resumed when full oral intake of food and fluids is allowed. Lithium may prolong the effects of anesthetics and neuromuscular blocking drugs.

## Use in Special Populations

### Use in Various Ethnic Groups

Antidepressant drug therapy for nonwhite populations in the United States is based primarily on dosage recommendations, pharmacokinetic data, and adverse effects derived from white recipients. However, several studies document differences in drug effects in nonwhite populations. The differences are mainly attributed to genetic or ethnic variations in drug-metabolizing enzymes in the liver. Although all ethnic groups are genetically heterogeneous and individual members may respond differently, health care providers must consider potential differences in responses to drug therapy.

African Americans tend to have higher plasma drug levels for a given dose, respond more rapidly, experience a higher incidence of adverse effects, and metabolize TCAAs more slowly than whites. To decrease adverse effects, initial doses may need to be lower than those given to whites, and later doses should be titrated according to clinical response and serum drug levels. In addition, baseline and periodic ECGs are recommended to detect adverse drug effects on the heart. Studies have not been done with newer antidepressants. With lithium, African Americans report more adverse reactions than whites and may need smaller doses.

Asians tend to metabolize antidepressant drugs slowly and therefore have higher plasma drug levels for a given dose than whites. Most studies have been done with TCAAs and a limited number of Asian subgroups. Thus, it cannot be assumed that all antidepressant drugs and all people of Asian heritage respond

the same. To avoid drug toxicity, initial doses should be approximately half the usual doses given to whites, and later doses should be titrated according to clinical response and serum drug levels. This recommendation is supported by a survey from several Asian countries that reported the use of much smaller doses of TCAAs than in the United States. In addition, baseline and periodic ECGs are also recommended for Asian patients to detect adverse drug effects on the heart. Studies have not been done with newer antidepressants. With lithium, there are no apparent differences between effects in Asians and whites.

Information regarding the reaction of the Hispanic population to antidepressant drugs is largely unknown. Few studies have been performed; some report a need for lower doses of TCAAs and greater susceptibility to adverse effects, whereas others report no differences between Hispanics and whites.

### Use in Children

Between 3% and 5% of children and adolescents in the United States are affected by major depression; the risk for depression increases after puberty. Antidepressant drugs are widely prescribed in children and adolescents, in whom depression commonly occurs. However, only a few drugs are actually FDA approved for use in the pediatric population, and the FDA warns against the use of paroxetine in children and adolescents. TCAAs are not efficacious for depression in children and adolescents (Level A). There is only limited evidence in support of SSRIs for treating depression in children and adolescents, and these medications should be reserved for treatment of severe depression (Level B). Because of the increased risk of suicidality, children and adolescents taking all antidepressants must be closely monitored (Level C).

For most children and adolescents, it is probably best to reserve drug therapy for those who do not respond to nonpharmacologic treatments such as cognitive behavior therapy (Level A) and those whose depression is persistent or severe enough to impair function in usual activities of daily living. The long-term effects of antidepressant drugs on the developing brain are unknown. FDA-approved SSRIs are considered first-line antidepressants and safer than TCAAs and MAO inhibitors for children with depression. Fluoxetine is approved for treatment of pediatric major depression. (In addition, fluoxetine, sertraline, and fluvoxamine are approved for treatment of obsessive-compulsive disorder in children.) Common adverse effects include sedation and activation; it is often difficult to distinguish therapeutic effects (improvement of mood, increased energy and motivation) from the adverse effects of behavioral activation (agitation, hypomania, restlessness).

Safety and effectiveness have not been established for MAO inhibitors in children younger than 16 years of age or for bupropion, duloxetine, mirtazapine, and venlafaxine in children younger than 18 years of age.

TCAAs are not recommended for use in children younger than 12 years of age except for short-term treatment of enuresis in children older than 6 years of age. Amitriptyline, desipramine, imipramine, and nortriptyline are the TCAAs most commonly prescribed to treat depression in children older

than 12 years of age. Because of potentially serious adverse effects, blood pressure, ECGs, and plasma drug levels should be monitored. There is evidence that children metabolize TCAs faster than adults, and withdrawal symptoms (e.g., increased GI motility, malaise, and headache) are more common in children than in adults. Several TCAs are approved for treatment of depression in adolescents. (Clomipramine is approved for treatment of obsessive-compulsive disorder in children, and imipramine is also approved for treating childhood enuresis in children older than 6 years of age.)

Divided doses may be better tolerated and minimize withdrawal symptoms. When a TCA is used for enuresis, effectiveness may decrease over time, and no residual benefits continue after the drug is stopped. Common adverse effects include sedation, fatigue, nervousness, and sleep disorders. A TCA probably is not a drug of first choice for adolescents because TCAs are more toxic in overdose than other antidepressants, and suicide is a leading cause of death in adolescents.

For adolescents, it may be important to discuss sexual effects because the SSRIs and SNRIs cause a high incidence of sexual dysfunction (e.g., anorgasmia, decreased libido, erectile dysfunction). Bupropion and mirtazapine are unlikely to cause sexual dysfunction.

Lithium is not approved for use in children younger than 12 years of age, but it has been used to treat bipolar disorder and aggressiveness. Children normally excrete lithium more rapidly than adults. As with adults, initial doses should be relatively low and gradually increased according to regular measurements of serum drug levels. Risperidone has recently been approved by the FDA for use in adolescents aged 10 to 17 years with type I bipolar disorder. It can be used alone or in combination with lithium or valproate for the treatment of acute mania or mixed episodes.

### Use in Older Adults

SSRIs are the drugs of choice in older adults as in younger ones because they produce fewer sedative, anticholinergic, cardiotoxic, and psychomotor adverse effects than the TCAs and related antidepressants. These drugs produce similar adverse effects in older adults as in younger adults. Although their effects in older adults are not well delineated, SSRIs may be eliminated more slowly, and smaller or less frequent doses may be prudent. SNRIs may also be used in older adults, with smaller initial doses and increments recommended. The weight loss often associated with SSRIs and SNRIs may be undesirable in older adults. Use of maintenance antidepressant therapy is beneficial to prevent recurrence of depression in older adults.

TCAs may cause or aggravate conditions that are common in older adults (e.g., cardiac conduction abnormalities, urinary retention, narrow-angle glaucoma). In addition, impaired compensatory mechanisms make older adults more likely to experience anticholinergic effects, confusion, hypotension, and sedation. If a TCA is chosen for an older adult, nortriptyline or desipramine is preferred. In addition, any TCA should be given in small doses initially and gradually increased over several weeks, if necessary, to achieve therapeutic effects. Initial and maintenance doses should be small

because the drugs are metabolized and excreted more slowly than in younger adults. Initial dosage should be decreased by 30% to 50% to avoid serious adverse reactions; increments should be small. Vital signs, serum drug levels, and ECGs should be monitored regularly.

MAO inhibitors may be more likely to cause hypertensive crises in older adults because cardiovascular, renal, and hepatic functions are often diminished.

With lithium, initial doses should be low and increased gradually, according to regular measurements of serum drug levels.

### Use in Patients With Renal Impairment

Antidepressants should be used cautiously in the presence of severe renal impairment. Mild or moderate impairment contributes to few adverse effects, but severe impairment may increase plasma drug levels and adverse effects of virtually all antidepressants. Thus, small initial doses, slow increases, and less frequent dosing are indicated.

Lithium is eliminated only by the kidneys, and it has a very narrow therapeutic range. If given to a patient with renal impairment or unstable renal function, the dose must be markedly reduced and plasma lithium levels must be closely monitored.

### Use in Patients With Hepatic Impairment

Hepatic impairment leads to reduced first-pass metabolism of most antidepressant drugs, resulting in higher plasma levels. The drugs should be used cautiously in patients with severe liver impairment. Cautious use means lower doses, longer intervals between doses, and slower dose increases than usual. Duloxetine is not recommended for use in patients with any hepatic insufficiency.

Fluoxetine and sertraline are less readily metabolized to their active metabolites in patients with hepatic impairment. For example, in patients with cirrhosis, the average half-life of fluoxetine may increase from 2 to 3 days to more than 7 days and that of norfluoxetine, the active metabolite, from 7 to 9 days to 12 days. Clearance of sertraline is also decreased in patients with cirrhosis. Paroxetine has a short half-life and no active metabolites, but increased plasma levels can occur with severe hepatic impairment.

TCAs are also less readily metabolized in people with severe hepatic impairment (e.g., severe cirrhosis). This increases the risk of adverse effects such as sedation and hypotension.

### Use in Patients With Critical Illness

Critically ill patients may be receiving an antidepressant when the critical illness develops or may need a drug to combat the depression that often develops with major illness. The decision to continue or start an antidepressant should be based on a thorough assessment of the patient's condition, other drugs being given, potential adverse drug effects, and other factors. If an antidepressant is given, its use must be cautious and slow and the patient's responses carefully monitored because critically ill patients are often frail and unstable, with multiple organ dysfunctions.

### Use in Home Care

Whatever the primary problem for which a home care nurse is visiting a patient, he or she must be vigilant for signs and symptoms of major depression. Depression often accompanies any serious physical illness and may occur in many other circumstances as well. The main role of the nurse may be recognizing depressive states and referring patients for treatment. If an antidepressant medication was recently started, the nurse may need to remind the patient that it usually takes 2 to 4 weeks to take effect. The nurse should encourage

the patient to continue taking the medication. In addition, the nurse should observe the patient's response and assess for suicidal thoughts or plans, especially at the beginning of therapy or when dosages are increased or decreased. The family should be taught to report any change in the patient's behavior, especially anxiety, agitation, panic attacks, insomnia, irritability, hostility, impulsivity, akathisia, hypomania, and mania. A patient who has one or more of these symptoms may be at greater risk for worsening depression or suicidality.

## Nursing Actions Antidepressants

### NURSING ACTIONS

#### 1. Administer accurately

- Give most selective serotonin reuptake inhibitors (SSRIs) once daily in the morning; citalopram, escitalopram, and sertraline may be given morning or evening.
- Mix sertraline oral concentrate (20 mg/mL) in 4 oz of water, ginger ale, lemon/lime soda, lemonade, or orange juice only; give immediately after mixing.
- Give tricyclic antidepressants (TCAs) and mirtazapine at bedtime.
- Give venlafaxine and lithium with food.

#### 2. Observe for therapeutic effects

- With antidepressants for depression, observe for statements of feeling better or less depressed; increased appetite, physical activity, and interest in surroundings; improved sleep patterns; improved appearance; decreased anxiety; decreased somatic complaints.
- With antidepressants for anxiety disorders, observe for decreased symptoms of the disorders (see Chap. 8).
- With lithium, observe for decreases in manic behavior and mood swings.

#### 3. Observe for adverse effects

- With SSRIs and SNRIs, observe for dizziness, headache, nervousness, insomnia, nausea, diarrhea, dizziness, dry mouth, sedation, skin rash, sexual dysfunction.
- With TCAs, observe for:
  - Central nervous system (CNS) effects—drowsiness, dizziness, confusion, poor memory
  - GI effects—nausea, dry mouth, constipation
  - Cardiovascular effects—cardiac dysrhythmias, tachycardia, orthostatic hypotension
  - Other effects—blurred vision, urinary retention, sexual dysfunction, weight gain or loss
- With monoamine oxidase (MAO) inhibitors, observe for blurred vision, constipation, dizziness, dry mouth, hypotension, urinary retention, hypoglycemia.

### RATIONALE/EXPLANATION

To prevent insomnia

Manufacturer's recommendations

To aid sleep and decrease daytime sedation

To decrease gastrointestinal (GI) effects (e.g., nausea and vomiting)

Therapeutic effects occur 2–4 weeks after drug therapy is started.

Therapeutic effects do not occur until approximately 7–10 days after therapeutic serum drug levels (1–1.5 mEq/L with acute mania; 0.6–1.2 mEq/L for maintenance therapy) are attained. In mania, a benzodiazepine or an antipsychotic drug is usually given to reduce agitation and control behavior until the lithium takes effect.

GI upset and diarrhea are common with SSRIs; GI upset, diarrhea, agitation, and insomnia are common with venlafaxine. Although numerous adverse effects may occur, they are usually less serious than those occurring with most other antidepressants. Compared with the TCAs, SSRIs and other newer drugs are less likely to cause significant sedation, hypotension, and cardiac dysrhythmias, but they are more likely to cause nausea, nervousness, and insomnia.

Most adverse effects result from anticholinergic or antiadrenergic activity. Cardiovascular effects are most serious in overdose.

Anticholinergic effects are common. Hypoglycemia results from a drug-induced reduction in blood sugar.

## Nursing Actions Antidepressants (continued)

### NURSING ACTIONS

- d. With bupropion, observe for seizure activity, CNS stimulation (agitation, insomnia, hyperactivity, hallucinations, delusions), headache, nausea and vomiting, weight loss.
- e. With mirtazapine, observe for sedation, confusion, dry mouth, constipation, nausea and vomiting, hypotension, tachycardia, urinary retention, photosensitivity, skin rash, weight gain.
- f. With lithium, observe for:
  - (1) Metallic taste, hand tremors, nausea, polyuria, polydipsia, diarrhea, muscular weakness, fatigue, edema, weight gain
  - (2) More severe nausea and diarrhea, vomiting, ataxia, incoordination, dizziness, slurred speech, blurred vision, tinnitus, muscle twitching and tremors, increased muscle tone

(3) Leukocytosis

#### 4. Observe for drug interactions

- a. Drugs that increase effects of SSRIs:

(1) Cimetidine

(2) MAO inhibitors

(3) Linezolid

(4) Sumatriptan

(5) Nonsteroidal anti-inflammatory drugs (NSAIDs), aspirin, warfarin

(6) Metoclopramide, sibutramine tramadol

- b. Drugs that decrease effects of SSRIs:

(1) Carbamazepine, phenytoin, rifampin

(2) Cyproheptadine

- c. Drugs that increase effects of mirtazapine and venlafaxine:

(1) MAO inhibitors

### RATIONALE/EXPLANATION

Adverse effects are most likely to occur if recommended doses are exceeded. Note that bupropion has few, if any, effects on cardiac conduction and does not cause orthostatic hypotension.

Common effects are drowsiness, dizziness, and weight gain. Has CNS depressant and anticholinergic effects.

Most patients who take lithium experience adverse effects. Symptoms listed in (1) are common, occur at therapeutic serum drug levels (0.6–1.2 mEq/L), and usually subside during the first few weeks of drug therapy. Symptoms listed in (2) occur at higher serum drug levels (1.5–2.5 mEq/L). Nausea may be decreased by giving lithium with meals. Propranolol (Inderal), 20–120 mg daily, may be given to control tremors. Severe adverse effects may be managed by decreasing lithium dosage, omitting a few doses, or discontinuing the drug temporarily. Toxic symptoms occur at serum drug levels above 2.5 mEq/L.

Lithium mobilizes white blood cells (WBCs) from bone marrow to the bloodstream. Maximum increase in WBCs occurs in 7–10 days.

Drug interactions with the SSRIs vary with individual drugs. May increase serum drug levels of SSRIs by slowing their metabolism

**SSRIs and MAO inhibitors should not be given concurrently or close together because serious and fatal reactions have occurred.** The reaction, attributed to excess serotonin and called the serotonin syndrome, may cause hyperthermia, muscle spasm, agitation, delirium, and coma. To avoid this reaction, an SSRI should not be started for at least 2 weeks after an MAO inhibitor is discontinued, and an MAO inhibitor should not be started for at least 2 weeks after an SSRI has been discontinued (5 weeks with fluoxetine, because of its long half-life).

The antibiotic linezolid is a reversible nonselective MAO inhibitor (see above).

Postmarketing studies report concomitant use of SSRIs and sumatriptan may result in weakness, hyperreflexia, and incoordination.

Serotonin release by platelets plays a role in hemostasis, and SSRIs may interfere with this release, resulting in an increased incidence of GI bleeding. Concomitant use of NSAIDs, aspirin, or warfarin potentiates this risk. Increased risk of serotonin syndrome

These drugs induce liver enzymes that accelerate the metabolism of the SSRIs.

This is an antihistamine with antiserotonin effects.

See SSRIs, above. **These drugs and MAO inhibitors should not be given concurrently or close together because serious and fatal reactions have occurred.** Mirtazapine should be stopped at least 14 days and venlafaxine at least 7 days before starting an MAO inhibitor, and an MAO inhibitor should be stopped at least 14 days before starting mirtazapine or venlafaxine.

## NURSING ACTIONS

## RATIONALE/EXPLANATION

<p>d. Drugs that <i>increase</i> the effects of duloxetine:</p> <ul style="list-style-type: none"> <li>(1) CYP1A2 inhibitors (fluvoxamine, quinolone antibiotics)</li> <li>(2) CYP2D6 inhibitors (fluoxetine, quinidine, paroxetine)</li> <li>(3) MAO inhibitors (MAOIs)</li> </ul>	<p>These drugs prevent metabolism of duloxetine, increasing serum levels.</p> <p>These drugs prevent metabolism of duloxetine, increasing serum levels.</p> <p><b>Duloxetine and MAOIs should not be given concurrently or close together because serious and fatal reactions have occurred.</b> Duloxetine should not be given within 14 days of stopping an MAOI, and an MAOI should not be given within 5 days of stopping duloxetine.</p>

## Key Concepts

- Major depression is associated with impaired ability to function in usual activities and relationships.
- Postnatal depression is a major depressive episode occurring after the birth of a child.
- Bipolar disorder type I is characterized by episodes of major depression plus mania and occurs equally in men and women.
- Bipolar disorder type II is characterized by episodes of major depression plus hypomanic episodes and occurs more frequently in women.
- Antidepressants must be taken for 2 to 4 weeks before depressive symptoms improve.
- A **BLACK BOX WARNING** alerts health care providers to the increased risk of suicidal ideation in children, adolescents, and young adults 18 to 24 years of age when taking antidepressant medications.
- SSRIs are considered to be first-line medications in the treatment of depression because they have a more favorable side effect profile (e.g., GI symptoms, sexual dysfunction, CNS stimulation, and increased risk of GI bleeding).
- TCAs, second-line medications in the treatment of depression, produce a high incidence of adverse effects (e.g., sedation, orthostatic hypotension, cardiac dysrhythmias, anticholinergic effects, and weight gain).
- MAO inhibitors are considered third-line medications in the treatment of depression because of a high incidence of food and drug interactions which potentially lead to hypertensive crisis.
- Serotonin syndrome, a serious and sometimes fatal reaction characterized by hypertensive crisis, hyperpyrexia, extreme agitation progressing to delirium and coma, muscle rigidity, and seizures, may occur due to combined therapy with an SSRI or SNRI and an MAO inhibitor or other drug that potentiates serotonin neurotransmission. An SSRI or SNRI and an MAO inhibitor should not be given concurrently or within 2 weeks of each other. Fluoxetine, because of a long half-life, must be discontinued at least 5 weeks before starting an MAO inhibitor.
- SNRIs are similar to SSRIs in terms of therapeutic effects but exhibit more anticholinergic, CNS sedation, and cardiac conduction abnormalities.
- Some antidepressant drugs are highly toxic and potentially lethal when taken in large doses.
- Antidepressant discontinuation syndrome has been reported with sudden termination of most antidepressant drugs.
- SSRIs are the drugs of choice in older adults with depression.
- Moist antidepressants should be used cautiously in the presence of renal or hepatic impairment.
- Lithium is the drug of choice to treat bipolar disorder. Lithium has a narrow therapeutic index, and dosage is determined by serum lithium levels, control of symptoms, and occurrence of adverse effects. Therapeutic range for serum lithium level is 0.5 to 1.2 milliequivalents per liter.
- Anticonvulsants (e.g., carbamazepine, lamotrigine, and valproic acid) are also used to treat bipolar disorder.
- Atypical antipsychotics are useful in the treatment of the acute mania phase of bipolar disorder.
- Most authorities agree that there is insufficient evidence to support the use of St John's wort for treatment of depression.

## Review and Application Exercises

### Short Answer Exercises

1. During the initial assessment of any patient, what kinds of appearances or behaviors may indicate depression?
2. Is antidepressant drug therapy indicated for most episodes of temporary sadness? Why or why not?
3. What are the major groups of antidepressant drugs?
4. How do the drugs act to relieve depression?
5. When a patient begins antidepressant drug therapy, why is it important to explain that relief of depression may not occur for a few weeks?
6. What are common adverse effects of TCAs, and how may they be minimized?
7. What is the advantage of giving a TCA at bedtime rather than in the morning?
8. For a patient taking an MAO inhibitor, what information would you provide for preventing a hypertensive crisis?
9. How do the SSRIs differ from TCAs?
10. How do the newer drugs, including mirtazapine and venlafaxine, compare with the SSRIs in terms of adverse effects and adverse drug–drug interactions?
11. List the main elements of treatment of antidepressant overdoses.
12. What are common adverse effects of lithium, and how may they be minimized?

13. What is the nurse's role in assessing and managing depression in special populations? In the home setting?

### NCLEX-Style Questions

14. A nurse is teaching the importance of proper diet to a patient taking tranylcypromine (Parnate), an MAO inhibitor, for depression. Which of the following food selections by the patient indicates that further teaching is needed?
- a tossed salad and a bowl of vegetable soup
  - a sandwich with salami and Swiss cheese
  - a hamburger and french fries
  - a cold plate with cottage cheese, chicken salad, and grapes
15. A patient taking lithium is having problems with coordination and unstable gait. The patient's lithium level is 2.3 milliequivalents per liter. The nurse should do which of the following?
- Continue to administer the lithium three times per day.
  - Skip a dose of lithium and then resume the regular medication schedule.
  - Administer an extra dose of lithium.
  - Withhold the lithium and notify the prescriber of the lithium level.
16. Today your patient begins a new drug regimen of escitalopram (Lexapro) for depression. Before administering this medication, you should assess for which of the following?
- prior recent use of MAO inhibitor antidepressants
  - prior diet high in tyramine-containing foods
  - history of cigarette use
  - history of seizure disorders
17. Your patient has been taking imipramine (Tofranil) for 1 week for depression. He tells you he is going to stop taking this medication because it isn't working. Your best response is which of the following?
- "Contact your prescriber about taking a different antidepressant medication."
  - "It may take up to 4 weeks before this medication makes you feel better."
  - "You should slowly taper rather than suddenly discontinue this medication."
  - "You should take an extra dose today to build up your blood level and get faster results."

# Antiseizure Drugs

## KEY TERMS

- Anticonvulsant
- Convulsion
- Epilepsy
- Gingival hyperplasia
- Monotherapy
- Seizure
- Seizure threshold
- Status epilepticus
- Tonic-clonic

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Identify types and potential causes of seizures.
2. Discuss major factors that influence choice of an antiseizure drug for a patient with a seizure disorder.
3. Recognize characteristics and effects of commonly used antiseizure drugs.
4. Differentiate between older and more recent antiseizure drugs.
5. Compare advantages and disadvantages between monotherapy and combination drug therapy for seizure disorders.
6. Apply the nursing process with patients receiving antiseizure drugs.
7. Describe strategies for prevention and treatment of status epilepticus.
8. Discuss the use of antiseizure drugs in special populations.

## Applying Your Knowledge

Frank DeLaney is an 18-year-old college freshman who has been diagnosed with generalized and partial seizures. He has experienced at least three tonic-clonic seizures in the past 6 months and was started on phenytoin 1 month ago. The phenytoin has decreased the number of seizures but has not been successful in controlling the seizures to the degree the patient would like. The prescriber at the student health center has added carbamazepine to the antiseizure regimen. You are working in the student health center and are counseling Frank about his disease process and medical regimen.

## Introduction

### Seizure Disorders

The terms *seizure* and *convulsion* are often used interchangeably, although they are not the same. A seizure involves a brief episode of abnormal electrical activity in nerve cells of the brain that may or may not be accompanied by visible changes in appearance or behavior. A convulsion is a tonic-clonic type of seizure characterized by spasmodic contractions of involuntary muscles.

Seizures may occur as single events in response to hypoglycemia, fever, electrolyte imbalances, overdoses of numerous drugs (e.g., amphetamine, cocaine, isoniazid, lidocaine, lithium, methylphenidate, antipsychotics, theophylline), and withdrawal of alcohol or sedative-hypnotic drugs. Treatment of the underlying problem or temporary use of an antiseizure drug may relieve the seizures. An antiseizure drug is also called an antiepileptic drug (AED) or an *anti-convulsant*.

## Epilepsy

When seizures occur in a chronic, recurrent pattern, they characterize a disorder known as *epilepsy*, which usually requires long-term drug therapy. Epilepsy is characterized by sudden, abnormal, hypersynchronous firing of neurons diagnosed by clinical signs and symptoms of seizure activity and by the presence of abnormal brain wave patterns on the electroencephalogram. Epilepsy can be classified as idiopathic or attributable to a secondary cause. Secondary causes in infancy include developmental defects, metabolic disease, or birth injury. Fever is a common cause during late infancy and early childhood, and inherited forms usually begin in childhood or adolescence. When epilepsy begins in adulthood, it is often caused by an acquired neurologic disorder (e.g., head injury, stroke, brain tumor) or alcohol and other drug effects. The incidence of epilepsy is higher in young children and older adults than in other age groups.

Seizures are broadly classified as partial or generalized. Partial seizures begin in a specific area of the brain and often indicate a localized brain lesion such as birth injury, trauma, stroke, or tumor. They produce symptoms ranging from simple motor and sensory manifestations to more complex abnormal movements and bizarre behavior. Movements are usually automatic, repetitive, and inappropriate to the situation, such as chewing, swallowing, or aversive movements (automatisms). In simple partial seizures, consciousness is not impaired; in complex partial seizures, the level of consciousness is decreased.

Generalized seizures are bilateral and symmetric and have no discernible point of origin in the brain. The most common type is the *tonic-clonic* or major motor seizure. The tonic phase involves sustained contraction of skeletal muscles; abnormal postures, such as opisthotonos; and absence of respiration, during which the person becomes cyanotic. The clonic phase is characterized by rapid rhythmic and symmetric jerking movements of the body. Tonic-clonic seizures are sometimes preceded by an aura—a brief warning, such as a flash of light or a specific sound or smell. In children, febrile seizures (i.e., tonic-clonic seizures that occur with fever in the absence of other identifiable causes) are the most common form of epilepsy.

Another type of generalized seizure is the absence seizure, characterized by abrupt alterations in consciousness that last only a few seconds. Other types of generalized seizures include the myoclonic type (contraction of a muscle or group of muscles) and the akinetic type (absence of movement). Some people are subject to mixed seizures.

*Status epilepticus* is a life-threatening emergency characterized by generalized tonic-clonic convulsions lasting for several minutes or occurring at close intervals during which the patient does not regain consciousness. Hypotension, hypoxia, and cardiac dysrhythmias may also occur. There is a high risk of permanent brain damage and death unless prompt, appropriate treatment is instituted. In a person taking medications for a diagnosed seizure disorder, the most common cause of status epilepticus is abruptly stopping AEDs. In other patients, regardless of whether they have a diagnosed seizure disorder, causes of

status epilepticus include brain trauma or tumors, systemic or central nervous system (CNS) infections, alcohol withdrawal, and overdoses of drugs (e.g., cocaine, theophylline).

## General Characteristics of Antiseizure Drugs

Antiseizure drugs can usually control seizure activity but do not cure the underlying disorder. Numerous difficulties, for both clinicians and patients, have been associated with AED therapy, including trials of different drugs; consideration of monotherapy versus combination therapy using two or more drugs; the need to titrate dosage over time; lack of seizure control while drugs are being selected and dosages adjusted; social stigma and adverse drug effects, often leading to poor patient compliance; and undesirable drug interactions among AEDs and between AEDs and other medications. Attempts to overcome these difficulties have led to the development of several new drugs in recent years.

Drug therapy for epilepsy is rapidly evolving as older, more toxic drugs are being replaced by newer drugs with better adverse effect profiles that maintain better control of seizures. In this chapter, older drugs that are still commonly used (phenytoin, carbamazepine, ethosuximide, phenobarbital, valproate) as well as newer drugs (gabapentin, lamotrigine, levetiracetam, oxcarbazepine, tiagabine, topiramate, zonisamide) are discussed.

## Mechanism of Action

Although the exact mechanism of action of most AEDs is unknown, the drugs are thought to suppress seizures in one of the following ways: by decreasing movement of ions into nerve cells, by altering the activity of neurotransmitters (e.g., gamma-aminobutyric acid [GABA], glutamate), or by a combination of these mechanisms. Because movement of sodium and calcium ions is required for normal conduction of nerve impulses, blocking these ions decreases responsiveness to stimuli and results in stabilized, less excitable cell membranes. Increasing the activity of GABA, the major inhibitory neurotransmitter in the brain, and decreasing the activity of glutamate, the major excitatory neurotransmitter, also decrease nerve cell excitability. The actions of both sodium channel blockers (e.g., phenytoin, oxcarbazepine) and GABA enhancers (e.g., benzodiazepines, most of the newer AEDs) increase the amount of stimulation required to produce a seizure (called the *seizure threshold*). Overall, the AEDs are thought to stabilize neuronal membranes and decrease neuronal firing in response to stimuli. Some seem able to suppress abnormal neuronal firing without suppressing normal neurotransmission.

## Indications for Use

The major clinical indication for AEDs is the prevention or treatment of seizures, especially the chronic recurring seizures

of epilepsy. Indications for particular drugs depend on the types and severity of seizures involved. For example, most of the newer drugs are indicated for use with one or two other AEDs to treat more severe seizure disorders that do not respond to a single drug. However, oxcarbazepine is approved for monotherapy, and studies indicate that most of the other newer drugs may also be effective as monotherapy in some types of seizures.

In addition to maintenance treatment of epilepsy, AEDs are used to stop acute, tonic-clonic convulsions and status epilepticus. The drug of choice is an intravenous (IV) benzodiazepine, usually lorazepam. A systematic review of trials in both adult and pediatric patients concluded lorazepam was significantly better than diazepam or phenytoin for the immediate control of status epilepticus (Level A). After acute seizure activity is controlled, a longer-acting drug, such as phenytoin or fosphenytoin, is given to prevent recurrence. AEDs also are used prophylactically in patients with brain trauma from injury or surgery.

In addition to seizure disorders, AEDs are used to treat bipolar disorder (e.g., carbamazepine, valproate). The Food and Drug Administration (FDA) has recently approved valproate for the treatment of acute mania. Carbamazepine has also been found useful, especially in more refractory bipolar episodes. Often these medications are combined with lithium for maximum effect. Both drugs are also used in the management of chronic neuropathic pain. Carbamazepine is approved for treatment of the pain associated with trigeminal neuralgia.

Gabapentin is the first oral medication approved by the FDA for the management of postherpetic neuralgia. Studies indicate that patients receiving gabapentin experienced significant pain relief, improvement in sleep, and improved overall quality of life. Some of the other, newer AEDs are being tested for effectiveness in relation to bipolar, neuropathic pain, and other disorders. Because the drugs are being used for other indi-

cations than seizure disorders, some people suggest they be called neuromodulators or neurostabilizers rather than AEDs or anticonvulsants.

## Contraindications to Use

AEDs are contraindicated or must be used with caution in patients with CNS depression. Phenytoin, carbamazepine, gabapentin, lamotrigine, levetiracetam, oxcarbazepine, tiagabine, topiramate, and valproate are contraindicated in patients who have experienced a hypersensitivity reaction to the particular drug (usually manifested by a skin rash, arthralgia, and other symptoms). Phenytoin, carbamazepine, ethosuximide, lamotrigine, topiramate, and zonisamide are contraindicated or must be used cautiously in patients with hepatic or renal impairment. Additional contraindications include phenytoin in patients with sinus bradycardia or heart block, carbamazepine in those with bone marrow depression (e.g., leukopenia, agranulocytosis), and tiagabine and valproic acid in people with liver disease. All of the drugs must be used cautiously during pregnancy because they are teratogenic in animals.

## Individual Drugs

Most AEDs are well absorbed with oral administration and are usually given by this route. Most are metabolized in the liver, and a few are eliminated mainly through the kidneys. The large majority commonly produce adverse effects such as ataxia (impaired muscular coordination such as a staggering gait when trying to walk), confusion, dizziness, and drowsiness. Some may cause serious or life-threatening adverse effects such as cardiac dysrhythmias, bone marrow depression, or pancreatitis. Because AEDs are so diverse, they cannot be adequately discussed as groups. Consequently, the drugs are described indi-

Table 11-1

### Drugs at a Glance: Antiseizure Drugs

Generic/Trade Name	Types of Seizures Used to Treat	ROUTES AND DOSAGE RANGES			Remarks
		Adults	Children		
Carbamazepine (Tegretol)	Partial, generalized tonic-clonic, and mixed seizures	Epilepsy, PO 200 mg twice daily, increased gradually to 600–1200 mg daily if needed, in 3 or 4 divided doses Trigeminal neuralgia, PO 200 mg daily, increased gradually to 1200 mg if necessary Bipolar disorder, PO 400 mg in 2 divided doses, increased gradually to 1600 mg if necessary	>12 y: PO 200 mg twice daily; may increase to 1000 mg daily for children 12–15 years and 1200 mg for children over 15 y, if necessary 6–12 y: PO 100 mg twice daily (tablet) or 50 mg 4 times daily (suspension), increase to 1000 mg daily if necessary, in 3 or 4 divided doses	<ul style="list-style-type: none"> <li>■ Available in oral and chewable tablets, extended-release tablets and capsules, and a suspension of 100 mg/5 mL</li> <li>■ The suspension is absorbed more rapidly and produces higher peak drug levels than tablets.</li> <li>■ Therapeutic serum drug level is 4 to 12 mcg/mL (SI units, 17–51 μmol/L).</li> </ul>	

Generic/Trade Name	Types of Seizures Used to Treat	ROUTES AND DOSAGE RANGES		
		Adults	Children	Remarks
<b>Clonazepam</b> (Klonopin)	Myoclonic or akinetic seizures, alone or with other AEDs; possibly effective in generalized tonic-clonic and psychomotor seizures	PO 1.5 mg/d, increased by 0.5 mg/d every 3–7 d if necessary; maximum dose, 20 mg/d	PO 0.01–0.03 mg/kg/d, increased by 0.25–0.5 mg/d every 3–7 days if necessary; maximum dose, 0.2 mg/kg/d	Schedule IV drug
<b>Clorazepate</b> (Tranxene)	Partial seizures, with other AEDs	PO maximal initial dose 7.5 mg 3 times daily; increased by 7.5 mg every week, if necessary; maximum dose, 90 mg/d	>12 y: PO same as adults 9–12 y: PO maximal initial dose 7.5 mg two times daily; increased by 7.5 mg every week, if necessary; maximum dose, 60 mg/d	Schedule IV drug
<b>Diazepam</b> (Valium)	Acute convulsive seizures, status epilepticus	IV 5–10 mg no faster than 2 mg/min; repeat every 5–10 min if needed; maximum dose, 30 mg. Repeat in 2–4 h if necessary; maximum dose, 100 mg/24 h	>30 d and <5 y of age: IV 0.2–0.5 mg over 2–3 min, every 2–5 min up to a maximum of 5 mg 5 y and older: IV 1 mg every 2–5 min up to a maximum of 10 mg. Repeat in 2–4 h if necessary.	Schedule IV drug
<b>Ethosuximide</b> (Zarontin)	Absence seizures; also may be effective in myoclonic and akinetic epilepsy	PO initially 500 mg/d, increased by 250 mg weekly until seizures are controlled or toxicity occurs; maximum dose, 1500 mg/d	PO initially 250 mg/d, increased at weekly intervals until seizures are controlled or toxicity occurs; maximum dose, approximately 750–1000 mg/d	Available in oral capsules and syrup Therapeutic serum drug level is 40–80 mcg/mL.
<b>Fosphenytoin</b> (Cerebyx)	Status epilepticus and short-term use in clients who cannot take oral phenytoin	Nonemergent seizures, IV, IM loading dose 10–20 mg PE/kg; maintenance dose 4–6 mg PE/kg/d; status epilepticus, IV 15–20 mg PE/kg, at a rate of 100–150 mg PE/min	<12 y: Loading dose (if not previous phenytoin): 10–20 mg PE/kg IV no faster than 3 mg PE/kg/min (no >150 mg/min) Maintenance dose, 4–6 mg PE/kg/d divided into 2 or more doses	Much easier to give IV than phenytoin; can also be given IM
<b>Gabapentin</b> (Neurontin)	Partial seizures, with other AEDs	PO 900 mg daily, in 3 divided doses; increased up to 1800 mg/d if necessary. Intervals between doses should not exceed 12 h. Renal impairment: Crcl >60 mL/min, 400 mg 3 times daily (1200 mg/d); Crcl 30–60 mL/min, 300 mg 2 times daily (600 mg/d); Crcl 15–30 mL/min, 300 mg once daily; Crcl <15 mL/min, 300 mg every other day. For patients on hemodialysis, 200–300 mg after each 4 h of hemodialysis.	>12 y: PO 900–1800 mg/d, in 3 divided doses (same as adults) 3–12 y: 10–15 mg/kg/d, in 3 divided doses, increased if necessary. Intervals between doses should not exceed 12 h.	Does not cause significant drug–drug interactions Clinical trial data indicate that monitoring serum levels is not necessary for safe use.

Table 11-1

## Drugs at a Glance: Antiseizure Drugs (continued)

Generic/Trade Name	Types of Seizures Used To Treat	ROUTES AND DOSAGE RANGES		Remarks
		Adults	Children	
<b>Lamotrigine</b> (Lamictal)	Partial seizures, with other AEDs Lennox-Gastaut syndrome, with other AEDs	<p>With AEDs other than valproic acid: PO 50 mg once daily for 2 wk, then 50 mg twice daily (100 mg/d) for 2 wk, then increase by 100 mg/d at weekly intervals to a maintenance dose. Usual maintenance dose, 300–500 mg/d in 2 divided doses.</p> <p>With AEDs including valproic acid: PO 25 mg every other day for 2 wk, then 25 mg once daily for 2 wk, then increase by 25 to 50 mg/d every 1–2 wk to a maintenance dose. Usual maintenance dose, 100–150 mg/d in 2 divided doses.</p>	<p>2–12 y: With enzyme-inducing AEDs, initially, PO 0.15 mg/kg/d in 1 or 2 doses for 2 wk. If calculated dose is 2.5–5 mg, give 5 mg on alternate days for 2 wk, then 0.3 mg/kg/d in 1 or 2 doses, rounded to nearest 5 mg, for 2 wk.</p> <p>Maintenance dose, PO 5–15 mg/kg/d in 2 divided doses</p> <p>&gt;12 y: With enzyme-inducing AEDs, initially, PO 25 mg every other day for 2 wk, then 25 mg daily for 2 wk</p> <p>Maintenance dose, PO 100–400 mg daily in 1 or 2 divided doses</p> <p>With valproic acid, PO 50 mg daily for 2 wk, then 100 mg daily in 2 divided doses for 2 wk</p> <p>Maintenance dose, PO 300–500 mg daily in 1 or 2 doses</p>	Valproic acid slows lamotrigine's metabolism by approximately 50%. If lamotrigine is combined with other AEDs plus valproic acid, dosage must be substantially reduced.
<b>Levetiracetam</b> (Keppra)	Partial seizures, with other AEDs	<p>PO 500 mg twice daily initially, increased by 1000 mg/d every 2 wk, if necessary. Maximum dose, 3000 mg daily.</p> <p><i>Renal Impairment:</i> Crcl &gt;80, 500–1500 mg; Crcl 50–80, 500–1000 mg; Crcl 30–50, 250–750 mg; Crcl &lt;30, 250–500 mg</p> <p>End-stage renal disease, on hemodialysis, 500–1000 mg, with a supplemental dose of half the total daily dose (250–500 mg)</p>	For adjunctive treatment of partial seizures or refractory seizures: 4–5 y: 10 mg/kg PO twice daily, can increase the daily dose every 2 wk by increments of 20 mg/kg to recommended dose of 30 mg/kg twice daily (60 mg/kg/d).	Tablets should be swallowed whole; should not crush or chew tablets
<b>Lorazepam</b> (Ativan)	Acute convulsive seizures, status epilepticus	IV 2–10 mg, diluted in an equal amount of sterile water for injection, 0.9% sodium chloride injection, or 5% dextrose in water, and injected over 2 min	0.1 mg/kg IV over 2–5 min for status. A second dose of 0.05 mg/kg IV may be repeated in 10–15 min if needed.	Schedule IV drug

Generic/Trade Name	Types of Seizures Used To Treat	ROUTES AND DOSAGE RANGES		Remarks
		Adults	Children	
<b>Oxcarbazepine</b> (Trileptal)	Partial seizures, as monotherapy or with other AEDs in adults, with other AEDs in children 4–16 years old	PO 600 mg twice daily (1200 mg/d); maximum dose, 2400 mg/d Severe renal impairment (Crcl <30 mL/min), PO 300 mg twice daily (600 mg/d) and increased slowly until response achieved	With other AEDs, PO 8–10 mg/kg/d, not to exceed 600 mg twice daily. Titrate to reach target dose over 2 wk.	<ul style="list-style-type: none"> <li>Available in 150-, 300-, and 600-mg scored tablets and a 60 mg/mL fruit-flavored suspension</li> </ul>
<b>Phenobarbital</b>	Generalized tonic-clonic and partial seizures	PO 100–300 mg daily in 2–3 divided doses	PO 5 mg/kg per day in 2–3 divided doses	Serum drug levels of 10–25 mcg/mL are in the therapeutic range.
<b>P Phenytoin</b> (Dilantin)	Generalized tonic-clonic and some partial seizures Prevention and treatment of seizures occurring during or after neurosurgery	PO 100 mg three times daily initially; 300 mg (long-acting) once daily as maintenance IV 100 mg q6–8h; maximum 50 mg/min	PO 4–7 mg/kg/d in divided doses. Dosing children is highly variable; dosage adjustment based on serum concentrations.	<ul style="list-style-type: none"> <li>Available in chewable tablets, oral suspension, immediate-release and extended-release capsules, and solution for injection</li> <li>Therapeutic serum level is 5–20 mcg/mL (SI units 40–80 μmol/L). Concentrations at or above the upper therapeutic level may be associated with toxicity.</li> </ul>
<b>Tiagabine</b> (Gabitril)	Partial seizures, with other AEDs	PO 4 mg daily for 1 wk, increased by 4–8 mg/wk until desired effect; maximum dose 56 mg/d in 2–4 divided doses.	12–18 y: PO 4 mg daily for 1 wk, increased to 8 mg/d in 2 divided doses for 1 wk; then increased by 4–8 mg/wk up to a maximum of 32 mg/d in 2 to 4 divided doses <12 y: not recommended.	Most experience obtained in patients receiving at least one concomitant enzymeinducing AED. Use in noninduced patients (e.g., those receiving valproate monotherapy) may require lower doses or a slower dose titration.
<b>Topiramate</b> (Topamax)	Partial seizures, with other AEDs	PO 25–50 mg daily, increased by 25–50 mg per week until response. Usual dose, 400 mg daily in 2 divided doses.	2–16 y: PO wk 1, 25 mg every P.M., increase by 1–3 mg/kg/d at 1- or 2-wk intervals until response. Usual dose 5–9 mg/kg/d, in 2 divided doses.	

(continued on page 202)

Table 11-1

## Drugs at a Glance: Antiseizure Drugs (continued)

Generic/Trade Name	Types of Seizures Used To Treat	ROUTES AND DOSAGE RANGES		Remarks
		Adults	Children	
<b>Valproic acid</b> (Depakene capsules); <b>Sodium valproate</b> (Depakene syrup, Depacon injection); <b>Divalproex sodium</b> (Depakote enteric-coated tablets)	Absence, mixed, and complex partial seizures	PO 10–15 mg/kg/d, increase weekly by 5–10 mg/kg/d, until seizures controlled, adverse effects occur, or the maximum dose (60 mg/kg/d) is reached. Give amounts >250 mg/d in divided doses. Usual daily dose, 1000–1600 mg, in divided doses.  IV client's usual dose, diluted in 5% dextrose or 0.9% sodium chloride injection	PO 15–30 mg/kg/d	<ul style="list-style-type: none"> <li>■ Therapeutic serum levels are 50–100 mcg/mL (SI units 350–700 μmol/L)</li> <li>■ Note: Dosage ranges are the same for the different formulations; doses are in valproic acid equivalents.</li> <li>■ Do not give IV &gt;14 d; switch to oral product when possible. Several formulations of valproic acid are available in the United States. These products may contain valproic acid as the acid, as the sodium salt (sodium valproate), or a combination of the two (divalproex sodium).</li> </ul>
<b>Zonisamide</b> (Zonegran)	Partial seizures, with other AEDs	PO 100–200 mg daily as a single dose or as 2–3 divided doses; increase by 100 mg/d every 1–2 wk if necessary; maximum dose, 600 mg daily	<16 y: 1–2 mg/kg PO given once daily or in divided doses twice daily; increase by 1–2 mg/kg/d only every 1–2 wk. Target range is 4–8 mg/kg/d.	Individuals allergic to sulfonamide should not take zonisamide.

AED, antiepileptic drug; Crcl, creatinine clearance; μmol/L, micromol/L; PE, phenytoin equivalent.

vidually. Types of seizures for which the drugs are used and specific dosages are listed in Table 11-1.

**P Phenytoin** (Dilantin), the prototype, is one of the oldest and most widely used AEDs. It is often the initial drug of choice, especially in adults. In addition to treatment of seizure disorders, it is sometimes used to treat cardiac dysrhythmias.

With oral phenytoin, the rate and extent of absorption vary with the drug formulation. Peak plasma drug levels occur in 2 to 3 hours with prompt-acting forms and in about 12 hours in long-acting forms. Intramuscular (IM) phenytoin is poorly absorbed and not recommended. The drug is metabolized in the liver to inactive metabolites that are excreted in the urine.

Phenytoin is highly bound (90%) to plasma proteins, and only the free drug (the fraction not bound to plasma albumin) is therapeutically active. For most people, dosage is calculated

on the basis of the total phenytoin value. The recognized therapeutic range, assuming a normal plasma albumin level, reflects the amount of phenytoin that is bound to albumin along with the unbound (free) portion. Monitoring the free phenytoin serum level (normal levels 0.8 to 2.0 mcg/mL) should be done in patients with altered albumin levels (elderly persons or those with cirrhosis, burns, malnutrition, cachexia, or nephrotic syndrome) and with factors that may decrease the affinity of phenytoin for albumin or cause displacement of the drug (e.g., renal failure, interacting drugs [warfarin, salicylate, valproate], or increased bilirubin). Conditions or factors that decrease binding increase the available free portion of the drug and therefore these patients require lower-than-normal total plasma levels to achieve the normal therapeutic effects.

The most common adverse effects of phenytoin affect the CNS (e.g., ataxia, drowsiness, lethargy) and gastrointestinal (GI) tract (e.g., nausea, vomiting). *Gingival hyperplasia*, an overgrowth of gum tissue, is also common, especially in children. Long-term use may lead to an increased risk of osteoporosis because of its effect on vitamin D metabolism. Serious reactions are uncommon but may include allergic reactions, hepatitis, nephritis, bone marrow depression, and mental confusion.

Phenytoin may interact with many other drugs, mainly because it induces drug-metabolizing enzymes in the liver. Thus, it can increase the metabolism of itself and many other drugs, both AEDs and non-AEDs. In addition, many other drugs can affect phenytoin metabolism and protein binding.

Phenytoin is available as a capsule (generic and brand name), chewable tablet, oral suspension, and injectable solution. The injectable solution is highly irritating to tissues, and special techniques are required when the drug is given IV. Patients should not switch between generic and trade name formulations of phenytoin because of differences in absorption and bioavailability. If a patient is stabilized on a generic formulation and switches to Dilantin, there is a risk of higher serum phenytoin levels and toxicity. If a patient takes Dilantin and switches to a generic form, there is a risk of lower serum phenytoin levels, loss of therapeutic effectiveness, and seizures. There may also be differences in bioavailability among generic formulations manufactured by different companies.

### Applying Your Knowledge 11-1

How do you determine if Frank is receiving an adequate dosage of phenytoin?

**Fosphenytoin** (Cerebyx) is a water-soluble prodrug formulation that is rapidly hydrolyzed to phenytoin after IV or IM injection. It is approved for treatment of status epilepticus and for short-term use in patients who cannot take oral phenytoin. In contrast to other preparations of injectable phenytoin, fosphenytoin causes minimal tissue irritation, can be diluted with 5% dextrose or 0.9% sodium chloride solution, and can be given IV more rapidly. Dose, concentration in dosing solutions, and infusion rate of IV fosphenytoin is expressed as phenytoin sodium equivalents (PE) to prevent the need for calculating molecular weight–based adjustments when converting between fosphenytoin and phenytoin sodium doses. Fosphenytoin is available in 2-mL and 10-mL vials with 50 mg PE/mL (fosphenytoin 50 mg PE = phenytoin 50 mg). For IV administration, fosphenytoin can be diluted to a concentration of 1.5 to 25 mg PE/mL, and infused at a maximal rate of 150 mg PE/minute.

**Carbamazepine** (Tegretol) is used to treat seizure disorders as well as trigeminal neuralgia and bipolar disorder. It is given orally, and peak blood levels are reached in about 1.5 hours with the liquid suspension, in 4 to 5 hours with conventional tablets, and in 3 to 12 hours with extended-release forms (tablets and capsules). Carbamazepine is metabolized in the

liver to an active metabolite. Because it induces its own metabolism, its half-life shortens with chronic administration. It is contraindicated in patients with previous bone marrow depression or hypersensitivity to carbamazepine and in those taking monoamine oxidase (MAO) inhibitors. MAO inhibitors should be discontinued at least 14 days before carbamazepine is started. Different brands may not be bioequivalent and should not be used interchangeably without evaluating serum blood levels. The drug has a narrow therapeutic index and the FDA has issued a **BLACK BOX WARNING** regarding the development of an aplastic anemia and agranulocytosis with use of carbamazepine.

### Applying Your Knowledge 11-2

Even though Frank has not indicated a history of a psychiatric disorder, what question should you ask before Frank begins treatment with the carbamazepine?

**Clonazepam** (Klonopin), **clorazepate** (Tranxene), **diazepam** (Valium), and **lorazepam** (Ativan) are benzodiazepines (see Chap. 8) used in seizure disorders. Clonazepam and clorazepate are used in long-term treatment of seizure disorders, alone or with other AEDs. Tolerance to antiseizure effects develops with long-term use. Clonazepam has a long half-life and may require weeks of continued administration to achieve therapeutic serum blood levels. As with other benzodiazepines, clonazepam produces physical dependence and withdrawal symptoms. Because of clonazepam's long half-life, withdrawal symptoms may appear several days after administration is stopped. Abrupt withdrawal may precipitate seizure activity or status epilepticus.

Diazepam and lorazepam are used to terminate acute convulsive seizures, especially the life-threatening seizures of status epilepticus. Diazepam has a short duration of action and must be given in repeated doses. Lorazepam has become the drug of choice to treat status epilepticus because its effects last longer than those of diazepam.

**Ethosuximide** (Zarontin) is the AED of choice for absence seizures and may be used with other AEDs for treatment of mixed types of seizures. It is well absorbed after oral administration and reaches peak serum levels in 3 to 7 hours; a steady-state serum concentration is reached in about 5 days. It is eliminated mainly by hepatic metabolism to inactive metabolites, and about 20% is excreted unchanged through the kidneys. Its elimination half-life is approximately 30 hours in children and 60 hours in adults.

**Gabapentin** (Neurontin) is used with other AEDs for treatment of partial seizures. In addition, it is commonly used to treat postherpetic neuralgia and other conditions such as chronic pain syndromes, including neuropathies (i.e., diabetic and others). Gabapentin is 60% absorbed with usual doses, circulates largely in a free state because of minimal binding to plasma proteins, is not appreciably metabolized, and is eliminated by the kidneys as unchanged drug. Its elimination

half-life is 5 to 7 hours in patients with normal renal function and as much as 50 hours in patients with impaired renal function, depending on creatinine clearance.

Adverse effects of gabapentin include dizziness, drowsiness, fatigue, loss of muscle coordination, tremor, nausea, vomiting, abnormal vision, gingivitis, and pruritus. Most adverse effects subside spontaneously or with dosage reduction. However, the first dose of gabapentin should be administered at bedtime, because the drug can cause significant somnolence and dizziness with the first dose. Gabapentin reportedly does not cause significant drug–drug interactions. Because the drug is eliminated only by the kidneys, dosage must be reduced in patients with renal impairment. Although it is structurally related to GABA, the drug does not interact with GABA receptors in the brain; its mechanism of action is unknown.

**Lamotrigine** (Lamictal) is used with other AEDs for treatment of partial seizures. It is thought to reduce the release of glutamate, an excitatory neurotransmitter, in the brain. It is well absorbed after oral administration, with peak plasma levels reached in 1.5 to 4.5 hours. Lamotrigine is about 55% bound to plasma proteins. It is metabolized in the liver to an inactive metabolite and eliminated mainly in the urine.

Adverse effects of lamotrigine include dizziness, drowsiness, headache, ataxia, blurred or double vision, nausea and vomiting, and weakness. The FDA has issued a **BLACK BOX WARNING** related to the potential development of serious dermatologic reactions. Because a serious skin rash may occur, especially in children, lamotrigine should not be given to children younger than 16 years of age and should be discontinued at the first sign of skin rash in an adult. Skin rash is more likely to occur with concomitant valproic acid therapy, high lamotrigine starting dose, and rapid titration rate. It may resolve if lamotrigine is discontinued, but it progresses in some patients to more severe forms, such as Stevens-Johnson syndrome or toxic epidermal necrosis.

Lamotrigine has little effect on the metabolism of other AEDs, but other AEDs affect its metabolism. Phenytoin, carbamazepine, and phenobarbital induce drug-metabolizing enzymes in the liver and accelerate its metabolism. Valproic acid inhibits those enzymes and thereby slows its metabolism by approximately 50%. If lamotrigine is combined with other AEDs plus valproic acid, dosage must be substantially reduced. To discontinue, dosage should be tapered over at least 2 weeks.

**Levetiracetam** (Keppra) is a newer drug approved for treatment of partial seizures, in combination with other AEDs. It is chemically unrelated to other AEDs, and its mechanism of action is unknown. It inhibits abnormal neuronal firing but does not affect normal neuronal excitability or function.

Levetiracetam is well and rapidly absorbed with oral administration; peak plasma levels occur in about 1 hour. Food reduces peak plasma levels by 20%, and these levels do not occur until 1.5 hours; however, this does not affect the extent of drug absorption. The drug is minimally bound (10%) to plasma proteins and reaches steady-state plasma concentrations after 2 days of twice-daily administration. This rapid attainment of therapeutic effects is especially useful for

patients with frequent or severe seizures. The majority of a dose (66%) is eliminated by the kidneys as unchanged drug, and the dose must be reduced in patients with impaired renal function. The drug is not metabolized by the liver and does not affect the hepatic metabolism of other drugs. Thus, it has a low potential for drug interactions.

Levetiracetam was well tolerated in clinical trials, and the incidence of adverse events was similar to that of placebo. Common adverse effects include drowsiness, dizziness, and fatigue. Others include decreases in red and white blood cell counts, double vision, amnesia, anxiety, ataxia, emotional lability, hostility, nervousness, paresthesia, pharyngitis, and rhinitis.

Overall, levetiracetam has pharmacokinetic and other characteristics that may make it especially useful in patients who require combination AED therapy, who take drugs with increased potential for drug interactions, or who have impaired liver function.

**Oxcarbazepine** (Trileptal) is a newer drug that is structurally related to carbamazepine. It is approved for both monotherapy and adjunctive (with other AEDs) therapy in adults with partial seizures and for adjunctive therapy only in children. For patients receiving carbamazepine or oxcarbazepine, either drug may be substituted for the other without tapering the dose of one or gradually increasing the dose of the other. However, the equivalent dosage of oxcarbazepine is 50% higher than the carbamazepine dosage. In older adults, the recommended equivalent oxcarbazepine dosage is 20% higher than the carbamazepine dosage.

Oxcarbazepine is well absorbed after oral administration, with peak plasma levels occurring in about 5 hours. Most effects are attributed to an active metabolite produced during first-pass metabolism in the liver; the metabolite is 40% protein bound. The elimination half-life is 2 hours for oxcarbazepine and 9 hours for the metabolite. The metabolite is conjugated with glucuronic acid in the liver and excreted in the urine, along with a small amount of unchanged drug. Dosage must be reduced in patients with severe renal impairment (i.e., creatinine clearance < 30 mL/min).

Adverse effects are similar in adult and pediatric patients and when oxcarbazepine is used alone or with other AEDs. They include cardiac dysrhythmias, drowsiness, dizziness, hypotension, nausea, vomiting, skin rash, and hyponatremia. A Cochrane systematic review indicated that oxcarbazepine added to other AEDs was significantly more effective than placebo in decreasing seizure frequency in adults and children with drug-resistant partial epilepsy (Level A). Because of the risk of hyponatremia, oxcarbazepine should be used with caution in patients taking other drugs that decrease serum sodium levels, and serum sodium levels should be monitored periodically during maintenance therapy. Some studies indicate that skin reactions occur less often with oxcarbazepine than with carbamazepine.

Several drug–drug interactions may occur with oxcarbazepine. The drug inhibits cytochrome P450 2C19 enzymes and induces 3A4 enzymes to influence the metabolism of other drugs metabolized by these enzymes. For example, oxcar-

bazepine increases metabolism of estrogens and may decrease the effectiveness of oral contraceptives and postmenopausal estrogen replacement therapy. In addition, other drugs that induce cytochrome P450 enzymes, including phenytoin, may reduce plasma levels of the active metabolite by about one third. Drugs that inhibit these enzymes (e.g., cimetidine, erythromycin) do not significantly affect the elimination of oxcarbazepine or its metabolite.

**Phenobarbital** is a long-acting barbiturate that is used alone or with another AED (most often phenytoin). Its use has declined with the advent of other AEDs that cause less sedation and cognitive impairment. CNS depression and other adverse effects associated with barbiturates may occur, but drug dependence and barbiturate intoxication are unlikely with usual antiepileptic doses. Because phenobarbital has a long half-life (50 to 140 hours), it takes 2 to 3 weeks to reach therapeutic serum levels and 3 to 4 weeks to reach a steady-state concentration. It is metabolized in the liver; about 25% is eliminated unchanged in the urine. It induces drug-metabolizing enzymes in the liver and thereby accelerates the metabolism of most AEDs when given with them. Effects on other drugs begin 1 or 2 weeks after phenobarbital therapy is started.

**Tiagabine** (Gabitril), which may increase GABA levels in the brain, is used with other AEDs in patients with partial seizures. After oral administration, tiagabine is well absorbed; peak plasma levels occur in about 45 minutes if taken on an empty stomach and 2.5 hours if taken with food. It is highly protein bound (96%) and is extensively metabolized in the liver by the cytochrome P450 3A family of enzymes. Only 1% of the drug is excreted unchanged in the urine, and the metabolites are excreted in urine and feces. The elimination half-life is 4 to 7 hours in patients receiving enzyme-inducing AEDs (e.g., phenytoin, carbamazepine). Patients with impaired liver function may need smaller doses because the drug is cleared more slowly. CNS effects (e.g., confusion, drowsiness, impaired concentration or speech) are the most common adverse effects. GI upset and a serious skin rash may also occur.

**Topiramate** (Topamax), which has a broad spectrum of antiseizure activity, may act by increasing the effects of GABA and other mechanisms. It is rapidly absorbed and produces peak plasma levels about 2 hours after oral administration. The average elimination half-life is about 21 hours, and steady-state concentrations are reached in about 4 days with normal renal function. It is 20% bound to plasma proteins. Topiramate is not extensively metabolized and is primarily eliminated unchanged through the kidneys. For patients with a creatinine clearance below 70 milliliters per minute, dosage should be reduced by one half.

The most common adverse effects are ataxia, drowsiness, dizziness, and nausea. Renal stones may also occur. Interventions to help prevent renal stones include maintaining an adequate fluid intake, avoiding concurrent use of topiramate with other drugs associated with renal stone formation or increased urinary pH (e.g., triamterene, zonisamide), and avoiding topiramate in people with conditions requiring fluid restriction (e.g., heart failure) or a history of renal stones. Additive CNS

depression may occur with alcohol and other CNS depressant drugs.

**Valproic acid** preparations (Depakene, Depakote, Depacon) are chemically unrelated to other AEDs. They are thought to enhance the effects of GABA in the brain and are also used to treat manic reactions in bipolar disorder and to prevent migraine headache. Valproic acid preparations are well absorbed after oral administration and produce peak plasma levels in 1 to 4 hours (15 minutes to 2 hours with the syrup). They are highly bound (90%) to plasma proteins. They are primarily metabolized in the liver, and metabolites are excreted through the kidneys. Valproic acid (Depakene) is available in capsules, and sodium valproate is a syrup formulation. Divalproex sodium (Depakote) contains equal parts of valproic acid and sodium valproate and is available as delayed-release tablets and sprinkle capsules. Depacon is an injectable formulation of valproate. Dosages of all formulations are expressed in valproic acid equivalents. The FDA has issued a **BLACK BOX WARNING** as hepatic failure and life-threatening pancreatitis have been reported in both children and adults receiving valproate. In addition, valproate can produce teratogenic effects such as neural tube defects if taken during pregnancy.

Depakene, Depakote, and Depacon all produce less sedation and cognitive impairment than phenytoin and phenobarbital. Potentially serious adverse effects, although uncommon, include hepatotoxicity and pancreatitis. The drugs are contraindicated in people who have had hypersensitivity reactions to any of the preparations and people with hepatic disease or impaired hepatic function.

**Zonisamide** (Zonegran) is chemically a sulfonamide. (It is contraindicated for use in patients who are allergic to sulfonamides.) It is approved for adjunctive treatment of partial seizures and may also be effective for monotherapy and generalized seizures. It is thought to act by inhibiting the entry of sodium and calcium ions into nerve cells.

Zonisamide is well absorbed with oral administration and produces peak plasma levels in 2 to 6 hours. It is 40% bound to plasma proteins and also binds extensively to red blood cells. Its elimination half-life is about 63 hours in plasma and more than 100 hours in red blood cells. It is metabolized by the cytochrome P450 3A enzymes and perhaps other pathways. It is excreted in the urine as unchanged drug (35%) and metabolites (65%). Patients with impaired renal function may require lower doses or a slower titration schedule.

Adverse effects of zonisamide include drowsiness, dizziness, ataxia, confusion, abnormal thinking, nervousness, and fatigue, which can be reduced by increasing the dosage gradually, over several weeks. There is also a risk of kidney stones, which is higher in patients with an inadequate fluid intake or who also take topiramate or triamterene. Skin rash, including the life-threatening Stevens-Johnson syndrome, has been observed.

Drugs that induce the cytochrome P450 enzymes (e.g., carbamazepine, phenytoin) increase the metabolism of zonisamide and reduce its half-life. However, administration with cimetidine, which inhibits the cytochrome P450 enzymes, does not seem to inhibit zonisamide metabolism or increase its half-life.

Zonisamide apparently does not induce or inhibit cytochrome P450 enzymes and therefore has little effect on the metabolism of other drugs.

## Nursing Process

### Assessment

Assess patient status in relation to seizure activity and other factors:

- If the patient has a known seizure disorder and is taking antiseizure drugs, helpful assessment data can be obtained by interviewing the client. Some questions and guidelines include the following:
  - How long has the patient had the seizure disorder?
  - How long has it been since seizure activity occurred, or what is the frequency of seizures?
  - Does any particular situation or activity precipitate a seizure?
  - How does the seizure affect the patient? For example, what parts of the body are involved? Does he or she lose consciousness? Is he or she drowsy and tired afterward?
  - Which antiseizure drugs are taken? How do they affect the patient? How long has the patient taken the drugs? Is the currently ordered dosage the same as what the patient has been taking? Does the patient usually take the drugs as prescribed, or does he or she find it difficult to do so?
  - What other drugs are taken? This includes both prescription and nonprescription drugs, as well as those taken regularly or periodically. This information is necessary because many drugs interact with antiseizure drugs to decrease seizure control or increase drug toxicity.
  - What is the patient's attitude toward the seizure disorder? Clues to attitude may include terminology, willingness or reluctance to discuss the seizure disorder, compliance or rejection of drug therapy, and others.
- Check reports of serum drug levels for abnormal values.
- Identify risk factors for seizure disorders. In people without previous seizure activity, seizure disorders may develop with brain surgery, head injury, hypoxia, hypoglycemia, drug overdosage (CNS stimulants, such as amphetamines or cocaine, or local anesthetics, such as lidocaine), and withdrawal from CNS depressants, such as alcohol and barbiturates.
- To observe and record seizure activity accurately, note the location (localized or generalized); specific characteristics of abnormal movements or behavior; duration; concomi-

tant events, such as loss of consciousness and loss of bowel or bladder control; and postseizure behavior.

- Assess for risk of status epilepticus. Risk factors include recent changes in antiseizure drug therapy, chronic alcohol ingestion, use of drugs known to cause seizures, and infection.

### Nursing Diagnoses

- Ineffective Coping related to denial of the disease process and need for long-term drug therapy
- Deficient Knowledge: Disease process
- Deficient Knowledge: Drug effects
- Risk for Injury: Trauma related to ataxia, dizziness, confusion
- Risk for Injury: Seizure activity or drug toxicity
- Ineffective Management of Therapeutic Regimen: Individual: Underuse of Medications

### Planning/Goals

The patient will

- Take medications as prescribed
- Experience control of seizures
- Avoid serious adverse drug effects
- Verbalize knowledge of the disease process and treatment regimen
- Avoid discontinuing antiseizure medications abruptly
- Keep follow-up appointments with health care providers

### Interventions

Use measures to minimize seizure activity. Guidelines include the following:

- Help the patient identify conditions under which seizures are likely to occur. These precipitating factors, to be avoided or decreased when possible, may include ingestion of alcoholic beverages or stimulant drugs; fever; severe physical or emotional stress; and sensory stimuli, such as flashing lights and loud noises. Identification of precipitating factors is important because lifestyle changes (e.g., reducing stress, reducing alcohol and caffeine intake, increasing exercise, improving sleep and diet) and treatment of existing disorders can reduce the frequency of seizures.
- Assist the patient in planning how to get enough rest and exercise and eat a balanced diet, if needed.
- Discuss the seizure disorder, the plan for treatment, and the importance of complying with prescribed drug therapy with the patient and family members (see accompanying patient teaching display).
- Involve the patient in decision making when possible.
- Inform the patient and family that seizure control is not gained immediately when drug therapy is started. The goal

is to avoid unrealistic expectations and excessive frustration while drugs and dosages are being changed in an effort to determine the best regimen for the patient.

- Discuss social and economic factors that promote or prevent compliance.
- Protect a patient experiencing a generalized tonic-clonic seizure by
  - Placing a small pillow or piece of clothing under the head if injury could be sustained from the ground or floor
  - Not restraining the patient's movements; fractures may result
  - Loosening tight clothing, especially around the neck and chest, to promote respiration
  - Turning the patient to one side so that accumulated secretions can drain from the mouth and throat when convulsive movements stop. The cyanosis, abnormal movements, and loss of consciousness that characterize a generalized tonic-clonic seizure can be quite alarming to witnesses. Most of these seizures, however, subside within 3 or 4 minutes, and the person starts responding and regaining normal skin color. If the person has one seizure after another (status epilepticus), has trouble breathing or continued cyanosis, or has sustained an injury, further care is needed, and a physician should be notified immediately.
- When risk factors for seizures, especially status epilepticus, are identified, try to prevent or minimize their occurrence.

## Evaluation

- Interview and observe for decrease in or absence of seizure activity.
- Interview and observe for avoidance of adverse drug effects, especially those that impair safety.
- When available, check laboratory reports of serum drug levels for therapeutic ranges or evidence of underdosing or overdosing.

## Principles of Therapy

### Goal of Therapy

Drug therapy is the main treatment of epilepsy for patients of all ages. The goal is to control seizure activity with minimal adverse drug effects. To meet this goal, therapy must be individualized. In most patients, treatment with a single AED is sufficient to meet this goal. However, in 20% to 30% of patients, two or more AEDs are required. In general, combination therapy is associated with more severe adverse effects, interactions among AEDs, poor compliance, and higher costs.

## Drug Selection

Several factors should be considered when developing a therapeutic regimen using one or more AEDs.

### Seizure Type

Type of seizure is a major factor in drug selection. Therefore, an accurate diagnosis is essential before drug therapy is started. In general, for activity against both partial and generalized seizures, the AEDs lamotrigine, levetiracetam, topiramate, valproic acid, and zonisamide are used. For partial seizures, carbamazepine, gabapentin, oxcarbazepine, phenobarbital, phenytoin, and tiagabine are considered most useful. For absence seizures, ethosuximide is the drug of choice, and clonazepam and valproate are also effective. For mixed seizures, a combination of drugs is usually necessary.

Guidelines for newer drugs are evolving as research studies are performed and clinical experience with their use increases. Most of these agents are approved for combination therapy with other AEDs in patients whose seizures are not adequately controlled with a single drug. However, oxcarbazepine is approved for monotherapy of partial seizures, and some other drugs are also thought to be effective as monotherapy (e.g., lamotrigine, valproate).

### Adverse Effects

Adverse effects may be the deciding factor in choosing an AED because most types of seizures can be treated effectively by a variety of drugs. The use of carbamazepine and valproic acid increased largely because they cause less sedation and cognitive and psychomotor impairment than phenobarbital and phenytoin. Most of the newer AEDs reportedly cause fewer adverse effects and are better tolerated than the older drugs, even though these newer drugs may also cause potentially serious adverse effects. Fewer and milder adverse effects may greatly increase a patient's willingness to comply with the prescribed regimen and attain seizure control.

### Monotherapy Versus Combination Therapy

A single drug (*monotherapy*) is recommended when possible. If effective in controlling seizures, monotherapy has the advantages of fewer adverse drug effects, fewer drug–drug interactions, lower cost, and usually greater patient compliance. If the first drug, in adequate dosage, fails to control seizures or causes unacceptable adverse effects, then another agent should be tried as monotherapy. Most practitioners recommend sequential trials of two to three agents as monotherapy before considering combination therapy.

When substituting one AED for another, the second drug should be added and allowed to reach therapeutic blood levels before the first drug is gradually decreased in dosage and discontinued. This is not necessary when substituting oxcarbazepine for carbamazepine or vice versa, because the drugs are similar.

When monotherapy is ineffective, a second, and sometimes a third, drug may be added. If combination therapy is

## Patient Teaching Guidelines

## Antiseizure Medications

### General Considerations

- Take the medications as prescribed. This is extremely important. These drugs must be taken regularly to maintain blood levels adequate to control seizure activity. At the same time, additional doses must not be taken because of increased risks of serious adverse reactions.
- Do not suddenly stop taking any antiseizure medication. Severe, even life-threatening, seizures may occur if the drugs are stopped abruptly.
- Discuss any problems (e.g., seizure activity, excessive drowsiness, other adverse effects) associated with an antiseizure medication with the prescribing clinician or other health care professional. Adjusting dose or time of administration may relieve the problems.
- Do not drive a car, operate machinery, or perform other activities requiring physical and mental alertness when drowsy from antiseizure medications. Excessive drowsiness, decreased physical coordination, and decreased mental alertness increase the likelihood of injury.
- Do not take other drugs without the physician's knowledge and inform any other physician or dentist about taking antiseizure medications. There are many potential drug interactions in which the effects of the antiseizure drug or other drugs may be altered when drugs are given concomitantly.
- Do not take any other drugs that cause drowsiness, including over-the-counter antihistamines and sleep aids.
- Carry identification, such as a MedicAlert device, with the name and dose of the medication being taken. This is necessary for rapid and appropriate treatment in the event of a seizure, accidental injury, or other emergency situation.
- Notify your clinician if you become pregnant or intend to become pregnant during therapy. Oxcarbazepine (Trileptal) decreases the effectiveness of oral contraceptive drugs. Many antiseizure medications are teratogenic.
- Notify your clinician if you are breast-feeding or intend to breast-feed during therapy.

### Self-Administration

- Take most antiseizure medications with food or a full glass of fluid. This will prevent or decrease nausea, vomiting, and gastric distress, which are adverse reactions to most of these drugs. Levetiracetam (Keppra), oxcarbazepine (Trileptal), topiramate (Topamax), and zonisamide (Zonegran) may be taken with or without food.
- When taking generic phenytoin or the Dilantin brand of phenytoin:

1. Do not switch from a generic to Dilantin, or vice versa, without discussing with the prescribing clinician. There are differences in formulations that may upset seizure control and cause adverse effects.
  2. Ask your clinician if you should take (or give a child) supplements of folic acid, calcium, vitamin D, or vitamin K. These supplements may help to prevent some adverse effects of phenytoin.
  3. Brush and floss your teeth and have regular dental care to prevent or delay a gum disorder called *gingival hyperplasia*.
  4. If you have diabetes, you may need to check your blood sugar more often or take a higher dose of your antidiabetic medication. Phenytoin may inhibit the release of insulin and increase blood sugar.
  5. Notify your clinician or another health care professional if you develop a skin rash, severe nausea and vomiting, swollen glands, bleeding, swollen or tender gums, yellowish skin or eyes, joint pain, unexplained fever, sore throat, unusual bleeding or bruising, persistent headache, or any indication of infection or bleeding, and if you become pregnant.
  6. If you are taking phenytoin liquid suspension or giving it to a child, mix it thoroughly immediately before use and measure it with a calibrated medicine cup or a measuring teaspoon. Do not use regular teaspoons because they hold varying amounts of medication.
- If you are taking oxcarbazepine liquid suspension or giving it to a child, mix it thoroughly immediately before use. Measure it with the syringe supplied by the manufacturer and squirt the medication directly into the mouth. Store the suspension at room temperature and use the bottle within 7 weeks or discard the amount remaining. It is helpful to write the date opened and the expiration date on the container.
  - With valproic acid, the regular capsule should not be opened and the tablet should not be crushed for administration. The sprinkle capsule may be opened and the contents sprinkled on soft food for administration. The syrup formulation may be diluted in water or milk but should not be mixed in carbonated beverages.
  - Swallow tablets or capsules of valproic acid (Depakene or Depakote) whole; chewing or crushing may cause irritation of the mouth and throat.
  - Taking valproic acid at bedtime may reduce dizziness and drowsiness.
  - Lamotrigine may cause photosensitivity. When outdoors, wear protective clothing and sunscreen.
  - If taking lamotrigine, notify the clinician immediately if a skin rash or decreased seizure control develops.

ineffective, the clinician may need to reassess the patient for type of seizure, medical conditions or drug–drug interactions that aggravate the seizure disorder or decrease the effectiveness of AEDs, and compliance with the prescribed drug therapy regimen.

### Dosage Form

Dosage forms may increase seizure control, patient convenience, and compliance. For example, extended-release or long-

acting dosage forms can maintain more consistent serum drug levels and decrease frequency of administration. Most of the AEDs are available in oral tablets or capsules, and a few are available as oral liquids or injectable solutions.

### Cost

Cost should be considered because it may be a major factor in patient compliance. Although the newer drugs are generally effective and better tolerated than older agents, they are also

quite expensive. When possible, clinicians can encourage compliance by choosing drugs that are covered by patients' insurance plans or, for uninsured patients, choosing less expensive drug therapy regimens or facilitating enrollment of the patient in manufacturer or state drug discount programs.

### Pregnancy Risk

Sexually active adolescent girls and women of childbearing potential who require an AED must be evaluated and monitored very closely because all of the AEDs are considered teratogenic. In general, infants exposed to one AED have a significantly higher risk of birth defects than those who are not exposed, and infants exposed to two or more AEDs have a significantly higher risk than those exposed to one AED.

### Drug Dosage

The dosage of most drugs is determined empirically by observation of seizure control and adverse effects.

- Usually, larger doses are needed for a single drug than for multiple drugs; for patients with a large body mass (assuming normal liver and kidney function); and in cases of trauma, surgery, and emotional stress.
- Smaller doses are usually required for patients who have liver disease or who are taking multiple drugs. Smaller doses of gabapentin, levetiracetam, and topiramate must be given in the presence of renal impairment, and smaller doses of lamotrigine must be given when combined with valproic acid and another AED.
- For most drugs, initial doses are relatively low and gradually increased until seizures are controlled or adverse effects occur. Then doses may be lowered to the minimum effective level, to decrease adverse effects. Adverse effects are more likely to occur during initiation of treatment. If treatment is started too aggressively, patients may be unwilling to continue a particular medication even if doses are reduced in amount or frequency of administration.
- When one AED is being substituted for another, dosage of the one being added is gradually increased while the one being discontinued is gradually decreased. The first drug is usually stopped when therapeutic effects or therapeutic serum drug levels of the second drug are attained.
- When an AED is being discontinued, its dosage should always be tapered gradually, usually over 1 to 3 months. Abruptly stopping an AED may exacerbate seizures or cause status epilepticus.
- When fosphenytoin is substituted for oral phenytoin, the same total daily dosage (in phenytoin equivalents) may be given IV or IM.
- For patients receiving carbamazepine or oxcarbazepine, either agent may be substituted for the other without gradual reduction or titration of the dose. For most patients, the equivalent oxcarbazepine dosage is 50% higher than the carbamazepine dosage. When switching between agents in older adults, the recommended equivalent oxcar-

bazepine dosage is 20% higher than the carbamazepine dosage.

### Monitoring Antiepileptic Drug Therapy

The effectiveness of drug therapy is evaluated primarily by patient response in terms of therapeutic or adverse effects. Periodic measurements of serum drug levels are recommended, especially when multiple AEDs are being given. This strategy helps to

- Document blood levels associated with particular drug dosages, seizure control, or adverse drug effects
- Assess and document therapeutic failures
- Assess for drug malabsorption or patient noncompliance
- Guide dosage adjustments
- Evaluate possible drug-related adverse effects

To be useful, serum drug levels must be interpreted in relation to clinical responses, because there are wide variations among patients receiving similar doses, probably due to differences in hepatic metabolism. In other words, doses should not be increased or decreased solely to maintain a certain serum drug level. In addition, the timing of collection of blood samples in relation to drug administration is important. For routine monitoring, blood samples should generally be obtained in the morning, before the first daily dose of an AED.

Several antiseizure drugs have the potential to cause blood, liver, or kidney disorders. For this reason, it is usually recommended that baseline blood studies (e.g., complete blood count, platelet count) and liver function tests (e.g., bilirubin, serum protein, aspartate aminotransferase) be performed before drug therapy starts and periodically thereafter.

When drug therapy fails to control seizures, there are several possible causes. A common one is the patient's failure to take the antiseizure drug as prescribed. Other causes include incorrect diagnosis of the type of seizure, use of the wrong drug for the type of seizure, inadequate drug dosage, and too-frequent changes or premature withdrawal of drugs. Additional causes may include drug overdoses (e.g., theophylline), severe electrolyte imbalances (e.g., hyponatremia), or use of alcohol or recreational drugs.

### Duration and Discontinuation of Therapy

Antiseizure drug therapy may be discontinued for some patients, usually after a seizure-free period of at least 2 years. Although opinions differ about whether, when, and how the drugs should be discontinued, studies indicate that medications can be stopped in approximately two thirds of patients whose epilepsy is completely controlled with drug therapy. Advantages of discontinuation include avoiding adverse drug effects and decreasing costs; disadvantages include recurrence of seizures, with possible status epilepticus. Even if drugs cannot be stopped completely, periodic attempts to decrease the number or dosage of drugs are probably desirable to minimize

adverse reactions. Discontinuing drugs, changing drugs, or changing dosage must be done gradually over 2 to 3 months for each drug and with close medical supervision because sudden withdrawal or dosage decreases may cause status epilepticus. Only one drug should be reduced in dosage or gradually discontinued at a time.

## Toxicity: Recognition and Management

Signs and symptoms of overdose and toxicity are usually extensions of known adverse effects. Severe overdoses disturb vital functions (e.g., CNS depression with confusion, impaired consciousness and possible coma, respiratory depression; cardiovascular problems such as dysrhythmias and hypotension) and are life threatening. Fatalities have been reported with most antiseizure drugs.

If toxicity is suspected, serum drug levels should be assessed in patients taking those drugs with established therapeutic ranges. There are no specific antidotes, and treatment is symptomatic and supportive. For example, gastric lavage and activated charcoal may be indicated to prevent absorption of additional drug; an endotracheal tube should be inserted prior to lavage, to prevent aspiration. (Activated charcoal is not effective in adsorbing topiramate and is not recommended for topiramate overdose.) Hemodialysis is effective in removing drugs that are poorly bound to plasma proteins and that are excreted mainly or partly by the kidneys (e.g., gabapentin, levetiracetam, topiramate, valproate). Vital signs, electrocardiogram, level of consciousness, pupillary reflexes, and urine output should be monitored.

## Effects of Antiepileptic Drugs on Nonantiepileptic Drugs

Interactions between AEDs and many non-AEDs may be clinically significant. Because AEDs depress the CNS and cause drowsiness, their combination with any other CNS depressants may cause excessive sedation and other adverse CNS effects. AEDs may also decrease the effects of numerous other drugs, mainly by inducing drug-metabolizing enzymes in the liver. Enzyme induction means that the affected drugs are metabolized and eliminated more quickly. In some cases, larger doses of the affected drugs are needed to achieve therapeutic effects.

The older AEDs produce more effects on non-AEDs than newer agents. Phenytoin reduces the effects of cardiovascular drugs (e.g., amiodarone, digoxin, disopyramide, dopamine, mexiletine, quinidine), female sex hormones (i.e., estrogens, oral contraceptives, levonorgestrel), adrenal corticosteroids, antipsychotic drugs (e.g., phenothiazines, haloperidol), oral antidiabetic agents (e.g., sulfonylureas), doxycycline, furosemide, levodopa, methadone, and theophylline. The consequence of increasing metabolism of oral contraceptives may be unintended pregnancy. The consequence of decreasing the effects of sulfonylureas may be greater difficulty in controlling blood sugar levels in diabetic patients who require both drugs. Phenytoin decreases the therapeutic effects of acetaminophen

but may increase the risk of hepatotoxicity by accelerating production of the metabolite that damages the liver. Carbamazepine reduces the effects of tricyclic antidepressants, oral anticoagulants, oral contraceptives, bupropion, cyclosporine, doxycycline, felodipine, and haloperidol. Carbamazepine has the same effects on acetaminophen as phenytoin.

Few interactions have been reported with the newer drugs. Topiramate decreases effects of digoxin and oral contraceptives. Levetiracetam does not induce or inhibit hepatic metabolism of drugs, and risks of interactions are minimal. Oxcarbazepine decreases effectiveness of felodipine and oral contraceptives (a barrier type of contraception is recommended during oxcarbazepine therapy). Zonisamide interacts with other AEDs, but no interactions have been reported with non-AEDs. More interactions with these drugs may be observed with longer clinical use.

## Treatment of Status Epilepticus

An IV benzodiazepine (e.g., lorazepam 0.1 mg/kg at 2 mg/minute) is the drug of choice for rapid control of tonic-clonic seizures. However, seizures often recur unless the benzodiazepine is repeated or another, longer-acting drug, such as IV phenytoin (20 mg/kg at 50 mg/minute) or fosphenytoin (20 mg/kg phenytoin equivalents at 150 mg/minute), is given. Further treatment is based on the patient's response to these medications. Because there is a risk of significant respiratory depression with IV benzodiazepines, personnel and supplies for emergency resuscitation must be readily available.

## Use in Special Populations

### Use in Children

Oral drugs are absorbed slowly and inefficiently in newborns. If an antiseizure drug is necessary during the first 7 to 10 days of life, IM phenobarbital is effective. Metabolism and excretion also are delayed during the first 2 weeks of life, but rates become more rapid than those of adults by 2 to 3 months of age. In infants and children, oral drugs are rapidly absorbed and have short half-lives. This produces therapeutic serum drug levels earlier in children than in adults. Rates of metabolism and excretion also are increased. Consequently, children require higher doses per kilogram of body weight than adults.

The rapid rate of drug elimination persists until approximately 6 years of age and then decreases until it stabilizes at around the adult rate by 10 to 14 years of age. AEDs must be used cautiously to avoid excessive sedation and interference with learning and social development.

There is little information about the effects of the newer AEDs in children. Most of the drugs are approved for use in children (i.e., gabapentin, lamotrigine, oxcarbazepine, tiagabine, and topiramate, but not levetiracetam and zonisamide). Oxcarbazepine is metabolized faster in children younger than 8 years of age, and the rate of metabolism is similar to that in adults after 8 years of age. Several studies indicated that oxcarbazepine is effective in monotherapy and combination therapy, with relatively few and mild adverse

effects. Reports of behavioral problems, aggression, thought disorders, and hyperkinesias have been reported with the use of gabapentin in children 3 to 12 years of age.

### Use in Older Adults

Seizure disorders commonly occur in older adults and require drug therapy. Older adults often have multiple medical conditions, take multiple drugs, and have decreases in protein binding and liver and kidney function. As a result, older adults are at high risk of adverse drug effects and adverse drug–drug interactions with AEDs. For example, reduced levels of serum albumin may increase the active portion of highly protein bound AEDs (e.g., phenytoin, valproic acid) and increase risks for adverse effects even when total serum drug concentrations are normal. Similarly, decreased elimination by the liver and kidneys may lead to drug accumulation, with subsequent risks of dizziness, impaired coordination, and injuries due to falls.

In addition to the ataxia, confusion, dizziness, and drowsiness that may occur with most AEDs, older adults are also more likely to develop some adverse effects associated with specific drugs. For example, with carbamazepine they may develop hyponatremia, especially if they also take sodium-losing diuretics (e.g., furosemide, hydrochlorothiazide), or cardiac dysrhythmias, especially if they have underlying heart disease. Older adults with pre-existing heart disease should have a thorough cardiac evaluation before starting carbamazepine therapy. These effects may also occur with oxcarbazepine. With valproic acid, older adults may develop a tremor that is difficult to diagnose because of its gradual onset and similarity to the tremor occurring with Parkinson's disease. The tremor is often dose-related and reverses when the drug is reduced in dosage or discontinued.

Most of these potential problems can be averted or minimized by using AEDs very cautiously in older adults. In general, small initial doses, slow titration to desired doses, and small maintenance doses are needed. Using controlled-release formulations to minimize peak plasma concentrations may also be helpful. In addition, frequent assessment of patients for adverse effects and periodic monitoring of serum drug levels, liver function, and kidney function are indicated.

### Use in Patients With Renal Impairment

Phenytoin is often used to prevent or treat seizure disorders in patients who are seriously ill. With renal impairment, protein binding is decreased and the amount of free, active drug is higher than in patients with normal renal function. Total phenytoin levels are still more commonly obtained in routine clinical practice; however, free levels are more relevant in the setting of renal failure. The use of phenobarbital in patients with severe renal impairment requires markedly reduced dosage, close monitoring of plasma drug levels, and frequent observation for toxic effects. Smaller doses of gabapentin, levetiracetam, oxcarbazepine, topiramate, and zonisamide must be given in the presence of renal impairment because these drugs are eliminated primarily through the kidneys. Dosage of oxcarbazepine should be decreased by 50% in patients with creati-

nine clearance of less than 30 milliliters per minute. Zonisamide should not be given to patients with renal failure and should be discontinued in patients who develop acute renal failure or increased serum creatinine and blood urea nitrogen levels during therapy. Elimination of tiagabine is not significantly affected by renal insufficiency, renal failure, or hemodialysis, and dose adjustment for renal dysfunction is not necessary. Renal stones have been reported with topiramate and zonisamide.

### Use in Patients With Hepatic Impairment

Most AEDs are metabolized in the liver and may accumulate in the presence of liver disease or impaired liver function. The drugs should be used cautiously. Tiagabine is cleared more slowly in patients with liver impairment. Increased plasma levels of unbound tiagabine, increased elimination half-life, and increased frequency of neurologic adverse effects (e.g., ataxia, dizziness, drowsiness, tremor) have been observed in patients with mild and moderate hepatic insufficiency. Doses may need to be reduced or given at less frequent intervals. Topiramate may also be cleared more slowly even though it is eliminated mainly through the kidneys and does not undergo significant hepatic metabolism. It should be used with caution in the presence of hepatic impairment.

Valproic acid is a hepatotoxic drug and contraindicated for use in patients with hepatic impairment. No dosage adjustment is indicated with levetiracetam, oxcarbazepine, or zonisamide.

### Use in Patients With Critical Illness

Phenytoin is often used to prevent or treat seizure disorders in critically ill patients, including those with head injuries. Phenytoin therapy can best be monitored by measuring free serum phenytoin concentrations, but laboratories usually report the total serum drug concentration. In some patients, a low total phenytoin level may still be therapeutic, and a dosage increase is not indicated. The occurrence of nystagmus (abnormal movements of the eyeball) indicates phenytoin toxicity; the drug should be reduced in dosage or discontinued until serum levels decrease. Because phenytoin is extensively metabolized in the liver, patients with severe illnesses may metabolize the drug more slowly and therefore experience toxicity.

For patients in critical care units for other disorders, a history of long-term antiepileptic therapy may be a risk factor for seizures, including status epilepticus, if the AED is stopped abruptly. At the same time, the use of continuous nasogastric enteral feedings may decrease the absorption of phenytoin administered through the same route, predisposing the patient to the risk of seizure activity. In addition, continuing an AED may complicate drug therapy for other conditions because of adverse effects and potential drug–drug interactions. For example, phenytoin decreases ventricular automaticity and should not be used in critically ill patients with sinus bradycardia or heart block.

### Use in Home Care

The home care nurse must work with patients and family members to implement and monitor AED therapy. When an

AED is started, a few weeks may be required to titrate the dosage and determine whether the chosen drug is effective in controlling seizures. The nurse can play an important role in clinical assessment of the patient in three ways: (1) interviewing the family about the occurrence of seizures (a log of date, time, duration, and characteristics of seizures can be very helpful), (2) ensuring that the patient keeps appointments for serum drug level testing and follow-up care, and (3) encouraging compliance with the prescribed regimen. With long-term use of the drugs, the nurse must monitor the patient for therapeutic and adverse drug effects, especially with changes in drugs or dosages. The nurse can also play a role in drawing the blood for levels of anticonvulsants to ensure appropriate dosing. With any evidence that the patient is not taking medica-

tion as directed, the nurse may need to review the potential loss of seizure control and potential for status epilepticus.

### Applying Your Knowledge 11-3

#### How Can You Avoid This Medication Error?

Frank is scheduled for an outpatient diagnostic test that requires him to be NPO after midnight. So, you advise him not to eat or drink anything after midnight, including medication, the night before his procedure. The next morning, before Frank has his procedure, he experiences a tonic-clonic seizure.

## Nursing Actions Antiseizure Drugs

### NURSING ACTIONS

#### 1. Administer accurately

- a. Give on a regular schedule about the same time each day.
- b. Give most oral antiseizure drugs after meals or with a full glass of water or other fluid; levetiracetam, oxcarbazepine, topiramate, and zonisamide may be taken with or without food.
- c. To give phenytoin:
  - (1) Shake oral suspensions of the drug vigorously before pouring and always use the same measuring equipment.
  - (2) Do not mix parenteral phenytoin in the same syringe with any other drug.
  - (3) Give phenytoin as an undiluted intravenous (IV) bolus injection at a rate not exceeding 50 mg/min, then flush the IV line with normal saline or dilute in 50–100 mL of normal saline (0.9% NaCl) and administer over approximately 30–60 minutes. If piggybacked into a primary IV line, the primary IV solution must be normal saline or the line must be flushed with normal saline before and after administration of phenytoin. An in-line filter is recommended.
- d. To give IV fosphenytoin:
  - (1) Check the physician's order and the drug concentration carefully.
  - (2) Dilute the dose in 5% dextrose or 0.9% sodium chloride solution to a concentration of 1.5 mg PE/mL to 25 mg PE/mL and infuse no faster than 150 mg PE/min.

### RATIONALE/EXPLANATION

To maintain therapeutic blood levels of drugs Most antiseizure drugs cause some gastric irritation, nausea, or vomiting. Taking the drugs with food or fluid helps decrease gastrointestinal side effects.

In suspensions, particles of drug are suspended in water or other liquid. On standing, drug particles settle to the bottom of the container. Shaking the container is necessary to distribute drug particles in the liquid vehicle. If the contents are not mixed well every time a dose is given, the liquid vehicle will be given initially, and the concentrated drug will be given later. That is, underdosage will occur at first, and little if any therapeutic benefit will result. Overdosage will follow, and the risks of serious toxicity are greatly increased. Using the same measuring container ensures consistent dosage. Calibrated medication cups or measuring teaspoons or tablespoons are acceptable. Regular household teaspoons and tablespoons used for eating and serving are not acceptable because sizes vary widely.

Phenytoin solution is highly alkaline (pH approximately 12) and physically incompatible with other drugs. A precipitate occurs if mixing is attempted.

Phenytoin cannot be diluted or given in IV fluids other than normal saline because it precipitates within minutes. Slow administration and dilution decrease local venous irritation from the highly alkaline drug solution. Rapid administration must be avoided because it may produce myocardial depression, hypotension, cardiac dysrhythmias, and even cardiac arrest.

The dose is expressed in phenytoin equivalents (PE; fosphenytoin 50 mg PE = phenytoin 50 mg).

The drug is preferably diluted in the pharmacy and labeled with the concentration and duration of the infusion. For a 100-mg PE dose, diluting with 4 mL yields the maximum concentration of 25 mg PE/mL; this amount could be infused in about 1 min at the maximal recommended rate. A 1-g loading dose could be added to 50 mL of 0.9% sodium chloride and infused in approximately 10 min at the maximal recommended rate.

**NURSING ACTIONS**

(3) Consult a pharmacist or the manufacturer's literature if any aspect of the dose or instructions for administration are unclear.

- e. To give carbamazepine and phenytoin suspensions by nasogastric (NG) feeding tube, dilute with an equal amount of water, and rinse the NG tube before and after administration.
- f. To give oxcarbazepine suspension, use the 10-mL oral dosing syringe provided by the manufacturer with each bottle. Also check expiration date.

**2. Observe for therapeutic effects**

- a. When the drug is given on a long-term basis to prevent seizures, observe for a decrease in or absence of seizure activity.
- b. When the drug is given to stop an acute convulsive seizure, seizure activity usually slows or stops within a few minutes.

**3. Observe for adverse effects**

- a. Central nervous system (CNS) effects—ataxia, dizziness, drowsiness, double vision
- b. Gastrointestinal effects—anorexia, nausea, vomiting
- c. Hypersensitivity reactions—often manifested by skin disorders such as rash, urticaria, exfoliative dermatitis, Stevens-Johnson syndrome (a severe reaction accompanied by headache, arthralgia, and other symptoms in addition to skin lesions)
- d. Blood dyscrasias—anemia, leukopenia, thrombocytopenia, agranulocytosis
- e. Respiratory depression
- f. Liver damage—hepatitis symptoms, jaundice, abnormal liver function test results
- g. Gingival hyperplasia
- h. Hypocalcemia
- i. Hyponatremia
- j. Lymphadenopathy resembling malignant lymphoma
- k. Pancreatitis
- l. Kidney stones

**RATIONALE/EXPLANATION**

To avoid error

Absorption is slow and decreased, possibly because of drug adherence to the NG tube. Dilution and tube irrigation decrease such adherence.

For accurate measurement and a reminder that the suspension is given orally only. The suspension is stored at room temperature and must be used within 7 weeks after opening the bottle.

Therapeutic effects begin later with antiseizure drugs than with most other drug groups because the antiseizure drugs have relatively long half-lives. Optimum therapeutic benefits of phenytoin occur approximately 7–10 days after drug therapy is started.

Intravenous lorazepam is the drug of choice for controlling an acute convulsion.

These effects are common, especially during the first week or two of drug therapy.

These common effects of oral drugs can be reduced by taking the drugs with food or a full glass of water.

These may occur with almost all the antiseizure drugs. Some are mild; some are potentially serious but rare. These skin reactions are usually sufficient reason to discontinue the drug. About 25%–30% of patients with allergic reactions to carbamazepine are likely to be allergic to oxcarbazepine.

Most antiseizure drugs decrease blood levels of folic acid, which may progress to megaloblastic anemia. The other disorders indicate bone marrow depression and are potentially life threatening. They do not usually occur with phenytoin, but may infrequently occur with most other antiseizure drugs. This is not likely to be a significant adverse reaction except when a depressant drug, such as lorazepam, is given IV to control acute seizures, such as status epilepticus. Even then, respiratory depression can be minimized by avoiding over-dosage and rapid administration.

Hepatic damage may occur with phenytoin, and fatal hepatotoxicity has been reported with valproic acid.

Occurs often with phenytoin, especially in children. It may be prevented or delayed by vigorous oral hygiene.

May occur when antiseizure drugs are taken in high doses and over long periods

May occur with carbamazepine and oxcarbazepine, especially if taken concurrently with sodium-losing diuretics (e.g., furosemide, hydrochlorothiazide). Usually transient and levels return to normal with fluid restriction or dose reduction.

This reaction has occurred with several antiseizure drugs, most often with phenytoin.

Life-threatening pancreatitis has occurred after short- and long-term therapy with valproic acid. Patients should be monitored for the development of acute abdominal pain, nausea, and vomiting.

May occur with topiramate and zonisamide. Inadequate fluid intake or concurrent administration of triamterene may increase risk.

(continued on page 214)

## Nursing Actions Antipsychotic Drugs (continued)

### NURSING ACTIONS

### RATIONALE/EXPLANATION

#### 4. Observe for drug interactions

##### a. Drugs that *increase* effects of antiseizure drugs:

- (1) CNS depressants—alcohol, sedating antihistamines, benzodiazepines, opioid analgesics, sedatives
- (2) Most other antiseizure drugs

Additive CNS depression

##### b. Drugs that *decrease* effects of antiseizure drugs:

- (1) Tricyclic antidepressants, antipsychotic drugs
- (2) Carbamazepine, phenytoin, and other enzyme inducers

Additive or synergistic effects. The drugs are often given in combination, to increase therapeutic effects.

These drugs may lower the seizure threshold and precipitate seizures. Dosage of antiseizure drugs may need to be increased.

These drugs inhibit themselves and other antiseizure drugs by activating liver enzymes and accelerating the rate of drug metabolism.

##### c. Additional drugs that alter effects of phenytoin and fosphenytoin:

- (1) Alcohol (acute ingestion), allopurinol, amiodarone, benzodiazepines, chlorpheniramine, cimetidine, flucanazole, fluoxetine, isoniazid, metronidazole, miconazole, omeprazole, paroxetine, sertraline, and trimethoprim increase effects.
- (2) Alcohol (chronic ingestion), antacids, antineoplastics, folic acid, pyridoxine, rifampin, sucralfate, and theophylline decrease effects.
- (3) Phenobarbital has variable interactions with phenytoin.

These drugs increase phenytoin toxicity by inhibiting hepatic metabolism of phenytoin or by displacing it from plasma protein-binding sites.

These drugs decrease effects of phenytoin by decreasing absorption, accelerating metabolism, or by unknown mechanisms.

Phenytoin and phenobarbital have complex interactions with unpredictable effects. Although phenobarbital induces drug metabolism in the liver and may increase the rate of metabolism of other anticonvulsant drugs, its interaction with phenytoin differs. Phenobarbital apparently decreases serum levels of phenytoin and perhaps its half-life. Still, the anticonvulsant effects of the two drugs together are greater than those of either drug given alone. The interaction apparently varies with dosage, route, time of administration, the degree of liver enzyme induction already present, and other factors. Thus, whether a significant interaction will occur in a client is unpredictable. Probably the most important clinical implication is that close observation of the patient is necessary when either drug is being added or withdrawn.

##### d. Additional drugs that alter effects of carbamazepine:

- (1) Cimetidine, clarithromycin, diltiazem, erythromycin, haloperidol, isoniazid, valproic acid, and verapamil increase effects.

Most of these drugs inhibit the cytochrome P450 enzymes (1A2, 2C8, and/or 3A4 groups) that normally metabolize carbamazepine, thereby increasing blood levels of carbamazepine. Valproic acid inhibits an epoxide hydrolase enzyme and causes an active metabolite to accumulate. Toxicity may result even if carbamazepine blood levels are at therapeutic concentrations.

- (2) Alcohol, phenytoin, and phenobarbital decrease effects.

These drugs increase activity of hepatic drug-metabolizing enzymes, thereby decreasing blood levels of carbamazepine.

##### e. Drugs that alter the effects of gabapentin:

- (1) Antacids

Reduce absorption of gabapentin. Gabapentin should be given at least 2 hours after a dose of an antacid to decrease interference with absorption.

##### f. Drugs that alter effects of lamotrigine:

- (1) Valproic acid increases effects.
- (2) Carbamazepine, phenytoin, and phenobarbital decrease effects.

Valproic acid inhibits the liver enzymes that metabolize lamotrigine, thereby increasing blood levels and slowing metabolism of lamotrigine. As a result, lamotrigine dosage must be substantially reduced when the drug is given in a multidrug regimen that includes valproic acid.

These drugs induce drug-metabolizing enzymes in the liver and thereby increase the rate of metabolism of themselves and of lamotrigine.

NURSING ACTIONS	RATIONALE/EXPLANATION
g. Drugs that <i>decrease</i> effects of oxcarbazepine: (1) Phenobarbital, phenytoin, valproic acid, verapamil	These drugs induce drug-metabolizing enzymes in the liver and thereby increase the metabolism and hasten the elimination of oxcarbazepine.
h. Drug that <i>increase</i> effects of phenobarbital: (1) Valproic acid	May increase plasma levels of phenobarbital as much as 40%, probably by inhibiting liver metabolizing enzymes
i. Additional drugs that <i>increases</i> effects of valproate: (1) Cimetidine  (2) Salicylates	Inhibits drug-metabolizing enzymes, thereby slowing elimination from the body and increasing blood levels of valproic acid. Displace valproic acid from binding sites on plasma proteins, thereby increasing the serum level of unbound valproic acid
j. Drugs that <i>decrease</i> effects of zonisamide: (1) Carbamazepine, phenytoin, phenobarbital	These drugs induce drug-metabolizing enzymes in the liver and thereby increase the metabolism and hasten the elimination of zonisamide.
k. Interactions with clonazepam, lorazepam, and diazepam	These drugs are benzodiazepines, discussed in Chapter 8.

## Key Concepts

- Seizures are classified as idiopathic or secondary (caused by tumors, metabolic disorders, overdoses of numerous drugs, or withdrawal of alcohol or sedative-hypnotic drugs).
- When seizures occur in a chronic, recurrent pattern, they characterize a disorder known as epilepsy, which usually requires long-term drug therapy.
- Types of seizure include generalized (generalized tonic-clonic seizures) and partial and (simple or complex, depending on whether consciousness is altered).
- Status epilepticus is a life-threatening emergency that may result in hypotension, hypoxia, cardiac dysrhythmias, permanent brain damage, and death unless prompt, appropriate treatment is instituted.
- Newer antiepileptic medications have better adverse effect profiles with enhanced seizure control.
- Monotherapy should guide initial management of seizure disorders.
- When an AED is being discontinued, its dosage should always be tapered gradually, usually over 1 to 3 months. Abruptly stopping an AED may exacerbate seizures or cause status epilepticus.
- Serum drug levels monitoring is useful for most AEDs and must be interpreted in relation to clinical responses.
- Adverse effect profiles vary with individual AEDs; potential teratogenic adverse effects, drug interactions, hypersensitivity reactions, and blood dyscrasias have been reported.
- All doses of fosphenytoin should be prescribed in terms of its phenytoin equivalent (PE).
- **BLACK BOX WARNINGS** have been issued by the FDA for the following AEDs: carbamazepine, divalproex sodium, lamotrigine, and valproic acid and its derivatives.

## Review and Application Exercises

### Short Answer Exercises

1. For a patient with a newly developed seizure disorder, why is it important to verify the type of seizure by electroencephalogram before starting AEDs?
2. What are the indications for use of the major AEDs?
3. What are the major adverse effects of commonly used AEDs, and how can they be minimized?
4. What are the advantages and disadvantages of treatment with a single drug and of treatment with multiple drugs?
5. Which of the benzodiazepines are used as AEDs?
6. What are the advantages of carbamazepine and valproic acid compared with the benzodiazepines, phenytoin, and phenobarbital?
7. How are the newer drugs similar to or different from phenytoin?
8. What is the treatment of choice for an acute convulsion or status epilepticus?
9. Why is it important when teaching patients to emphasize that none of the AEDs should be stopped abruptly?

10. How can a home care nurse monitor AED therapy during a home visit?

### NCLEX-Style Questions

11. An 18-year-old patient presents to the clinic with complaints of breast tenderness, nausea, vomiting, and absence of menses for 2 months. She has a history of a seizure disorder that is well controlled with oxcarbazepine (Trileptal). She believes that she has been taking her oral contraceptives as directed but asks if she could be pregnant. The nurse recognizes that the best response to the patient's question is which of the following?
- "Oxcarbazepine can decrease the effectiveness of oral contraceptive drugs, so we need to do a pregnancy test."
  - "You can't be pregnant if you have been taking your pills correctly."
  - "Don't worry; birth control pills are very effective."
  - "Taking antiseizure drugs with oral contraceptives significantly decreases your risk of pregnancy."
12. A patient scheduled for her next dose of phenytoin (Dilantin) has a serum plasma phenytoin level of 16 mcg/mL. Based on this information, the nurse should do which of the following?
- Administer the drug.
  - Hold the dose and obtain another plasma drug level before the next dose.
  - Hold the drug and notify the prescriber.
  - Administer half of the prescribed dose.
13. A patient taking gabapentin (Neurontin) begins to exhibit tremors, dizziness, and abnormal vision. The nurse should assess the patient for signs of which of the following?
- additional adverse effects of gabapentin
  - liver dysfunction
  - impending seizure activity
  - cardiac toxicity and dysrhythmias
14. A patient is started on phenytoin (Dilantin). A teaching plan for the patient should include strategies to minimize which of the following common side effects?
- hypoglycemia
  - photosensitivity
  - gingival hyperplasia
  - hyponatremia
15. A patient is brought to the emergency department with ongoing tonic-clonic seizure activity. The health care provider orders lorazepam (Ativan) 4 mg IV. Lorazepam is the drug of choice for which of the following types of seizures?
- partial seizures
  - tonic-clonic seizures
  - absence seizures
  - status epilepticus

# Antiparkinson Drugs

## KEY TERMS

- Akinesia
- Anticholinergic drugs
- Basal ganglia
- Bradykinesia
- Dopaminergic drugs
- Extrapyramidal reactions
- Hypertensive crisis
- “Off-time”
- Parkinson’s disease
- Parkinsonism
- Substantia nigra

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Describe major characteristics of Parkinson’s disease.
2. Differentiate the types of commonly used antiparkinson drugs.
3. Discuss therapeutic and adverse effects of dopaminergic and anticholinergic drugs.
4. Discuss the use of antiparkinson drugs in selected populations.
5. Apply the nursing process with patients experiencing parkinsonism.

## Applying Your Knowledge

Lee Sung is an 81-year-old woman who had been experiencing hand tremors, slow movement, a shuffling gait, and excessive salivation. Her physician diagnosed her with Parkinson’s disease and started her on levodopa/carbidopa 25/100 four times a day and benzotropine mesylate at bedtime. Following a fall, she is admitted for evaluation.

## Introduction

*Parkinson’s disease* (also called *parkinsonism*) is a chronic, progressive, degenerative disorder of the central nervous system (CNS) characterized by resting tremor, bradykinesia, rigidity, and postural instability. Approximately 85% of the 1.5 million Americans with Parkinson’s disease are over the age of 50. Parkinson’s disease occurs slightly more often in men than in women. The disease occurs more often in Caucasian and Hispanic/Latino individuals than in African Americans. Idiopathic parkinsonism results from progressive destruction of or degenerative changes in dopamine-producing nerve cells in the *substantia nigra* in the *basal ganglia*, the area in the midbrain that controls smooth voluntary movement. The cause of the nerve-cell damage is unknown; age-related degeneration, genetics, and exposure to environmental toxins are possible etiologic factors. A total of nine genetic linkages and four genes have been associated with Parkinson’s disease, including mutations of alpha-synuclein and parkin genes. A high incidence of mutation in the parkin-2 gene has been associated with early-onset parkinsonism. Signs and symptoms of Parkinson’s disease also may occur with other CNS diseases, brain tumors, and head injuries. Drugs that deplete dopamine stores or block dopamine receptors, including the older antipsychotic drugs (phenothiazines and haloperidol), reserpine, and metoclopramide, can produce movement disorders such as secondary parkinsonism (also known as *extrapyramidal reactions*, see Chap. 9).

The basal ganglia in the brain normally contain substantial amounts of the neurotransmitters dopamine and acetylcholine. The correct balance of dopamine and acetylcholine is important in regulating posture, muscle tone, and voluntary movement. People with Parkinson’s disease have an imbalance in these neurotransmitters, resulting in a decrease in inhibitory brain dopamine and a relative increase in excitatory acetylcholine.

The first symptom of Parkinson's disease is often a resting tremor that begins in the fingers and thumb of one hand (pill-rolling movements), eventually spreading over one side of the body and progressing to the contralateral limbs. Other common symptoms include slow movement (*bradykinesia*), inability to move (*akinesia*), rigid limbs, shuffling gait, stooped posture, mask-like facial expression, and a soft speaking voice. Less common symptoms may include depression, personality changes, loss of appetite, sleep disturbances, speech impairment, or sexual difficulty. Approximately 15% to 20% of individuals with Parkinson's disease develop dementia. The severity of disease manifestations usually worsen over time. However, disease progression is often quite gradual, and patients may retain near-normal functional abilities for several years.

## General Characteristics of Antiparkinson Drugs

Drugs used in Parkinson's disease help correct the neurotransmitter imbalance by increasing levels of dopamine (*dopaminergic drugs*) or inhibiting the actions of acetylcholine in the brain (*anticholinergic drugs*).

### Dopaminergic Drugs

Levodopa, carbidopa, amantadine, bromocriptine, entacapone, pramipexole, ropinirole, rotigotine-transdermal, selegiline, tolcapone, and rasagiline increase dopamine concentrations in the brain, exerting dopaminergic activity, directly or indirectly.

**P Levodopa** (L-dopa) is the mainstay of drug therapy for idiopathic parkinsonism. Carbidopa is used only in conjunction with levodopa. The other drugs are used as adjunctive agents, usually with levodopa.

### Mechanism of Action

Dopaminergic drugs increase the amount of dopamine in the brain by various mechanisms (Fig. 12-1). Amantadine increases dopamine release and decreases dopamine reuptake by presynaptic nerve fibers. Bromocriptine, pramipexole, ropinirole, and rotigotine-transdermal are dopamine agonists that directly stimulate postsynaptic dopamine receptors. Levodopa is a precursor substance that is converted to dopamine. Selegiline selectively blocks one of the enzymes (MAO-B) that normally inactivates dopamine. Rasagiline is an irreversible MAO inhibitor. It is effective in blocking the MAO-B enzyme; however, studies have not yet established whether rasagiline is *selective* for the MAO-B enzyme. Entacapone and tolcapone block another enzyme (COMT) that normally inactivates dopamine and levodopa.

### Indications for Use

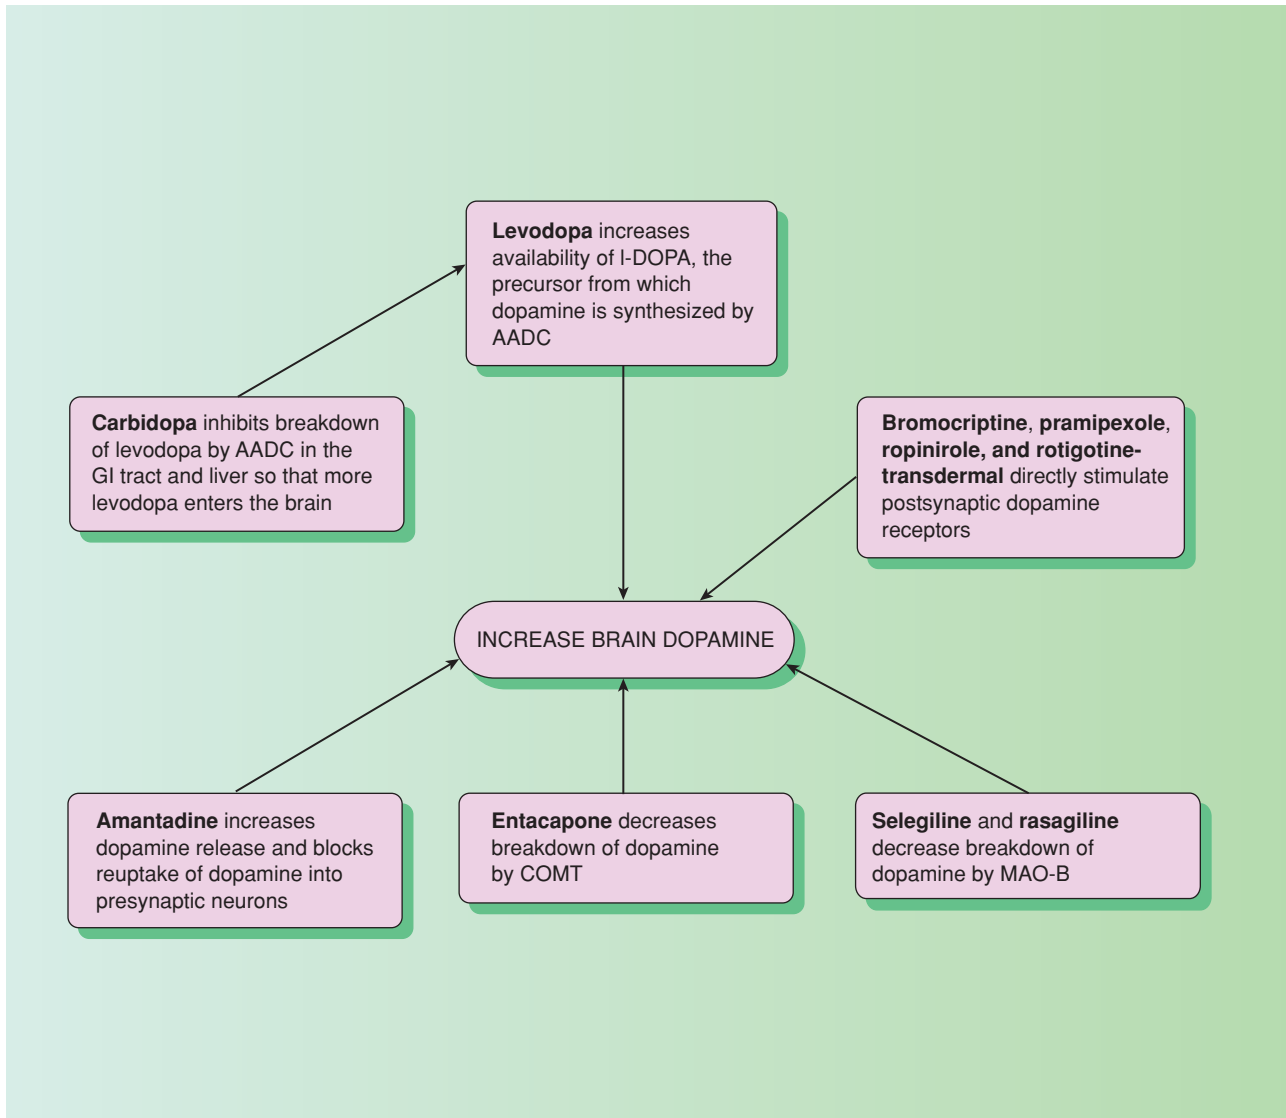

Amantadine, entacapone, levodopa, pramipexole, rasagiline, ropinirole, rotigotine-transdermal, selegiline, and tolcapone are indicated for the treatment of idiopathic parkinsonism. Amantadine is also therapeutic for secondary parkinsonism

(or extrapyramidal reaction). Carbidopa is used only to decrease peripheral breakdown of levodopa and allow more to reach the brain.

Some of the other drugs have additional uses. Bromocriptine is also used in the treatment of acromegaly, amenorrhea, and galactorrhea associated with hyperprolactinemia. Selegiline-transdermal has been approved to treat major depressive disorder. The Food and Drug Administration (FDA) has issued a **BLACK BOX WARNING** regarding an increased risk of suicidality in children and adolescents when treated with antidepressant including selegiline-transdermal. Dopaminergic drugs (e.g., levodopa, cabergoline, pramipexole, ropinirole, and rotigotine-transdermal) may also be prescribed to reduce the symptoms of restless leg syndrome (RLS). Individuals with RLS, also known as Ekbom's syndrome, experience paresthesias of the muscles, particularly in the calf and thighs, creating the urge to move. The paresthesia is relieved by movement, returning when the individual is at rest or trying to sleep. The disorder may result in insomnia, mental distress, and in some cases suicide. Historically, amantadine has been prescribed to prevent or treat influenza A viral infections; however, the Advisory Committee on Immunization Practices (ACIP) of the CDC no longer recommends this practice due to high levels of viral resistance to amantadine.

### Contraindications to Use

Levodopa is contraindicated in patients with known hypersensitivity to the drug. Because levodopa can dilate pupils and raise intraocular pressure, it is contraindicated in narrow-angle glaucoma. Levodopa may activate malignant melanoma; therefore, it should not be administered to individuals with suspicious skin lesions or a history of melanoma. Concurrent administration of nonselective MAO inhibitors (used in the treatment of depression) and levodopa can result in extreme elevations in blood pressure or *hypertensive crisis*. To avoid this adverse effect, MAO-A inhibitors should be discontinued 14 days prior to beginning levodopa therapy. In addition, levodopa must be used with caution in patients with severe cardiovascular, pulmonary, renal, hepatic, or endocrine disorders; depression; and peptic ulcer disease. Safe use in pregnancy has not been established. Bromocriptine is an ergot derivative and therefore is contraindicated in people who are hypersensitive to ergot alkaloids or who have uncontrolled hypertension. Entacapone, rasagiline, rotigotine-transdermal, selegiline, and tolcapone are contraindicated in people with hypersensitivity reactions to the drugs. Rasagiline is also contraindicated with foods containing tyramine or sympathomimetic amine-containing medications (e.g., nonprescription cold/cold preparations and anesthetics) due to the risk of hypertensive crisis and with antidepressants (e.g., tricyclics, SSRIs, SNRIs, mirtazapine), meperidine, and dextromethorphan due to the potential for inducing serotonin syndrome. Rotigotine-transdermal is contraindicated in patients with hypersensitivity to sulfites; this may be more common in patients who also have asthma. Tolcapone is also contraindicated in patients with liver disease.

**Figure 12-1** ■ Mechanisms by which dopaminergic drugs increase dopamine in the brain. AADC, amino acid decarboxylase; COMT, catechol-O-methyltransferase; MAO-B, monoamine oxidase B.

## Anticholinergic Drugs

Anticholinergic drugs are discussed in Chapter 20 and are described here only in relation to their use in the treatment of Parkinson's disease. Only anticholinergic drugs that are centrally active (i.e., those that penetrate the blood–brain barrier) are useful in treating parkinsonism. Atropine and scopolamine are centrally active but are not used because of a high incidence of adverse reactions. In addition to the primary anticholinergic drugs, an antihistamine (diphenhydramine) is used for parkinsonism because of its strong anticholinergic effects.

### Mechanism of Action

Anticholinergic drugs decrease the effects of acetylcholine. This decreases the relative excess of acetylcholine in relation to the amount of dopamine that occurs in Parkinson's disease.

### Indications for Use

Anticholinergic drugs are used in idiopathic parkinsonism to decrease salivation, spasticity, and tremors. They are used primarily in people who have minimal symptoms or who cannot tolerate levodopa, or in combination with other antiparkinson drugs. Anticholinergic drugs are usually not effective for bradykinesia or other symptoms of Parkinson's disease. Anticholinergic agents also are used to relieve symptoms of secondary parkinsonism (extrapyramidal reaction) that can occur with the use of antipsychotic drugs. If used for this purpose, a course of therapy of approximately 3 months is recommended because symptoms usually subside by then, even if the antipsychotic drug is continued.

### Contraindications to Use

Because anticholinergic drugs can increase intraocular pressure, due to mydriasis and cycloplegia, they are contraindicated

in patients with glaucoma. Anticholinergic drugs are contraindicated in gastrointestinal (GI) obstruction, prostatic hypertrophy, and urinary bladder-neck obstruction due to their effect on smooth muscle and sphincter tone. Anticholinergic drugs are contraindicated in myasthenia gravis, because blockade of acetylcholine receptor sites at neuromuscular synapses exacerbates muscle weakness. The drugs must be used cautiously in patients with cardiovascular disorders (e.g., tachycardia, dysrhythmias, and hypertension) because parasympathetic blockade may allow a harmful increase in sympathetic dominance. Anticholinergic drugs must be used cautiously in the presence of liver or kidney disease. Because acetylcholine is an important neurotransmitter with regard to memory function, these drugs must be used with caution in elderly patients with pre-existing cognitive impairments.

## Individual Antiparkinson Drugs

Dopaminergic antiparkinson drugs are described in this section. See Chapter 20 for further discussion of individual anticholinergic drugs. Trade names, routes, and dosage ranges for both dopaminergic and anticholinergic agents commonly used to treat Parkinson's disease are listed in Table 12-1. A discussion of nutritional supplements and botanicals that have been suggested to have beneficial effects on parkinsonism are dis-

## Evidence-Based Practice

### 12-1 Nutritional and Botanical Alternative Therapies for Parkinson's Disease

Several nutritional supplements and botanicals have been suggested to have beneficial effects on parkinsonism. Among these are the antioxidant vitamin E, which has been proposed as a neuroprotectant because of its antioxidant properties; *Mucuna puriens*, a legume and a rich natural source of vitamin E; and coenzyme Q<sub>10</sub>, also known as ubiquinone, a cofactor in the synthesis of adenosine triphosphate (ATP). In a guideline entitled, "Practice parameter: Neuroprotective strategies and alternative therapies for Parkinson disease (an evidence-based review)," the Quality Standards Subcommittee of the American Academy of Neurology reviewed the evidence and made recommendations regarding several supplements and botanical treatments. This guideline, published in 2006, included the following treatment recommendations:

- Treatment with 2000 units of vitamin E should not be considered for neuroprotection (Level B) or symptomatic treatment of Parkinson's disease (Level B).
- There is insufficient evidence to support or refute the use of coenzyme Q<sub>10</sub> for neuroprotection (Level U).
- There is insufficient evidence to support or refute the use of *Mucuna puriens* for the treatment of motor symptoms of Parkinson's disease (Level U).

For complete guidelines regarding alternative therapies for Parkinson's disease, please consult National Guideline Clearinghouse at [www.guideline.gov](http://www.guideline.gov)

Table 12-1

## Drugs at a Glance: Antiparkinson Drugs

GENERIC/TRADE NAME	ROUTES AND DOSAGE RANGES
<b>Dopaminergic Agents</b>	
<b>P Levodopa</b>	PO 0.5–1 g/d initially in 3 or 4 divided doses, increase gradually by no more than 0.75 g/d, every 3–7 d. The rate of dosage increase depends mainly on the client's tolerance of adverse effects, especially nausea and vomiting. Average maintenance dose, 3–6 g/d; maximum dose, 8 g/d. Dosage must be reduced when carbidopa is also given (see carbidopa, below).
<b>Carbidopa (Lodosyn)</b>	PO 70–100 mg/d, depending on dosage of levodopa; maximum dose, 200 mg/d
<b>Levodopa/carbidopa (Sinemet)</b>	<i>Patients not receiving levodopa:</i> PO 1 tablet of 25 mg carbidopa/100 mg levodopa 3 times daily or 1 tablet of 10 mg carbidopa/100 mg levodopa 3 or 4 times daily, increased by 1 tablet every day or every other day until a dosage of 8 tablets daily is reached <i>Sinemet CR</i> PO 1 tablet twice daily at least 6 h apart initially, increased up to 8 tablets daily and q4h intervals if necessary <i>Patients receiving levodopa:</i> Discontinue levodopa at least 8 h before starting Sinemet. PO 1 tablet of 25 mg carbidopa/250 mg levodopa 3 or 4 times daily for clients taking >1500 mg levodopa or 1 tablet of 25 mg carbidopa/100 mg levodopa for clients taking <1500 mg levodopa
<b>Levodopa/carbidopa/entacapone (Stalevo)</b>	Patients already taking the drugs separately can be switched to the combination tablet containing an equivalent amount of each drug. For patients taking >600 mg levodopa daily when starting entacapone, dosage should be titrated and stabilized with the individual drugs before using the combination product. Patients taking <600 mg levodopa daily may be started directly on the corresponding dosage of Stalevo, but levodopa dosage may need to be reduced.

GENERIC/TRADE NAME	ROUTES AND DOSAGE RANGES
<b>Amantadine</b> (Symmetrel)	PO 100 mg twice a day
<b>Bromocriptine</b> (Parlodel)	PO 1.25 mg twice a day with meals, increased by 2.5 mg/d every 2–4 wk if necessary for therapeutic benefit. Reduce dose gradually if severe adverse effects occur.
<b>Entacapone</b> (Comtan)	PO 200 mg with each dose of levodopa/carbidopa, up to 8 times (1600 mg) daily
<b>Pramipexole</b> (Mirapex)	PO wk 1, 0.125 mg 3 times daily; wk 2, 0.25 mg 3 times daily; wk 3, 0.5 mg 3 times daily; wk 4, 0.75 mg 3 times daily; wk 5, 1 mg 3 times daily; wk 6, 1.25 mg 3 times daily; wk 7, 1.5 mg 3 times daily Renal impairment: Creatinine clearance (Crcl) > 60 mL/min, 0.125 mg 3 times daily initially, up to a maximum of 1.5 mg 3 times daily; Crcl 35–59 mL/min, 0.125 mg 2 times daily initially, up to a maximum of 1.5 mg 2 times daily; Crcl 15–34 mL/min, 0.125 mg once daily, up to a maximum of 1.5 mg once daily
<b>Rasagiline</b> (Azilect)	PO 1 mg/d. When combined with levodopa, the starting dose is 0.5 mg/d and may be increased to 1 mg/d if necessary.
<b>Ropinirole</b> (Requip)	PO wk 1, 0.25 mg 3 times daily; wk 2, 0.5 mg 3 times daily; wk 3, 0.75 mg 3 times daily; wk 4, 1 mg 3 times daily
<b>Rotigotine-transdermal</b> (Neupro)	TDS: 2 mg/24 h initially, increase in weekly increments of 2 mg/24 h up to a maximum dose of 8 mg/24 h.
<b>Selegiline</b> (Eldepryl)	PO 5 mg twice daily, morning and noon
<b>Anticholinergic Agents</b>	
<b>Benzotropine</b> (Cogentin)	PO 0.5–1 mg at bedtime initially, gradually increased to 4–6 mg daily if necessary
<b>Diphenhydramine</b> (Benadryl)	PO 25 mg 3 times daily, gradually increased to 50 mg 4 times daily if necessary Adults: Drug-induced extrapyramidal reactions, IM, IV 10–50 mg; maximal single dose, 100 mg; maximal daily dose, 400 mg Children: Drug-induced extrapyramidal reactions, IM 5 mg/kg per day; maximal daily dose, 300 mg
<b>Trihexyphenidyl</b> (Trihexy)	PO 1–2 mg daily initially, gradually increased to 12–15 mg daily, until therapeutic or adverse effects occur Adults: Drug-induced extrapyramidal reactions, PO 1 mg initially, gradually increased to 5–15 mg daily if necessary

TDS, transdermal delivery system.

cussed in Evidence-Based Practice Box 12-1. No supplements are currently recommended by the American Academy of Neurology practice guidelines.

**P Levodopa** is the most effective drug available for the treatment of Parkinson's disease. It relieves all major symptoms, especially bradykinesia and rigidity. Levodopa does not alter the underlying disease process, but it may improve a patient's quality of life.

Levodopa acts to replace dopamine in the basal ganglia of the brain. Dopamine cannot be used for replacement therapy because it does not penetrate the blood–brain barrier. Levodopa readily penetrates the CNS and is converted to dopamine by the enzyme amino acid decarboxylase (AADC). The dopamine is stored in presynaptic dopaminergic neurons and functions like endogenous dopamine. In advanced stages of Parkinson's disease, there are fewer dopaminergic neurons and thus less storage capacity for dopamine derived from levodopa. As a result, levodopa has a shorter duration of action and drug effects “wear off” between doses or during duration of action (“off-time”), resulting in sudden fluctuations in symptoms including severe hypomobility (freezing). Apomorphine

injection is a non-ergot dopamine agonist approved for acute intermittent treatment of these sudden episodic symptoms. Similar to other opioids, apomorphine may cause nausea and vomiting and should be administered concurrently with the antiemetic, trimethobenzamide. Due to the occurrence of hypotension and loss of consciousness, apomorphine should not be given with 5-HT<sub>3</sub> antagonists (e.g., ondansetron, granisetron, dolasetron, palonosetron, and alosetron). In peripheral tissues (e.g., GI tract, liver), levodopa is metabolized extensively by AADC and to a lesser extent by COMT. Because most levodopa is metabolized in peripheral tissues, large doses are required to obtain therapeutic levels of dopamine in the brain. These large amounts increase adverse drug effects. To reduce levodopa dosage and decrease adverse effects, carbidopa, an AADC inhibitor, is given to decrease the peripheral metabolism of levodopa. The combination of levodopa and carbidopa greatly increases the amount of available levodopa, so that levodopa dosage can be reduced by approximately 70%. The two drugs are usually given together in a fixed-dose formulation called Sinemet. When carbidopa inhibits the decarboxylase pathway of levodopa metabolism,

the COMT pathway becomes more important (see entacapone and tolcapone, COMT inhibitors, below). A newer product, Stalevo, combines levodopa, carbidopa, and entacapone to further decrease metabolism of levodopa.

Levodopa is well absorbed from the small intestine after oral administration, reaches peak serum levels within 30 to 90 minutes, and has a short serum half-life (1–3 hours). Absorption is decreased by delayed gastric emptying, hyperacidity of gastric secretions, and competition with amino acids (from digestion of protein foods) for sites of absorption in the small intestine. Pyridoxine (vitamin B<sub>6</sub>) promotes the breakdown of levodopa, reducing its effectiveness. Levodopa is metabolized to 30 or more metabolites, some of which are pharmacologically active and probably contribute to drug toxicity; the metabolites are excreted primarily in the urine, usually within 24 hours.

Because of adverse effects and recurrence of parkinsonian symptoms after a few years of levodopa therapy, levodopa is usually reserved for patients with significant symptoms and functional disabilities. In addition to treating Parkinson's disease, levodopa also may be useful in other CNS disorders in which symptoms of parkinsonism occur (e.g., juvenile Huntington's chorea, chronic manganese poisoning). Levodopa relieves only parkinsonian symptoms in these conditions.

### Applying Your Knowledge 12-1

Mrs. Sung tells you that she has a friend who takes her medication for Parkinson's disease once a day, and questions you why she must take her medication more than once a day. What is the most appropriate response?

.....

**Carbidopa** (Lodosyn) inhibits the enzyme AADC. As a result, less levodopa is decarboxylated in peripheral tissues; more levodopa reaches the brain, where it is decarboxylated to dopamine; and much smaller doses of levodopa can be given. Carbidopa does not penetrate the blood–brain barrier. Although carbidopa is available alone, it is most often given in the levodopa/carbidopa fixed-dose combination product, Sinemet.

**Amantadine** (Symmetrel) increases the release and inhibits the reuptake of dopamine in the brain, thereby increasing dopamine levels. The drug relieves symptoms rapidly, within 1 to 5 days, but it loses efficacy with 6 to 8 weeks of continuous administration. Consequently, it is usually given for 2- to 3-week periods during initiation of drug therapy with longer-acting agents (e.g., levodopa) or when symptoms worsen. Amantadine is often given with levodopa. Compared with other antiparkinson drugs, amantadine is considered less effective than levodopa but more effective than anticholinergic agents.

Amantadine is well absorbed from the GI tract and has a relatively long duration of action. It is excreted unchanged in the urine. Dosage must be reduced with impaired renal function to avoid drug accumulation.

**Bromocriptine** (Parlodel) is an ergot derivative that directly stimulates dopamine receptors in the brain. It is used

in the treatment of idiopathic Parkinson's disease, with levodopa/carbidopa, to prolong effectiveness and allow reduced dosage of levodopa. Cabergoline is a synthetic ergot long-acting dopamine agonist, approved by the FDA for use in hyperprolactinemia. An unlabeled use of this medication has been to improve motor symptoms of parkinsonism; however, the higher dosage required to treat parkinsonism is associated with increased risk for the development of serious heart valve damage due to fibrosis. Another ergot dopamine agonist, pergolide (Permax), was removed from the market for similar adverse effects on heart valves.

**Entacapone** (Comtan) and **tolcapone** (Tasmar) are COMT inhibitors. COMT plays a role in brain metabolism of dopamine and metabolizes approximately 10% of peripheral levodopa. By inhibiting COMT, entacapone and tolcapone increase levels of dopamine in the brain and relieve symptoms more effectively and consistently. Although the main mechanism of action seems to be inhibiting the metabolism of levodopa in the bloodstream, the drugs may also inhibit COMT in the brain and prolong the activity of dopamine at the synapse. These drugs are used only in conjunction with levodopa/carbidopa, and dosage of levodopa must be reduced.

Entacapone is well absorbed with oral administration and reaches a peak plasma level in 1 hour. It is highly protein bound (98%), has a half-life of about 2.5 hours, and is metabolized in the liver to an inactive metabolite. Dosage must be reduced by 50% in the presence of impaired liver function. The parent drug and the metabolite are 90% excreted through the biliary tract and feces; 10% is excreted in the urine. Adverse effects include confusion, dizziness, drowsiness, hallucinations, nausea, and vomiting. These can be reduced by lowering the dose of either levodopa or entacapone. Although there were few instances of liver enzyme elevation or hemoglobin decreases during clinical trials, it is recommended that liver enzymes and red blood cell counts be done periodically.

Tolcapone is also well absorbed with oral administration. Its elimination half-life is 2 to 3 hours, and it is metabolized in the liver. During clinical trials, diarrhea was a common adverse effect. Because of several reports of liver damage and deaths from liver failure, the FDA has issued a **BLACK BOX WARNING**. Tolcapone should be used only in patients who do not respond to other drugs. When used, liver aminotransferase enzymes (serum alanine aminotransferase [ALT] and aspartate aminotransferase [AST]) should be monitored every 2 weeks for 1 year, then every 4 weeks for 6 months, then every 2 months. Tolcapone should be discontinued if ALT and AST are elevated, if symptoms of liver failure occur (anorexia, abdominal tenderness, dark urine, jaundice, clay-colored stools), or if parkinsonian symptoms do not improve after 3 weeks of taking tolcapone.

**Pramipexole** (Mirapex), **ropinirole** (Requip), and **rotigotine-transdermal** (Neupro) stimulate dopamine receptors in the brain. They are approved for both beginning and advanced stages of Parkinson's disease. In early stages, one of these drugs can be used alone to improve motor performance, improve ability to participate in usual activities of daily living, and

delay levodopa therapy. In advanced stages, one of these drugs can be used with levodopa and perhaps other antiparkinson drugs to provide more consistent relief of symptoms between doses of levodopa and allow reduced dosage of levodopa. These drugs are not ergot derivatives and may not cause some adverse effects associated with bromocriptine (e.g., pulmonary and peritoneal fibrosis, constriction of coronary arteries).

Pramipexole is rapidly absorbed with oral administration. Peak serum levels are reached in 1 to 3 hours after a dose and steady-state concentrations in about 2 days. It is less than 20% bound to plasma proteins and has an elimination half-life of 8 to 12 hours. Most of the drug is excreted unchanged in the urine; only 10% of the drug is metabolized. As a result, renal failure may cause higher-than-usual plasma levels and possible toxicity, but hepatic disease is unlikely to alter drug effects.

Ropinirole is also well absorbed with oral administration. It reaches peak serum levels in 1 to 2 hours and steady-state concentrations within 2 days. It is 40% bound to plasma proteins and has an elimination half-life of 6 hours. It is metabolized by the cytochrome P450 enzymes in the liver to inactive metabolites, which are excreted through the kidneys. Less than 10% of ropinirole is excreted unchanged in the urine. Thus, liver failure may decrease metabolism, allow drug accumulation, and increase adverse effects. Renal failure does not appear to alter drug effects.

Rotigotine is the first transdermal system to treat early idiopathic Parkinson's disease. The 24-hour duration of the transdermal system offers extended symptom control and significantly decreases the amount of "off-time". Onset of action is 1 to 3 hours after placing the patch, with peak action at 15 to 18 hours. The most common side effects reported include application site reactions, somnolence, nausea and vomiting, and dizziness.

**Selegiline** (Eldepryl) inhibits metabolism of dopamine by monoamine oxidase (MAO), which exists in two types, MAO-A and MAO-B, both of which are found in the CNS and peripheral tissues. They are differentiated by their relative specificities for individual catecholamines. MAO-A acts more specifically on tyramine, norepinephrine, epinephrine, and serotonin. This enzyme is the main subtype in GI mucosa and in the liver and is responsible for metabolizing dietary tyramine. If MAO-A is inhibited in the intestine, tyramine in various foods is absorbed systemically rather than deactivated. As a result, there is excessive stimulation of the sympathetic nervous system and severe hypertension and stroke can occur. This is sometimes called the "cheese reaction" because aged cheeses are high in tyramine. This life-threatening reaction can also occur with some medications (e.g., sympathomimetics) that are normally metabolized by MAO. MAO-B metabolizes dopamine; in the brain, most MAO activity is due to type B. At oral dosages of 10 milligrams per day or less, selegiline inhibits MAO-B *selectively* and is unlikely to cause severe hypertension and stroke. However, at dosages greater than 10 milligrams per day, selectivity is lost and metabolism of both MAO-A and MAO-B is inhibited. Dosages greater than 10 milligrams per day should be avoided in patients with Parkin-

son's disease. Selegiline inhibition of MAO-B is irreversible, and drug effects persist until more MAO is synthesized in the brain, which may take several months.

In early Parkinson's disease, selegiline may be effective as monotherapy (Level A). In advanced disease, it is given to enhance the effects of levodopa. Its addition aids symptom control and allows the dosage of levodopa/carbidopa to be reduced. Once proposed to have neuroprotective properties, it is now believed that there is insufficient evidence to recommend the use of selegiline to confer neuroprotection in patients with Parkinson's disease (Level U).

**Rasagiline** is the newest irreversible MAO inhibitor. It is indicated for initial treatment for idiopathic parkinsonism and as an adjunct therapy with levodopa to reduce "off time" when movements are poorly controlled. Because it has not been determined to be selective for MAO-B in humans, care must be taken to avoid tyramine-containing foods as well as sympathomimetic medications to prevent hypertensive crisis. In addition, rasagiline has the potential to increase serotonin neurotransmission. When given with other drugs that enhance stimulation of serotonergic receptors (e.g., antidepressants, St. John's wort, dextromethorphan, and meperidine), serotonin syndrome, a potential fatal CNS toxicity reaction characterized by hyperpyrexia and death, can occur. Rasagiline should be discontinued at least 14 days before beginning treatment with most antidepressants or other MAO inhibitors. Fluoxetine should be discontinued at least 5 weeks before initiating rasagiline, due to its long half-life. Rasagiline is well absorbed orally, metabolized in the liver, and excreted primarily by the kidney.

## Nursing Process

### Assessment

Assess for signs and symptoms of Parkinson's disease and drug-induced extrapyramidal reactions. These may include the following, depending on the severity and stage of progression.

- Slow movements (bradykinesia) and difficulty in changing positions, assuming an upright position, eating, dressing, and other self-care activities
- Stooped posture
- Accelerating gait with short steps
- Tremor at rest (e.g., "pill rolling" movements of fingers)
- Rigidity of arms, legs, and neck
- Mask-like, immobile facial expression
- Speech problems (e.g., low volume, monotonous tone, rapid, difficult to understand)
- Excessive salivation and drooling
- Dysphagia
- Excessive sweating
- Constipation from decreased intestinal motility
- Mental depression from self-consciousness and embarrassment over physical appearance and activity limitations.

*Nursing Process continues on page 224*

The intellect is usually intact until the late stages of the disease process.

## Nursing Diagnoses

- Bathing/Grooming Self-Care Deficit related to tremors and impaired motor function
- Impaired Physical Mobility related to alterations in balance and coordination
- Deficient Knowledge: Safe usage and effects of anti-parkinson drugs
- Imbalanced Nutrition: Less Than Body Requirements related to difficulty in chewing and swallowing food

## Planning/Goals

### The patient will

- Experience relief of excessive salivation, muscle rigidity, spasticity, and tremors
- Experience improved motor function, mobility, and self-care abilities
- Increase knowledge of the disease process and drug therapy
- Take medications as instructed
- Avoid falls and other injuries from the disease process or drug therapy.

## Interventions

Use measures to assist the patient and family in coping with symptoms and maintaining function. These include the following:

- Provide physical therapy for heel-to-toe gait training; widening stance to increase balance and base of support; other exercises.
- Encourage ambulation and frequent changes of position, assisted if necessary.
- Help with active and passive range-of-motion exercises.
- Encourage self-care as much as possible. Cutting meat; opening cartons; giving frequent, small meals; and allowing privacy during mealtime may be helpful. If the client has difficulty chewing or swallowing, chopped or soft foods may be necessary. Hook-and-loop-type fasteners or zippers are easier to handle than buttons. Slip-on shoes are easier to manage than laced ones.
- Spend time with the patient and encourage socialization with other people. Victims of Parkinson's disease tend to become withdrawn, isolated, and depressed.
- Schedule rest periods. Tremor and rigidity are aggravated by fatigue and emotional stress.
- Provide facial tissues if drooling is a problem.
- Provide appropriate patient teaching related to drug therapy (see accompanying display).

## Evaluation

- Interview and observe for relief of symptoms.
- Interview and observe for increased mobility and participation in activities of daily living.
- Interview and observe regarding correct usage of medications

## Patient Teaching Guidelines Antiparkinson Drugs

### General Considerations

- Beneficial effects of antiparkinson drugs may not occur for a few weeks; do not stop taking the drugs before they have had a chance to work.
- Do not take other drugs without the physician's knowledge and consent. This is necessary to avoid adverse drug interactions. Prescription and nonprescription drugs may interact with antiparkinson drugs to increase or decrease effects.
- Avoid driving an automobile or operating other potentially hazardous machinery if vision is blurred or drowsiness occurs with levodopa.
- Change positions slowly, especially when assuming an upright position, and wear elastic stockings, if needed, to prevent dizziness from a drop in blood pressure.
- Pathologic gambling, increased libido, and hypersexuality have been reported with dopamine agonist medications.

### Self- or Caregiver Administration

- Take antiparkinson drugs with or just after food to prevent or reduce anorexia, nausea, and vomiting.
- Do not crush or chew levodopa/carbidopa Sinemet CR. It is formulated to be released slowly; crushing or chewing destroys this feature.

- Take or give selegiline in the morning and at noon. This schedule decreases stimulating effects that may interfere with sleep if the drug is taken in the evening.
- Take or give entacapone with each dose of levodopa/carbidopa, up to 8 times daily.
- Decrease excessive mouth dryness by maintaining an adequate fluid intake (2000–3000 mL daily if not contraindicated) and using sugarless chewing gum and hard candies. Both anticholinergics and levodopa may cause mouth dryness. This is usually a therapeutic effect in Parkinson's disease. However, excessive mouth dryness causes discomfort and dental caries.
- Report adverse effects. Adverse effects can often be reduced by changing drugs or dosages. However, some adverse effects usually must be tolerated for control of disease symptoms.
- With rotigotine-transdermal, apply to clean dry intact-skin on abdomen, thigh, hip, flank, shoulder or upper arm. Rotate sites and do not reuse a site in less than 14 days. If shaving is necessary, wait 3 days to use the site. If the patch comes off, reapply to a fresh site.
- Remove rotigotine-transdermal patch before an MRI or cardioversion to avoid skin burns.

## Applying Your Knowledge 12-2

Because Mrs. Sung was admitted following a fall and is experiencing many of the typical symptoms of a person with Parkinson's disease, she may be having ongoing difficulty with ambulation. What referral should you initiate to improve her safety?

## Principles of Therapy

### Goals of Therapy

Antiparkinson drugs aim to control symptoms, maintain functional ability in activities of daily living, minimize adverse drug effects, and slow disease progression.

### Drug Selection

Choices of antiparkinson drugs depend largely on the type of parkinsonism (e.g., idiopathic or drug induced) and the severity of symptoms. In addition, because of difficulties with levodopa therapy (e.g., adverse effects, loss of effectiveness in a few years, possible acceleration of the loss of dopaminergic neurons in the brain), several drug therapy strategies and combinations are used to delay the start of levodopa therapy and, after it is started, to reduce levodopa dosage. Whenever possible, drug selection should be evidence based.

- For secondary parkinsonism, an anticholinergic agent is usually recommended; however, amantadine is also effective.
- For early idiopathic parkinsonism, when symptoms and functional disability are relatively mild, several drugs may be used in monotherapy. Selegiline may be considered as initial symptomatic treatment prior to beginning therapy with other dopaminergic agents (Level A).
- Amantadine may be used with patients with motor fluctuations for reducing dyskinesia (Level C). An anticholinergic agent may also be effective, relieving tremor in approximately 50% of patients.
- Either levodopa or a dopamine agonist may be prescribed as the initial dopaminergic agent in the treatment of Parkinson's disease. Levodopa is a better choice for improving motor disability, but dopamine agonists are better at lessening motor complications (Level A).
- For advanced idiopathic parkinsonism, a combination of medications is used. Two advantages of combination therapy are better control of symptoms and reduced dosage of individual drugs.
- The following recommendations are for reducing "off-time". Entacapone and rasagiline may be prescribed to reduce "off-time" with levodopa therapy (Level A). Pramipexole, ropinirole, and tolcapone can also be considered to reduce "off-time" (Level B); however, tolcapone requires careful monitoring for liver failure. Apomorphine, cabergoline (off-

label use), and selegiline may be considered to reduce "off-time" (Level C). Rotigotine has been shown to significantly reduce "off-time" over a sustained 24-hour transdermal delivery of medication. Sustained-release carbidopa/levodopa and bromocriptine may be disregarded to reduce "off-time" (Level C). There is no difference in the rate of motor complications between intermediate-release levodopa and sustained-release levodopa formulations when initiating levodopa therapy (Level B).

- An anticholinergic agent may be given with levodopa alone or with a levodopa/carbidopa combination.
- Amantadine may be given in combination with levodopa or other antiparkinson agents.
- A dopamine agonist is usually given with levodopa/carbidopa. The combination provides more effective relief of symptoms and allows lower dosage of levodopa. Although available dopamine agonists are similarly effective, pramipexole, ropinirole, and rotigotine-transdermal cause less severe adverse effects than ergots such as bromocriptine.
- The levodopa/carbidopa combination is probably the most effective drug when bradykinesia and rigidity become prominent. However, because levodopa becomes less effective after approximately 5 to 7 years, many clinicians use other drugs first and reserve levodopa for use when symptoms become more severe.
- Selegiline may be given with levodopa/carbidopa and with entacapone, because selegiline acts in the brain and entacapone acts peripherally.
- Entacapone is used only with levodopa/carbidopa; simultaneous administration of carbidopa and entacapone significantly increases the plasma half-life of levodopa. (Stalevo is a newer product that combines levodopa, carbidopa, and entacapone.)
- Tolcapone should be used only when other drugs are ineffective, because of its association with liver failure.
- Rasagiline may be used as monotherapy or as an adjunct to levodopa.
- When changes are made in a drug therapy regimen, one change at a time is recommended so that effects of the change are clear.

### Drug Dosage

The dosage of antiparkinson drugs is highly individualized. The general rule is to start with low initial dosage and gradually increase it until therapeutic effects, adverse effects, or maximum drug dosage is achieved. Additional guidelines include the following:

- The optimal dose is the lowest one that allows the patient to function adequately. Optimal dosage may not be established for 6 to 8 weeks with levodopa.
- Dosages need to be adjusted as parkinsonism progresses.
- Dosage must be individualized for levodopa and carbidopa. Only 5% to 10% of a dose of levodopa reaches the CNS,

even with the addition of carbidopa. When carbidopa is given with levodopa, the dosage of levodopa must be reduced by approximately 75%. A daily dose of approximately 70 to 100 milligrams of carbidopa is required to saturate peripheral AADC. At least 12 hours should elapse between the last dose of levodopa and initiation of carbidopa/levodopa therapy to avoid drug toxicity.

- A levodopa/carbidopa combination is available in three dosage formulations (10 mg carbidopa/100 mg levodopa, 25 mg carbidopa/100 mg levodopa, and 25 mg carbidopa/250 mg levodopa) of immediate-release tablets (Sinemet) and two dosage formulations (25 mg carbidopa/100 mg levodopa, 50 mg carbidopa/200 mg levodopa) of sustained-release tablets (Sinemet CR). Various preparations can be mixed to administer optimal amounts of each ingredient. Sinemet CR is not as well absorbed as the short-acting form, and a patient being transferred to Sinemet CR needs a dosage increase of approximately one third.
- With levodopa, dosage should be gradually increased to the desired therapeutic level. In addition, therapeutic effects may be increased and adverse effects decreased by frequent administration of small doses.
- With pramipexole, ropinirole, and rotigotine-transdermal, dosage is started at low levels and gradually increased over several weeks. When the drugs are discontinued, they should be tapered in dosage over 1 week. With pramipexole, lower doses are indicated in older adults and those with renal impairment; with ropinirole and rotigotine-transdermal lower doses may be needed with hepatic impairment.
- Entacapone (200 mg) should be taken with each dose of levodopa (up to 8 times per day). Each tablet of Stalevo contains 200 milligrams of entacapone along with various amounts of levodopa and carbidopa.
- When combinations of drugs are used, dosage adjustments of individual components are often necessary. When levodopa is added to a regimen of anticholinergic drug therapy, for example, the anticholinergic drug need not be discontinued or reduced in dosage. However, when a dopaminergic drug is added to a regimen containing levodopa/carbidopa, dosage of levodopa/carbidopa must be reduced.
- Rasagiline may be used as monotherapy or as an adjunct with levodopa. When used with levodopa, reduced dosages of both rasagiline and levodopa are indicated. In the presence of mild liver dysfunction or concurrent therapy with ciprofloxacin or other CYP1A2 inhibitors, rasagiline dosage should be reduced by half.

### Applying Your Knowledge 12-3

#### How Can You Avoid This Medication Error?

The physician writes a drug order for levodopa/carbidopa 25/100. The pharmacy supplies Sinemet CR 25/100 and you administer the medication.

## Use in Special Populations

### Use in Children

Safety and effectiveness for use in children have not been established for most antiparkinson drugs, including the centrally acting anticholinergics (all ages), levodopa (<12 years), and bromocriptine (<15 years). Because parkinsonism is a degenerative disorder of adults, antiparkinson drugs are most likely to be used in children for other purposes, anticholinergics are sometimes given to children who have drug-induced extrapyramidal reactions.

### Use in Older Adults

Dosage of amantadine may need to be reduced because the drug is excreted mainly through the kidneys, and renal function is usually decreased in older adults. Dosage of levodopa/carbidopa may need to be reduced because of an age-related decrease in peripheral AADC, the enzyme that carbidopa inhibits.

Anticholinergic drugs may cause blurred vision, dry mouth, tachycardia, and urinary retention. They also decrease sweating and may cause fever or heatstroke. Fever may occur in any age group, but heatstroke is more likely to occur in older adults, especially with cardiovascular disease, strenuous activity, and high environmental temperatures. When centrally active anticholinergics are given for Parkinson's disease, agitation, mental confusion, hallucinations, and psychosis may occur. Many other drugs in addition to the primary anticholinergics have significant anticholinergic activity, such as some antihistamines in over-the-counter cold remedies and sleep aids, tricyclic antidepressants, and phenothiazine antipsychotic drugs. When anticholinergic drugs are needed in older adults, dosage should be minimized, combinations of drugs with anticholinergic effects should be avoided, and patients should be closely monitored for adverse drug effects.

Older patients are at increased risk of having hallucinations with dopamine agonist drugs. Pramipexole dosage may need to be reduced in older adults with impaired renal function. Changes in the skin of patients over the age of 80 may result in increased absorption and higher blood levels of rotigotine-transdermal.

### Use in Patients With Renal Impairment

With amantadine, excretion is primarily via the kidneys, and the drug should be used with caution in patients with renal failure. With pramipexole, clearance is reduced in patients with moderate or severe renal impairment, and lower initial and maintenance doses are recommended. With ropinirole, rotigotine-transdermal, and entacapone, no dosage adjustments are needed for renal impairment.

### Use in Patients With Hepatic Impairment

With ropinirole and rasagiline, cautious use in patients with hepatic impairment is warranted, and dosage may need to be reduced. Reduced dosages of rotigotine-transdermal are indicated with severe hepatic impairment. With tolcapone, ele-

vated liver enzymes and deaths from liver failure have been reported, prompting a **BLACK BOX WARNING** by the FDA regarding the potential for acute liver failure. Tolcapone therapy should not be initiated for any individual with liver disease or elevated liver enzymes. Liver transaminase enzymes should be monitored frequently on the schedule previously described. The drug should be withdrawn and not reinstated at the earliest sign of liver dysfunction. With entacapone periodic measurements of liver transaminase enzymes are recommended, although liver failure has not been associated with this drug.

### Use in Home Care

The home care nurse can help patients and caregivers understand that the purpose of drug therapy is to control symptoms and that noticeable improvement may not occur for several weeks. Also, the nurse can encourage patients to consult physical therapists, speech therapists, and dietitians to help maintain their ability to perform activities of daily living. In addition, teaching about preventing or managing adverse drug effects may be necessary. Caregivers may need to be informed that most activities (e.g., eating, dressing) take longer and require considerable effort by patients with parkinsonism.

## Nursing Actions Antiparkinson Drugs

### NURSING ACTIONS

#### 1. Administer accurately

- a. Give most antiparkinson drugs with or just after food; entacapone can be given without regard to meals.
- b. Do not crush Sinemet CR and instruct clients not to chew the tablet.
- c. Do not give levodopa with iron preparations or multivitamin–mineral preparations containing iron.
- d. Give selegiline in the morning and at noon.
- e. Give entacapone with each dose of levodopa/carbidopa, up to 8 times daily.  
Apply rotigotine-transdermal system to clean dry intact skin on abdomen, thigh, hip, flank, shoulder, or upper arm. Rotate sites & do not reuse a site in less than 14 days. Wait 3 days to use a site if shaving is necessary.

#### 2. Observe for therapeutic effects

- a. With anticholinergic agents, observe for decreased tremor, salivation, drooling, and sweating.
- b. With levodopa and dopaminergic agents, observe for improvement in mobility, balance, posture, gait, speech, handwriting, and self-care ability. Drooling and seborrhea may be abolished, and mood may be elevated.

#### 3. Observe for adverse effects

- a. With anticholinergic drugs, observe for atropine-like effects, such as:
  - (1) Tachycardia and palpitations
  - (2) Excessive CNS stimulation (tremor, restlessness, confusion, hallucinations, delirium)
  - (3) Sedation and drowsiness
  - (4) Constipation, impaction, paralytic ileus

### RATIONALE/EXPLANATION

To prevent or reduce nausea and vomiting

Crushing and chewing destroys the controlled-release feature of the formulation.

Iron decreases absorption of levodopa.

To decrease central nervous system (CNS) stimulating effects that may interfere with sleep if the drug is taken in the evening

These measures promote optimal absorption.

Decreased salivation and sweating are therapeutic effects when these drugs are used in Parkinson's disease, but they are adverse effects when the drugs are used in other disorders.

Therapeutic effects are usually evident within 2–3 weeks, as levodopa dosage approaches 2–3 g/d, but may not reach optimum levels for 6 months.

These effects may occur with usual therapeutic doses but are not likely to be serious except in people with underlying heart disease.

This effect is most likely to occur with large doses of trihexyphenidyl (Trihexy) or benztropine (Cogentin). It may occur with levodopa.

These are most likely to occur with benztropine. The drug has antihistaminic and anticholinergic properties, and sedation is attributed to the antihistamine effect.

These effects result from decreased gastrointestinal motility and muscle tone. They may be severe because decreased intestinal motility and constipation also are characteristics of Parkinson's disease; thus, additive effects may occur.

## Nursing Actions Antiparkinson Drugs (continued)

NURSING ACTIONS	RATIONALE/EXPLANATION
(5) Urinary retention	This reaction is caused by loss of muscle tone in the bladder and is most likely to occur in elderly men who have enlarged prostate glands.
(6) Dilated pupils (mydriasis), blurred vision, photophobia	Ocular effects are due to paralysis of accommodation and relaxation of the ciliary muscle and the sphincter muscle of the iris.
b. With levodopa, observe for:	
(1) Anorexia, nausea, and vomiting	These symptoms usually disappear after a few months of drug therapy. They may be minimized by giving levodopa with food, gradually increasing dosage, administering smaller doses more frequently or adding carbidopa so that dosage of levodopa can be reduced.
(2) Orthostatic hypotension—check blood pressure in both sitting and standing positions q4h while the client is awake.	This effect is common during the first few weeks but usually subsides eventually. It can be minimized by arising slowly from supine or sitting positions and by wearing elastic stockings.
(3) Cardiac dysrhythmias (tachycardia, premature ventricular contractions) and increased myocardial contractility	Levodopa and its metabolites stimulate beta-adrenergic receptors in the heart. People with pre-existing coronary artery disease may need a beta-adrenergic blocking agent (e.g., propranolol) to counteract these effects.
(4) Dyskinesia—involuntary movements that may involve only the tongue, mouth, and face or the whole body	Dyskinesia eventually develops in most people who take levodopa. It is related to duration of levodopa therapy rather than dosage. Carbidopa may heighten this adverse effect, and there is no way to prevent it except by decreasing levodopa dosage. Many people prefer dyskinesia to lowering drug dosage and subsequent return of the parkinsonism symptoms.
(5) CNS stimulation—restlessness, agitation, confusion, delirium	This is more likely to occur with levodopa/carbidopa combination drug therapy.
(6) Abrupt swings in motor function (on–off phenomenon)	This fluctuation may indicate progression of the disease process. It often occurs after long-term levodopa use.
c. With amantadine, observe for:	
(1) CNS stimulation—insomnia, hyperexcitability, ataxia, dizziness, slurred speech, mental confusion, hallucinations	Compared with other antiparkinson drugs, amantadine produces few adverse effects. The ones that occur are mild, transient, and reversible. However, adverse effects increase if daily dosage exceeds 200 mg.
(2) Livedo reticularis—patchy, bluish discoloration of skin on the legs	This is a benign but cosmetically unappealing condition. It usually occurs with long-term use of amantadine and disappears when the drug is discontinued.
d. With bromocriptine, observe for:	
(1) Nausea	These symptoms are usually mild and can be minimized by starting with low doses and increasing the dose gradually until the desired effect is achieved. If adverse effects do occur, they usually disappear with a decrease in dosage.
(2) Confusion and hallucinations	These effects occurred more commonly than others during clinical trials.
(3) Hypotension	
e. With pramipexole and ropinirole, observe for:	
(1) Nausea	
(2) Confusion, hallucinations	
(3) Dizziness, drowsiness	
(4) Dyskinesias	
(5) Orthostatic hypotension	
f. With selegiline, observe for:	
(1) CNS effects—agitation, ataxia, bradykinesia, confusion, dizziness, dyskinesias, hallucinations, insomnia	
(2) Nausea, abdominal pain	
g. With rasagiline observe for:	These effects occurred more commonly than others in clinical trials.
(1) Arthralgia	
(2) Dyspepsia	
(3) Depression	
(4) Orthostatic hypotension	
(5) Flu-like syndrome	

**NURSING ACTIONS**

- h. With entacapone and tolcapone, observe for:
- (1) Anorexia, nausea, vomiting, diarrhea, constipation
  - (2) Dizziness, drowsiness
  - (3) Dyskinesias and dystonias
  - (4) Hallucinations
  - (5) Orthostatic hypotension
- i. With rotigotine-transdermal observe for:
- (1) Skin irritation
  - (2) Nausea and vomiting
  - (3) Somnolence
  - (4) Dizziness
  - (5) Orthostatic hypotension

**4. Observe for drug interactions**

- a. Drugs that *increase* effects of anticholinergic drugs:
- (1) Antihistamines, disopyramide (Norpace), thiothixene (Navane), phenothiazines, and tricyclic antidepressants
- b. Drugs that *decrease* effects of anticholinergic drugs:
- (1) Cholinergic agents
- c. Drugs that *increase* effects of levodopa:
- (1) Amantadine, anticholinergic agents, bromocriptine, carbidopa, entacapone, pramipexole, ropinirole, selegiline, tolcapone, rotigotine-transdermal.
  - (2) Tricyclic antidepressants
  - (3) Monoamine oxidase type A (MAO-A) inhibitors, including isocarboxazid (Marplan), phenelzine (Nardil), and tranylcypromine (Parnate)
- d. Drugs that *decrease* effects of levodopa:
- (1) Anticholinergics
  - (2) Alcohol; benzodiazepines (e.g., diazepam [Valium]); antiemetics; antipsychotics such as phenothiazines, haloperidol (Haldol), and thiothixene (Navane)
  - (3) Oral iron preparations
  - (4) Pyridoxine (vitamin B<sub>6</sub>)
- e. Drugs that *increase* effects of rasagiline:
- (1) Ciprofloxacin

**RATIONALE/EXPLANATION**

These effects occurred more commonly than others during clinical trials.

These effects occurred more commonly than others during clinical trials.

These drugs have anticholinergic properties and produce additive anticholinergic effects.

These drugs counteract the inhibition of gastrointestinal motility and tone, which is a side effect of anticholinergic drug therapy.

These drugs are often used in combination for treatment of Parkinson's disease.

These drugs potentiate levodopa effects and increase the risk of cardiac arrhythmias in people with heart disease. The combination of a catecholamine precursor (levodopa) and MAO-A inhibitors that decrease metabolism of catecholamines can result in excessive amounts of dopamine, epinephrine, and norepinephrine. Heart palpitations, headache, hypertensive crisis, and stroke may occur. Levodopa and MAO-A inhibitors should not be given concurrently. Also, levodopa should not be started within 2 weeks after an MAO-A inhibitor is discontinued. Effects of MAO-A inhibitors persist for 1–2 weeks after their discontinuation.

These effects are unlikely to occur with selegiline, an MAO-B inhibitor, which more selectively inhibits the metabolism of dopamine. However, selectivity may be lost at doses higher than the recommended 10 mg/d. Selegiline is used with levodopa. Rasagiline is also indicated for adjunctive therapy with levodopa.

Although anticholinergics are often given with levodopa for increased antiparkinson effects, they also may decrease effects of levodopa by delaying gastric emptying. This causes more levodopa to be metabolized in the stomach and decreases the amount available for absorption from the intestine.

The mechanisms by which most of these drugs decrease effects of levodopa are not clear. Phenothiazines block dopamine receptors in the basal ganglia. Iron binds with levodopa and reduces levodopa absorption, possibly by as much as 50%.

Pyridoxine stimulates decarboxylase, the enzyme that converts levodopa to dopamine. As a result, more levodopa is metabolized in peripheral tissues, and less reaches the CNS, where antiparkinson effects occur.

Inhibits CYP1A2 enzymes responsible for the metabolism of rasagiline.

## Nursing Actions Antiparkinson Drugs (continued)

### NURSING ACTIONS

- (2) Antidepressants (SSRIs, MAOIs, St. John's wort),  
Dextromethorphan, Meperidine
- f. Drugs that decrease effects of dopaminergic antiparkinson drugs:
- (1) Antipsychotic drugs
  - (2) Metoclopramide (Reglan)

### RATIONALE/EXPLANATION

Combining drugs that enhance serotonin neurotransmission by different mechanisms can result in excessive serotonin neurotransmission, a potentially fatal condition called serotonin syndrome, characterized by CNS toxicity and hyperpyrexia.

Rasagiline should be discontinued 14 days before treatment with any of these drugs. Fluoxetine should be discontinued 5 weeks before treatment with rasagiline due to the long half-life of fluoxetine.

These drugs are dopamine antagonists and therefore inhibit the effects of dopamine agonists.

## Key Concepts

- Parkinsonism is a progressive neurodegenerative disorder characterized by a deficit of dopamine and a relative excess of acetylcholine.
- Classic symptoms of Parkinson's disease include resting tremor, bradykinesia, rigidity, and postural instability.
- Dopaminergic drugs increase dopamine concentrations in the brain, exerting dopaminergic activity, directly or indirectly.
- Dopamine activity can be increased by increasing dopamine release and reducing neuronal reuptake (amantadine), directly stimulating dopamine receptors (apomorphine, bromocriptine, pramipexole, ropinirole, rotigotine-transdermal), replacement of dopamine or its precursor (levodopa), or inhibition of metabolism of dopamine by MAO or COMT enzymes (rasagiline, selegiline, entacapone, tolcapone).
- Carbidopa prevents levodopa breakdown in the periphery, resulting in higher brain concentrations with lower levodopa dosages.
- Anticholinergic drugs (e.g., benztropine, trihexyphenidyl, and diphenhydramine) decrease the effect of acetylcholine in the brain.
- Combinations of antiparkinson drugs are often given to reduce dosages and achieve better control of symptoms.
- Care must be taken to avoid serious food or drug interactions that may diminish treatment effectiveness (levodopa) or be potentially fatal (selegiline and rasagiline).

## Review and Application Exercises

### Short Answer Exercises

1. Which neurotransmitter is deficient in idiopathic and drug-induced parkinsonism?
2. How do the antiparkinson drugs act to alter the level of the deficient neurotransmitter?
3. What are the advantages and disadvantages of the various drugs used to treat parkinsonism?
4. Why is it desirable to delay the start of levodopa therapy and, after it is started, to reduce dosage as much as possible?
5. What is the rationale for various combinations of antiparkinson drugs?

6. What are the major adverse effects of antiparkinson drugs, and how can they be minimized?

### NCLEX-Style Questions

7. A patient's wife has asked the nurse for an explanation of how an imbalance in neurotransmitters in Parkinson's disease affects her husband. The nurse is correct in telling her that the disease is involved in an imbalance of neurotransmitters in which of the following structures?
  - a. basal ganglia
  - b. cerebral cortex
  - c. limbic system
  - d. reticular activating system

8. The nurse is able to explain the use of medications for Parkinson's disease, using core knowledge that the main pathophysiology of Parkinson's disease is a decrease in the brain content of which of the following substances?
  - a. acetylcholine
  - b. serotonin
  - c. glutamate
  - d. dopamine
9. Periodic assessment of a patient with parkinsonism should include which of the following?
  - a. blood tests of liver function
  - b. blood tests of kidney function
  - c. evaluation of mental status
  - d. evaluation of responses to drug therapy
10. The main purpose of combination drug therapy for parkinsonism is to
  - a. stop disease progression
  - b. relieve adverse effects of other drugs
  - c. reduce dosage of levodopa
  - d. delay the need for drug therapy
11. The nurse demonstrates understanding of the use of combination therapy for Parkinson's disease by knowing that carbidopa is usually given along with levodopa because it
  - a. crosses the blood-brain barrier and acts centrally
  - b. inhibits peripheral breakdown of levodopa
  - c. directly stimulates dopamine receptors in the brain
  - d. decreases adverse effects of anticholinergic antiparkinson drugs

## Skeletal Muscle Relaxants

## KEY TERMS

- Clonic
- Malignant hyperthermia
- Muscle spasm
- Spasticity
- Tonic

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Discuss common symptoms and disorders for which skeletal muscle relaxants are used.
2. Differentiate uses and effects of selected skeletal muscle relaxants.
3. Describe nonpharmacologic interventions to relieve muscle spasm and spasticity.
4. Apply the nursing process with patients experiencing muscle spasm or spasticity.

## Applying Your Knowledge

Annette Milewski, age 52, has had multiple sclerosis since she was 33 years of age. She is prescribed baclofen (Lioresal) 15 mg PO 3 times per day to control spasticity. Her family and a home health aide provide the care she requires. You are the home health nurse visiting for her monthly evaluation.

## Introduction

Skeletal muscle relaxants are used to decrease muscle spasm or spasticity that occurs in certain neurologic and musculoskeletal disorders. (Neuromuscular blocking agents used as adjuncts to general anesthesia for surgery are included in Appendix C.)

## Muscle Spasm

*Muscle spasm* or cramp is a sudden, involuntary, painful muscle contraction that occurs with musculoskeletal trauma (e.g., overuse or injury of skeletal muscle, twisting a joint, or tearing a ligament as with a sprain) or inflammation (e.g., bursitis, arthritis). Muscle spasm also occurs with acute or chronic low back pain. Spasms may be *clonic* (alternating contraction and relaxation) or *tonic* (sustained contraction). Muscle spasms commonly occur and may cause significant disability when inflammation, edema, and pain interfere with coordination and mobility.

## Spasticity

*Spasticity* involves increased muscle tone or contraction and stiff, awkward movements. It occurs in neurologic disorders such as multiple sclerosis, spinal cord injury, traumatic brain injury, cerebral palsy, and post-stroke syndrome. Because spasticity is caused by nerve damage in the brain and spinal cord, it is a permanent condition that may be painful and disabling.

In patients with spinal cord injury, spasticity requires treatment when it impairs safety, mobility, and the ability to perform activities of daily living (e.g., self-care in hygiene, eating, dressing, and

work or recreational activities). Stimuli that precipitate spasms vary from one individual to another and may include muscle stretching, bladder infections or stones, constipation and bowel distention, or infections. Each person should be assessed for personal precipitating factors, so that these factors can be avoided if possible. Treatment measures include passive range-of-motion and muscle-stretching exercises and antispasmodic medications (e.g., baclofen, dantrolene).

## Multiple Sclerosis

Multiple sclerosis (MS), a major cause of neurologic disability among young and middle-aged adults, occurs more often in women than in men and usually has a pattern of exacerbations and remissions. It is considered an autoimmune disorder that occurs in genetically susceptible individuals, and its cause is unknown. MS involves destruction of portions of the myelin sheath that covers nerves in the brain, spinal cord, and optic nerve. Myelin normally insulates the neuron from electrical activity and conducts electrical impulses rapidly along nerve fibers. When myelin is destroyed (a process called demyelination, which probably results from inflammation), fibrotic lesions are formed and nerve conduction is slowed or blocked around the lesions. Lesions in various states of development (e.g., acute, subacute, chronic) often occur at multiple sites in the central nervous system (CNS). Muscle weakness and other symptoms vary according to the location and duration of the myelin damage.

In recent years, researchers have discovered that nerve cells can be repaired (remyelinated) if the process that damaged the myelin is stopped before the oligodendrocytes (the cells that form myelin) are destroyed. Other researchers are trying to develop methods for enhancing nerve conduction velocity in demyelinated nerves.

People with minimal symptoms do not require treatment but should be encouraged to maintain a healthy lifestyle. Those with more extensive symptoms should try to avoid emotional stress, extremes of environmental temperature, infections, and excessive fatigue. Physical therapy may help maintain muscle tone, and occupational therapy may help maintain ability to perform activities of daily living.

Drug therapy for MS may involve various medications for different stages of the disease (see Evidence-Based Practice Box 13-1). Corticosteroids, potent anti-inflammatory drugs, are used to treat acute exacerbations (see Chap. 23); interferon beta, glatiramer, and mitoxantrone suppress the immune system and are given to prevent relapses (see Chap. 41). Other drugs (e.g., antibiotics, antidepressants, anticonvulsants for neuropathic pain) are used to treat symptoms. A skeletal muscle relaxant (e.g., baclofen, tizanidine, or dantrolene) is used to treat the symptom of spasticity. In some cases, decreasing spasticity may not be desirable, because patients with severe leg weakness may require some degree of spasticity to ambulate. In cases of severe spasticity, baclofen may be given intrathecally through an implanted subcutaneous pump.

## Evidence-Based Practice

### 13-1 Drug Therapy for Relapsing, Remitting Multiple Sclerosis

#### Acute Exacerbations

- High-dose methylprednisolone (e.g., 500–1000 mg IV daily for 3–5 days) (Level A)

#### Disease-Modifying Drugs

- Interferon beta-1a (Avonex, Rebif) and interferon beta-1b (Betaseron) (Level A). In 2005, the FDA issued a warning that “Severe hepatic injury, including cases of hepatic failure, has been reported in patients taking Avonex.”
- Glatiramer (Copaxone) (Level A)
- Mitoxantrone (Novantrone) (Level B). In 2005, the FDA issued a warning about risks of cardiotoxicity and secondary acute myelogenous leukemia (AML).

Sources: Information adapted from Goodin et al. (2002) and the National Collaborating Centre for Chronic Conditions (United Kingdom) (2004) (articles obtained from the National Guideline Clearinghouse at [www.guideline.gov](http://www.guideline.gov)). Please consult the cited journals or the National Guideline Clearinghouse for additional information regarding drug therapy of MS.

## Applying Your Knowledge 13-1

What general teaching points should you emphasize with Mrs. Milewski and her caregivers to prevent exacerbation of symptoms?

## General Characteristics of Skeletal Muscle Relaxants

### Mechanism of Action

All skeletal muscle relaxants except dantrolene are centrally active drugs. Pharmacologic action is usually attributed to general depression of the CNS but may involve blockage of nerve impulses that cause increased muscle tone and contraction. It is unclear whether relief of pain results from muscle relaxation or sedative effects. In addition, although parenteral administration of some drugs (e.g., diazepam, methocarbamol) relieves pain associated with acute musculoskeletal trauma or inflammation, it is uncertain whether oral administration of usual doses exerts a beneficial effect in acute or chronic disorders.

Baclofen and diazepam increase the effects of gamma-aminobutyric acid, an inhibitory neurotransmitter. Tizanidine inhibits motor neurons in the brain. Dantrolene is the only skeletal muscle relaxant that acts peripherally on the muscle itself; it inhibits the release of calcium in skeletal muscle cells, thereby decreasing the strength of muscle contraction.

## Indications for Use

Skeletal muscle relaxants are used primarily as adjuncts to other treatment measures such as physical therapy. Occasionally, parenteral agents are given to facilitate orthopedic procedures and examinations. In spastic disorders, skeletal muscle relaxants are indicated when spasticity causes severe pain or inability to tolerate physical therapy, sit in a wheelchair, or participate in self-care activities of daily living (e.g., eating, dressing). The drugs should not be given if they cause excessive muscle weakness and impair rather than facilitate mobility and function. Dantrolene also is indicated for prevention and treatment of *malignant hyperthermia* (see “Individual Drugs”).

## Contraindications to Use

Most skeletal muscle relaxants cause CNS depression and have the same contraindications as other CNS depressants. They should be used cautiously in patients with impaired renal or hepatic function or respiratory depression and in patients who must be alert for activities of daily living (e.g., driving a car, operating potentially hazardous machinery). Cyclobenzaprine has high levels of anticholinergic activity and therefore should be used cautiously in patients with glaucoma, urinary retention, cardiac dysrhythmias, or tachycardia.

### Applying Your Knowledge 13-2

During your assessment, you note that Mrs. Milewski is having more weakness in her lower extremities during this visit as compared with your visit 1 month ago. You also note that the prescriber has recently increased the dose of baclofen from 10 to 15 mg. How would you respond?

.....

## Individual Drugs

Individual skeletal muscle relaxants are described below. Routes and dosage ranges are listed in Table 13-1.

**Baclofen** (Lioresal) is used mainly to treat spasticity in MS and spinal cord injuries. It is contraindicated in people with hypersensitivity reactions and in those with muscle spasm from rheumatic disorders. It can be given orally and intrathecally through an implanted subcutaneous pump. Check the literature from the pump manufacturer for information about pump implantation and drug infusion techniques.

Oral baclofen begins to act in 1 hour, peaks in 2 hours, and lasts 4 to 8 hours. It is metabolized in the liver and excreted in urine; its half-life is 3 to 4 hours. Dosage must be reduced in patients with impaired renal function. Common adverse effects include drowsiness, dizziness, confusion, constipation, fatigue, headache, hypotension, insomnia, nausea, and weakness. When discontinued, dosage should be tapered and the drug withdrawn over 1 to 2 weeks.

**Carisoprodol** (Soma) is used to relieve discomfort from acute, painful musculoskeletal disorders. It is not recom-

mended for long-term use. If used long term or in high doses, it can cause physical dependence, and it may cause symptoms of withdrawal if stopped abruptly. The drug is contraindicated in patients with intermittent porphyria, a rare metabolic disorder characterized by acute abdominal pain and neurologic symptoms. Oral drug acts within 30 minutes, peaks in 1 to 2 hours, and lasts 4 to 6 hours. It is metabolized in the liver and has a half-life of 8 hours. Common adverse effects include drowsiness, dizziness, and impaired motor coordination.

**Cyclobenzaprine** (Flexeril) has the same indication for use as carisoprodol. It is contraindicated in patients with cardiovascular disorders (e.g., recent myocardial infarction, dysrhythmias, heart block) or hyperthyroidism. The oral drug acts in 1 hour, peaks in 4 to 6 hours, and lasts 12 to 24 hours. The half-life is 1 to 3 days. Duration of use should not exceed 3 weeks. Common adverse effects are drowsiness, dizziness, and anticholinergic effects (e.g., dry mouth, constipation, urinary retention, tachycardia).

**Dantrolene** (Dantrium) acts directly on skeletal muscle to inhibit muscle contraction. It is used to relieve spasticity in neurologic disorders (e.g., MS, spinal cord injury) and to prevent or treat malignant hyperthermia, a rare but life-threatening complication of anesthesia characterized by hypercarbia, metabolic acidosis, skeletal muscle rigidity, fever, and cyanosis. For preoperative prophylaxis in people with previous episodes of malignant hyperthermia, the drug is given orally for 1 to 2 days before surgery. For intraoperative malignant hyperthermia, the drug is given intravenously (IV). After an occurrence during surgery, the drug is given orally for 1 to 3 days to prevent recurrence of symptoms.

Oral dantrolene acts slowly, peaking in 4 to 6 hours and lasting 8 to 10 hours, whereas IV drug acts more quickly and lasts 6 to 8 hours. Common adverse effects include drowsiness, dizziness, diarrhea, and fatigue. The most serious adverse effect is potentially fatal hepatitis, with jaundice and other symptoms that usually occur within 1 month of starting drug therapy. Liver function tests should be monitored periodically in all patients receiving dantrolene. These adverse effects do not occur with short-term use of IV drug for malignant hyperthermia.

**Metaxalone** (Skelaxin) is used to relieve discomfort from acute, painful musculoskeletal disorders. It is contraindicated in patients with anemias or severe renal or hepatic impairment. Oral drug acts within 60 minutes, peaks in 2 hours, and lasts 4 to 6 hours. It has a half-life of 2 to 3 hours, is metabolized in the liver, and is excreted in urine. Common adverse effects include drowsiness, dizziness, and nausea; hepatotoxicity and hemolytic anemia may also occur. Liver function should be monitored during therapy.

**Methocarbamol** (Robaxin) is used to relieve discomfort from acute, painful musculoskeletal disorders. It may also be used to treat tetanus. The parenteral form is contraindicated in patients with renal impairment, because the solution contains polyethylene glycol. The oral drug acts within 30 minutes and peaks in 2 hours, and the parenteral drug acts rapidly, but peak and duration of action are unknown. Methocarbamol has a

Table 13-1

## Drugs at a Glance: Skeletal Muscle Relaxants

## ROUTES AND DOSAGE RANGES

Generic/Trade Name	Adults	Children
<b>Baclofen</b> (Lioresal)	PO 5 mg 3 times daily for 3 d; 10 mg 3 times daily for 3 d; 15 mg 3 times daily for 3 d; then 20 mg 3 times daily, if necessary Intrathecal via implanted pump: Dosage varies widely; see manufacturer's recommendations.	<12 years: Safety not established
<b>Carisoprodol</b> (Soma)	PO 350 mg 3 or 4 times daily, with the last dose at bedtime	<12 years: Not recommended
<b>Cyclobenzaprine</b> (Flexeril)	PO 10 mg 3 times daily. Maximal recommended duration, 3 weeks; maximal recommended dose, 60 mg daily	<15 years: Safety and effectiveness have not been established.
<b>Dantrolene</b> (Dantrium)	PO 25 mg daily initially, gradually increased weekly (by increments of 50–100 mg/d) to a maximal dose of 400 mg daily in 4 divided doses Preoperative prophylaxis of malignant hyperthermia: PO 4–8 mg/kg/d in 3–4 divided doses for 1 or 2 days before surgery Intraoperative malignant hyperthermia: IV push 1 mg/kg initially, continued until symptoms are relieved or a maximum total dose of 10 mg/kg has been given Postcrisis follow-up treatment: PO 4–8 mg/kg/d in 4 divided doses for 1–3 days	Spasticity: PO 1 mg/kg/d initially, gradually increased to a maximal dose of 3 mg/kg 4 times daily, not to exceed 400 mg daily Malignant hyperthermia: Same as adult
<b>Diazepam</b> (Valium)	PO 2–10 mg 3 or 4 times daily IM, IV 5–10 mg repeated in 3–4 hours if necessary	PO 0.12–0.8 mg/kg/d in 3 or 4 divided doses IM, IV 0.04–0.2 mg/kg in a single dose, not to exceed 0.6 mg/kg within an 8-h period
<b>Metaxalone</b> (Skelaxin)	PO 800 mg 3 or 4 times daily	>12 years: Same as adult <12 years: Safety and effectiveness have not been established.
<b>Methocarbamol</b> (Robaxin)	PO 1.5–2 g 4 times daily for 48–72 hours, reduced to 1 g 4 times daily for maintenance IM 500 mg q8h IV 1–3 g daily at a rate not to exceed 300 mg/min (3 mL of 10% injection). Do not give IV more than 3 days.	Safety and effectiveness have not been established except for treatment of tetanus (IV 15 mg/kg every 6 h as indicated).
<b>Tizanidine</b> (Zanaflex)	PO 4 mg q6–8h initially, increased gradually if needed. Maximum of 3 doses and 36 mg in 24 h	Safety and effectiveness have not been established.

half-life of 1 to 2 hours. It is metabolized in the liver and excreted in urine and feces. Common adverse effects with oral drug include drowsiness, dizziness, nausea, and urticaria; effects with injected drug also include fainting, incoordination, and hypotension. The drug may also give urine a green, brown, or black color. This is considered a harmless effect, but patients should be informed about it.

**Tizanidine** (Zanaflex) is an  $\alpha_2$ -adrenergic agonist, similar to clonidine, that is used to treat spasticity in patients

with MS, spinal cord injury, or brain trauma. It should be used cautiously in patients with renal or hepatic impairment and hypotension. It is given orally, and it begins to act within 30 to 60 minutes, peaks in 1 to 2 hours, and lasts 3 to 4 hours. Its half-life is 3 to 4 hours. It is metabolized in the liver and excreted in urine. Common adverse effects include drowsiness, dizziness, constipation, dry mouth, and hypotension. Hypotension may be significant and occur at usual doses. The drug may also cause psychotic symptoms, including hallucinations.

## Nursing Process

### Assessment

Assess for muscle spasm and spasticity.

- With muscle spasm, assess for:
  - **Pain.** This is a prominent symptom of muscle spasm and is usually aggravated by movement. Try to determine the location as specifically as possible, as well as the intensity, duration, and precipitating factors (e.g., traumatic injury, strenuous exercise).
  - **Accompanying signs and symptoms,** such as bruises (ecchymoses), edema, or signs of inflammation (redness, heat, edema, tenderness to touch)
- With spasticity, assess for pain and impaired functional ability in self-care (e.g., eating, dressing). In addition, severe spasticity interferes with ambulation and other movement as well as exercises to maintain joint and muscle mobility.

### Nursing Diagnoses

- Pain related to muscle spasm
- Impaired Physical Mobility related to spasm and pain
- Bathing/Hygiene Self-Care Deficit related to spasm and pain
- Deficient Knowledge: Nondrug measures to relieve muscle spasm, pain, and spasticity and safe usage of skeletal muscle relaxants
- Risk for Injury: Dizziness, sedation related to CNS depression

### Planning/Goals

The patient will

- Experience relief of pain and spasm
- Experience improved motor function
- Increase self-care abilities in activities of daily living
- Take medications as instructed
- Use nondrug measures appropriately
- Be safeguarded when sedated from drug therapy

### Interventions

Use adjunctive measures for muscle spasm and spasticity.

- Physical therapy (massage, moist heat, exercises)
- Relaxation techniques
- Correct posture and lifting techniques (e.g., stooping rather than bending to lift objects, holding heavy objects close to the body, *not* lifting excessive amounts of weight)
- Regular exercise and use of warm-up exercises. Strenuous exercise performed on an occasional basis (e.g., weekly or monthly) is more likely to cause acute muscle spasm.

## Evaluation

- Interview and observe for relief of symptoms.
- Interview and observe regarding correct usage of medications and nondrug therapeutic measures.

## Principles of Therapy

### Goals of Therapy

Skeletal muscle relaxants aim to relieve pain, muscle spasm, and muscle spasticity without impairing the ability to perform self-care activities of daily living.

### Applying Your Knowledge 13-3

Mrs. Milewski's family gives her all of her morning medications as soon as she wakes up. Mrs. Milewski is complaining about an upset stomach. What should be changed?

.....

### Drug Selection

Choice of a skeletal muscle relaxant depends mainly on the disorder being treated.

- For acute muscle spasm and pain, oral or parenteral drugs may be used. These drugs cause sedation and other adverse effects and are recommended for short-term use. Cyclobenzaprine should not be used longer than 3 weeks.
- For orthopedic procedures, parenteral agents are preferred because they have greater sedative and pain-relieving effects.
- For spasticity in people with MS, baclofen (Lioresal) and tizanidine (Zanaflex) are approved. The two drugs are similarly effective, but tizanidine may cause fewer adverse effects.
- None of the skeletal muscle relaxants has been established as safe for use during pregnancy and lactation.
- For children, the drug should be chosen from those with established pediatric dosages.

### Use in Special Populations

#### Use in Children

For most of the skeletal muscle relaxants, safety and effectiveness for use in children 12 years of age and younger have not been established. The drugs should be used only when clearly indicated, for short periods, when close supervision is available for monitoring drug effects (especially sedation), and when mobility and alertness are not required.

#### Use in Older Adults

Any CNS depressant or sedating drug should be used cautiously in older adults. Risks of falls, mental confusion, and other

## Patient Teaching Guidelines

## Skeletal Muscle Relaxants

### General Considerations

- Use nondrug measures, such as exercises and applications of heat and cold, to decrease muscle spasm and spasticity.
- Avoid activities that require mental alertness or physical coordination (e.g., driving an automobile, operating potentially dangerous machinery) if drowsy from medication.
- Do not take other drugs without the physician's knowledge, including nonprescription drugs. The major risk occurs with concurrent use of alcohol, antihistamines, sleeping aids, or other drugs that cause drowsiness.

- Avoid herbal preparations that cause drowsiness or sleep, including valerian.

### Self-Administration

- Take the drugs with milk or food, to avoid nausea and stomach irritation.
- Do not stop drugs abruptly. Dosage should be decreased gradually, especially with baclofen (Lioresal), carisoprodol (Soma), and cyclobenzaprine (Flexeril). Suddenly stopping baclofen may cause hallucinations; stopping the other drugs may cause fatigue, headache, and nausea.

adverse effects are higher because of impaired drug metabolism and excretion.

### Use in Patients With Renal Impairment

The skeletal muscle relaxants should be used cautiously in patients with renal impairment. Dosage of baclofen must be reduced.

### Use in Patients With Hepatic Impairment

Dantrolene may cause potentially fatal hepatitis, with jaundice and other symptoms that usually occur within 1 month of starting drug therapy. Liver function tests should be monitored periodically in all patients receiving dantrolene.

Metaxalone and tizanidine can cause liver damage. Thus, liver function should be assessed before starting either drug and periodically during treatment. If liver damage occurs, the drugs should be stopped. The drugs should not be given to patients with pre-existing liver disease.

### Use in Home Care

The home care nurse is likely to be involved with the use of baclofen, dantrolene, or tizanidine in chronic spastic disorders. Patients may need continued assessment of drug effects, monitoring of functional abilities, assistance in arranging blood tests of liver function, and other care. Caregivers may need instruction about nonpharmacologic interventions to help prevent or relieve spasticity.

## Nursing Actions

## Skeletal Muscle Relaxants

### NURSING ACTIONS

#### 1. Administer accurately

- a. Give baclofen and metaxalone with milk or food.
- b. Do not mix parenteral diazepam in a syringe with any other drugs.
- c. Inject intravenous (IV) diazepam directly into a vein or the injection site nearest the vein (during continuous IV infusions) at a rate of approximately 2 mg/min.
- d. Avoid extravasation with IV diazepam, and inject intramuscular (IM) diazepam deeply into a gluteal muscle.
- e. With IV methocarbamol, inject or infuse slowly, no more than 3 mL/min.
- f. With IV methocarbamol, have the patient lie down during and at least 15 minutes after administration.
- g. Avoid extravasation with IV methocarbamol, and give IM methocarbamol deeply into a gluteal muscle (no more than 5mL per site).

#### 2. Observe for therapeutic effects

- a. When the drug is given for acute muscle spasm, observe for:
  - (1) Decreased pain and tenderness
  - (2) Increased mobility
  - (3) Increased ability to participate in activities of daily living

### RATIONALE/EXPLANATION

To decrease gastrointestinal distress  
Diazepam is physically incompatible with other drugs.

Diazepam may cause a precipitate if diluted. Avoid contact with IV solutions as much as possible. A slow rate of injection minimizes the risks of respiratory depression and apnea.  
To prevent or reduce tissue irritation

Rapid administration may cause bradycardia, hypotension, and dizziness.

To minimize orthostatic hypotension and other adverse drug effects

Parenteral methocarbamol is a hypertonic solution that is very irritating to tissues. Thrombophlebitis may occur at IV injection sites, and sloughing of tissue may occur at sites of extravasation or IM injections.

Therapeutic effects usually occur within 30 minutes after IV injection of diazepam or methocarbamol.

## Nursing Actions Skeletal Muscle Relaxants (continued)

### NURSING ACTIONS

### RATIONALE/EXPLANATION

- b. When the drug is given for spasticity in chronic neurologic disorders, observe for:
- (1) Increased ability to maintain posture and balance
  - (2) Increased ability for self-care (e.g., eating and dressing)
  - (3) Increased tolerance for physical therapy and exercises

#### 3. Observe for adverse effects

- a. With centrally active agents, observe for:
- (1) Drowsiness and dizziness
  - (2) Blurred vision, lethargy, flushing
  - (3) Nausea, vomiting, abdominal distress, constipation or diarrhea, ataxia, areflexia, flaccid paralysis, respiratory depression, tachycardia, hypotension
  - (4) Hypersensitivity—skin rash, pruritus
  - (5) Psychological or physical dependence with diazepam and other antianxiety agents
- b. With a peripherally active agent (dantrolene), observe for:
- (1) Drowsiness, fatigue, lethargy, weakness, nausea, vomiting
  - (2) Headache, anorexia, nervousness
  - (3) Hepatotoxicity

These are the most common adverse effects. These effects occur more often with IV administration of drugs. They are usually transient. These effects are most likely to occur with large oral doses.

The drug should be discontinued if hypersensitivity reactions occur. Serious allergic reactions (e.g., anaphylaxis) are rare. Most likely to occur with long-term use of large doses

Adverse effects are usually transient. These effects are the most common.

#### Less common effects

This potentially serious adverse effect is most likely to occur in people older than 35 years of age who have taken the drug 60 days or longer. Women older than 35 years of age who take estrogens have the highest risk. Hepatotoxicity can be prevented or minimized by administering the lowest effective dose, monitoring liver enzymes (aspartate aminotransferase [AST] and alanine aminotransferase [ALT]) during therapy, and discontinuing the drug if no beneficial effects occur within 45 days.

#### 4. Observe for drug interactions

- a. Drugs that *increase* effects of skeletal muscle relaxants:
- (1) Central nervous system (CNS) depressants (alcohol, antianxiety agents, antidepressants, antihistamines, antipsychotic drugs, sedative-hypnotics)
  - (2) Monoamine oxidase inhibitors
  - (3) Antihypertensive agents

Additive CNS depression with increased risks of excessive sedation and respiratory depression or apnea

May potentiate effects by inhibiting metabolism of muscle relaxants

Increased hypotension, especially with tizanidine

## Key Concepts

- Muscle spasms usually result from trauma to the affected skeletal muscle.
- Spasticity results from damage to nerves in the brain and spinal cord.
- Both muscle spasms and spasticity can cause pain and disability.
- Physical therapy and other nonpharmacologic treatments are useful in treating muscle spasm and spasticity.
- Most muscle relaxant drugs are CNS depressants; only dantrolene acts on the muscle.
- The etiology of multiple sclerosis (MS) is unknown, and there is presently no cure.
- Drugs used to relieve spasticity with MS are baclofen and tizanidine.
- Other drugs used to treat MS include corticosteroids, disease-modifying drugs, and drugs used to treat various symptoms other than spasticity.

## Review and Application Exercises

### Short Answer Exercises

1. How do skeletal muscle relaxants act to relieve spasm and pain?
2. What are the indications for the use of skeletal muscle relaxants?
3. What are the contraindications to the use of skeletal muscle relaxants?
4. What are the major adverse effects of skeletal muscle relaxants, and how can they be minimized?
5. What are some nonpharmacologic interventions to use instead of, or along with, skeletal muscle relaxants?

### NCLEX-Style Questions

6. The nurse who is administering baclofen (Lioresal) knows that the adverse effect she needs to monitor most closely includes which of the following?
  - a. muscle spasms
  - b. insomnia
  - c. nervousness
  - d. hypotension
7. Which of the following muscle relaxants is the only one that acts peripherally on muscles?
  - a. dantrolene (Dantrium)
  - b. baclofen (Lioresal)
  - c. methocarbamol (Robaxin)
  - d. diazepam (Valium)
8. A patient with MS who has progressive and severe leg weakness has questions about his medications. The provider has discontinued his antispasmodic and he wants to know why this may be the case. The nurse is correct in telling him that
  - a. There are no effective medications that reduce spasticity in MS.
  - b. Spasticity is not an effect of MS.
  - c. He may need some degree of spasticity to ambulate, which may be why the medication was eliminated, but he should ask his provider.
  - d. His provider was concerned about serious side effects from the medications.

# Substance Abuse Disorders

## KEY TERMS

- Alcohol abuse
- Hallucinogen
- Physical dependence
- Psychological dependence
- Substance abuse
- Tolerance

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Identify risk factors for development of drug dependence.
2. Describe the effects of alcohol, cocaine, marijuana, and nicotine on selected body organs.
3. Compare and contrast characteristics of dependence associated with alcohol, benzodiazepines, cocaine, and opiates.
4. Describe specific antidotes for overdoses of central nervous system (CNS) depressant drugs and the circumstances indicating their use.
5. Outline major elements of treatment for overdoses of commonly abused drugs that do not have antidotes.
6. Describe interventions to prevent or manage withdrawal reactions associated with alcohol, benzodiazepines, cocaine and other CNS stimulants, and opiates.

## Applying Your Knowledge

Bryan Wilson is a 24-year-old man who regularly uses marijuana, alcohol, and tobacco. He also occasionally uses cocaine as a recreational drug. He is seen in the ER in acute intoxication. He is admitted for withdrawal and treatment.

## Introduction

*Substance abuse* is a significant health, social, economic, and legal problem. It is often associated with substantial damage to the abuser and society (e.g., crime, child and spouse abuse, traumatic injury, chronic health problems, death). In this chapter, substance abuse is defined as self-administration of a drug for prolonged periods or in excessive amounts to the point of producing physical or psychological dependence, impairing functions of body organs, reducing the ability to function in usual activities of daily living, and decreasing the ability and motivation to function as a productive member of society.

Most drugs of abuse are those that affect the CNS and alter the state of consciousness. Commonly abused drugs include CNS depressants (e.g., alcohol, antianxiety and sedative-hypnotic agents, opioid analgesics), CNS stimulants (e.g., cocaine, methamphetamine, methylphenidate, nicotine), and other mind-altering drugs (e.g., marijuana, “ecstasy”). Although these drugs produce different effects, they are associated with feelings of pleasure, positive reinforcement, and compulsive self-administration. Most are also associated with *tolerance* if used repeatedly. This means that the body adjusts to the drugs so that higher doses are needed to achieve feelings of pleasure (“reward”) or stave off withdrawal symptoms (“punishment”). Both reward and punishment serve to reinforce continued substance abuse.

Many drugs of abuse activate the pleasure or reward system in the brain by altering neurotransmission systems. For example, cocaine and methamphetamine increase the availability of the neurotransmitters dopamine and norepinephrine. Prolonged drug abuse damages nerve cells in the brain and alters brain functions. The damage is long lasting.

Drugs of abuse seem to be readily available. Internet Web sites have become an important source of the drugs. In some instances, instructions for manufacturing particular drugs are available. Although patterns of drug abuse vary in particular populations and in geographic areas, continuing trends seem to include increased use of methamphetamine, “club drugs,” prescription drugs, and using multiple drugs at the same time.

## Dependence

Characteristics of drug dependence include craving a drug, often with unsuccessful attempts to decrease its use; compulsive drug-seeking behavior; physical dependence (withdrawal symptoms if drug use is decreased or stopped); and continuing to take a drug despite adverse consequences (e.g., drug-related illnesses, mental or legal problems, job loss or decreased ability to function in an occupation, impaired family relationships).

*Psychological dependence* involves feelings of satisfaction and pleasure from taking the drug. These feelings, perceived as extremely desirable by the drug-dependent person, contribute to acute intoxication, development and maintenance of drug-abuse patterns, and return to drug-taking behavior after periods of abstinence.

*Physical dependence* involves physiologic adaptation to chronic use of a drug so that unpleasant symptoms occur when the drug is stopped, when its action is antagonized by another drug, or when its dosage is decreased. The withdrawal or abstinence syndrome produces specific manifestations according to the type of drug and does not occur as long as adequate dosage is maintained. Attempts to avoid withdrawal symptoms reinforce psychological dependence and promote continuing drug use and relapses to drug-taking behavior. Tolerance is often an element of drug dependence, and increasing doses are therefore required to obtain psychological effects or avoid physical with-

drawal symptoms. A person may be dependent on several drugs; most substance abusers use multiple drugs.

Drug dependence is a complex phenomenon. Although the cause is unknown, one theory is that drugs stimulate or inhibit neurotransmitters in the brain to produce pleasure and euphoria or to decrease unpleasant feelings such as anxiety. For example, dopaminergic neurons in the limbic system are associated with the brain’s reward system and are thought to be sites of action of alcohol, amphetamines, cocaine, nicotine, and opiates. These major drugs of abuse increase dopaminergic transmission and the availability of dopamine. For example, amphetamines promote dopamine release and inhibit its reuptake, and cocaine inhibits dopamine reuptake. These actions are believed to stimulate the brain’s reward system and lead to compulsive drug administration and abuse.

The noradrenergic neurotransmission system, which uses norepinephrine as its neurotransmitter, is often involved as well as the dopaminergic system. Noradrenergic neurons innervate the limbic system and cerebral cortex and are important in setting mood and affect. Drugs that alter noradrenergic transmission have profound effects on mood and affect. Amphetamines and cocaine increase noradrenergic transmission, as with dopaminergic transmission, by promoting the release of norepinephrine and/or inhibiting its reuptake. Increased norepinephrine leads to mood elevation and euphoria, which promotes continued drug abuse. Increased norepinephrine also leads to major adverse effects of amphetamines and cocaine, including myocardial infarction, severe hypertension, and stroke, as well as profound mood swings from euphoria to depression.

Other factors important in developing drug dependence include the specific drug; the amount, frequency, and route of administration; the person’s psychological and physiologic characteristics; and environmental or circumstantial characteristics. Peer pressure is often an important factor in initial and continuing drug ingestion. A genetic factor seems evident in *alcohol abuse*: Studies indicate that children of abusers are at risk of becoming abusers themselves, even if reared away from the abusing parent. See Box 14-1 for additional general characteristics of substance abuse and dependence.

### Box 14-1

### Characteristics of Substance Abuse and Dependence

- Substance abuse involves all socioeconomic levels and affects all age groups. It is especially prevalent among adolescents and young adults. Patterns of abuse may vary by age group. For example, adolescents and young adults are more likely to use illicit drugs and older adults are more likely to abuse alcohol and prescription drugs. Health care professionals (e.g., physicians, pharmacists, nurses) are also considered at high risk for development of substance abuse disorders, at least partly because of easy access.
- A person who abuses one drug is likely to abuse others.
- Multiple drugs are often abused concurrently. Alcohol, for example, is often used with other drugs of abuse, probably because it is legal and readily available. In addition, alcohol, marijuana, opioids, and sedatives are often used to combat the anxiety and nervousness induced by cocaine, methamphetamine, and other CNS stimulants.
- Drug effects vary according to the type of substance being abused, the amount, route of administration, duration of use, and phase of substance abuse (e.g., acute intoxication, withdrawal syndromes, organ damage, medical illness). Thus, acute intoxication often produces profound behavioral changes and chronic abuse often leads to serious organ damage and impaired ability to function in work, family, or social settings. Withdrawal symptoms are

## Box 14-1

## Characteristics of Substance Abuse and Dependence (continued)

characteristic of particular types of drugs and are usually opposite to the effects originally produced. For example, withdrawal symptoms of alcohol and sedative-type drugs are mainly agitation, nervousness, and hyperactivity.

- Abusers of alcohol and other drugs are not reliable sources of information about the types or amounts of drugs used. Most abusers understate the amount and frequency of substance use; heroin addicts may overstate the amount used in attempts to obtain higher doses of methadone. In addition, those who use illegal street drugs may not know what they have taken because of varying purity, potency, additives, contaminants, names, and substitutions of one drug for another.
- Substance abusers rarely seek health care unless circumstances force the issue. Thus, most substance abuse comes to the attention of health care professionals when the

abuser experiences a complication such as acute intoxication, withdrawal, or serious medical problems resulting from chronic drug overuse, misuse, or abuse.

- Smoking or inhaling drug vapors is a preferred route of administration for cocaine, marijuana, and nicotine because the drugs are rapidly absorbed from the large surface area of the lungs. Then, they rapidly circulate to the heart and brain without dilution by the systemic circulation or metabolism by enzymes.
- Substance abusers who inject drugs intravenously (IV) are prey to serious problems because they use impure drugs of unknown potency, contaminated needles, poor hygiene, and other dangerous practices. Specific problems include overdoses, death, and numerous infections (e.g., hepatitis, human immunodeficiency virus infection, endocarditis, phlebitis, cellulitis at injection sites).

Many drugs abused for their mind-altering properties have clinical usefulness and are discussed elsewhere: “Antianxiety and Sedative-Hypnotic Drugs” (Chap. 8), “Opioid Analgesics and Pain Management” (Chap. 6), and “Central Nervous Sys-

tem Stimulants” (Chap. 15). This chapter describes commonly abused substances, characteristics and treatment of substance-related disorders, and drugs used to treat substance-related disorders (Table 14-1).

Table 14-1

## Drugs at a Glance: Drugs Used to Treat Substance Abuse Disorders

GENERIC/ TRADE NAME	INDICATIONS FOR USE	ROUTES AND DOSAGE RANGES	COMMENTS
<b>Bupropion</b> (Zyban)	Smoking cessation	PO 150 mg once daily for 3 d, then increase to 150 mg twice daily, at least 8 h apart. Maximum dose, 300 mg/d	
<b>Chlordiazepoxide</b> (Librium)	Alcohol detoxification; benzodiazepine withdrawal	PO 50 mg q6–8h initially, then tapered over 1–2 wk	
<b>Clonidine</b> (Catapres)	Alcohol withdrawal; opiate withdrawal	<i>Alcohol withdrawal</i> : PO 0.3–0.6 mg q6h <i>Opiate withdrawal</i> : PO 2 mcg/kg 3 times daily for 7–10 d	Unlabeled uses May cause hypotension
<b>Disulfiram</b> (Antabuse)	Chronic alcohol abuse, to prevent continued alcohol ingestion	PO 125–500 mg daily	Limited effectiveness because many alcoholics will not take the drug; should not be given until at least 12 h after alcohol ingestion
<b>Flumazenil</b> (Romazicon)	Acute intoxication or overdose of benzodiazepine antianxiety or sedative-hypnotic drugs	IV 0.1–0.2 mg/min up to 1 mg	May precipitate acute withdrawal symptoms
<b>Haloperidol</b> (Haldol)	Psychotic symptoms associated with acute intoxication with cocaine and other CNS stimulants	IM 2–5 mg q 30 min–6 h PRN for psychotic behavior	Other antipsychotic agents may also be used.

GENERIC/ TRADE NAME	INDICATIONS FOR USE	ROUTES AND DOSAGE RANGES	COMMENTS
<b>Lorazepam</b> (Ativan)	Excessive CNS stimulation associated with acute intoxication with cocaine and other CNS stimulants, hallucinogens, marijuana, inhalants, and phencyclidine; alcohol withdrawal	<i>Agitation:</i> IM q 30 min–6 h PRN; <i>alcohol withdrawal hallucinations or seizures:</i> IM 2 mg, repeated if necessary; <i>benzodiazepine withdrawal:</i> PO 2 mg q6–8h initially, then tapered over 1–2 wk	1 wk of tapering usually adequate for withdrawal from short-acting benzodiazepines; 2 wk needed for long-acting benzodiazepines
<b>Methadone</b>	Opioid withdrawal; maintenance therapy for heroin addiction	<i>Withdrawal:</i> PO 20–80 mg daily initially, reduced by 5–10 mg daily over 7–10 days; <i>maintenance:</i> PO 20–80 mg daily	Maintenance doses of 60–80 mg daily more effective than 20–30 mg daily to decrease heroin use
<b>Naloxone</b> (Narcan)	Acute intoxication or overdose of opioids (heroin, morphine, others)	IV 0.4–2 mg q3min	May precipitate acute withdrawal symptoms
<b>Naltrexone</b> (ReVia, Vivitrol)	Opioid dependence; alcohol dependence	PO 50 mg daily IM (Vivitrol) 380 mg once monthly in buttocks	With opiate dependence, should not be started until patient is opioid-free for at least 7 days
<b>Nicotine</b> (Habitrol, Nicoderm CQ, Nicorette, Nicotrol, Nicotrol Inhaler, Nicotrol NS)	Aid smoking cessation by relieving nicotine withdrawal symptoms	<i>Transdermal patches, Habitrol, Nicoderm:</i> 21 mg/d for 6 wk; then 14 mg/d for 2 wk; then 7 mg/d for 2 wk <i>Nicotrol patch:</i> 15 mg/16 h for 6 wk <i>Nicotrol chewing gum:</i> 1 piece every 1–2 h for wk 1–6; 1 piece every 2–4 h for wk 7–9; 1 piece every 4–8 h for wk 10–12 <i>Nicotrol inhaler:</i> 6–12 cartridges/d for 3 mo, then gradually taper dosage over 6–12 wk, then discontinue <i>Nicotrol nasal spray:</i> 1 spray to each nostril, every 1–2 h, to a maximum of 80 sprays (40 mg) per day for heavy smokers. Taper by using less often or spraying 1 nostril per dose.	Should not be used while continuing to smoke because of high risk of serious adverse effects Used patches contain enough nicotine to be toxic to children and pets; they should be discarded in a safe manner.
<b>Varenicline</b> (Chantix)	Smoking cessation	PO days 1–3, 0.5 mg once daily; days 4–7, 0.5 mg twice daily; day 8 through end of treatment (total of 12–24 wk), 1 mg twice daily	

CNS, Central nervous system

## Central Nervous System Depressants

CNS depressants are drugs that slow down or “depress” brain activity. They include alcohol, antianxiety and sedative-hypnotic agents, and opiates.

### Alcohol (Ethanol)

Alcohol is commonly abused around the world. It is legal and readily available, and its use is accepted in most societies. Excessive amounts and long-term abuse damages essentially all organ systems of the body. Alcohol is thought to exert its effects on the CNS mainly by enhancing the activity of gamma-aminobutyric acid, an inhibitory neurotransmitter, or by

inhibiting the activity of glutamate, an excitatory neurotransmitter. Other neurotransmitters (e.g., dopamine, opioid peptides, serotonin) may also be affected.

When alcohol is ingested orally, a portion is inactivated in the stomach (by the enzyme alcohol dehydrogenase) and not absorbed systemically. Women have less enzyme activity than men and therefore absorb about 30% more alcohol than men when comparable amounts are ingested according to weight and size. As a result, women are especially vulnerable to adverse effects of alcohol, including more rapid intoxication from smaller amounts of alcohol and earlier development of hepatic cirrhosis and other complications of alcohol abuse.

In men and women, alcohol is absorbed partly from the stomach but mostly from the upper small intestine. It is rapidly absorbed when the stomach and small intestine are empty.

Food delays absorption by diluting the alcohol and delaying gastric emptying. After it is absorbed, alcohol is quickly distributed to all body tissues, partly because it is lipid soluble and crosses cell membranes easily. The alcohol concentration in the brain rapidly approaches that in the blood, and CNS effects usually occur within a few minutes. These effects depend on the amount ingested, how rapidly it was ingested, whether the stomach was empty, and other factors. Effects with acute intoxication usually progress from feelings of euphoria and relaxation to impaired mental and motor functions, stupor, and sleep. Excited behavior may occur because of depression of the cerebral cortex, which normally controls behavior. The person may seem more talkative and outgoing or more impulsive and aggressive because inhibitions and self-control are decreased.

The rate of alcohol metabolism largely determines the duration of CNS effects. Most alcohol is oxidized in the liver to acetaldehyde, which can be used for energy or converted to fat and stored. When metabolized to acetaldehyde, alcohol no longer exerts depressant effects on the CNS. Although the rate of metabolism differs with acute ingestion or chronic intake and some other factors, it is approximately 120 milligrams per kilogram of body weight or 10 milliliters per hour. This is the amount of alcohol contained in approximately 2/3 ounce of whiskey, 3 to 4 ounces of wine, or 8 to 12 ounces of beer. *Alcohol is metabolized at the same rate regardless of the amount present in body tissues.*

In older adults, the pharmacokinetics of alcohol are essentially the same as in younger adults. However, equivalent amounts of alcohol produce higher blood levels in older adults because of changes in body composition (e.g., a greater proportion of fatty tissue).

Alcohol may cause significant interactions when used with other drugs. These interactions often differ between acute and chronic ingestion. Acute ingestion inhibits drug-metabolizing enzymes, which slows the metabolism of some drugs, thereby increasing their effects and the likelihood of toxicity. Chronic ingestion induces metabolizing enzymes. This increases the rate of metabolism and decreases drug effects. Long-term ingestion of large amounts of alcohol, however, causes liver damage and impaired ability to metabolize drugs. Because so many variables influence alcohol's interactions with other drugs, it is difficult to predict effects of interactions in particular people. However, some important interactions include those with other CNS depressants, antihypertensive agents, antidiabetic agents, oral anticoagulants, and disulfiram. These are summarized in Box 14-2.

### Alcohol Dependence and Its Treatment

Alcohol dependence involves acute or chronic consumption of alcohol in excess of the limits accepted by the person's culture, at times considered inappropriate by that culture, and to the extent that physical health and social relationships are impaired. Psychological dependence, physical dependence, tolerance, and cross-tolerance with other CNS depressants are prominent characteristics.

Acute intoxication impairs thinking, judgment, and psychomotor coordination. These impairments lead to poor work

#### Box 14-2

### Alcohol Interactions With Other Drugs

- With other CNS depressants (e.g., sedative-hypnotics, opioid analgesics, antianxiety agents, antipsychotic agents, general anesthetics, tricyclic antidepressants), alcohol potentiates CNS depression and increases risks of excessive sedation, respiratory depression, and impaired mental and physical functioning. Combining alcohol with these drugs may be lethal and should be avoided.
- With antihypertensive agents, alcohol potentiates vasodilation and hypotensive effects.
- With oral antidiabetic drugs that decrease blood sugar, alcohol potentiates hypoglycemic effects. These drugs include acarbose (Precose), exenatide (Byetta), glipizide (Glucotrol), glyburide (DiaBeta), glimepiride (Amaryl), miglitol (Glyset), nateglinide (Starlix), pioglitazone (Actos), pramlintide (Symlin), repaglinide (Prandin), and rosiglitazone (Avandia). With metformin (Glucophage), alcohol may increase the risk of lactic acidosis.
- With oral anticoagulants (e.g., warfarin), alcohol interactions vary. Acute ingestion increases anticoagulant effects and the risk of bleeding. Chronic ingestion decreases anticoagulant effects by inducing drug-metabolizing enzymes in the liver and increasing the rate of warfarin metabolism. However, if chronic ingestion has caused liver damage, metabolism of warfarin may be slowed. This increases the risk of excessive anticoagulant effect and bleeding.
- With disulfiram (Antabuse), alcohol produces significant distress (flushing, tachycardia, bronchospasm, sweating, nausea and vomiting). This reaction may be used to treat alcohol dependence.
- A disulfiram-like reaction also may occur with other drugs, including the antimicrobial drugs cefoperazone (Cefobid) and metronidazole (Flagyl).

performance, accidents, and disturbed relationships with other people. Conscious control of behavior is lost, and exhibitionism and aggressiveness often result. Chronic ingestion may cause severe organ damage and mental problems.

Signs and symptoms of alcohol withdrawal include agitation, anxiety, tremors, sweating, nausea, tachycardia, fever, hyperreflexia, postural hypotension, and, if severe, convulsions and delirium. Delirium tremens, the most serious form of alcohol withdrawal, is characterized by confusion, disorientation, delusions, visual hallucinations, and other signs of acute psychosis. The intensity of the alcohol withdrawal syndrome varies with the duration and amount of alcohol ingestion. Withdrawal symptoms start within a few hours after a person's last drink and last for several days; moderate to severe withdrawal symptoms often lead to hospitalization in a critical care unit.

Alcohol dependence is a progressive illness, and early recognition and treatment are desirable. The alcohol-dependent person is unlikely to seek treatment for alcohol abuse unless an acute illness or other situation forces the issue. He or she is likely, however, to seek treatment for other disorders, such as

nervousness, anxiety, depression, insomnia, and gastroenteritis. Thus, health professionals may recognize alcohol abuse in its early stages if they are aware of indicative assessment data.

If the patient does not admit that alcohol abuse is a problem and agrees to participate in a treatment program, success is unlikely. The patient may fail to make return visits or may seek treatment elsewhere. If the patient agrees to treatment, the three primary approaches are psychological counseling, referral to a self-help group such as Alcoholics Anonymous, and drug therapy.

### Applying Your Knowledge 14-1

For Mr. Wilson's treatment to be successful, what are the primary approaches that should be used?

Acute intoxication with alcohol does not usually require treatment. If the patient is hyperactive and combative, a sedative-type drug may be given. The patient must be closely observed because sedatives potentiate alcohol, and excessive CNS depression may occur. If the patient is already sedated and stuporous, he or she can be allowed to sleep off the alcohol effects. If the patient is comatose, supportive measures are indicated. For example, respiratory depression may require insertion of an artificial airway and mechanical ventilation.

Benzodiazepine antianxiety agents are the drugs of choice for treating alcohol withdrawal syndromes. They can help the patient participate in rehabilitation programs and can be gradually reduced in dosage and discontinued. They provide adequate sedation and have a significant anticonvulsant effect. Some physicians prefer a benzodiazepine with a long half-life (e.g., diazepam [Valium] or **chlordiazepoxide** [Librium]), whereas others prefer one with a short half-life (e.g., **lorazepam** [Ativan] or oxazepam). Lorazepam and oxazepam are less likely to accumulate and may be best for older adults or patients with hepatic disease. Alcoholic patients usually require high doses of benzodiazepines because of the drugs' cross-tolerance with alcohol.

Seizures require treatment if they are repeated or continuous. Antiseizure drugs need not be given for more than a few days unless the person has a pre-existing seizure disorder. **Clonidine** (Catapres) may be given to reduce symptoms (e.g., hyperactivity, tremors) associated with excessive stimulation of the sympathetic nervous system. Midazolam or propofol may be useful for treating delirium tremens because their doses can be easily titrated to manage the symptoms.

### Applying Your Knowledge 14-2

Although Mr. Wilson's acute intoxication may not require treatment, his chronic abuse of alcohol will result in the need for treatment of alcohol withdrawal symptoms. The physician prescribes a benzodiazepine. Why?

Drug therapy for maintenance of sobriety is limited, mainly because of poor compliance. The drugs approved for this purpose include **disulfiram** (Antabuse) and **naltrexone** (ReVia, Vivitrol). Disulfiram interferes with hepatic metabolism of alcohol and allows accumulation of acetaldehyde. If alcohol is ingested during disulfiram therapy, acetaldehyde causes nausea and vomiting, dyspnea, hypotension, tachycardia, syncope, blurred vision, headache, and confusion. Severe reactions include respiratory depression, cardiovascular collapse, cardiac dysrhythmias, myocardial infarction, congestive heart failure, unconsciousness, convulsions, and death. The reaction lasts as long as alcohol is present in the blood. Ingestion of prescription and over-the-counter medications that contain alcohol may cause a reaction in the disulfiram-treated alcoholic. Disulfiram alone may produce adverse reactions of drowsiness, fatigue, impotence, headache, and dermatitis. Disulfiram also interferes with the metabolism of phenytoin and warfarin, which may increase blood levels of the drugs and increase their toxicity. Because of these reactions, disulfiram must be given only with the patient's full consent, cooperation, and knowledge.

Naltrexone is an opiate antagonist that reduces craving for alcohol and increases abstinence rates when combined with psychosocial treatment. A possible mechanism is blockade of the endogenous opioid system, which is thought to reinforce alcohol craving and consumption. The most common adverse effect is nausea; others include anxiety, dizziness, drowsiness, headache, insomnia, nervousness, and vomiting. Naltrexone is hepatotoxic in high doses and contraindicated in patients with acute hepatitis or liver failure. Formerly an oral tablet that required daily administration, with which adherence is a problem, naltrexone is now available in an extended-release solution (Vivitrol) that can be injected once each month.

In addition to drug therapy to treat withdrawal and maintain sobriety, alcohol abusers often need treatment of coexisting medical illnesses and psychiatric disorders, such as depression. Antidepressant drugs seem to decrease alcohol intake as well as relieve depression in this population.

### Applying Your Knowledge 14-3

Preparations are being made for Mr. Wilson's discharge and outpatient therapy. He is prescribed Antabuse. Why is he given this drug, and what will he experience if he consumes alcohol while taking it?

## Benzodiazepines

Benzodiazepines are widely used for antianxiety and sedative-hypnotic effects (see Chap. 8) and are also widely abused, mainly by people who also abuse alcohol and/or other drugs. Benzodiazepines rarely cause respiratory depression or death, even in overdose, unless taken with alcohol or other drugs. They may, however, cause oversedation, memory impairment, poor motor coordination, and confusion. Withdrawal reactions

can be extremely uncomfortable. Symptoms begin 12 to 24 hours after the last dose of a short-acting drug such as alprazolam (Xanax) and peak at 24 to 72 hours. With long-acting drugs such as diazepam and chlorthalidone, symptoms begin 24 to 48 hours after the last dose and peak within 5 to 8 days.

Combining any of these drugs with each other or with alcohol can cause serious depression of vital functions and death. Unfortunately, abusers often combine drugs in their quest for a greater “high” or to relieve the unpleasant effects of CNS stimulants and other street drugs.

### **Benzodiazepine Dependence and Its Treatment**

This type of dependence resembles alcohol dependence in symptoms of intoxication and withdrawal. Other characteristics include physical dependence, psychological dependence, tolerance, and cross-tolerance. Signs and symptoms of withdrawal include anxiety, tremors and muscle twitching, weakness, dizziness, distorted visual perceptions, nausea and vomiting, insomnia, nightmares, tachycardia, weight loss, postural hypotension, generalized tonic-clonic seizures, and delirium that resembles the delirium tremens of alcoholism or a major psychotic episode. Convulsions are more likely to occur during the first 48 hours of withdrawal and delirium after 48 to 72 hours.

Treatment may involve overdose and withdrawal syndromes. Overdose produces intoxication similar to that produced by alcohol. There may be a period of excitement and emotional lability followed by progressively increasing signs of CNS depression (e.g., impaired mental function, muscular incoordination, sedation). Treatment is unnecessary for mild overdose if vital functions are adequate. The patient usually sleeps off the effects of the drug. The rate of recovery depends primarily on the amount of drug ingested and its rate of metabolism. More severe overdoses cause respiratory depression and coma.

**Flumazenil** (Romazicon) is a specific antidote that can reverse benzodiazepine-induced sedation, coma, and respiratory depression. The drug competes with benzodiazepines for benzodiazepine receptors. It has a short duration of action, and repeated IV injections are usually needed. Recipients must be closely observed because symptoms of overdose may recur when the effects of a dose of flumazenil subside and because the drug may precipitate acute withdrawal symptoms (e.g., agitation, confusion, seizures) in benzodiazepine abusers.

Treatment of withdrawal may involve administration of a benzodiazepine to relieve acute signs and symptoms and then tapering the dose until the drug can be discontinued. Benzodiazepine withdrawal syndromes can be life threatening. The person may experience cardiovascular collapse, generalized tonic-clonic seizures, and acute psychotic episodes. These can be prevented by gradually withdrawing the offending drug. If they do occur, each situation requires specific drug therapy and supportive measures. Withdrawal reactions should be supervised and managed by experienced people, such as health care professionals or staff at detoxification centers.

## **Opioids**

Opioids are potent analgesics and extensively used in pain management (see Chap. 6). They are also commonly abused. Legal opioid analgesics are increasingly being diverted from their appropriate use and bought and sold as street drugs. Because therapeutic opioids are discussed elsewhere, the focus here is heroin, a common drug of abuse. It is a Schedule I drug in the United States and is not used therapeutically.

Heroin produces the same effects as naturally occurring endorphins and other opioid drugs. The drug rapidly enters the brain, where it is converted to morphine. Morphine stimulates opioid receptors in the reward system of the brain, which causes greater amounts of dopamine to be released.

Heroin may be taken by IV injection, smoking, or nasal application (snorting). IV injection produces intense euphoria, which occurs within seconds, lasts a few minutes, and is followed by a period of sedation. Effects diminish over approximately 4 hours, depending on the dose. Addicts may inject several times daily, cycling between desired effects and symptoms of withdrawal. Tolerance to euphoric effects develops rapidly, leading to dosage escalation and continued use to avoid withdrawal. Like other opioids, heroin causes severe respiratory depression with overdose and produces a characteristic abstinence syndrome.

### **Opioid Dependence and Its Treatment**

Opioids produce tolerance and high degrees of psychological and physical dependence. Most other drugs that produce dependence do so with prolonged usage of large doses, but morphine-like drugs produce dependence with repeated administration of small doses. Medical usage of these drugs produces physical dependence and tolerance but rarely leads to use or abuse for mind-altering effects. Thus, “addiction” should not be an issue when the drugs are needed for pain management in patients with cancer or other severe illnesses. Although deaths from overdoses of opioid analgesics (e.g., oxycodone, hydrocodone, methadone, fentanyl) have increased in recent years, these deaths are usually associated with nonmedical use rather than pain management. Also, most overdose deaths involve multiple drugs.

Acute effects of opioid administration vary according to dosage, route of administration, and physical and mental characteristics of the user. They may produce euphoria, sedation, analgesia, respiratory depression, postural hypotension, vasodilation, pupil constriction, and constipation.

Treatment may be needed for overdose or withdrawal syndromes. Overdose may produce severe respiratory depression and coma. Insertion of an endotracheal tube and mechanical ventilation may be required. Drug therapy consists of an opioid antagonist (e.g., naloxone) to reverse opioid effects. Giving an opioid antagonist can precipitate withdrawal symptoms. If there is no response to the opioid antagonist, the symptoms may be caused by depressant drugs other than opioids. In addition to profound respiratory depression, pulmonary edema, hypoglycemia, pneumonia, cellulitis, and other infections often accompany opioid overdose and require specific treatment measures.

Symptoms of opioid withdrawal may resemble severe flu, with rhinorrhea, sneezing, yawning, lacrimation, abdominal cramping, leg cramping, piloerection (gooseflesh), nausea, vomiting, diarrhea, and dilated pupils. Onset and duration of symptoms are determined by the half-life of the abused opioid. For example, symptoms occur within 36 to 72 hours and last about 7 to 10 days with heroin. They occur in 72 to 96 hours and last at least 14 days with methadone.

Signs and symptoms of withdrawal can be reversed immediately by giving the drug producing the dependence. Therapeutic withdrawal involves gradually reducing dosage over several days. Clonidine, a drug used mainly for hypertension, is sometimes used to relieve withdrawal symptoms associated with excessive stimulation of the sympathetic nervous system.

Ideally, the goal of treatment for opioid abuse is abstinence from further opioid usage. Because this goal is rarely met, long-term drug therapy may be used to treat heroin dependence. One method uses opioid substitutes to prevent withdrawal symptoms and improve a lifestyle that revolves around obtaining, using, and recovering from a drug. **Methadone** has long been used for this purpose, usually a single, daily oral dose given in a methadone clinic. Proponents say that methadone blocks euphoria produced by heroin, acts longer, and reduces preoccupation with drug use. This allows a more normal lifestyle for the patient and reduces morbidity and mortality associated with the use of illegal and injected drugs. Also, because methadone is free, the heroin addict does not commit crimes to obtain drugs. Opponents say that methadone maintenance only substitutes one type of drug dependence for another. In addition, a substantial percentage of those receiving methadone maintenance therapy abuse other drugs, including cocaine.

A second treatment option is **naltrexone** (ReVia), an opioid antagonist that prevents opioids from occupying receptor sites and thereby prevents their physiologic effects. Used to maintain opioid-free states in the opioid addict, it is recommended for use in conjunction with psychological counseling to promote patient motivation and compliance. If the patient taking naltrexone has mild or moderate pain, nonopioid analgesics (e.g., acetaminophen or a nonsteroidal anti-inflammatory drug) should be given. If the patient has severe pain and requires an opioid, it should be given in a setting staffed and equipped for cardiopulmonary resuscitation because respiratory depression may be deeper and more prolonged than usual. In addition, patients needing elective surgery and opioid analgesics should be instructed to stop taking naltrexone at least 72 hours before the scheduled procedure.

A third drug therapy option is **buprenorphine** (Buprenex), a Schedule III agonist-antagonist analgesic that is occasionally injected therapeutically to relieve pain and is also a drug of abuse. It is given orally (Subutex, Suboxone) to treat opioid dependence. Suboxone also contains naloxone, a narcotic antagonist, to prevent buprenorphine abuse for mind-altering effects. Physicians who prescribe the drug for outpatient use must meet several restrictions and are required to have 8 hours of special training.

## Central Nervous System Stimulants

### Amphetamines and Related Drugs

Amphetamines and some related drugs (see Chap. 15) are used therapeutically for narcolepsy and attention deficit-hyperactivity disorder (ADHD). However, amphetamines are more important as drugs of abuse than therapeutic agents. The effects of amphetamines are similar to those of cocaine. The drugs increase the activity of norepinephrine and dopamine by increasing their release, blocking their reuptake, and inhibiting the enzyme (monoamine oxidase) that normally metabolizes catecholamine neurotransmitters.

Methamphetamine is a commonly abused drug that is often manufactured in illegal “meth labs.” Purchase and possession of the ingredients for its manufacture are restricted by law. The drug is taken orally, by IV injection, and by inhalation (after chemical treatment to produce crystals, which are then heated and the vapors smoked or inhaled). Inhalation or IV injection produces a pleasurable sensation that lasts only a few minutes.

Methylphenidate (Ritalin, others), a prescription drug used to treat ADHD, is increasingly being used for nonmedical purposes. The drug is obtained by diverting it from legitimate channels (e.g., buying, stealing, sharing among friends). A mild CNS stimulant, methylphenidate tablets are taken orally, crushed and taken intranasally, or dissolved in water and injected. The pattern of abuse is similar to that of other CNS stimulants, with episodes of binge use followed by severe depression and continued use despite serious adverse consequences.

### Amphetamine Dependence and Its Treatment

Amphetamines and related drugs produce stimulation and euphoria. Small amounts produce mental alertness, wakefulness, and increased energy for a few hours. Tolerance develops rapidly, so users increase the amount and frequency of administration to regain the state of stimulation, continuing use as long as the drug is available and then “crashing” with profound fatigue and depression. Large amounts and long-term use damages the brain and may cause aggression, hallucinations, memory loss, paranoia, psychosis, and violence as well as serious cardiac dysrhythmias, severe dental disease, and stroke.

Acute ingestion of these drugs masks underlying fatigue or depression; withdrawal allows these conditions to emerge in an exaggerated form. The resulting exhaustion and depression reinforce the compulsion to continue using the drugs. Users may take them alone or to counteract the effects of other drugs. In the latter case, these drugs may be part of a pattern of polydrug use in which CNS depressants such as alcohol or sedative-type drugs (“downers”) are alternated with CNS stimulants, such as amphetamines (“uppers”).

Treatment is mainly concerned with overdosage because these drugs do not produce physical dependence and

withdrawal as alcohol, opioids, and sedative-hypnotic drugs do. The patient is likely to be hyperactive, agitated, and hallucinating (toxic psychosis) and may have tachycardia, fever, and other symptoms. Symptomatic treatment includes sedation, lowering of body temperature, and administration of an antipsychotic drug. Sedative-type drugs must be used with great caution, however, because depression and sleep usually follow amphetamine use, and these after-effects can be aggravated by sedative administration.

## Cocaine

Cocaine is a popular drug of abuse. It produces strong CNS stimulation by preventing reuptake of catecholamine neurotransmitters (e.g., dopamine, norepinephrine), which increases and prolongs neurotransmitter effects. The two main drug forms are cocaine hydrochloride powder and “crack.” Crack is strong, inexpensive, and extremely addicting. It is prepared by altering cocaine hydrochloride with chemicals and heat to form rock-like formations of cocaine base. The process removes impurities and results in a very potent drug. Cocaine powder is commonly inhaled (snorted) through the nose; “crack” is heated and the vapors inhaled. Both forms are rapidly absorbed; peak blood levels are higher with “crack” than with cocaine powder. The effects of cocaine use are very short. The euphoria from smoking “crack” lasts about 5 to 10 minutes and that from snorting the powder may last 15 to 30 minutes. Cocaine is also metabolized and eliminated rapidly; the half-life is about 1 hour.

In addition to intense euphoria, acute use of cocaine or “crack” produces increased energy and alertness, sexual arousal, tachycardia, increased blood pressure, and restlessness. High doses can cause cardiac dysrhythmias, convulsions, myocardial infarction, respiratory failure, stroke, and death, even in young, healthy adults and even with initial exposure. Cocaine withdrawal begins within hours of stopping drug use and lasts up to several days. Symptoms include depression (which may be profound), drowsiness, fatigue, and sleep disturbances (e.g., nightmares).

When cocaine and alcohol are present in the body at the same time, the drugs are converted to cocaethylene, a substance that has a longer duration of action and is more toxic to the brain than either drug alone. This mixture is the most common two-drug combination that results in drug-related death.

### Cocaine Dependence and Its Treatment

Cocaine is not thought to produce physical dependence. However, the euphoria associated with intake and the depression and fatigue associated with stopping intake are believed to induce psychological dependence and compulsive use. Because cocaine effects are very brief, users often ingest the drug every few minutes as long as it is available. Crack cocaine reportedly can cause psychological dependence with one use.

Drug therapy of cocaine dependence is largely symptomatic. Thus, agitation and hyperactivity may be treated with a benzodiazepine antianxiety agent, psychosis may be treated with **haloperidol** (Haldol) or another antipsychotic agent, car-

diac dysrhythmias may be treated with usual antidysrhythmic drugs, myocardial infarction may be treated by standard methods, and so forth. Initial detoxification and long-term treatment are best accomplished in centers or units that specialize in substance-abuse disorders. Long-term treatment of cocaine abuse usually involves psychotherapy, behavioral therapy, and 12-step programs. In addition, many patients also abuse other drugs and need treatment for coexisting psychiatric disorders.

## Nicotine

Nicotine, one of many active ingredients in tobacco products, is the ingredient that promotes compulsive use, abuse, and dependence. Inhaling smoke from a cigarette produces CNS stimulation in a few seconds. The average cigarette contains approximately 6 to 8 milligrams of nicotine and delivers approximately 1 milligram of nicotine systemically to the smoker (most is burned or dissipated as “sidestream” smoke). Nicotine obtained from chewing tobacco produces longer-lasting effects because it is more slowly absorbed than inhaled nicotine. Nicotine produces its effects by increasing levels of dopamine and other substances in the brain.

Nicotine is readily absorbed through the lungs, skin, and mucous membranes. It is extensively metabolized, mainly in the liver, and its metabolites are eliminated by the kidneys. It is also excreted in breast milk of nursing mothers. Adverse effects include nausea in new smokers at low blood levels and in experienced smokers at blood levels higher than their accustomed levels. Nicotine poisoning can occur in infants and children from ingestion of tobacco products, skin contact with used nicotine transdermal patches, or chewing nicotine gum. Poisoning may also occur with accidental ingestion of insecticide sprays containing nicotine. Oral ingestion usually causes vomiting, which limits the amount of nicotine absorbed. Toxic effects of a large dose may include hypertension, cardiac dysrhythmias, convulsions, coma, respiratory arrest, and paralysis of skeletal muscle. With chronic tobacco use, nicotine is implicated in the vascular disease and sudden cardiac death associated with smoking. However, the role of nicotine in the etiology of other disorders (e.g., cancer, pulmonary disease) associated with chronic use of tobacco is unknown.

### Nicotine Dependence and Its Treatment

Nicotine dependence is characterized by compulsive use and the development of tolerance and physical dependence. Mental depression is also associated with nicotine dependence. Cigarette smokers may smoke to obtain the perceived pleasure of nicotine’s effects, avoid the discomfort of nicotine withdrawal, or both. Evidence indicates a compulsion to smoke when blood levels of nicotine become low. Abstinence from smoking leads to signs and symptoms of withdrawal (e.g., anxiety, irritability, difficulty concentrating, restlessness, headache, increased appetite, weight gain, sleep disturbances), which usually begin within 24 hours of the last exposure to nicotine.

Most tobacco users who quit do so on their own. For those who are strongly dependent and unable or unwilling to quit on

their own, there are two main methods of treatment. One method is nicotine replacement therapy with drug formulations of nicotine. These products prevent or reduce withdrawal symptoms, but they do not produce the subjective effects or peak blood levels seen with cigarettes.

Nicotine is available in transdermal patches, chewing gum, an oral inhaler, and a nasal spray. The gum, inhaler, and spray are used intermittently during the day; the transdermal patch is applied once daily. Transdermal patches produce a steady blood level of nicotine and patients seem to use them more consistently than they use the other products. The patches and gum are available over-the-counter; the inhaler and nasal spray require a prescription. The products are contraindicated in people with significant cardiovascular disease (angina pectoris, dysrhythmias, or recent myocardial infarction). Adverse effects include soreness of mouth and throat (with gum), nausea, vomiting, dizziness, hypertension, dysrhythmias, confusion, and skin irritation at sites of transdermal patch application. Nicotine products are intended to be used for limited periods of 3 to 6 months, with tapering of dosage and discontinuation. Although they are effective in helping smokers achieve abstinence, many users resume smoking.

Other smoking-cessation drugs for nicotine dependence include bupropion, an antidepressant (see Chap. 10) and **varenicline** (Chantix). The antidepressant formulation of **bupropion** is marketed as Wellbutrin; the smoking-cessation formulation is Zyban, a sustained-release tablet. Varenicline (Chantix) blocks some nicotine receptors and thereby decreases the ability of nicotine to stimulate dopamine activity in the brain (the “reward” system). It also stimulates some other nicotine receptors and thereby decreases symptoms of nicotine withdrawal (the “punishment” system). Both medications are generally well tolerated. The most common adverse effects are insomnia with bupropion and nausea with varenicline.

Overall, treatment regimens that combine counseling and behavioral therapy with drug therapy are more successful than those using drug therapy alone. In addition, a combination of drugs (e.g., Zyban and nicotine transdermal patches) may be more effective than either drug alone.

## Marijuana

Marijuana and other cannabis preparations are obtained from *Cannabis sativa*, the hemp plant, which grows in most parts of the world, including the entire United States. Marijuana and hashish are the two cannabis preparations used in the United States. Marijuana is obtained from leaves and stems; hashish, prepared from plant resin, is 5 to 10 times as potent as commonly available marijuana. These cannabis preparations contain several related compounds called cannabinoids. Delta-9-tetrahydrocannabinol ( $\Delta$ -9-THC) is the main psychoactive ingredient, but metabolites and other constituents also may exert pharmacologic activity. THC binds to and activates cannabinoid receptors in areas of the brain that control memory, thought, concentration, time and depth perception, and coordinated movement. THC decreases activity of the neurons in each of these areas and thereby impairs these functions.

It also stimulates dopamine and the reward system of the brain, thereby producing euphoria, relaxation, and more intense sensations.

Cannabis preparations are difficult to classify. Some people call them depressants; some call them stimulants; and others label them as mind-altering, hallucinogenic, psychotomimetic, or unique in terms of fitting into drug categories. It is also difficult to predict the effects of these drugs. Factors that influence a person’s response include dose, route of administration, personality traits, and the amount of active ingredients, which varies with the climate and soil where the plants are grown and with the method of preparation. Reportedly, the THC content of marijuana products is higher now than previously, so that effects may be even more unpredictable.

Marijuana can be taken orally but is more often smoked and inhaled through the lungs. It is more potent and more rapid in its actions when inhaled. After smoking, subjective effects begin in about 10 minutes and last 2 to 3 hours. However, THC accumulates in fatty tissues and has a long half-life, so that impairment of musculoskeletal coordination and other adverse effects may last for more than 24 hours. Low doses are mildly intoxicating and similar to small amounts of alcohol. Large doses can produce panic reactions and hallucinations similar to acute psychosis. Effects wear off as THC is metabolized to inactive products.

Numerous adverse effects have been reported with marijuana use. In addition to CNS effects and impaired ability to perform common tasks of everyday life, THC may cause serious cardiovascular (e.g., hypertension, bradycardia, vasoconstriction; hypotension may occur with high doses), respiratory (e.g., damage to mucosa, chronic bronchitis with cough and wheezing, respiratory infections, possibly increased risk of lung cancer because the amount of some carcinogens is much higher in marijuana than in tobacco smoke), and other physiologic effects, especially with chronic use. In addition, there is a high risk of infection, especially in patients with acquired immunodeficiency syndrome (AIDS) or other immune system impairments, because marijuana products can be contaminated with fecal matter and various microorganisms (e.g., aspergillus, salmonella). Some authorities believe that adverse effects are now more common and serious than previously thought, because of the higher THC content in marijuana preparations.

Except for dronabinol (Marinol), marijuana and other cannabis preparations are illegal and not used therapeutically in most of the United States. Dronabinol, a formulation of  $\Delta$ -9-THC, is used to treat nausea and vomiting associated with anticancer drugs and to stimulate appetite in patients with AIDS. The risks of abuse are high, and the drug may cause physical and psychological dependence. It is a Schedule III controlled drug. Cannabinoids can also decrease intraocular pressure and may be useful in treating glaucoma. Some people promote legalization of marijuana for medical uses. However, clinicians state that such usage is no more effective than available legal treatments that have less abuse potential.

### Marijuana Dependence and Its Treatment

Tolerance and psychological dependence do not usually develop with occasional use but may occur with chronic use; physical dependence rarely occurs. There is no specific treatment other than abstinence.

### Hallucinogens

Hallucinogenic drugs include a variety of substances that cause mood changes, anxiety, distorted sensory perceptions, hallucinations, delusions, depersonalization, pupil dilation, elevated body temperature, and elevated blood pressure.

### Dextromethorphan

Dextromethorphan is a cough suppressant found in many OTC multisymptom cold and cough remedies. It is a synthetic drug derived from an opioid analgesic. It does not have analgesic or sedative effects. It is a CNS depressant but is usually classified as a *hallucinogen* because of dissociative effects similar to those of phencyclidine (PCP) and ketamine (see below) when it is taken in the high doses characteristic of abuse. (The maximum recommended therapeutic dose is 120 mg in 24 hours, taken in 15- to 30-mg amounts every 4 to 6 hours; abusers may take as much as 360 mg at one time).

Adverse effects include blurred vision, brain damage, confusion, dizziness, drowsiness, excessive sweating, hallucinations, impaired breathing, impaired judgment and mental functioning, loss of consciousness, loss of physical coordination, muscle twitches, nausea and vomiting, paranoia, rapid and irregular heartbeat, seizures, slurred speech, and death. In addition, OTC products contain other ingredients (e.g., acetaminophen, antihistamines, decongestants) that are also toxic in overdose. In 2005, the Food and Drug Administration (FDA) issued a warning against DM abuse after the deaths of five teenagers were associated with the ingestion of DM capsules. Overdose requires emergency treatment and may involve activated charcoal and IV naloxone, a narcotic antagonist.

### LSD

LSD (lysergic acid diethylamide) is a synthetic derivative of a compound in ergot and some varieties of morning glory seeds. It is very potent, and small doses can alter normal brain functioning. LSD is usually distributed as a soluble powder and ingested in capsule, tablet, or liquid form. The exact mechanism of action is unknown, and effects cannot be predicted accurately. LSD alters sensory perceptions and thought processes; impairs most intellectual functions, such as memory and problem-solving ability; distorts perception of time and space; and produces sympathomimetic reactions, including increased blood pressure, heart rate, and body temperature, as well as pupil dilation. Adverse reactions include self-injury and possibly suicide, violent behavior, psychotic episodes, “flashbacks” (a phenomenon characterized by psychological effects and hallucinations that may recur days, weeks, or months after the drug is taken), and possible chromosomal damage resulting in birth defects.

### Mescaline

Mescaline is an alkaloid of the peyote cactus. It is the least active of the commonly used psychotomimetic agents but produces effects similar to those of LSD. It is usually ingested in the form of a soluble powder or capsule.

### Phencyclidine

Phencyclidine (PCP) produces excitement, delirium, hallucinations, and other profound psychological and physiologic effects, including a state of intoxication similar to that produced by alcohol; altered sensory perceptions; impaired thought processes; impaired motor skills; psychotic reactions; sedation and analgesia; nystagmus and diplopia; and pressor effects that can cause hypertensive crisis, cerebral hemorrhage, convulsions, coma, and death. Death from overdose also has occurred as a result of respiratory depression. Bizarre murders, suicides, and self-mutilations have been attributed to the schizophrenic reaction induced by PCP, especially in high doses. The drug also produces flashbacks.

PCP is usually distributed in liquid or crystal form and can be ingested, inhaled, or injected. It is usually sprayed or sprinkled on marijuana or herbs and smoked. Probably because it is cheap, easily synthesized, and readily available, PCP is often sold as LSD, mescaline, cocaine, or THC (the active ingredient in marijuana). It may also be added to marijuana without the user's knowledge. Consequently, the drug user may experience severe and unexpected reactions, including death.

### Hallucinogen Dependence and Its Treatment

Tolerance develops, but there is no apparent physical dependence or abstinence syndrome. Psychological dependence probably occurs but is usually not intense. Users may prefer one of these drugs, but they apparently do without or substitute another drug if the one they favor is unavailable. A major danger with these drugs is their ability to impair judgment and insight, which can lead to panic reactions in which users may try to injure themselves (e.g., by running into traffic). There is no specific treatment for hallucinogen dependence. Those who experience severe panic reactions may be kept in a safe, supportive environment until drug effects wear off or may be given a sedative-type drug.

### “Club” and “Date-Rape” Drugs

“Ecstasy,” flunitrazepam (Rohypnol), gamma-hydroxybutyrate (GHB), and ketamine are reported to be widely used, mainly by adolescents and young adults. The “club drug” designation stems from use at all-night dance parties called “raves”; the “date-rape drug” designation stems from reported use of these drugs in unaware females to facilitate sexual conquest.

### Ecstasy

Ecstasy (3,4-methylenedioxy-methamphetamine or MDMA) is an illegal, Schedule I derivative of amphetamine. It is structurally similar to methamphetamine and mescaline and produces stimulant and hallucinogenic effects. MDMA first became popular with adolescents and young adults at “raves,”

but its use has spread to a variety of settings and age groups. It is usually taken orally, as a tablet, but it may be crushed and snorted or injected. Users report increased energy and perception, euphoria, and feelings of closeness to others. These effects occur within an hour after oral ingestion and last 4 to 6 hours.

Ecstasy is extremely dangerous, and usage is decreasing as users become more aware of serious adverse effects. Adverse effects include acute psychiatric symptoms (e.g., anxiety, panic, depression, paranoid thinking), cardiac dysrhythmias, coma, dehydration, delirium, hypertension, hyperthermia, hyponatremia, rhabdomyolysis, seizures, tachycardia, and death. These effects have occurred with a single use. Another major concern is the drug's neurotoxicity. Early effects include spasmodic jerking, involuntary jaw clenching, and teeth grinding. Long-term or permanent changes may result from damage to the nerve cells in the brain that use serotonin as a neurotransmitter. MDMA increases the release and inhibits reuptake of serotonin. This action floods the brain with high amounts of serotonin, which is important in emotion, mood, and memory. Chronic use of MDMA may deplete serotonin and lead to sadness or depression, insomnia, memory impairment, low energy or passivity, and a decreased ability to feel emotions or pleasure.

In addition to the many adverse effects of MDMA, users also need to be concerned about the actual product they are taking. There have been numerous reports of other drugs (e.g., LSD, methamphetamine, ketamine, PCP) being sold as ecstasy. All of these drugs may have serious adverse effects as well.

MDMA is not thought to cause dependence or withdrawal syndromes. Emergency treatment of MDMA abuse usually involves decreasing the high body temperature, replacing fluids and electrolytes, and monitoring for cardiovascular complications.

### **Flunitrazepam (Rohypnol)**

Flunitrazepam is a benzodiazepine (see Chap. 8) that is manufactured and used in Europe and other parts of the world. It is a Schedule I drug in the United States and has never been approved for any therapeutic use. The drug is usually taken orally, but the tablets are sometimes ground into a powder and snorted. Flunitrazepam is often taken with other drugs, including alcohol, cocaine, heroin, or marijuana. In addition to intentional use, the odorless and colorless drug has reportedly been added to punch and other drinks at fraternity parties and other social events, leading to its designation as a "date-rape" drug.

Even when flunitrazepam is taken alone in relatively low doses, the drug can cause muscle relaxation, general sedative and hypnotic effects, and the appearance of intoxication, with slurred speech, poor coordination, swaying, and bloodshot eyes. These effects begin within 30 minutes, peak within 2 hours, and may last 8 hours or longer, depending on dosage. Other adverse effects include confusion, dizziness, drowsiness, hypotension, memory impairment, and visual disturbances. In high doses, flunitrazepam causes a loss of muscle control, loss of consciousness, and partial amnesia. Combining the drug with alcohol increases its adverse effects.

As with other benzodiazepines, flunitrazepam causes dependence. After dependence has developed, stopping the drug induces withdrawal symptoms such as extreme anxiety, confusion, headache, irritability, muscle pain, and restlessness. Cardiovascular collapse, convulsions, delirium, hallucinations, numbness and tingling of the extremities, and shock also may occur. Withdrawal seizures can occur a week or longer after stopping the drug. The main treatment for flunitrazepam dependence is gradually tapering and discontinuing the drug.

### **Gamma-Hydroxybutyrate (GHB)**

GHB is a Schedule I controlled drug whose only approved use in the United States is for research. It is a CNS depressant that is structurally related to the inhibitory neurotransmitter, gamma-aminobutyric acid (GABA). Usage of GHB has increased in recent years, mainly in the party or dance-club setting, and is increasingly involved in poisonings, overdoses, date rapes, visits to hospital emergency departments, and fatalities. Some users admit they took the drug intentionally; some say the drug was added to their drinks without their knowledge or consent. In addition to its use as a "club" or "date-rape" drug, GHB is sometimes used by body builders for alleged anabolic effects. Formerly sold in health food stores as a nutritional supplement with numerous claims of beneficial effects, the drug became a controlled drug in 2000 after serious illnesses and deaths were reported. However, precursor substances (that are converted to GHB in the body) are reportedly still available in gyms and health food stores as dietary supplements.

GHB is available in an odorless, colorless liquid or as a white powder and is taken orally, often combined with alcohol. Effects include drowsiness, respiratory depression, seizures, unconsciousness, and vomiting. As with other sedative drugs, respiratory depression leading to hypoxia and death is the most serious adverse effect. Treatment of acute toxicity is mainly symptomatic and supportive.

With chronic use, GHB and its precursors (gamma-butyrolactone, butanediol) are reported to induce tolerance and produce dependence. Withdrawal symptoms of severe agitation, mental status changes (including symptoms of psychosis), elevated blood pressure, and tachycardia occur within hours of the last dose.

### **Ketamine**

Ketamine is an anesthetic that is chemically related to PCP and used mainly by veterinarians. It has become a "recreational" drug, and its effects are similar to those of PCP and LSD (e.g., distorted senses and perceptions, dissociative reactions). The hallucinations produced by ketamine last about an hour, but the user's senses, judgment, coordination, and self-control may be impaired as long as 24 hours after the initial use of the drug. These effects produce a high risk of injuries. Other effects include respiratory depression, heart rate abnormalities, and a withdrawal syndrome. Ketamine is a Schedule III controlled substance.

Ketamine is usually injected, but it may be taken orally, smoked, or swallowed. It is sometimes added to marijuana cigarettes. Effects include increased blood pressure, tachycardia,

respiratory depression, airway obstruction, apnea, hypertonic muscles and movement disorders, and psychosis. With overdoses, seizures, polyneuropathy, increased intracranial pressure, respiratory arrest, and cardiac arrest may occur. With chronic use, flashbacks and other effects may last up to 2 years after stopping the drug. Long-term effects include tolerance and possibly physical and/or psychological dependence.

## Inhalants

These drugs include volatile solvents such as acetone, toluene, and gasoline, substances that produce chemical vapors that can be inhaled to induce mind-altering effects. These solvents may be constituents of some types of glues, plastic cements, aerosol sprays, butane lighter, spray paints, degreasers or cleaning fluids, paint thinners and removers, felt-tip marker fluids, and other products. Some general inhalation anesthetics, such as nitrous oxide, have also been abused to the point of dependence. Nitrous oxide may be an ingredient in whipped cream dispensers and products that boost octane levels in racing cars. Volatile solvents are most often abused by preadolescents and adolescents who squeeze glue into a plastic bag, for example, and sniff the fumes. Suffocation sometimes occurs when the sniffer loses consciousness while the bag covers the face.

These substances produce symptoms comparable with those of acute alcohol intoxication, including initial mild euphoria followed by ataxia, confusion, and disorientation. Some substances in gasoline and toluene also may produce symptoms similar to those produced by the hallucinogens, including euphoria, hallucinations, recklessness, and loss of self-control. Large doses may cause convulsions, coma, and death.

Inhalants can harm the brain, liver, heart, kidneys, and lungs, and abuse of any drug during adolescence may interfere with brain development. Substances containing gasoline, benzene, or carbon tetrachloride are especially likely to cause serious damage to the liver, kidneys, and bone marrow. Inhalants can also produce psychological dependence, and some produce tolerance. There is some question about whether physical dependence occurs. If it does occur, it is considered less intense than the physical dependence associated with alcohol and opioids.

## Nursing Process

### Assessment

Assess patients for signs of alcohol and other drug abuse, including abuse of prescription drugs such as antianxiety agents, opioids, and sedative-hypnotics. Some general screening-type questions are appropriate for any initial nursing assessment. The overall purpose of these questions is to determine whether a current or potential problem exists and whether additional information is needed. Some patients may refuse to answer or give answers that contradict other

assessment data. Denial of excessive drinking and of problems resulting from alcohol use is a prominent characteristic of alcoholism; underreporting the extent of drug use is common in other types of drug abuse as well. Useful information includes each specific drug, the amount, the frequency of administration, and the duration of administration. If answers to general questions reveal problem areas, such as long-term use of alcohol or psychotropic drugs, more specific questions can be formulated to assess the scope and depth of the problem. It may be especially difficult to obtain needed information about illegal “street drugs,” most of which have numerous, frequently changed names. For nurses who often encounter substance abusers, efforts to keep up with drug names and terminology may be helpful.

- Interview the patient regarding alcohol and other drug use to help determine immediate and long-term nursing care needs. For example, information may be obtained that would indicate the likelihood of a withdrawal reaction; the risk of increased or decreased effects of a variety of drugs; and the patient’s susceptibility to drug abuse. People who abuse one drug are likely to abuse others, and abuse of multiple drugs is a more common pattern than abuse of a single drug. These and other factors aid effective planning of nursing care.
- Assess behavior that may indicate drug abuse, such as alcohol on the breath, altered speech patterns, staggering gait, hyperactivity or hypoactivity, and other signs of excessive CNS depression or stimulation. Impairments in work performance and in interpersonal relationships also may be behavioral clues.
- Assess for disorders that may be caused by substance abuse. These disorders may include infections, liver disease, accidental injuries, and psychiatric problems of anxiety or depression. These disorders may be caused by other factors, of course, and are nonspecific.
- Check laboratory reports, when available, for abnormal liver function test results, indications of anemia, abnormal white blood cell counts, abnormal electrolytes (hypocalcemia, hypomagnesemia, and acidosis are common in alcoholics), and alcohol and drug levels in the blood.

### Nursing Diagnoses

- Ineffective Coping related to reliance on alcohol or other drugs
- Risk for Injury: Adverse effects of abused drug(s)
- Disturbed Thought Processes related to use of psychoactive drugs
- Risk for Other- or Self-Directed Violence related to disturbed thought processes, impaired judgment, and impulsive behavior
- Imbalanced Nutrition: Less Than Body Requirements related to drug effects and drug-seeking behavior

- Dysfunctional Family Processes: Alcoholism
- Risk for Injury: Infection, hepatitis, or AIDS related to use of contaminated needles and syringes for IV drugs

### Planning/Goals

- Safety will be maintained for patients impaired by alcohol and drug abuse.
- Information will be provided regarding drug effects and treatment resources.
- The patient's efforts toward stopping drug usage will be recognized and reinforced.

### Interventions

- Administer prescribed drugs correctly during acute intoxication or withdrawal.
- Decrease environmental stimuli for the person undergoing drug withdrawal.
- Record vital signs; cardiovascular, respiratory, and neurologic functions; mental status; and behavior at regular intervals.
- Support use of resources for stopping drug abuse (psychotherapy, treatment programs).
- Request patient referrals to psychiatric/mental health physicians, nurse clinical specialists, or self-help programs when indicated.
- Use therapeutic communication skills to discuss alcohol or other drug-related health problems, health-related benefits of stopping substance use or abuse, and available services or treatment options.
- Teach nondrug techniques for coping with stress and anxiety.
- Provide positive reinforcement for efforts toward quitting substance abuse.
- Inform smokers with young children in the home that cigarette smoke can precipitate or aggravate asthma and upper respiratory disorders in children.
- Inform smokers with nonsmoking spouses or other members of the household that secondhand smoke can increase the risks of cancer and lung disease in the nonsmokers as well as the smoker.
- For smokers who are concerned about weight gain if they quit smoking, emphasize that the health benefits of quitting far outweigh the disadvantages of gaining a few pounds, and discuss ways to control weight without smoking.

### Evaluation

- Observe for improved behavior (e.g., less impulsiveness, improved judgment and thought processes, commits no injury to self or others).

- Observe for use or avoidance of nonprescribed drugs while hospitalized.
- Interview to determine the client's insight into personal problems stemming from drug abuse.
- Verify enrollment in a treatment program.
- Observe for appropriate use of drugs to decrease abuse of other drugs.

## Principles of Therapy

### Prevention of Substance Abuse

Alcohol and other drug abuse have devastating effects on individuals and communities. The losses of worker productivity and the astronomical costs of dealing with associated crime, violence, traumatic injuries, medical illness, and psychiatric disorders are depleting governmental units of resources that could provide more benefit to society if used for education and other purposes. Consequently, all citizens need to be concerned about this modern plague and support efforts to prevent people from starting drug abuse in the first place. Although there are difficulties in trying to prevent conditions for which causes are not known, some of the following community-wide and individual measures may be helpful:

- Decrease the availability of commonly abused drugs. Most efforts at prevention have tried to reduce the supply of drugs. For example, laws designate certain drugs as illegal and provide penalties for possession or use of these drugs; regulate circumstances in which legal drugs, such as opioid analgesics, may be used; and regulate the sale of alcoholic beverages. In recent years, laws to restrict the availability of ingredients used to manufacture methamphetamine and those to increase cigarette taxes and prevent smoking in public places have been passed.

Despite these efforts, drugs of abuse seem to be widely available, in homes, on the street, and from Internet sources. In many cases, prescription sedatives, analgesics, or methylphenidate preparations are obtained by various means and used for nonmedical purposes. Thus, every individual or family member has a responsibility for safe use and storage of these drugs so they cannot be diverted to illegal, nonmedical use.

- Decrease the demand for drugs. It is a simple axiom that drugs of abuse would not be available if there were no market for them. Because decreasing demand involves changing attitudes, it is very difficult but more effective in the long run. In general, American society has had a permissive attitude toward the use of alcohol and other drugs of abuse. This climate may be changing somewhat as evidenced by public support of laws increasing the costs of tobacco products and banning smoking in public places. Efforts to change attitudes and decrease demand for drugs can be

made through education and counseling about such topics as drug effects and nondrug ways to cope with the stresses and problems of daily life. Although community-wide efforts are important and should be supported, each individual must take personal responsibility for drinking alcoholic beverages and taking mind-altering drugs for the purpose of “getting high.” Initially, conscious, voluntary choices are made to drink or not to drink, to take a drug or not to take it. This period varies somewhat, but drug dependence develops in most instances only after prolonged use. When mind-altering drugs are prescribed for a legitimate reason, the patient must use them in prescribed doses and preferably for a short time.

- Drug prescribers can help prevent drug abuse by prescribing drugs appropriately, prescribing mind-altering drugs in limited amounts and for limited periods, using nondrug measures when they are likely to be effective, educating patients about the drugs prescribed for them, participating in drug education programs, and recognizing, as early as possible, patients who are abusing or who are likely to abuse drugs. Some authorities recommend that physicians question all patients about smoking cigarettes and offer cessation treatment when indicated.
- Nurses can help prevent drug abuse by administering drugs appropriately, using nondrug measures when possible, teaching patients about drugs prescribed for them, and participating in drug education programs. Some resources for information and educational materials are listed in Box 14-3.
- Parents can help prevent drug abuse by talking to their children about the dangers of substance abuse (e.g., brain damage and other serious health problems, as well as traumatic injuries, sexually transmitted diseases, etc.), limiting availability of abused substances in the home (e.g., alcohol; prescription pain relievers such as Percocet, Vicodin, and OxyContin; prescription sedatives such as Xanax; prescription methylphenidate for ADHD; OTC cold and cough remedies containing dextromethorphan; household products that can be abused by inhalation), monitoring the use and amounts of those products that are available, minimizing their own use of drugs, and avoiding heavy cigarette smoking. Children are more likely to use illegal drugs if their parents have a generally permissive attitude about drug taking, if either parent takes mind-altering drugs regularly, and if either parent is a heavy cigarette smoker.
- Substance abuse often starts during adolescence and is especially hazardous then, because the brain is still developing and especially vulnerable to damage. Teenagers obtain prescription drugs from prescribers (e.g., for ADHD; with tales of anxiety and stress or difficulty sleeping), friends, stealing them from family members, ordering them over the Internet, as well as on the street from dealers (who may be friends or schoolmates). Preteens may also abuse drugs, including alcohol, cough syrup containing dextromethorphan, and inhalants.
- Pregnant women should avoid alcohol, nicotine, and other drugs of abuse because of potentially harmful effects on the fetus.

## Goals of Therapy

The major goals of treatment for substance abuse are detoxification, initiation of abstinence, and prevention of relapse. Patients who are likely to benefit from treatment are those who admit that substance abuse is causing significant problems in their ability to function in activities of daily living. Despite advances in treatment and the many adverse consequences of substance abuse, relapses to drug-taking behavior are common among those who have been detoxified or even abstinent for varying periods of time.

## Treatment of Substance Abuse

Treatments for substance abuse are limited but increasing; more treatment facilities are needed. For most health professionals, contact with substance abusers is more likely to occur in acute situations, such as intoxication or overdose, withdrawal syndromes, or various medical-surgical illnesses associated with the substance abuse. In general, treatment depends on the type, extent, and duration of drug-taking behavior and the particular situation for which treatment is needed.

Psychological rehabilitation efforts should be part of any treatment program for a drug-dependent person. Several approaches may be useful, including inpatient and outpatient psychotherapy, voluntary self-help groups (e.g., Alcoholics Anonymous, Narcotics Anonymous), and other types of emotional support and counseling. Substance abusers are assisted

and encouraged to develop more healthful coping skills to deal with life stresses and to alter the environment or relationships in which substance abuse occurs. Much of this counseling is done by health care providers who specialize in treatment of drug dependence.

In addition to or along with “talk” therapy (e.g., cognitive behavior therapy), an intervention with some success is contingency management (also called motivational incentives), in which incentives or rewards are given for not using drugs (e.g., as evidenced by drug-free urine tests) with abusers of cocaine, marijuana, and methamphetamine. Rewards include vouchers of some kind that can be used to purchase various products. In one study, patients who remained abstinent for the entire treatment period of 14 weeks received vouchers for \$570, which could be exchanged for movie passes, sports or hobby equipment, and other purchases that would not enable or encourage substance abuse.

Drug therapy is limited in treating drug dependence for several reasons. First, specific antidotes are available only for benzodiazepines (flumazenil) and opioid narcotics (naloxone). Second, there is a high risk of substituting one abused drug for another. Third, there are significant drawbacks to giving CNS stimulants to reverse effects of CNS depressants, and vice versa. Fourth, there is often inadequate information about the types and amounts of drugs taken.

Two of the more successful drug therapy regimens are methadone administration for heroin dependence and nicotine replacement or other drug therapy (e.g., bupropion or varenicline) for nicotine dependence. With both treatments, however, a combination of drug therapy and counseling is more effective than either alone.

Despite these drawbacks, however, there are some clinical indications for drug therapy, including treatment of overdose or withdrawal syndromes. Even when drug therapy is indicated, there are few guidelines for optimal use. Doses, for example, must often be estimated initially and then titrated according to response. Drug therapy may be provided by primary care prescribers or prescribers who specialize in treatment of drug dependence.

General care of patients with drug overdose is primarily symptomatic and supportive. The aim of treatment is usually to support vital functions, such as respiration and circulation, until the drug is metabolized and eliminated from the body. For example, respiratory depression from an overdose of a CNS depressant drug may be treated by inserting an artificial airway and mechanical ventilation. Removal of some drugs can be hastened by hemodialysis.

Treatment of substance abuse may be complicated by the presence of other disorders. For example, medical illnesses and other psychiatric disorders are common.

## Key Concepts

- Drug abuse damages the brain and other body organs.
- Health professionals most often encounter substance abusers when they are intoxicated, overdosed, undergoing withdrawal, or have illnesses stemming from substance abuse.
- Drug therapy for substance abuse is most effective when combined with counseling and psychotherapy.
- Because substance abuse often starts during childhood and adolescence, health professionals, parents, teachers, and others need to teach children about risks of drug abuse and strategies to resist peer pressure to use drugs of abuse, limit access to drugs of abuse, and support programs and activities designed to decrease drug abuse in this population.

## Review and Application Exercises

### Short Answer Exercises

1. Why is it important to assess each patient in relation to alcohol and other substance abuse?
2. What are the signs and symptoms of overdose with alcohol, benzodiazepine antianxiety or sedative-hypnotic agents, cocaine, and opiates?
3. What are general interventions for treatment of drug overdoses?
4. What are specific antidotes for opioid and benzodiazepine overdoses, and how are they administered?
5. Which commonly abused drugs may produce life-threatening withdrawal reactions if stopped abruptly?

6. How can severe withdrawal syndromes be prevented, minimized, or safely managed?
7. What are the advantages of treating substance abuse disorders in centers established for that purpose?

### NCLEX-Style Questions

8. The nurse who is caring for a patient who has been abusing alcohol may expect to see what symptom as the patient enters withdrawal?
  - a. sleep
  - b. muscle relaxation
  - c. euphoria
  - d. agitation

9. The nurse taking care of an adolescent with a history of compulsive drug use is questioned by her parents about the reasons behind such drug use. The nurse is most correct when she states that compulsive drug use is attributed mainly to
  - a. drug stimulation of the “reward” center in the brain
  - b. a belief that the drugs are not harmful
  - c. parental pressure to do well in school
  - d. a permissive attitude toward taking drugs by parents and society
10. The nurse may expect an order to administer flumazenil (Romazicon) as an antidote for a patient admitted with an overdose of
  - a. alcohol
  - b. benzodiazepines
  - c. opioids
  - d. amphetamines
11. The nurse who is caring for a patient admitted with acute overdosage of cocaine knows that this is most likely to cause
  - a. severe lung damage
  - b. anaphylaxis
  - c. life-threatening cardiac dysrhythmias
  - d. hypotension
12. Which of the following drug products can be used to aid smoking cessation?
  - a. naltrexone (ReVia)
  - b. disulfiram (Antabuse)
  - c. bupropion (Zyban)
  - d. dronabinol (Marinol)

# Central Nervous System Stimulants

## KEY TERMS

- Attention deficit-hyperactivity disorder (ADHD)
- Narcolepsy

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Describe general characteristics of central nervous system (CNS) stimulants.
2. Discuss reasons for decreased use of amphetamines for therapeutic purposes.
3. Discuss the rationale for treating attention deficit-hyperactivity disorder with CNS stimulants.
4. Identify effects and sources of caffeine.
5. Identify nursing interventions to prevent, recognize, and treat stimulant overdose.

## Applying Your Knowledge

Kevin Granata was diagnosed with attention deficit-hyperactivity disorder (ADHD) at age 8. He is now 11 years old and a student at the school where you are the school nurse. As a result of taking methylphenidate (Ritalin) 15 mg daily and receiving individual counseling, Kevin's attention span and school performance improved.

Part of the annual school physical examination for all children is to track height and weight. Kevin's height and weight is less than normal for his age group, and he has lost weight since his examination last year. When you talk with his teachers, they report that he is restless in class and has an extremely short attention span. He has had more difficulty getting along with his classmates.

## Introduction

Many drugs stimulate the central nervous system (CNS), but only a few are used therapeutically, and their indications for use are limited. Two disorders treated with CNS stimulants are *attention deficit-hyperactivity disorder (ADHD)* and *narcolepsy*.

### Attention Deficit-Hyperactivity Disorder (ADHD)

ADHD is the most common psychiatric or neurobehavioral disorder in children. It is usually diagnosed between 3 and 7 years of age and may affect as many as 6% to 7% of school-age children. It is characterized by persistent hyperactivity, a short attention span, difficulty completing assigned tasks or schoolwork, restlessness, and impulsiveness. Such behaviors make it difficult for the child to get along with others (e.g., family members, peer groups, teachers) and to function in situations requiring controlled behavior (e.g., classrooms).

ADHD continues into adolescence and adulthood in approximately 50% of cases and may affect 4% of adults in the United States. In adolescents and adults, hyperactivity is not prominent,

but impulsiveness, inattention, and difficulties in structured settings such as school or work may continue. In addition, some studies indicate that children with ADHD are more likely to have learning disabilities, mood disorders, and substance abuse disorders as adolescents and adults. A major criterion for diagnosing later ADHD is a previous diagnosis of ADHD by 7 years of age. Some authorities believe this age limit is too restrictive. The diagnosis of ADHD in adults has greatly increased in recent years, with a concomitant increase in the use of prescribed CNS stimulants for its treatment.

## Narcolepsy

Narcolepsy is a sleep disorder characterized by daytime “sleep attacks” in which the person goes to sleep at any place or at any time. Signs and symptoms also include excessive daytime drowsiness, fatigue, muscle weakness and hallucinations at onset of sleep, and disturbances of nighttime sleep patterns. The hazards of drowsiness during normal waking hours and suddenly going to sleep in unsafe environments restrict activities of daily living.

Narcolepsy affects men and women equally and usually begins during the teenage or young adult years. Its cause is unknown, and sleep studies are required for an accurate diagnosis. In addition to drug therapy, prevention of sleep deprivation, regular sleeping and waking times, avoiding shift work, and short naps may be helpful in reducing daytime sleepiness. However, even adequate amounts of nighttime sleep do not produce full alertness.

## General Characteristics of Stimulants

CNS stimulants act by facilitating initiation and transmission of nerve impulses that excite other cells. The drugs are somewhat selective in their actions at lower doses but tend to involve the entire CNS at higher doses. In ADHD, the drugs improve academic performance, behavior, and interpersonal relationships. Major groups of stimulants are amphetamines and related drugs and xanthines.

Amphetamines increase the amounts of norepinephrine, dopamine, and possibly serotonin in the brain, thereby producing mood elevation or euphoria, increasing mental alertness and capacity for work, decreasing fatigue and drowsiness, and prolonging wakefulness. However, large doses produce signs of excessive CNS stimulation (e.g., agitation, confusion, hyperactivity, difficulty concentrating on tasks, hyperactivity, nervousness, restlessness) and sympathetic nervous system stimulation (e.g., increased heart rate and blood pressure, pupil dilation, slowed gastrointestinal [GI] motility, and other symptoms). Overdoses can result in psychosis, convulsions, stroke, cardiac arrest, and death.

Amphetamines are Schedule II drugs under the Controlled Substances Act and have a high potential for drug abuse and dependence. These drugs are widely sold on the street and commonly abused (see Chap. 14). Amphetamine-

related drugs (methylphenidate and dexamethylphenidate) have essentially the same effects as the amphetamines and are also Schedule II drugs. These drugs have long had **BLACK BOX WARNINGS** about the risk of drug dependence. In recent years, warnings have been added to all drugs used to treat ADHD about the risks of sudden death, serious cardiovascular problems (e.g., heart attack, hypertension), and psychiatric illnesses (e.g., psychosis, aggression, mania).

Xanthines stimulate the cerebral cortex, increasing mental alertness and decreasing drowsiness and fatigue. Other effects include myocardial stimulation with increased cardiac output and heart rate, diuresis, and increased secretion of pepsin and hydrochloric acid. Large doses can impair mental and physical functions by producing agitation, anxiety, cardiac dysrhythmias, gastritis, insomnia, nervousness and restlessness.

## Indications for Use

Amphetamines and methylphenidate are used in the treatment of narcolepsy and ADHD. Atomoxetine and dexamethylphenidate are indicated only for ADHD. Caffeine (a xanthine) is an ingredient in nonprescription analgesics and stimulants that promote wakefulness (e.g., NoDoz). A combination of caffeine and sodium benzoate is occasionally used as a respiratory stimulant in neonates. Modafinil is approved only for treatment of narcolepsy.

## Contraindications to Use

CNS stimulants also stimulate the cardiovascular system and thus are contraindicated in patients with cardiovascular disorders (e.g., angina, dysrhythmias, hypertension) that are likely to be aggravated by the drugs. They also are contraindicated in patients with anxiety or agitation, glaucoma, or hyperthyroidism. They are usually contraindicated in patients with a history of drug abuse. Caffeine is not recommended for people with cardiac dysrhythmias, a history of stroke, peptic ulcer disease, bipolar mood disorder, and schizophrenia.

## Individual Drugs

Individual drugs are described below. Dosages are listed in Table 15-1.

### Amphetamines and Related Drugs

**P Amphetamine**, dextroamphetamine (Dexedrine), and methamphetamine (Desoxyn) are closely related drugs that share characteristics of the amphetamines as a group. Except for the amphetamine/dextroamphetamine mixture of **Adderall**, which is used for treatment of ADHD in children and adults, amphetamines are more important as drugs of abuse than as therapeutic agents. A newer amphetamine, **lisdexamfetamine** (Vyvanse), is approved for treatment of ADHD. The drug reportedly delays the stimulation associated with other amphetamines and may be less prone to abuse.

**Methylphenidate** (e.g., Ritalin) is chemically related to amphetamines and produces similar actions and adverse effects.

Table 15-1

Drugs at a Glance: Central Nervous System Stimulants

Names/Indications for Use	ROUTES AND DOSAGE RANGES	
	Adults	Children
<b>Amphetamines</b>		
<b>P Amphetamine</b> ADHD Narcolepsy	Narcolepsy: PO 5–60 mg/d in divided doses	Narcolepsy: 6 y and older: PO 5 mg/d initially, increased at weekly intervals if necessary ADHD: 3–5 y: PO 2.5 mg/d initially, increased at weekly intervals if necessary 6 y and older: PO 5 mg once or twice daily initially, increased at weekly intervals until optimal response or maximum dose of 40 mg/d
<b>Dextroamphetamine</b> (Dexedrine) ADHD Narcolepsy		Narcolepsy: 6 y and older: PO 5 mg/d initially, increased at weekly intervals to effective dose ADHD: 3–5 y: PO 2.5 mg/d initially, increased at weekly intervals until response 6 y and older: PO 5 mg once or twice daily initially, increased at weekly intervals until optimal response or maximum dose of 40 mg/d
<b>Lisdexamfetamine</b> (Vyvanse) ADHD in Children		ADHD: 6–12 y: PO 30 mg once daily, increased if necessary. Maximum dose, 70 mg/d
<b>Methamphetamine</b> (Desoxyn) ADHD in children		PO 5 mg/d initially, increased if necessary. Usual dose 20–25 mg/d, in 2 divided doses.
<b>Amphetamine mixture</b> (Adderall, Adderall XR) ADHD Narcolepsy	Narcolepsy: PO 10 mg/d initially, increased if necessary ADHD: Extended release, 20 mg/d	ADHD: 3–5 y: PO 2.5 mg/d, increased if necessary 6 y and older: PO 5 mg 1–2 times daily, increased if necessary. Maximum dose 40 mg/d in 1–3 divided doses. Extended release: 6 y and older: PO 5–10 mg/d, increased at weekly intervals if necessary. Maximum dose, 30 mg/d. 13–17 y: PO 10 mg once daily, increased to 20 mg if necessary
<b>Amphetamine-Related Drugs</b>		
<b>Dexmethylphenidate</b> (Focalin, Focalin XR) ADHD	PO 5–10 mg/d, increased if necessary. Maximum dose, 20 mg/d.	6 y and older: PO 2.5–5 mg/d, increased if necessary. Maximum dose 20 mg/d.
<b>Methylphenidate</b> (MPH) (Immediate release[IR]), Generic MPH, Methylin, Ritalin)  (Extended release, Concerta, Metadate CD, Metadate ER, Methylin ER, Ritalin LA, Ritalin SR, Daytrana skin patch) ADHD Narcolepsy	ADHD: IR: PO 2.5–5 mg twice daily, before breakfast and lunch; increased by 5–10 mg/d at weekly intervals if necessary. Maximum dose 90 mg/d. ADHD: Metadate CD, Ritalin LA: PO 20 mg once daily, increased if necessary. Maximum dose, 60 mg/d. Narcolepsy: PO 10 mg 2–3 times daily, up to 60 mg/d	6 y and older: ADHD IR: PO 2.5–5 mg twice daily, before breakfast and lunch; increased by 5–10 mg/d at weekly intervals if necessary. Maximum dose 90 mg/d.  Concerta PO: 18 mg once daily, increased if necessary. Maximum dose 54 mg/d for children 6–12 y, 72 mg/d for children 13–17 y Metadate ER, Methylin ER, Ritalin SR may be substituted once the daily dose is titrated with immediate-release MPH tablets and the 8-hour dose corresponds to the extended release tablet size. Daytrana topical to skin for 9 h/d, 10 mg first week, then increase dose weekly until desired response

(continued on page 260)

Table 15-1

## Drugs at a Glance: Central Nervous System Stimulants (continued)

Names/Indications for Use	ROUTES AND DOSAGE RANGES	
	Adults	Children
<b>Other Drugs</b>		
<b>Atomoxetine</b> (Strattera) ADHD	PO 40 mg/d initially, increased after 3 d to 80 mg/d; given as a single dose in the morning, or as 2 divided doses in morning and early evening	Weight 70 kg or more: PO 0.5 mg/kg/d, increased after 3 d to approximately 1.2 mg/kg/d; given as a single dose in the morning, or as 2 divided doses in morning and early evening
<b>Modafinil</b> (Provigil) Narcolepsy; shift work disorder; excessive daytime sleepiness	PO 200 mg once daily, in the morning. Dosage should be reduced by 50% with severe hepatic impairment.	Dosage not established for children under 16 years of age.

It is well absorbed after oral administration. In children, peak plasma levels occur in about 2 hours with immediate-release tablets and in about 5 hours with extended-release tablets. The drug is mostly metabolized in the liver and excreted in the urine. Methylphenidate is marketed by generic and various trade names and in several dosage forms, including immediate release and chewable tablets, extended release capsules, and a transdermal patch. These dosage forms are not interchangeable. Methylphenidate has become a drug of abuse and its nonmedical use, alone or with other drugs, has increased emergency department visits by adolescents and young adults.

**Dexamethylphenidate** (Focalin) is very similar to methylphenidate and the amphetamines. It is well absorbed after oral administration and reaches peak plasma levels in 1 to 1.5 hours. It is metabolized in the liver and excreted in urine.

### Xanthines

**Caffeine** is a frequently consumed CNS stimulant worldwide, and most is obtained from dietary sources (e.g., coffee, tea, soft drinks). The caffeine content of coffee and tea beverages is determined by the particular coffee bean or tea leaf and the method of preparation. Caffeine is added to about 70% of the soft drinks ingested in the United States. In addition, so-called energy drinks are widely used, especially by teenagers and young adults. These products contain large amounts of caffeine and most contain large amounts of sugar.

In low to moderate amounts, caffeine increases alertness, wakefulness, and capacity for work; decreases fatigue; and delays sleep. Large amounts cause anxiety, agitation, diarrhea, hyperactivity, insomnia, irritability, nausea, nervousness, premature ventricular contractions, restlessness, tachycardia, tremors, and vomiting. Toxic amounts may cause delirium and seizures. With large amounts or chronic use, caffeine has been implicated as a causative or aggravating factor in cardiovascular disease (hypertension, dysrhythmias), GI disorders (esophageal reflux, peptic ulcers), reproductive disorders, osteoporosis (may increase loss of calcium in urine), psychiatric disturbances, and drug-abuse liability.

Caffeine produces tolerance to its stimulating effects and physical dependence occurs. Abstinence produces withdrawal symptoms, including drowsiness, fatigue, headache, and irritability, within 18 to 24 hours after stopping caffeine intake.

Caffeine is well absorbed from the GI tract and reaches a peak blood level within 30 to 45 minutes of oral ingestion. It easily crosses the blood-brain barrier and has a half-life of 3.5 to 5 hours. It is extensively metabolized, mainly in the liver, and excreted mainly in urine.

Pharmaceutical preparations of caffeine include an oral drug and a solution for injection. Caffeine is an ingredient in some nonprescription analgesic preparations and may increase analgesia. It is combined with an ergot alkaloid to treat migraine headaches (e.g., Cafergot) and is the active ingredient in nonprescription stimulant (antislleep) preparations. A combination of caffeine and sodium benzoate is used as a respiratory stimulant in neonatal apnea unresponsive to other therapies.

Because of the widespread ingestion of caffeine-containing beverages and the wide availability of over-the-counter products that contain caffeine, toxicity may result from concomitant consumption of caffeine from several sources. Some authorities recommend that normal, healthy, nonpregnant adults consume no more than 250 milligrams of caffeine daily. Common sources and amounts of caffeine are summarized in Table 15-2.

**Theophylline** preparations are xanthines used in the treatment of respiratory disorders, such as asthma and bronchitis. In these conditions, the desired effect is bronchodilation and improvement of breathing; CNS stimulation is then an adverse effect (see Chap. 44).

### Other Drugs

**Atomoxetine** (Strattera), a second-line drug for the treatment of ADHD in children and adults, has a low risk of abuse and dependence compared with the other drugs used for ADHD. It acts to inhibit reuptake of norepinephrine in nerve synapses. It is not a controlled drug. Atomoxetine is rapidly absorbed with oral administration, with peak plasma levels in 1 to 2 hours. It is highly protein bound (98%), and elimination half-life is

Table 15-2

## Sources of Caffeine

SOURCE	AMOUNT (oz)	CAFFEINE (mg)	COMMENTS
<b>Coffee</b>			
Brewed, regular	5–8	40–180	Caffeine content varies with product and preparation.
Instant	5–8	30–120	
Espresso	2	120	
Starbucks (regular)	12	58–279	
	16	116–372	
<b>Tea</b>			
Brewed, leaf or bag	8	80	Caffeine content varies with product and preparation.
Instant	8	50	
Iced	12	70	
<b>Soft Drinks</b>			
Coke, Diet Coke	12	45	Most other cola drinks contain 35–45 mg/12 oz.
Pepsi, Diet Pepsi	12	38	
Mountain Dew	12	54	
<b>Energy Drinks</b>			
Amp	8.4	75	Sugar 31 g (6 tsp)
Full throttle	16	141	Sugar 58 g (12 tsp)
Monster	16	140	Sugar 54 g (11 tsp)
Red Bull	8	80	Sugar 39 g (8 tsp)
Rockstar	16	160	Sugar 60 g (12 tsp)
SoBe Adrenaline Rush	8.3	79	Sugar 35 g (7 tsp)
SoBe No Fear	16	66	Sugar 66 g (13 tsp)
Tab Energy	10.5	95	Sugar 0 g
<b>OTC Analgesics</b>			
Anacin, Vanquish	1 tablet or caplet	30	
APAP-Plus, Excedrin, Midol	1 tablet, caplet, or geltab	60–65	
<b>OTC Antisleep Products</b>			
Caffedrine, NoDoz, Vivarin	1 tablet or capsule	200	
<b>OTC Diuretic</b>			
Aqua-Ban	1 tablet	100	PO 2 tablets 3 times daily
<b>Prescription Drugs</b>			
Cafergot	1 tablet	100	Also contains ergotamine. PO 2 tablets at onset of migraine, then 1 tablet every hour if needed, up to 6 tablets per attack or 2 suppositories per attack
	1 rectal suppository	100	
Fiorinal	1 capsule	40	Also contains a barbiturate and is a Schedule III controlled drug. PO 1–2 caplets every 4 hours, up to 6 caplets in 24 hours.

about 5 hours. Atomoxetine is metabolized in the liver by cytochrome P450 enzymes 2D6 and 2C19 and is excreted mainly in urine. Dosage should be reduced by 50% with moderate hepatic insufficiency and by 75% with severe hepatic insufficiency. The drug may be taken with or without food. Common adverse effects include abdominal pain, anorexia, cough, dry mouth, headache, insomnia, nausea, and vomiting.

There is a **BLACK BOX WARNING** that suicidal ideation may occur in children and adolescents.

**Modafinil** (Provigil) is used to treat narcolepsy and to improve wakefulness in other sleep disorders (e.g., obstructive sleep apnea/hypopnea syndrome, shift work sleep disorder). It is also used to decrease the fatigue associated with multiple sclerosis and other disorders.

Modafinil's ability to promote wakefulness is similar to that of amphetamines and methylphenidate, but its mechanism of action is unknown. Like other CNS stimulants, it has psychoactive effects that alter mood, perception, and thinking. It is a Schedule IV controlled drug. It is rapidly absorbed, reaches peak plasma levels in 2 to 4 hours, is 60% bound to plasma proteins, and is 90% metabolized by the liver to metabolites that are then excreted in urine.

Modafinil is not recommended for patients with a history of left ventricular hypertrophy or ischemic changes on electrocardiograms. Adverse effects include anxiety, chest pain, dizziness, dyspnea, dysrhythmias, headache, nausea, palpitations, and nervousness. Dosage should be reduced by 50% in patients with severe hepatic impairment.

## Herbal and Dietary Supplements

**Guarana** is made from the seeds of a South American shrub. The main active ingredient is caffeine, which is present in greater amounts than in coffee beans or dried tea leaves. Guarana is widely used as a source of caffeine by soft drink manufacturers. It is also used as a flavoring agent and is an ingredient in herbal stimulant and weight-loss products, energy drinks, vitamin supplements, candies, and chewing gums. The product, which may also contain theophylline and theobromine, is also available in teas, extracts, elixirs, capsules, and tablets of vari-

ous strengths. In general, the caffeine content of a guarana product is unknown, and guarana may not be listed as an ingredient. As a result, consumers may not know how much caffeine they are ingesting in products containing guarana.

As with caffeine from other sources, guarana may cause excessive nervousness and insomnia. It is contraindicated during pregnancy and lactation and should be used cautiously, if at all, in people who are sensitive to the effects of caffeine or who have cardiovascular disease. Overall, the use of guarana as a CNS stimulant and weight-loss aid is not recommended and should be discouraged.

## Nursing Process

### Assessment

- Assess use of stimulant and depressant drugs (prescribed, over-the-counter, or street drugs).
- Assess caffeine intake as a possible cause of anxiety, nervousness, insomnia, or tachycardia, alone or in combination with other CNS stimulants. Heavy users of caffeine may also be taking other psychoactive medications, especially CNS depressants such as antianxiety and sedative-hypnotic drugs.
- Try to identify potentially significant sources of caffeine intake.

## Patient Teaching Guidelines Caffeine

### General considerations

- There are numerous sources of caffeine, including coffee, cocoa, tea, most soft drinks, and several OTC medications. In addition, “energy drinks” (e.g., Red Bull, Monster, many others) containing high amounts of caffeine and sugar are popular with teenagers and young adult. They are aggressively marketed to this population for weight loss, increased endurance and wakefulness, decreased fatigue, and legal “highs.” Parents may think the drinks will help their children in school; coaches may think the drinks will help athletic performance. There is no evidence for these claims, and the risks of excessive caffeine intake are high. There are increasing visits to hospital emergency rooms and calls to poison centers for teens that become ill from excessive caffeine.

Some of the drinks also contain B vitamins, which can cause rapid heartbeat, heart palpitations, and numbness and tingling in the hands and feet when taken in large doses, and some are being mixed with alcoholic beverages. Two large companies produce “energy beers,” and a drink containing a mixture of Red Bull and vodka has been popular for several years. There is a great potential for traumatic injuries and alcohol poisoning with these products.

In general, authorities recommend no more than 250 milligrams of caffeine per day for healthy adults and little

to none for people with heart disease. Signs and symptoms of excess caffeine intake (e.g., anxiety, agitation, heart palpitations, insomnia, nausea, nervousness, tremors) usually occur with ingestion of 500 milligrams per day or more.

- Prevent nervousness, anxiety, tremors and insomnia from excessive intake by decreasing consumption of caffeinated beverages or by drinking decaffeinated coffee, tea, and cola. Sprite and 7 UP have no caffeine.
- Parents need to supervise and possibly limit their children's intake of caffeinated beverages, especially energy drinks. If children do consume such products, parents need to discuss with them the consequences of drinking too much.
- Parents and health care providers should caution high school and college students that caffeine, in any form, is not a substitute for adequate rest and sleep. Being tired and sleepy are normal and necessary resting mechanisms for the body.

### Self-Administration

- Limit intake of caffeinated beverages and read labels of over-the-counter stay-awake products and multi-ingredient pain reliever products so that you do not develop trouble sleeping as well as brain, heart, and stomach problems from excessive caffeine intake.

- Assess for conditions that are aggravated by CNS stimulants.
- For a child with possible ADHD, assess behavior as specifically and thoroughly as possible.
- For any patient receiving amphetamines or methylphenidate, assess behavior for signs of tolerance and abuse.

## Nursing Diagnoses

- Sleep Pattern Disturbance related to hyperactivity, nervousness, insomnia
- Risk for Injury: Adverse drug effects (excessive cardiac and CNS stimulation, drug dependence)
- Deficient Knowledge: Drug effects on children and adults
- Noncompliance: Overuse of drug

## Planning/Goals

### The patient will

- Take CNS stimulants safely and accurately
- Improve attention span and task performance (children and adults with ADHD) and decrease hyperactivity (children with ADHD)
- Have fewer sleep episodes during normal waking hours (for patients with narcolepsy)

## Interventions

- For a child receiving a CNS stimulant, assist parents in scheduling drug administration to increase beneficial effects and help prevent drug dependence and stunted growth. In addition, ask parents to control drug distribution and monitor the number of pills or capsules available and the number prescribed. The goals are to prevent overuse by the child for whom the drug is prescribed and to prevent the child from sharing his medication with other children who wish to take the drug for nonmedical purposes.
- Record weight at least weekly.
- Promote nutrition to avoid excessive weight loss.
- Provide information about the condition for which a stimulant drug is being given and the potential consequences of overusing the drug.

## Evaluation

- Ask parents and teachers of children with ADHD to report on behavior and academic performance.
- For adolescents and adults with ADHD, ask the patient or family about the patient's ability to function in work, school, or social environments.
- Assess for decreased inappropriate sleep episodes in patients with narcolepsy.

## Principles of Therapy

### Goals of Therapy

The main goal of therapy with CNS stimulants is to relieve symptoms of the disorders for which they are given. A secondary goal is to have patients use the drugs appropriately. Stimulants are often misused and abused by people who want to combat fatigue and delay sleep, such as long-distance drivers, students, and athletes. College students reportedly use stimulants as study aids. Use of stimulants for these purposes is not justified. These drugs are dangerous for drivers and those involved in similar activities and have no legitimate use in athletics.

### Applying Your Knowledge 15-1

A teacher comes to the health office and tells you that he has observed Kevin selling his methylphenidate (Ritalin) to the school's star soccer player. What advice will you give this teacher and what obligation do you have regarding Kevin's personal health information?

.....

### Drug Dosage

When a CNS stimulant is prescribed, it is started with a low dose that is then increased as necessary, usually at weekly intervals, until an effective dose (i.e., decreased symptoms) or the maximum daily dose is reached. In addition, the number of doses that can be obtained with one prescription should be limited. This action reduces the likelihood of drug dependence or diversion (use by people for whom the drug is not prescribed).

### Toxicity: Recognition and Management

Overdoses may occur with acute or chronic ingestion of large amounts of a single stimulant, combinations of stimulants, or concurrent ingestion of a stimulant and another drug that slows the metabolism of the stimulant. Signs of toxicity may include severe agitation, cardiac dysrhythmias, combativeness, confusion, delirium, hallucinations, high body temperature, hyperactivity, hypertension, insomnia, irritability, nervousness, panic states, restlessness, tremors, seizures, coma, circulatory collapse, and death.

Treatment is largely symptomatic and supportive. In general, place the patient in a cool room, monitor cardiac function and body temperature, and minimize external stimulation. Activated charcoal (1 g/kg of body weight) may be given. With amphetamines, urinary acidification, IV fluids, and IV diuretics (e.g., furosemide, mannitol) hasten drug excretion. IV diazepam or lorazepam may be given to control agitation, hyperactivity, or seizures, and haloperidol may be given to control symptoms of psychosis. If cardiovascular collapse occurs, fluid replacement and vasopressors may be used. If a long-

## Patient Teaching Guidelines

## CNS Stimulants for ADHD

### General Considerations

- When diagnosed with ADHD and before taking any medication for it, adult patients and parents of children should inform a health care provider about any other stimulant drugs being taken, involvement in strenuous activities of any kind, any heart disease, or any family history of sudden cardiac death. All ADHD drugs stimulate the heart and blood vessels. The effects are usually a faster heart-beat and increased blood pressure, but cardiac arrest, stroke, or sudden death may occur.
- These drugs may mask symptoms of fatigue, impair physical coordination, and cause dizziness or drowsiness. Use caution while driving or performing other tasks requiring alertness.
- Notify a health care provider of nervousness, insomnia, heart palpitations, vomiting, fever, or skin rash. These are adverse drug effects and dosage may need to be reduced.
- Avoid other stimulants, including caffeine.
- Record weight at least weekly; report excessive losses.
- The drugs may cause weight loss; caloric intake (of nutritional foods) may need to be increased, especially in children.
- Take stimulant drugs only as prescribed. These drugs have a high potential for abuse. The risks of serious health problems and drug dependence are lessened if they are

taken correctly. The likelihood of medical problems is greatly increased when ADHD medication is used improperly or in combination with other drugs.

- Get adequate rest and sleep. Do not take stimulant drugs to delay fatigue and sleep; these are normal, necessary resting mechanisms for the body.
- Keep these medications away from children, preferably in a locked cabinet. Parents (or a school nurse) need to dispense each dose and to be sure the drug is taken only by the child for whom it was prescribed.

### Self-Administration and Administration to Children

- Take (or give) regular tablets approximately 30 to 45 minutes before meals.
- Take (or give) the last dose of the day in the afternoon, before 6 P.M., to avoid interference with sleep.
- Ritalin SR, Concerta, Metadate CD, and Metadate ER are long-acting forms of methylphenidate. They should be swallowed whole, without crushing or chewing.
- Use the Daytrana skin patch exactly as prescribed. See the manufacturer's instructions for opening, applying, removing, and disposing of the skin patch.
- If excessive weight loss, nervousness, or insomnia develops, ask the prescribing physician if the dose can be reduced or taken on a different schedule to relieve these adverse effects.

acting form of the stimulant drug has been ingested, saline cathartics may be useful to remove undissolved drug granules.

With caffeine, ingestion of 15 to 30 milligrams per kilogram of body weight (e.g., 1–2 g for a person weighing 70 kg [150 lb]) may cause myocardial irritability, muscle tremors or spasms, and vomiting. Oral doses of 5 grams or more may cause death. Signs of toxicity are correlated with serum levels of caffeine. Several cups of coffee (or beverages that contain similar amounts of caffeine) may produce levels of 5 to 10 micrograms per liter and symptoms of agitation and tremors. Cardiac dysrhythmias and seizures occur at higher levels. Additional manifestations of caffeine toxicity include opisthotonus, decerebrate posturing, muscle hypertonicity, rhabdomyolysis with subsequent renal failure, pulmonary edema, hyperglycemia, hypokalemia, leukocytosis, ketosis, and metabolic acidosis.

Treatment is symptomatic and supportive, with activated charcoal if indicated. IV diazepam or lorazepam may be used to control seizures. Hemodialysis is indicated if the serum caffeine concentration is more than 100 micrograms per microliter or if life-threatening seizures or cardiac dysrhythmias occur.

### Applying Your Knowledge 15-2

Kevin comes to the health office complaining that his heart is racing. He is very agitated and has tremors in his hands. What actions should you initiate?

.....

## Effects of Central Nervous System Stimulants on Other Drugs

**Caffeine** may increase adverse effects of clozapine and theophylline by decreasing their metabolism and increasing their blood levels. It may increase effects of aspirin by increasing aspirin absorption. It may decrease effects of lithium by increasing lithium clearance. **Dexmethylphenidate** and **methylphenidate** may increase effects of phenytoin and antidepressants (selective serotonin reuptake inhibitors and tricyclics), and they may decrease effects of antihypertensive drugs. **Modafinil** may increase effects of citalopram, clomipramine, diazepam, phenytoin, propranolol, sertraline, tricyclic antidepressants, and warfarin. It may decrease effects of cyclosporine and oral contraceptives. **Atomoxetine** may increase the effects of drugs that stimulate cardiovascular function (e.g., increase heart rate and blood pressure).

## Use in Special Populations

### Use in Children

CNS stimulants are not recommended for ADHD in children younger than 3 years of age. When used, parents need to monitor their children's use of ADHD medications, and dosage must be carefully titrated and monitored to avoid excessive CNS stimulation, anorexia, and insomnia. Suppression of weight and height (e.g., less than the estimated average of 2 inches per year) may occur, and growth should be monitored

during drug therapy. In children with psychosis or Tourette's syndrome, CNS stimulants may exacerbate symptoms. In children and adolescents with pre-existing heart disease, usual doses of dextroamphetamine may cause sudden death.

In ADHD, careful documentation of baseline symptoms over approximately 1 month is necessary to establish the diagnosis and evaluate outcomes of treatment. This can be done with videotapes of behavior, observations and ratings by clinicians familiar with ADHD, and by interviewing the child, parents, or caretakers. Some authorities believe that this condition is overdiagnosed and that stimulant drugs are prescribed unnecessarily. Guidelines for treatment of ADHD include the following:

- Counseling and psychotherapy (e.g., parental counseling, family therapy) are recommended along with drug therapy for effective treatment and realistic expectations of outcomes.
- Young children may not require treatment until starting school. Then, the goal of drug therapy is to control symptoms, facilitate learning, and promote social development.
- Drug therapy is indicated when symptoms are moderate to severe; are present for several months; and interfere in social, academic, or behavioral functioning).
- Methylphenidate is commonly prescribed and usually given daily for the first 3 to 4 weeks of treatment to allow caregivers to assess beneficial and adverse effects. Desirable effects may include improvement in behavior, attention

span, and quality and quantity of school work and better relationships with other children and family members. Adverse effects include appetite suppression and weight loss, which may be worse during the first 6 months of therapy.

- A drug holiday (i.e., stopping drug therapy) is recommended at least annually to evaluate the child's treatment regimen. Dosage adjustments are usually needed as the child grows and hepatic metabolism slows. Also, drug holidays decrease weight loss and growth suppression.

### Applying Your Knowledge 15-3

What might be a drug-related reason for Kevin's weight loss? How would you instruct Kevin on the appropriate way to take his medicine?

### Use in Older Adults

CNS stimulants should be used cautiously in older adults. As with most other drugs, slowed metabolism and excretion increase the risks of accumulation and toxicity. Older adults are likely to experience anxiety, confusion, insomnia, and nervousness from excessive CNS stimulation. In addition, older adults often have cardiovascular disorders (e.g., angina, dysrhythmias, hypertension) that may be aggravated by the cardiac-stimulating effects of the drugs, including dietary caffeine. In general, reduced doses are safer in older adults.

## Nursing Actions

## Central Nervous System Stimulants

### NURSING ACTIONS

#### 1. Administer accurately

- a. Give the first dose of a CNS stimulant drug early in the day or upon awakening; give the last dose at least 6 hours before bedtime.
- b. For children with attention deficit-hyperactivity disorder (ADHD), give immediate-release forms of amphetamines and methylphenidate about 30–45 minutes before meals.
- c. Do not crush or open and instruct patients not to bite or chew long-acting forms of amphetamine mixture (Adderall XR) or methylphenidate (Concerta, Metadate CD, Metadate ER, Ritalin SR).
- d. With transdermal methylphenidate (Daytrana), follow instructions exactly for application, timing, removal, and disposal.
- e. Give atomoxetine with or without food.

#### 2. Observe for therapeutic effects

- a. Fewer "sleep attacks" with narcolepsy
- b. Improved behavior and performance of cognitive and psychomotor tasks with ADHD
- c. Increased mental alertness and decreased fatigue

### RATIONALE/EXPLANATION

To avoid interference with sleep. If insomnia occurs, give the last dose of the day at an earlier time or decrease the dose.

To minimize the drugs' appetite-suppressing effects and risks of interference with nutrition and growth

Breaking the tablets or capsules destroys the extended-release feature and allows the drug to be absorbed faster. An overdose may result.

Correct use is required for the most beneficial effects and fewest adverse effects. The skin patch should be removed after 9 hours.

Therapeutic effects depend on the reason for use. Effects of most ADHD drugs start within approximately 2 hours after drug administration.

(continued on page 266)

## Nursing Actions

### Central Nervous System Stimulants (continued)

#### NURSING ACTIONS

#### 3. Observe for adverse effects

- a. Excessive central nervous system (CNS) stimulation—  
anxiety, hyperactivity, nervousness, insomnia, tremors,  
convulsions, psychotic behavior
- b. Cardiovascular effects—tachycardia, other dysrhythmias,  
hypertension
- c. Gastrointestinal effects—anorexia, gastritis, weight loss,  
nausea, diarrhea, constipation
- d. With the methylphenidate patch (Daytrana), skin irrita-  
tion at the site of application

#### 4. Observe for drug interactions

- a. Drugs that *increase* the effects of CNS stimulants:

- (1) Other CNS stimulant drugs
- (2) Albuterol and related antiasthmatic drugs, pseu-  
doephedrine

- b. Drugs that *decrease* effects of CNS stimulants:

- (1) CNS depressants

- c. Drugs that *increase* effects of amphetamines:

- (1) Alkalinizing agents (e.g., antacids)

- (2) Monoamine oxidase (MAO) inhibitors

- d. Drugs that *decrease* effects of amphetamines:

- (1) Acidifying agents

- (2) Antipsychotic agents

- e. Drugs that *increase* effects of methylphenidate:

- (1) Chlorpromazine, fluoxetine, miconazole, paroxetine,  
ritonavir, ropinirole

- f. Drugs that *decrease* effects of methylphenidate:

- (1) Carbamazepine

- g. Drugs that *increase* effects of modafinil:

- (1) Clarithromycin, diclofenac, doxycycline, erythromycin,  
imatinib, itraconazole

- h. Drugs that *decrease* effects of modafinil:

- (1) Carbamazepine, phenytoin, rifampin

- i. Drugs that *increase* effects of caffeine:

- (1) Fluvoxamine, mexiletine, theophylline

- (2) Cimetidine, oral contraceptives

- j. Drugs that *decrease* effects of caffeine:

- (1) Carbamazepine, phenytoin, rifampin

#### RATIONALE/EXPLANATION

Adverse effects may occur with acute or chronic ingestion of any CNS stimulant drugs.

These reactions are more likely to occur with large doses.

These reactions are caused by the sympathomimetic effects of the drugs.

Skin irritation can be minimized by correct application and rotating sites.

Such combinations are potentially dangerous and should be avoided or minimized.

These drugs cause additive CNS- and cardiac-stimulating effects.

IV diazepam or lorazepam may be used to decrease agitation, hyperactivity, and seizures occurring with stimulant overdose.

Drugs that increase the alkalinity of the gastrointestinal tract increase intestinal absorption of amphetamines, and urinary alkalinizers decrease urinary excretion. Increased absorption and decreased excretion serve to potentiate drug effects. Potentiate amphetamines by slowing drug metabolism. These drugs thereby increase the risks of headache, subarachnoid hemorrhage, and other signs of a hypertensive crisis. The combination may cause death and should be avoided.

Urinary acidifying agents (e.g., ammonium chloride) increase urinary excretion and lower blood levels of amphetamines. Decreased absorption and increased excretion serve to decrease drug effects.

Decrease or antagonize the excessive CNS stimulation produced by amphetamines. Chlorpromazine (Thorazine) or haloperidol (Haldol) is sometimes used in treating amphetamine overdose.

These drugs inhibit the cytochrome P450 2D6 enzymes that normally metabolize methylphenidate

These drugs inhibit cytochrome P450 3A4 enzymes that partly metabolize modafinil.

These drugs induce cytochrome P450 3A4 enzymes that partly metabolize modafinil.

These drugs inhibit the cytochrome P450 1A2 enzymes that participate in the metabolism of caffeine. Decreased metabolism may increase adverse effects.

May impair caffeine metabolism

These drugs induce drug-metabolizing enzymes, thereby decreasing blood levels and increasing clearance of caffeine.

## Key Concepts

- ADHD is characterized by hyperactivity, impulsivity, and a short attention span.
- ADHD usually starts in childhood and may persist through adulthood.
- CNS stimulants improve behavior and attention in patients with ADHD.
- Narcolepsy is characterized by daytime drowsiness and unpredictable “sleep attacks.”
- Prescribed CNS stimulants are also abused and used for nonmedical purposes.
- All of the CNS stimulants, including caffeine, can cause life-threatening health problems with excessive intake.

## Review and Application Exercises

### Short Answer Exercises

1. What kinds of behaviors may indicate narcolepsy?
2. What kinds of behaviors may indicate ADHD?
3. What is the rationale for treating narcolepsy and ADHD with CNS stimulants?
4. What are the major adverse effects of CNS stimulants, and how may they be minimized?
5. Do you think children taking CNS stimulants for ADHD should have drug-free periods? Justify your answer.

### NCLEX-Style Questions

6. The nurse caring for a child with ADHD knows that when a CNS stimulant is used, the following outcomes may be expected:
  - a. increased behavioral problems
  - b. improved performance in schoolwork
  - c. decreased ability to complete a task
  - d. increased hyperactivity

7. The nurse caring for a child who is receiving a CNS stimulant for ADHD knows that it is most important to monitor for which of the following?
  - a. abnormal liver function
  - b. weight loss
  - c. fever
  - d. seizure activity
8. Caffeine and other CNS stimulants may cause which of the following adverse effects?
  - a. increased appetite
  - b. respiratory depression
  - c. sedation
  - d. cardiac dysrhythmias

## Drugs Affecting the Autonomic Nervous System

### Chapter Outline

- 16** ■ Physiology of the Autonomic Nervous System
- 17** ■ Adrenergic Drugs
- 18** ■ Antiadrenergic Drugs
- 19** ■ Cholinergic Drugs
- 20** ■ Anticholinergic Drugs

# Physiology of the Autonomic Nervous System

## KEY TERMS

- Adrenergic
- Antiadrenergic
- Anticholinergic
- Autonomic nervous system (ANS)
- Catechol-O-methyltransferase (COMT)
- Cholinergic
- Dopamine
- Down-regulation
- Effector organ
- Epinephrine
- First messenger
- Ligands
- Monoamine oxidase (MAO)
- Muscarinic
- Neurotransmitter
- Nicotinic
- Nitrous oxide
- Parasympathetic nervous system
- Postganglionic
- Preganglionic
- Receptor
- Second messenger
- Signal transduction
- Sympathetic nervous system
- Up-regulation

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Identify physiologic effects of the sympathetic nervous system.
2. Differentiate subtypes and functions of sympathetic nervous system receptors.
3. Identify physiologic effects of the parasympathetic nervous system.
4. Differentiate subtypes and functions of parasympathetic nervous system receptors.
5. Describe signal transduction and the intracellular events that occur when receptors of the autonomic nervous system are stimulated.
6. State names and general characteristics of drugs affecting the autonomic nervous system.

## Introduction

The nervous system is composed of two main divisions, the central nervous system (CNS) and the peripheral nervous system (PNS) (Fig. 16-1). The CNS includes the brain and spinal cord. It receives and processes incoming sensory information and responds by sending out signals that initiate or modify body processes.

The PNS includes all the neurons and ganglia found outside the CNS. The PNS includes afferent neurons and efferent neurons. Afferent neurons carry sensory input from the periphery to the CNS and modify motor output through the action of reflex arcs. Efferent neurons carry motor signals from the CNS to the peripheral areas of the body.

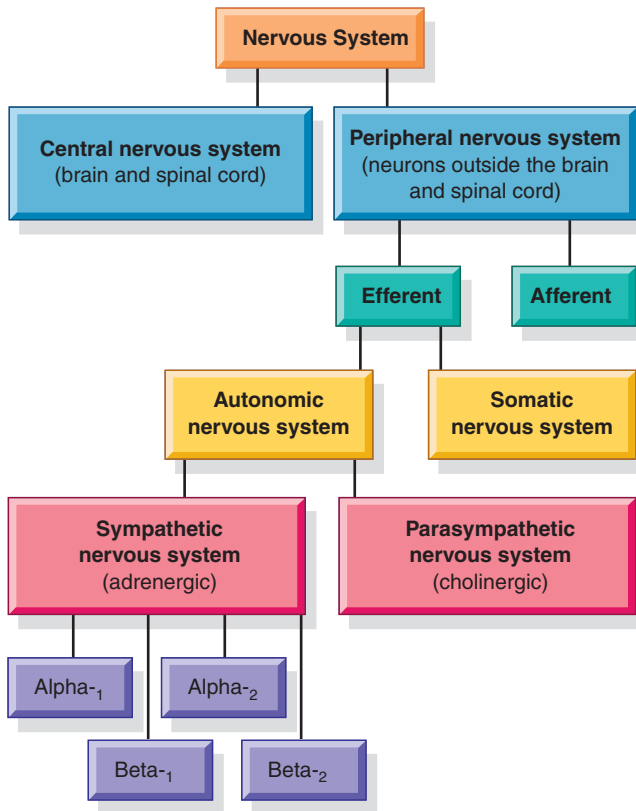

The efferent portion of the PNS is further subdivided into the somatic nervous system and the *autonomic nervous system* (ANS). The somatic nervous system innervates skeletal muscles and controls voluntary movement. The ANS, without conscious thought or effort, controls involuntary activities in smooth muscle, secretory glands, and in the visceral organs of the body such as the heart.

The functions of the ANS can be broadly described as activities designed to maintain a constant internal environment (homeostasis), to respond to stress or emergencies, and to repair body tissues. The ANS is regulated by centers in the CNS, including the hypothalamus, brain stem, and spinal cord. It is subdivided into the sympathetic nervous system and the parasympathetic nervous system.

## Structure and Function of the Autonomic Nervous System

Nerve impulses are generated and transmitted to body tissues in the *sympathetic nervous system* and the *parasympathetic nervous system*, as they are in the CNS (see Chap. 5). *Preganglionic* nerve

**Figure 16-1** ■ Divisions of the human nervous system.

impulses travel from the CNS along the presynaptic nerves to ganglia. Ganglia are bundles of nerve tissue composed of the terminal end of the presynaptic neuron and clusters of postsynaptic neuron cell bodies. A *neurotransmitter* is released from the terminal end of the presynaptic neuron, allowing the nervous impulse to bridge the synapse between the presynaptic and postsynaptic nerve. The *postganglionic* impulses travel from the ganglia to target or effector tissues of the heart, blood vessels, glands, other visceral organs, and smooth muscle. A neurotransmitter is released from the terminal end of the postsynaptic neuron, allowing the impulse to reach the effector tissue, stimulate a *receptor*, and bring about a response (Fig. 16-2).

The main neurotransmitters of the ANS are acetylcholine and norepinephrine (see Chap. 5). Acetylcholine is synthesized from acetylcoenzyme A and choline. It is released at preganglionic fibers of both the sympathetic nervous system and parasympathetic nervous system and at postganglionic fibers of the parasympathetic nervous system. Acetylcholine is also released from postganglionic sympathetic neurons that innervate the sweat glands and from motor neurons of the somatic nervous system that innervate the skeletal muscles. The nerve fibers that secrete acetylcholine are called cholinergic fibers. Acetylcholine acts on receptors in body organs and tissues to cause parasympathetic effects.

Norepinephrine is synthesized from the amino acid tyrosine by a series of enzymatic conversions that also produce

dopamine and *epinephrine* (i.e., tyrosine → dopamine → norepinephrine → epinephrine). Norepinephrine is the end product of this chemical reaction, except in the adrenal medulla, where most of the norepinephrine is converted to epinephrine. Norepinephrine is released at most postganglionic fibers of the sympathetic nervous system. Nerve fibers secreting norepinephrine are called adrenergic fibers. Norepinephrine acts on receptors in body organs and tissues to cause sympathetic effects.

Neurotransmitters, such as acetylcholine and norepinephrine, as well as medications and hormones that can bind to receptors in the ANS, are collectively called *ligands*. When receptors located on target tissues are stimulated by a ligand, a cascade of intracellular events known as signal transduction is initiated. The ligand that binds the receptor is the *first messenger*. In most cases, this ligand–receptor interaction activates a cell membrane–bound G protein and an effector enzyme, which then activate a molecule inside the cell called a *second messenger*. This second messenger is the link between events that are occurring outside the cell (i.e., receptor activation by the ligand) and resulting events that will occur inside the cell, such as opening ion channels, stimulating other enzymes, and increasing intracellular calcium levels. These intracellular events ultimately produce the physiologic responses to neurotransmitter and hormone release or drug administration. Figure 16-3 illustrates the intracellular events of *signal transduction* that occur when an adrenergic beta receptor is stimulated by epinephrine.

Involuntary organs and tissues in the body are innervated by both divisions of the ANS; however, most organs are predominantly controlled by one system. For example, in the gastrointestinal tract, the parasympathetic nervous system predominates and stimulation of the parasympathetic nervous system regulates the routine activities of digestion and elimination.

The two divisions of the ANS are usually antagonistic in their actions on a particular organ. When the sympathetic system excites a particular organ, the parasympathetic system often inhibits it and vice versa. Stimulation of the ANS causes excitatory effects in some organs but inhibitory effects in others. For example, sympathetic stimulation of the heart causes an increased rate and force of myocardial contraction; parasympathetic stimulation decreases rate and force of contraction, thereby resting the heart. In the gastrointestinal tract, stimulation of the parasympathetic nervous system promotes digestion; sympathetic stimulation decreases blood flow and impairs digestion. Exceptions to this antagonistic action include sweating and regulation of arteriolar blood-vessel diameter, which is controlled by the sympathetic nervous system.

## Sympathetic Nervous System

The sympathetic nervous system is stimulated by physical or emotional stress, such as strenuous exercise or work, pain, hemorrhage, intense emotions, and temperature extremes. Increased capacity for vigorous muscle activity in response to a perceived threat, whether real or imaginary, is often called the fight-or-flight reaction. Specific body responses include

**Figure 16-2** ■ Organization of the autonomic and somatic nervous systems.

- Increased arterial blood pressure and cardiac output
- Increased blood flow to the brain, heart, and skeletal muscles; decreased blood flow to viscera, skin, and other organs not needed for fight-or-flight
- Increased rate of cellular metabolism—increased oxygen consumption and carbon dioxide production
- Increased breakdown of muscle glycogen for energy
- Increased blood sugar
- Increased mental activity and ability to think clearly
- Increased muscle strength
- Increased rate of blood coagulation
- Increased rate and depth of respiration
- Pupil dilation to aid vision
- Increased sweating (Note that acetylcholine is the neurotransmitter for this sympathetic response. This is a deviation from the normal postganglionic neurotransmitter, which is norepinephrine.)

These responses are protective mechanisms designed to help the person cope with the stress or get away from it. The intensity and duration of the sympathetic response depends on the amounts of norepinephrine and epinephrine present.

Norepinephrine is synthesized in adrenergic nerve endings and released into the synapse when adrenergic nerve endings are stimulated. It exerts intense but brief effects on presynaptic and postsynaptic adrenergic receptors. The effects of norepinephrine are terminated by reuptake of most of the neurotransmitter back into the nerve endings, where it is packaged into vesicles for reuse as a neurotransmitter. This reuptake and termination process can be inhibited by cocaine and tricyclic antidepressant medications and is responsible for the activation of the sympathetic nervous system seen with these drugs. The remainder of the norepinephrine, which was not taken back into the nerve endings, diffuses into surrounding tissue fluids and blood or it is metabolized by *monoamine oxidase (MAO)* or *catechol-O-methyltransferase (COMT)*.

Norepinephrine also functions as a circulating neurohormone, along with epinephrine. In response to adrenergic nerve stimulation, norepinephrine and epinephrine are secreted into the bloodstream by the adrenal medullae and transported to all body tissues. They are continually present in arterial blood in amounts that vary according to the degree of stress present and the ability of the adrenal medullae to respond to stimuli. The larger proportion of the circulating hormones (approximately 80%) is epinephrine. These catecholamines exert the same effects on target tissues as those caused by direct stimulation of

**Figure 16-3** ■ Signal transduction mechanism for an adrenergic beta receptor. Epinephrine (1), the “first messenger,” interacts with a beta receptor (2). This hormone–receptor complex activates a G protein, which reacts with a guanosine triphosphate (GTP) (3). The activated G protein then activates the enzyme adenyl cyclase, which (4) catalyzes the conversion of adenosine triphosphate (ATP) to cyclic adenosine monophosphate (cAMP), the “second messenger.” (5) cAMP activates enzymes, which bring about the biologic responses to epinephrine (6).

the sympathetic nervous system. However, the effects last longer because the hormones are removed from the blood more slowly. These hormones are metabolized mainly in the liver by the enzymes MAO and COMT.

*Dopamine* is also an adrenergic neurotransmitter and catecholamine. In the brain, dopamine is essential for normal function (see Chap. 5). In peripheral tissues, its main effects are on the heart and blood vessels of the renal system and viscera, where it produces vasodilation.

### Adrenergic Receptors

When norepinephrine and epinephrine act on body cells that respond to sympathetic nerve or catecholamine stimulation, they interact with two distinct *adrenergic* receptors, alpha and beta. Norepinephrine acts mainly on alpha receptors; epinephrine acts on both alpha and beta receptors. These receptors have been further subdivided into alpha<sub>1</sub>, alpha<sub>2</sub>, beta<sub>1</sub>, and beta<sub>2</sub> receptors. A beta<sub>3</sub> receptor has been identified, and studies suggest that stimulation of this receptor may augment heat production, produce lipolysis (thermogenesis), and increase energy expenditure. Several compounds are being tested to treat obesity, hyperglycemia, and the problem of insulin resist-

ance in diabetes. Currently, there are no beta<sub>3</sub> agonist drugs approved by the Food and Drug Administration for human use.

When dopamine acts on body cells that respond to adrenergic stimulation, it can activate alpha<sub>1</sub> and beta<sub>1</sub> receptors as well as dopaminergic receptors. Only dopamine can activate dopaminergic receptors. Dopamine receptors are located in the brain, in blood vessels of the kidneys and other viscera, and probably in presynaptic sympathetic nerve terminals. Activation (agonism) of these receptors may result in stimulation or inhibition of cellular function. Like alpha and beta receptors, dopamine receptors are divided into several subtypes (D<sub>1</sub> to D<sub>5</sub>), and specific effects depend on which subtype of receptor is activated. Table 16-1 describes the locations of adrenergic receptors in the body and the response that occurs when each receptor is stimulated.

The intracellular events resulting from signal transduction after stimulation of adrenergic receptors are thought to include the following mechanisms:

- *Alpha<sub>1</sub> receptors:* Activation of alpha<sub>1</sub> receptors in smooth muscle cells is thought to open ion channels, allow calcium ions to move into the cell, and produce muscle

Table 16-1

## Adrenergic Receptors

TYPE	LOCATION	EFFECTS OF STIMULATION
Alpha <sub>1</sub>	Blood vessels	Vasoconstriction
	Kidney	Decreased renin secretion
	Intestinal smooth muscle	Relaxation
	Liver	Glycogenolysis, gluconeogenesis
	Genitourinary smooth muscle	Contraction
	Eye (radial muscle) Pregnant uterus Male sexual organs	Blinking, mydriasis Uterine contraction Ejaculation
Alpha <sub>2</sub>	Nerve endings	Inhibit release of norepinephrine
	Vascular smooth muscle	Vasoconstriction
	Pancreatic beta cells	Inhibit insulin secretion
	Platelets	Aggregation
Beta <sub>1</sub>	Heart	Increased heart rate, force of contraction, automaticity, and rate of atrioventricular conduction
	Kidney	Increased renin release
Beta <sub>2</sub>	Bronchioles	Bronchodilation
	Blood vessels	Vasodilation
	Gastrointestinal tract	Decreased motility and tone
	Liver	Glycogenolysis, gluconeogenesis
	Urinary bladder Pregnant uterus	Relaxed detrusor muscle Relaxation
Beta <sub>3</sub>	Adipose tissue Gastrointestinal tract	Increased metabolism
	Dopamine	Blood vessels of kidney, heart, other viscera Vasodilation

contraction (e.g., vasoconstriction, gastrointestinal and bladder-sphincter contraction).

- **Alpha<sub>2</sub> receptors:** In the brain, some of the norepinephrine released into the synaptic cleft between neurons returns to the nerve endings from which it was released and stimulates presynaptic alpha<sub>2</sub> receptors. This negative feedback prevents calcium-mediated release of norepinephrine from storage vesicles into the synapse, resulting in decreased sym-

pathetic outflow and an antiadrenergic effect. Also, cyclic adenosine monophosphate (cAMP) is decreased.

- **Beta<sub>1</sub>, beta<sub>2</sub>, and beta<sub>3</sub> receptors:** Activation of these receptors stimulates activity of adenylyl cyclase (an enzyme in cell membranes), which stimulates formation of cyclic adenosine monophosphate (cAMP). cAMP serves as a second messenger and can initiate several different intracellular actions, with specific actions depending on the type of cell. cAMP is rapidly degraded by an enzyme called phosphodiesterase to 5' adenosine monophosphate (AMP). Drugs such as theophylline inhibit phosphodiesterase and increase cAMP concentrations, resulting in bronchodilation (see Chap. 44).
- **Dopaminergic receptors D<sub>1</sub> and D<sub>5</sub>:** Activation of these receptors is thought to stimulate the production of cAMP, as does activation of beta<sub>1</sub> and beta<sub>2</sub> receptors.
- **Dopaminergic receptor D<sub>2</sub>:** Activation of this receptor is thought to inhibit formation of cAMP and to alter calcium- and potassium-ion currents. D<sub>3</sub> and D<sub>4</sub> receptors are subgrouped with D<sub>2</sub> receptors, but the effects of their activation have not been clearly delineated.

The number of receptors and the binding activity of receptors to target organs and tissues are dynamic and may be altered. These phenomena are most clearly understood with beta receptors. For example, when chronically exposed to high concentrations of substances that stimulate their function, the beta receptors decrease in number and become less efficient in stimulating adenylyl cyclase. The resulting decrease in beta-adrenergic responsiveness is called desensitization or *down-regulation* of receptors. Conversely, when chronically exposed to substances that block their function, the receptors may increase in number and become more efficient in stimulating adenylyl cyclase. The resulting increase in beta-adrenergic responsiveness, called hypersensitization or *up-regulation*, may lead to an exaggerated response when the blocking substance is withdrawn.

## Parasympathetic Nervous System

Functions stimulated by the parasympathetic nervous system are often described as resting, reparative, or vegetative functions. They include digestion, excretion, cardiac deceleration, anabolism, and near vision.

Approximately 75% of all parasympathetic nerve fibers are in the vagus nerves. These nerves supply the thoracic and abdominal organs; their branches go to the heart, lungs, esophagus, stomach, small intestine, the proximal half of the colon, the liver, gallbladder, pancreas, and the upper portions of the ureters. Other parasympathetic fibers supply pupillary sphincters and circular muscles of the eye; lacrimal, nasal, submaxillary, and parotid glands; descending colon and rectum; lower portions of the ureters and bladder; and genitalia.

Specific body responses to parasympathetic stimulation include

- Dilation of blood vessels in the skin
- Decreased heart rate, possibly bradycardia

- Increased secretion of digestive enzymes and motility of the gastrointestinal tract
- Constriction of smooth muscle of bronchi
- Increased secretions from glands in the lungs, stomach, intestines, and skin (sweat glands)
- Constricted pupils (from contraction of the circular muscle of the iris) and accommodation to near vision (from contraction of the ciliary muscle of the eye)
- Contraction of smooth muscle in the urinary bladder
- Contraction of skeletal muscle
- Release of *nitrous oxide* from the endothelium of blood vessels, resulting in decreased platelet aggregation, decreased inflammation, relaxation of vascular smooth muscle, and dilation of blood vessels

Parasympathetic responses are regulated by acetylcholine, a neurotransmitter in the brain, ANS, and neuromuscular junctions. Acetylcholine is formed in cholinergic nerve endings from choline and acetylcoenzyme A, in a chemical reaction catalyzed by choline acetyltransferase. After its release from the nerve ending, the effect of acetylcholine on receptors of the parasympathetic nervous system is brief and measured in milliseconds. The action of acetylcholine on receptors is terminated due to rapid metabolism by acetylcholinesterase, an enzyme present in the nerve ending and on the surface of the receptor organ. Acetylcholinesterase splits the active acetylcholine into inactive acetate and choline. The choline is taken up again by the presynaptic nerve terminal and reused to form more acetylcholine. Acetylcholine exerts excitatory effects at nerve synapses and neuromuscular junctions and inhibitory effects at some peripheral sites such as the heart.

### Cholinergic Receptors

When acetylcholine acts on body cells that respond to parasympathetic nerve stimulation, it interacts with two types of *cholinergic* receptors: *nicotinic* and *muscarinic*. Nicotinic receptors are located in motor nerves and skeletal muscle. When they are activated by acetylcholine, the cell membrane depolarizes and produces muscle contraction. Muscarinic receptors are located in most internal organs, including the cardiovascular, respiratory, gastrointestinal, and genitourinary systems. When muscarinic receptors are activated by acetylcholine, the affected cells may be excited or inhibited in their functions.

Nicotinic and muscarinic receptors have been further subdivided, with two types of nicotinic and five types of muscarinic receptors identified. Although the subtypes of cholinergic receptors have not been as well characterized as those of the adrenergic receptors, the intracellular events resulting from signal transduction after receptor stimulation are thought to include the following mechanisms:

- **Muscarinic<sub>1</sub> receptors:** Muscarinic<sub>1</sub> receptors are expressed primarily in the CNS, autonomic ganglia, and the gastric and salivary glands. Activation of these receptors results in a series of processes during which phospholipids in the cell membrane and inside the cell are broken down. One of the products of phospholipid metabolism is inositol phosphate. Inositol phosphate acts as a second messenger to increase the intracellular concentration of calcium. Calcium also acts as a second messenger and functions to activate several intracellular enzymes, initiate contraction of smooth muscle cells, increase secretions of exocrine glands, increase cognitive function, and decrease dopamine release.
  - **Muscarinic<sub>2</sub> receptors:** Receptor activation results in inhibition of adenylyl cyclase in the heart, smooth muscle, and brain. As a result, less cAMP is formed to act as a second messenger and stimulate intracellular activity. Receptor stimulation also results in activation of potassium channels in cell membranes of the heart. The overall consequences of M<sub>2</sub> activation are inhibition of cardiac function, increased contraction of smooth muscle, and inhibition of neuronal transmission.
  - **Muscarinic<sub>3</sub> receptors:** Muscarinic<sub>3</sub> receptors are expressed primarily in the CNS, smooth muscle, glands, and heart. Activation apparently causes the same cascade of intracellular processes as with activation of the M<sub>1</sub> receptors resulting in decreased dopamine release, increased smooth muscle contraction, and increased glandular secretion. In addition, nitrous oxide is generated from vascular endothelial cells, resulting in dilation of vessels.
  - **Muscarinic<sub>4</sub> receptors:** Activation of these receptors in the CNS results in a molecular response similar to M<sub>2</sub> receptor activation. Muscarinic<sub>4</sub> activation results in inhibition of neurotransmitter release in the CNS and periphery, analgesia, and facilitation of dopamine release.
  - **Muscarinic<sub>5</sub> receptors:** Receptor activation results in a molecular response similar to M<sub>1</sub> receptor activation. The receptor has been identified in central nervous system tissues (especially the substantia nigra); its activation results in dilation of cerebral arteries and arterioles and facilitation of dopamine release. Muscarinic<sub>5</sub> activation also plays a role in augmentation of drug-seeking behavior and reward.
- Although five muscarinic receptor subtypes have been identified, currently available drug therapies do not selectively differentiate among the various receptor subtypes.
- **Nicotinic<sub>n</sub> receptors:** These receptors are located on autonomic ganglia and the adrenal medulla. Activation results in enhanced transmission of nerve impulses at all parasympathetic and sympathetic ganglia and release of epinephrine from the adrenal medullae.
  - **Nicotinic<sub>m</sub> receptors:** These are located at neuromuscular junctions in skeletal muscle. Their activation causes muscle contraction.
  - **Nicotinic<sub>CNS</sub> receptors:** These receptors are located on presynaptic nerve fibers in the brain and spinal cord. Their activation promotes the release of acetylcholine in the cerebral cortex.

Nicotinic receptors are composed of five different protein subunits. The protein subunits that make up a nicotinic<sub>n</sub> receptor vary from those that make up a nicotinic<sub>m</sub> receptor, thus allowing the development of medications that are more selective in their actions. For example, neuromuscular blocking medications such as pancuronium, which act selectively at nicotinic<sub>m</sub> receptors, can paralyze skeletal muscles in patients when limiting movement is therapeutic (such as in the ventilated patient or during surgery), without adversely affecting the other functions of the ANS.

## Characteristics of Autonomic Drugs

Many drugs are used clinically because of their ability to stimulate or block activity of the sympathetic nervous system or parasympathetic nervous system. Drugs that stimulate activity act like endogenous neurotransmitter substances; drugs that block activity prevent the actions of both endogenous substances and stimulating drugs.

Because ANS receptors are widespread throughout the body, drugs that act on the ANS usually affect the entire body rather than certain organs and tissues. Drug effects depend on which branch of the ANS is involved and whether it is stimulated or inhibited by drug therapy. Thus, knowledge of the

physiology of the ANS is required if drug effects are to be understood and predicted. In addition, it is becoming increasingly important to understand receptor activity and the consequences of stimulation or inhibition. More drugs are being developed to stimulate or inhibit particular subtypes of receptors. This is part of the continuing effort to design drugs that act more selectively on particular body tissues and decrease adverse effects on other body tissues. For example, drugs such as terbutaline have been developed to stimulate beta<sub>2</sub> receptors in the respiratory tract and produce bronchodilation (a desired effect) with decreased stimulation of beta<sub>1</sub> receptors in the heart (an adverse effect).

The terminology used to describe autonomic drugs is often confusing because different terms are used to refer to the same phenomenon. Thus, sympathomimetic, *adrenergic*, and alpha- and beta-adrenergic agonists are used to describe a drug that has the same effects on the human body as stimulation of the sympathetic nervous system. Parasympathomimetic, cholinomimetic, and *cholinergic* are used to describe a drug that has the same effects on the body as stimulation of the parasympathetic nervous system. There are also drugs that oppose or block stimulation of these systems. Sympatholytic, *antiadrenergic*, and alpha- and beta-adrenergic blocking drugs inhibit sympathetic stimulation. Parasympatholytic, *anticholinergic*, and cholinergic blocking drugs inhibit parasympathetic stimulation. This book uses the terms adrenergic, antiadrenergic, cholinergic, and anticholinergic when describing medications.

## Key Concepts

- The ANS controls involuntary activities in smooth muscle, secretory glands, and in the visceral organs of the body such as the heart.
- The ANS functions to maintain homeostasis, to respond to stress, and to repair body tissues.
- The ANS is comprised of the sympathetic and parasympathetic nervous system; these two divisions are usually antagonistic in their actions on a particular organ. Exceptions to this antagonism are sweating and regulation of arteriolar diameter, which are controlled by the sympathetic nervous system.
- Release of neurotransmitters allows nerve impulses in the ANS to bridge synapses and travel from presynaptic to postsynaptic nerves, eventually stimulating receptors located on effector organs.
- Stimulation of receptors in the sympathetic nervous system produces adrenergic effects. Blockade of receptors produces antiadrenergic effects.
- Stimulation of receptors in the parasympathetic nervous system produces cholinergic effects. Blockade of receptors produces anticholinergic effects.
- Drugs that activate ANS receptors (function like endogenous neurotransmitters) stimulate the ANS.
- Drugs that block activity of ANS receptors prevent the actions of both endogenous neurotransmitters and ANS agonists.
- Adrenergic receptors include alpha and beta receptors as well as dopamine receptors; there are several subtypes.
- Cholinergic receptors include muscarinic and nicotinic receptors; there are several subtypes.
- The number of receptors in the ANS is dynamic and can be up-regulated or down-regulated as needed.

## Review and Application Exercises

---

### Short Answer Exercises

1. What are the major differences between the sympathetic and parasympathetic branches of the ANS?
2. What are the major sympathetic nervous system and parasympathetic nervous system neurotransmitters?
3. What are the locations and functions of sympathetic nervous system receptors?
4. What is meant when drugs are described as adrenergic, sympathomimetic, antiadrenergic, sympatholytic, cholinergic, or anticholinergic?

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Identify effects produced by stimulation of alpha- and beta-adrenergic receptors.
2. List characteristics of adrenergic drugs in terms of effects on body tissues, indications for use, adverse effects, nursing process implications, principles of therapy, and observation of patient responses.
3. Discuss use of epinephrine to treat anaphylactic shock, acute bronchospasm, and cardiac arrest.
4. Identify patients at risk for the adverse effects associated with adrenergic drugs.
5. List commonly used over-the-counter preparations and herbal preparations that contain adrenergic drugs.
6. Discuss principles of therapy and nursing process for using adrenergic drugs in special populations.
7. Describe signs and symptoms of toxicity due to noncatecholamine adrenergic drugs.
8. Discuss treatment of overdose with noncatecholamine adrenergic drugs.
9. Teach the patient about safe, effective use of adrenergic drugs.

## Applying Your Knowledge

Alexsey Sobechenko is a 71-year-old man with chronic obstructive pulmonary disease (COPD). He has had asthma for all of his adult life and is admitted to the hospital with acute respiratory distress secondary to pneumonia. He has a very modest pension and is covered by Medicare, which sometimes makes it difficult for him to pay for all of his medical supplies and medication. Although Mr. Sobechenko has never been a smoker, he did work as a welder for 45 years. Due to his acute bronchospasm, his physician orders epinephrine 1:10,000 IV stat.

## Introduction

*Adrenergic drugs* produce effects similar to those produced by stimulation of the sympathetic nervous system and therefore have widespread effects on body tissues (see Chap. 16). Major therapeutic uses and adverse effects of adrenergic medications derive from drug action on the heart, blood vessels, and lungs. Some adrenergic drugs are exogenous formulations of naturally occurring neurotransmitters and hormones, such as norepinephrine, epinephrine, and dopamine. Other adrenergic

medications, such as phenylephrine, pseudoephedrine, and isoproterenol, are synthetic chemical relatives of naturally occurring neurotransmitters and hormones.

Specific effects of adrenergic medications depend mainly on the type of *adrenergic receptor* activated by the drug. The drugs discussed in this chapter (epinephrine, ephedrine, pseudoephedrine, isoproterenol, and phenylephrine) affect multiple adrenergic receptors and have many clinical uses. Other adrenergic drugs are more selective for specific adrenergic receptors or are given topically to produce more localized therapeutic effects and fewer systemic adverse effects. These drugs have relatively restricted clinical indications and are discussed more extensively elsewhere (“Drugs Used in Hypotension and Shock,” Chap. 51; “Drugs for Asthma and Other Bronchoconstrictive Disorders,” Chap. 44; “Nasal Decongestants, Antitussives, and Cold Remedies,” Chap. 46; and “Drugs Used in Ophthalmic Conditions,” Chap. 63). Table 17-1 groups commonly used adrenergic drugs by adrenergic receptor activity and gives their clinical use.

## General Characteristics of Adrenergic Drugs

### Mechanisms of Action

Adrenergic drugs have three mechanisms of action. For the most part, adrenergic drugs interact directly with postsynaptic  $\alpha_1$ - or beta-adrenergic receptors on the surface membrane of target organs and tissues (Fig. 17-1). The drug–receptor complex then alters the permeability of the cell membrane to ions or extracellular enzymes. The influx of these molecules stimulates intracellular metabolism and production of other enzymes, structural proteins, energy, and other products required for cell function and reproduction. Epinephrine, isoproterenol, norepinephrine, and phenylephrine are examples of direct-acting adrenergic drugs.

Some adrenergic drugs exert indirect effects on *postsynaptic* adrenergic receptors. Indirect adrenergic effects may be produced by drugs such as amphetamines, which increase the amount of norepinephrine released into the synapse from storage sites in nerve endings (Fig. 17-2A). Norepinephrine then stimulates the alpha and beta receptors, producing sympathetic effects in the body. Inhibition of norepinephrine reuptake from the synapse is another mechanism that produces indirect adrenergic effects. Remember that norepinephrine reuptake is the major way that sympathetic nerve transmission is terminated. Drugs such as tricyclic antidepressants and cocaine block norepinephrine reuptake, resulting in stimulation of alpha- and beta-adrenergic receptors (Fig. 17-2B).

The third mechanism of adrenergic drug action is called mixed acting and is a combination of direct and indirect receptor stimulation. Mixed-acting drugs directly stimulate adrenergic receptors by binding to them and indirectly stimulate adrenergic receptors by increasing the release of norepineph-

Table 17-1

### Commonly Used Adrenergic Drugs

GENERIC/TRADE NAME	MAJOR CLINICAL USES
<b>Alpha and Beta Activity</b>	
<b>Dopamine</b>	Hypotension and shock
<b>Epinephrine</b> (Adrenalin)	Allergic reactions, cardiac arrest, hypotension and shock, local vasoconstriction, bronchodilation, cardiac stimulation, ophthalmic conditions
<b>Ephedrine</b>	Bronchodilation, cardiac stimulation, nasal decongestion
<b>Pseudoephedrine</b> (Sudafed)	Nasal decongestion
<b>Norepinephrine</b> (Levophed)	Hypotension and shock
<b>Alpha Activity</b>	
<b>Naphazoline hydrochloride</b> (Privine)	Nasal decongestion
<b>Oxymetazoline hydrochloride</b> (Afrin)	Nasal decongestion
<b>Phenylephrine</b> (Neo-Synephrine)	Hypotension and shock, nasal decongestion, ophthalmic conditions
<b>Tetrahydrozoline hydrochloride</b> (Ityzine, Visine)	Nasal decongestion, local vasoconstriction in the eye
<b>Beta Activity</b>	
<b>Albuterol</b> (Proventil)	Bronchodilation
<b>Arformoterol</b> (Brovana)	Bronchodilation
<b>Dobutamine</b> (Dobutrex)	Cardiac stimulation
<b>Formoterol</b> (Foradil)	Bronchodilation
<b>Isoproterenol</b> (Isuprel)	Bronchodilation, cardiac stimulation
<b>Metaproterenol</b> (Alupent)	Bronchodilation
<b>Pirbuterol</b> (Maxair)	Bronchodilation
<b>Salmeterol</b> (Serevent)	Bronchodilation
<b>Terbutaline</b> (Brethine)	Bronchodilation, preterm labor inhibition

rine into synapses. Ephedrine and pseudoephedrine are examples of mixed-acting adrenergic drugs.

Because many body tissues have both alpha and beta receptors, the effect produced by an adrenergic drug depends on the type of receptor activated and the number of affected receptors in a particular body tissue. Some adrenergic drugs are nonselective, acting on both alpha and beta receptors. Other medications are more selective, acting only on certain subtypes of receptors (see Table 17-1).

**Figure 17-1** ■ Mechanism of direct adrenergic drug action. Adrenergic drugs interact directly with postsynaptic  $\alpha_1$  and  $\beta$  receptors on target effector organs, activating the organ in a similar fashion as the neurotransmitter norepinephrine.

The predominant effect in response to activation of  $\alpha_1$  receptors by an adrenergic drug is vasoconstriction of blood vessels, which increases the blood pressure. This is sometimes referred to as a *pressor* (or *vasopressor*) effect.  $\alpha_1$ -activated vasoconstriction of blood vessels in nasal mucous membranes decreases nasal congestion, resulting in a *decongestant* effect. Other adrenergic effects resulting from  $\alpha_1$  activation

include mydriasis, contraction of gastrointestinal (GI) and genitourinary sphincters, and elevated blood glucose.

The predominant effect in response to activation of  $\beta_1$  receptors in the heart is cardiac stimulation.  $\beta_1$  activation results in increased force of myocardial contraction, or a positive inotropic effect; increased heart rate, or a positive chronotropic effect; and increased speed of electrical conduction in the heart, or a positive dromotropic effect. Another adrenergic effect resulting from  $\beta_1$  activation is increased renin secretion from the kidneys.

The predominant clinical effect in response to activation of  $\beta_2$  receptors is bronchodilation. Activation of  $\beta_2$  receptors in blood vessels results in vasodilation and increased blood flow to the heart, brain, and skeletal muscles, tissues needed for the “fight-or-flight” sympathetic response.  $\beta_2$  activation also results in hepatic glycogenolysis and gluconeogenesis and decreased pancreatic insulin secretion, resulting in hyperglycemia. Other adrenergic effects resulting from  $\beta_2$  activation include relaxation of smooth muscle in the uterus, urinary bladder, and GI tract.

Activation of  $\beta_3$ -adrenergic receptors produces lipolysis and increased release of free fatty acids into the blood.

It is interesting to note that drugs that activate  $\alpha_2$  receptors on *presynaptic* nerve fibers do not produce a sympathetic effect. These drugs inhibit the release of the neurotransmitter norepinephrine into synapses of the sympathetic nervous system, thus exerting an antiadrenergic response in the body. Although activation of presynaptic  $\alpha_2$  receptors in the periphery is not of clinical significance, activation of these receptors in the central nervous system (CNS) by medications is useful in treating hypertension (see Chaps. 18 and 52).

**Figure 17-2** ■ Mechanisms of indirect adrenergic drug action. Stimulation of postsynaptic  $\alpha_1$ ,  $\beta_1$ , and  $\beta_2$  receptors results from adrenergic medications that act indirectly, increasing the release of norepinephrine into the synapse (A) or inhibiting the reuptake of norepinephrine from the synapse (B).

## Indications for Use

Clinical indications for the use of adrenergic drugs stem mainly from their effects on the heart, blood vessels, and bronchi. They are often used as emergency drugs in the treatment of acute cardiovascular, respiratory, and allergic disorders.

In cardiac arrest, Stokes-Adams syndrome (sudden attacks of unconsciousness caused by heart block), and profound bradycardia, they may be used as cardiac stimulants. In hypotension and shock, they may be used to increase blood pressure. In hemorrhagic or hypovolemic shock, the drugs are second-line agents that may be used if adequate fluid volume replacement does not restore sufficient blood pressure and circulation to maintain organ perfusion.

In bronchial asthma and other obstructive pulmonary diseases, the drugs are used as bronchodilators to relieve bronchoconstriction and bronchospasm. In upper respiratory infections, including the common cold and sinusitis, they may be given orally or applied topically to the nasal mucosa to reduce nasal congestion (decongestant effect).

Adrenergic drugs are useful in treating a variety of symptoms of allergic disorders. Severe allergic reactions are characterized by hypotension, bronchoconstriction, and laryngoedema. As vasoconstrictors, the drugs are useful in correcting the hypotension that often accompanies severe allergic reactions. The drug-induced vasoconstriction of blood vessels in mucous membranes produces a decongestant effect to relieve edema in the respiratory tract, skin, and other tissues. As bronchodilators, the drugs also help relieve the bronchospasm of severe allergic reactions. Adrenergic drugs may be used to treat allergic rhinitis, acute hypersensitivity (anaphylactoid reactions to drugs, animal serums, insect stings, and other allergens), serum sickness, urticaria, and angioneurotic edema.

Other clinical uses of adrenergic drugs include relaxation of uterine musculature and inhibition of uterine contractions in preterm labor. They also may be added to local anesthetics for their vasoconstrictive effect, thus preventing unwanted systemic absorption of the anesthetic; prolonging anesthesia; and reducing bleeding. Topical uses include application to skin and mucous membranes for vasoconstriction and hemostatic effects and to the eyes for vasoconstriction and mydriasis.

## Contraindications to Use

Contraindications to using adrenergic drugs include cardiac dysrhythmias, angina pectoris, hypertension, hyperthyroidism, and cerebrovascular disease; stimulation of the sympathetic nervous system worsens these conditions. Narrow-angle glaucoma is a contraindication, because the drugs result in mydriasis, closure of the filtration angle of the eye, and increased intraocular pressure. Hypersensitivity to an adrenergic drug or any component is also a contraindication. For example, some adrenergic preparations contain sulfites, to which some people are allergic.

Adrenergic drugs are contraindicated with local anesthesia of distal areas with a single blood supply (e.g., fingers, toes, nose, ears) because of potential tissue damage and sloughing

from vasoconstriction. They should not be given during the second stage of labor because they may delay progression. They should be used with caution in patients with anxiety, insomnia, and psychiatric disorders because of their stimulant effects on the CNS and in older adults because of their cardiac- and CNS-stimulating effects.

## Individual Drugs

Adrenergic drugs are described in this section. Generic and trade names, routes, and dosages are listed in Table 17-2.

### Epinephrine and Other Adrenergic Drugs

**P** **Epinephrine** (Adrenalin) is the prototype of the adrenergic drugs. When it is given systemically, the effects may be therapeutic or adverse, depending on the reason for use, dosage, and route of administration. Epinephrine stimulates  $\alpha_1$  and all beta receptors. At usual doses, beta-adrenergic effects on the heart and vascular and other smooth muscles predominate. However, at high doses,  $\alpha_1$ -adrenergic effects (e.g., vasoconstriction) predominate. Numerous epinephrine solutions are available for various routes of administration (Table 17-3). Solutions vary widely in the amount of drug they contain. They must be used correctly to avoid potentially serious hazards.

The effects and clinical indications for epinephrine are the same as for most adrenergic drugs. Epinephrine is the adrenergic drug of choice for relieving the acute bronchospasm and laryngeal edema of anaphylactic shock, the most serious allergic reaction. It is used in cardiac arrest for its cardiac stimulant and peripheral vasoconstrictive effects. Peripheral vasoconstriction allows shunting of blood to the heart and brain, with increased perfusion pressure in the coronary and cerebral circulations. This action is thought to be the main beneficial effect in cardiac arrest and cardiopulmonary resuscitation (CPR). Epinephrine is also added to local anesthetics for vasoconstrictive effects, which include prolonging the action of the local anesthetic drug, preventing systemic absorption, and minimizing bleeding.

Epinephrine is not given orally, because enzymes in the GI tract and liver destroy it. It may be given by inhalation, injection, or topical application. Epinephrine crosses the placenta but not the blood-brain barrier. When given by injection, it acts rapidly but has a short duration of action. Intravenous (IV) epinephrine acts almost immediately to produce an increase in blood pressure; a positive inotropic and positive chronotropic effect on the myocardium; hyperglycemia; bronchodilation; and vasoconstriction of arterioles in the skin, mucosa, and most viscera. For acute asthma attacks, subcutaneous (Sub-Q) administration usually produces bronchodilation within 5 to 10 minutes; maximal effects may occur within 20 minutes. Parenteral epinephrine should be used with caution in infants and children, because syncope has occurred with use in asthmatic children. Most epinephrine is rapidly metabolized in the liver to inactive metabolites, which are

Table 17-2

## Drugs at a Glance: Selected Adrenergic Drugs

Generic/Trade Name	Use	PREPARATIONS, ROUTES, AND DOSAGE RANGES	
		Adults	Children
Epinephrine (Adrenalin)	Bronchodilator	<p><b>Aqueous epinephrine (1:1000 [1 mg/mL]):</b> Sub-Q/IM 0.1–0.25 mg q 20 min to 4 h PRN. Max dose 1 mg.</p> <p><b>IV injection (1:10,000 [0.1 mg/mL]):</b> IV 0.1–0.25 mg injected slowly</p> <p><b>Epinephrine 1% solution for inhalation (1:100):</b> Instill no more than 10 drops into nebulizer reservoir. Administer 1–3 inhalations 4–6 times/day.</p> <p><b>Metered-dose inhaler (160–250 mcg/puff):</b> 1 puff at onset of bronchospasm. Repeat if needed after 1–5 min. Dose is individualized to patients' needs.</p>	<p><b>Aqueous epinephrine (1:1000 sol [1 mg/mL]):</b> Sub-Q/IM 0.01 mg/kg q 20 min to 4 h PRN. Max dose 0.5 mg.</p> <p><b>Epinephrine 1% solution for inhalation (1:100):</b> Instill no more than 10 drops into nebulizer reservoir. Administer 1–3 inhalations 4–6 times/day.</p>
	Profound bradycardia/hypotension	<p><b>Continuous IV infusion:</b> 2–10 mcg/min</p>	<p><b>IV/IO injection (1:10,000 [0.1 mg/mL]):</b> IV 0.01 mg/kg q 3–5 min PRN</p>
	Cardiac arrest	<p><b>Aqueous epinephrine (1:1000 [1 mg/mL]):</b> IV 0.5 mg diluted to 10 mL with NS Or</p> <p><b>IV/IO injection (1:10,000 [0.1 mg/mL]):</b> IV 0.5–1 mg q 3–5 min PRN</p> <p><b>Endotracheally (1:10,000 [0.1 mg/mL]):</b> ETT 2–2.5 mg q 3–5 min PRN</p>	<p><b>IV/IO injection (1:10,000 [0.1 mg/mL]):</b> IV 0.01 mg/kg q 3–5 min PRN for infants and children (maximum dosage 1 mg). IV 0.03 mg/kg q 3–5 min PRN for neonates (maximum dosage 1 mg).</p> <p><b>Endotracheally (1:1000 [1 mg/mL]):</b> ETT up to 0.1 mg/kg q 3–5 min PRN (maximum dosage 10 mg for infants and children).</p>
	Allergic reaction/anaphylaxis	<p><b>Aqueous epinephrine (1:1000 [1 mg/mL]):</b> Sub-Q/IM 0.1–0.5 mg q 5–15 min. Max dose 1 mg.</p> <p><b>IV injection (1:10,000 [0.1 mg/mL]):</b> IV 0.1–0.25 mg over 5–10 min q 5–15 min PRN, THEN 1–4 mcg/min continuous infusion if severe anaphylactic shock.</p> <p><b>EpiPen Autoinjector:</b> IM 0.3 mg; may repeat</p>	<p><b>Aqueous epinephrine (1:1000 [1 mg/mL]):</b> Sub-Q/IM 0.01 mg/kg q 20 min–4 h PRN. Max dose 0.5 mg.</p> <p><b>IV injection (1:100,000 [0.01 mg/mL]):</b> IV 0.1 mg over 5–10 min once, THEN 0.1–1.5 mcg/kg/min continuous infusion</p> <p><b>EpiPen Jr. Autoinjector:</b> IM 0.15 mg; may repeat</p>
	Ophthalmic agent	<p><b>Epinephrine HCl 0.1%, 0.5%, 1%, and 2%:</b> 1–2 drops in eyes once or twice daily</p>	

		PREPARATIONS, ROUTES, AND DOSAGE RANGES	
Generic/Trade Name	Use	Adults	Children
	Nasal agent for hemostasis	<b>Epinephrine nasal solution 0.1% (1:1000):</b> 1–2 drops per nostril q 4–6 h	
<b>Ephedrine</b>	Asthma	PO: 12.5–25 mg q4h. Do not exceed 150 mg/24h	6–12 y: PO 6.25–12.5 mg q4–6h. 2–6 y: PO 0.3–0.5 mg/kg q4–6h
	Hypotension	IM, Sub-Q: 25–50 mg IV push: 5–25 mg/dose slowly, repeated q 5–10 min as needed then q3–4h. Do not exceed 150 mg/24h.	
	Nasal congestion	PO: 25–50 mg q4h 0.25% nasal spray or 1% nasal jelly	
<b>Pseudoephedrine (Sudafed)</b>	Nasal congestion	Give 30–60 mg PO q4–6h or 120 mg sustained-release formula q12h. Do not exceed 240 mg/24h.	6–12 y: PO 30 mg q6h. Do not exceed 120 mg/24h. 2–5 y: PO 15 mg q6h. Do not exceed 60 mg/24h.
<b>Isoproterenol (Isuprel)</b>	Cardiac dysrhythmias	IV 20–60 mcg (1–3 mL) bolus initially, followed by IV infusion. Can use 1:50,000 solution for IV bolus undiluted. For IV bolus using 1:5000 solution, dilute 0.2 mg to 10 mL with sodium chloride or 5% dextrose injection and give 1–3 mL. For IV infusion, dilute 2 mg of 1:5000 solution in 500 mL 5% dextrose injection. Dosage depends on type of dysrhythmia and ranges from 2–20 mcg/min. Titrate to patient's response.	
	Shock	IV infusion, Dilute 1 mg of 1:5000 solution in 500 mL 5% dextrose injection. Dosage ranges from 0.5–5 mcg/min. Titrate to patient's response.	
<b>Phenylephrine (Neo-Synephrine, others)</b>	Hypotension/shock	IM, Sub-Q: 2–5 mg q1–2h. Initial dose not to exceed 5 mg. Repeat no more often than every 10–15 min. IV bolus: 0.1 – 0.5 mg, diluted in NaCl injection, given slowly q 10–15 min as needed. Initial dose not to exceed 0.5 mg. IV infusion: 10 mg in 500 mL D5W or NS. Infuse at 100–180 mcg/min initially. When BP stable, reduce to maintenance rate of 40–60 mcg/min.	
	Nasal congestion	Nasal decongestants: 0.25%, 0.5%, 1.0% solutions 2–3 drops or sprays q4h. Therapy should not exceed 3 days.	
	Ophthalmic agent/mydriatic agent	Ophthalmic preparations: 2.5% or 10% solutions. Instill one drop. May be repeated in 10–60 min.	

IO, intraosseous, BP, blood pressure, D5W, dextrose 5% in water; NS, 0.9% sodium chloride.

then excreted in the urine. The remaining epinephrine is deactivated by reuptake at synaptic receptor sites. Epinephrine is excreted in breast milk.

Epinephrine is the active ingredient in many over-the-counter (OTC) inhalation products for asthma (e.g., MicroNe-

frin, Primatene Mist, others), producing bronchodilation. Treatment guidelines for asthma recommend use of anti-inflammatory medications (e.g., corticosteroids) and prescription bronchodilators (e.g., beta<sub>2</sub>-adrenergic agonists) for the optimal treatment of asthma. OTC epinephrine preparations

Table 17-3

### Epinephrine Concentrations and Administration Routes

FINAL CONCENTRATION	ROUTE
1% (1:100)	Inhalation
0.5% (1:200)	Subcutaneous
0.1% (1:1000)	Subcutaneous
	Intramuscular
0.01% (1:10,000)	Intravenous
0.001% (1:100,000)	Intradermal (in combination with local anesthetics)

have a short duration of action, which promotes frequent and excessive use. Prolonged use may cause adverse effects and result in the development of tolerance to the therapeutic effects of the drug. There is also concern by some health professionals that reliance on OTC medications may delay the asthmatic patient from seeking medical care. Another area of concern is the ozone-depleting propellants used in OTC inhalation products such as Primatene Mist. At this time, however, these medications have “essential use designation” by the Food and Drug Administration (FDA) because they constitute the only OTC inhalation products available to individuals with asthma. Supporters site that OTC bronchodilators are much less costly than prescription medications and are an affordable “rescue treatment” option for patients who do not have insurance coverage for prescription medications. People who have heart disease or are elderly should not use these products on a regular basis.

**Ephedrine** is a mixed-acting adrenergic drug that acts by stimulating  $\alpha_1$  and beta receptors and causing release of norepinephrine from presynaptic terminals. Its actions are less potent but longer lasting than those of epinephrine. Ephedrine produces more CNS stimulation than other adrenergic drugs. It may be used in the treatment of bronchial asthma to prevent bronchospasm, but it is less effective than epinephrine for acute bronchospasm and respiratory distress.

Ephedrine can be given orally or parenterally. When given orally, therapeutic effects occur within 1 hour and last 3 to 5 hours. When given Sub-Q, it acts in approximately 20 minutes, and its effects last approximately 60 minutes. When given intramuscularly, it acts in approximately 10 to 20 minutes, and its effects last less than 60 minutes. Ephedrine is excreted unchanged in the urine. Acidic urine increases the rate of drug elimination.

Ephedrine is a common ingredient in OTC antiasthma tablets (e.g., Bronkaid, Primatene, others). The tablets contain 12.5 to 25 milligrams of ephedrine and 100 to 130 milligrams of theophylline, a xanthine bronchodilator. Other clinical uses include shock associated with spinal or epidural anesthesia, Stokes-Adams syndrome, allergic disorders, nasal congestion, and eye disorders.

### Applying Your Knowledge 17-1

The nurse reviews the drug order. Why did the physician order this medication IV instead of PO?

**Pseudoephedrine** (Sudafed) is a related drug, stimulating  $\alpha_1$  and beta receptors. It is used as a bronchodilator and nasal decongestant. Pseudoephedrine is given orally and is available OTC alone and as an ingredient in several multi-ingredient sinus, allergy, and cold remedies. Pseudoephedrine is eliminated primarily in the urine. Its elimination may be slowed by alkaline urine, which promotes drug reabsorption in the renal tubules. Pseudoephedrine and ephedrine are ingredients used in making methamphetamine, a highly addictive and illegal drug of abuse. The Combat Methamphetamine Epidemic Act (part of the U.S. Patriot Act) requires drug stores to control OTC access to these drugs by placing these medications behind the counter and documenting each purchase by the customer.

**Isoproterenol** (Isuprel) is a synthetic catecholamine that acts on  $\beta_1$ - and  $\beta_2$ -adrenergic receptors. Its main actions are to stimulate the heart, dilate blood vessels in skeletal muscle, and relax bronchial smooth muscle. Compared with epinephrine, isoproterenol has similar cardiac stimulant effects, but it does not affect alpha receptors and therefore does not cause vasoconstriction. It is well absorbed when given by injection or as an aerosol. However, absorption is unreliable with sublingual and oral preparations, so their use is not recommended. It is metabolized more slowly than epinephrine by the enzyme catechol-O-methyltransferase (COMT). It is not well metabolized by monoamine oxidase (MAO), which may account for its slightly longer duration of action than epinephrine.

Isoproterenol may be used as a cardiac stimulant in heart block and cardiogenic shock and as a bronchodilator in respiratory conditions characterized by bronchospasm. However,  $\beta_2$ -selective agonists (e.g., albuterol, others) are preferred for bronchodilating effects because they cause less cardiac stimulation. Too-frequent use of inhaled isoproterenol may lead to tolerance and decreased bronchodilating effects.

**Phenylephrine** (e.g., Neo-Synephrine, others) is a synthetic drug that acts on alpha-adrenergic receptors to produce vasoconstriction. Vasoconstriction decreases cardiac output and renal perfusion and increases peripheral vascular resistance and blood pressure. There is little cardiac stimulation because phenylephrine does not activate  $\beta_1$  receptors in the heart or  $\beta_2$  receptors in blood vessels.

Phenylephrine may be given to increase blood pressure in hypotension and shock. Compared with epinephrine, phenylephrine produces longer lasting elevation of blood pressure (20–50 minutes with injection). When given systemically, phenylephrine produces a reflex bradycardia. This effect may be used therapeutically to relieve paroxysmal atrial tachycardia. However, other medications such as calcium channel blockers (see Chaps. 49 and 50) are more likely to be used for

this purpose. A **BLACK BOX WARNING** for parenteral use of Neo-Synephrine alerts prescribers to be familiar with complete prescribing information before use. Other uses of phenylephrine include local application for nasal decongestant and mydriatic effects. Phenylephrine is often an ingredient in prescription and nonprescription cold and allergy remedies. However, a recent systematic review and meta-analysis of oral phenylephrine demonstrated that the OTC 10-milligram dose is ineffective for treatment of nasal congestion. The low bioavailability of phenylephrine (38%) may contribute to this lack of efficacy at lower doses. Dosages of 25 milligrams or higher did demonstrate some effectiveness in reducing nasal congestion; however, this dosage exceeds the OTC recommended dose, potentially increasing the incidence of adverse effects. The reviewers recommended that OTC phenylephrine be classified as Category III (data are insufficient to classify as safe and effective, and further testing is required). Phenylephrine is excreted primarily in the urine.

## Herbal and Dietary Supplements

**Ephedra (ma huang)** is an OTC dietary supplement used for weight control, boosting sports performance, and increasing energy levels. Ephedra is a plant source of ephedrine alkaloids, including ephedrine and pseudoephedrine. The OTC use of ephedra has been linked to increased risk of hypertension, heart attack, stroke, and death. The Dietary Supplement Health and Education Act of 1994 grants the FDA the authority to remove a dietary supplement from the market if it “presents a significant or unreasonable risk of illness or injury when used according to its labeling or under ordinary conditions of use.” In 2004, using this law, the FDA prohibited the sale of any dietary supplements containing ephedrine alkaloids (i.e., ephedra).

## Nursing Process

### Assessment

Assess the patient’s status in relation to the following conditions.

- **Allergic disorders.** It is standard procedure to question a patient about allergies on initial contact or admission to a health care agency. If the patient reports a previous allergic reaction, try to determine what caused it and what specific symptoms occurred. It may be helpful to ask if swelling, breathing difficulty, or hives (urticaria) occurred. With anaphylactic reactions, severe respiratory distress (from bronchospasm and laryngeal edema) and profound hypotension (from vasodilation) may occur.
- **Asthma.** If the patient is known to have asthma, assess the frequency of attacks, the specific signs and symptoms experienced, the precipitating factors, the actions taken to obtain relief, and the use of bronchodilators or other med-

ications on a long-term basis. With acute bronchospasm, respiratory distress is clearly evidenced by loud, rapid, gasping, wheezing respirations. Acute asthma attacks may be precipitated by exposure to allergens or respiratory infections. When available, check arterial blood gas reports for the adequacy of oxygen–carbon dioxide gas exchange. Hypoxemia ( $\downarrow\text{PO}_2$ ), hypercarbia ( $\uparrow\text{PCO}_2$ ), and acidosis ( $\downarrow\text{pH}$ ) may occur with acute bronchospasm.

- **Chronic obstructive pulmonary disorders.** Emphysema and chronic bronchitis are characterized by bronchoconstriction and dyspnea with exercise or at rest. Check arterial blood gas reports when available. Hypoxemia, hypercarbia, and acidosis are likely with chronic bronchoconstriction. Acute bronchospasm may be superimposed on the chronic bronchoconstrictive disorder, especially with a respiratory infection.
- **Cardiovascular status.** Assess for conditions that are caused or aggravated by adrenergic drugs (e.g., angina, hypertension, tachydysrhythmias).

## Nursing Diagnoses

- Impaired Gas Exchange related to bronchoconstriction
- Ineffective Tissue Perfusion related to hypotension and shock or vasoconstriction with drug therapy
- Imbalanced Nutrition: Less than Body Requirements related to anorexia
- Disturbed Sleep Pattern: Insomnia, nervousness
- Noncompliance: Overuse
- Risk for Injury related to cardiac stimulation (dysrhythmias, hypertension)
- Deficient Knowledge: Drug effects and safe usage

## Planning/Goals

The patient will

- Receive or self-administer drugs accurately
- Experience relief of symptoms for which adrenergic drugs are given
- Comply with instructions for safe drug use
- Demonstrate knowledge of adverse drug effects to be reported
- Avoid preventable adverse drug effects
- Avoid combinations of adrenergic drugs

## Interventions

Use measures to prevent or minimize conditions for which adrenergic drugs are required.

- Decrease exposure to allergens. Allergens include cigarette smoke, foods, drugs, air pollutants, plant pollens, insect venoms, and animal dander. Specific allergens must be determined for each person.

- For patients with chronic lung disease, use measures to prevent respiratory infections. These include interventions to aid removal of respiratory secretions, such as adequate hydration, ambulation, deep-breathing and coughing exercises, and chest physiotherapy. Immunizations with pneumococcal pneumonia vaccine and annual influenza vaccine are also strongly recommended.
- When administering substances known to produce hypersensitivity reactions (penicillin and other antibiotics, allergy extracts, vaccines, local anesthetics), observe the recipient carefully for at least 30 minutes after administration. Have adrenergic and other emergency drugs and equipment readily available in case a reaction occurs.
- Use noninvasive interventions in addition to adrenergic medications when treating shock and hypotension. These include applying external pressure over a bleeding site to control hemorrhage and placing the patient in a recumbent position to improve venous return and blood pressure.

Provide appropriate teaching for drug therapy (see accompanying patient teaching display).

### Evaluation

- Observe for increased blood pressure and improved tissue perfusion when a drug is given for hypotension and shock or anaphylaxis.
- Interview and observe for improved breathing and arterial blood gas reports when a drug is given for bronchoconstriction or anaphylaxis.
- Interview and observe for decreased nasal congestion.

## Principles of Therapy

### Drug Selection and Administration

The choice of drug, dosage, and route of administration depends largely on the reason for use (see Table 17-1). Adrenergic drugs are given IV only for emergencies, such as cardiac

## Patient Teaching Guidelines Adrenergic Drugs

### General Considerations

- Take no other medications without the physician's knowledge and approval. Many over-the-counter (OTC) cold remedies and appetite suppressants contain adrenergic drugs. Use of these along with prescribed adrenergic drugs can result in overdose and serious cardiovascular or central nervous system problems. In addition, adrenergic drugs interact with numerous other drugs to increase or decrease effects; some of these interactions may be life threatening.
- Herbal preparations of ephedra or ma huang contain derivatives of ephedrine and should not be taken with other adrenergic medications. Excessive central nervous system and cardiovascular stimulation may result. (Sale of supplements containing ephedra was banned by the FDA in 2003.)
- Tell your health care provider if you are pregnant, breastfeeding, taking any other prescription or OTC drugs, or if you are allergic to sulfite preservatives.
- Use these drugs only as directed. The potential for abuse is high, especially for the patient with asthma or other chronic lung disease who is seeking relief from labored breathing. Some of these drugs are prescribed for long-term use, but excessive use does not increase therapeutic effects. Instead, it causes tolerance and decreased benefit from usual doses and increases the incidence and severity of adverse reactions.
- Frequent cardiac monitoring and checks of flow rate, blood pressure, and urine output are necessary if you are receiving intravenous adrenergic drugs to stimulate your heart or raise your blood pressure. These measures increase the safety and benefits of drug therapy rather than indicate the presence of a critical condition. Ask your nurse if you have concerns about your condition.

- You may feel anxious or tense; have difficulty sleeping; and experience palpitations, blurred vision, headache, tremor, dizziness, and pallor. These are effects of the medication. Use of relaxation techniques to promote rest and decrease muscle tension may be helpful.
- Use caution when driving or performing activities requiring alertness, dexterity, and good vision.
- Report adverse reactions such as fast pulse, palpitations, and chest pain so that drug dosage can be re-evaluated and therapy changed if needed.

### Self-Administration

- Do not use topical decongestants longer than 3 to 5 days. Long-term use may be habit forming. Burning on use and rebound congestion after the dose wears off are common. Stop using the medication gradually.
- Stinging may occur when using ophthalmic preparations. Do not let the tip of the applicator touch your eye or anything else during administration of the medication, to avoid contamination. Do not wear soft contact lenses while using ophthalmic adrenergic drugs; discoloration of the lenses may occur. Report blurred vision, headache, palpitations, and muscle tremors to your health care provider.
- Follow guidelines for use of your inhaler. Do not increase the dosage or frequency; tolerance may occur. Report chest pain, dizziness, or failure to obtain relief of symptoms. Saliva and sputum may be discolored pink with isoproterenol.
- Learn to self-administer an injection of epinephrine if you have severe allergies. Always carry your injection kit with you. Seek immediate medical care after self-injection of epinephrine.
- If you are diabetic, monitor your glucose levels carefully because adrenergic medications may elevate them.

arrest, severe arterial hypotension, circulatory shock, and anaphylactic shock. IV or Sub-Q epinephrine is the drug of choice in anaphylactic shock. No standard doses of individual adrenergic drugs are always effective; the dose must be individualized or titrated to the patient's response. This is especially true in emergencies, but it also applies to long-term use.

### Applying Your Knowledge 17-2

#### How Can You Avoid This Medication Error?

Epinephrine 1 mg is ordered to be given in a 1:10,000 dilution. You add 1 mL of normal saline and administer the drug.

### Treatment of Specific Disorders

Because adrenergic drugs are often used in crises, they must be readily available in all health care settings (e.g., hospitals, long-term care facilities, physicians' offices). All health care personnel should know where emergency drugs are stored.

#### Anaphylaxis

Anaphylactic shock or *anaphylaxis* is a type I immunoglobulin E-mediated allergic reaction to a foreign substance (*antigen*) that has entered the body. Some typical antigens include foods (e.g., shellfish, peanuts, eggs), medications (e.g., penicillin, vaccinations, enzymes, iodine contrast media), and insect bites/stings (e.g., bees, ants). During an anaphylactic reaction, mast cells release chemical mediators such as histamine, serotonin, platelet-activating factor, prostaglandins, and leukotrienes. The

resulting increased capillary permeability and smooth muscle contraction lead to edema, bronchospasm, and airway obstruction. Vasodilation results in hypotension and shock. Anaphylactic reactions occur on second or subsequent exposure to an antigen. Symptoms develop rapidly; typical symptom onset ranges from 30 minutes to 2 hours after exposure to the antigen.

Epinephrine is the drug of choice for the treatment of anaphylaxis (Level A). It relieves bronchospasm, laryngeal edema, and hypotension. In conjunction with its alpha (vasoconstriction) and beta (cardiac stimulation, bronchodilation) effects, epinephrine acts as a physiologic antagonist of histamine and other bronchoconstricting and vasodilating substances released during anaphylactic reactions. People susceptible to severe allergic responses should carry a syringe of epinephrine at all times. EpiPen and EpiPen Jr. are prefilled, autoinjection syringes for intramuscular self-administration of epinephrine in emergency situations (Figure 17-3). The thigh is the preferred site for autoinjection, providing more rapid absorption and higher blood levels of epinephrine than the arm in children and adults for either intramuscular or subcutaneous administration. Victims of anaphylaxis who have been taking beta-adrenergic blocking drugs (e.g., propranolol [Inderal]) do not respond as readily to epinephrine as those not taking beta blockers. Larger doses of epinephrine and large amounts of IV fluids may be required.

Adjunct medications that may be useful in treating severe cases of anaphylaxis include corticosteroids, norepinephrine, and aminophylline. Antihistamines are considered second-line treatment; their usefulness is limited because histamine plays a minor role in causing anaphylaxis compared with leukotrienes and other inflammatory mediators. Antihista-

**Figure 17-3** ■ To use the EpiPen Autoinjector, grasp the unit in your fist with the black tip pointing down. When ready to inject, activate the unit by removing the gray activation cap with your other hand. Firmly thrust the device into the outer thigh at a 90-degree angle and hold in place for several seconds. After removing the autoinjector, massage the injection site to enhance absorption. (Note: The injection can be made through clothing.)

mines should never be used alone in the treatment of anaphylaxis. Diphenhydramine is often used as a second-line adjunctive treatment; however, studies show that a combination of ranitidine and diphenhydramine is more efficacious than diphenhydramine alone.

### Applying Your Knowledge 17-3

The physician orders piperacillin/tazobactam, a beta-lactam antibiotic, to treat Mr. Sobechenko's pneumonia. Within 15 minutes of the start of the antibiotic infusion, the patient has an anaphylactic reaction. He is agitated and flushed and complains of palpitations. He is having severe difficulty breathing due to bronchospasm. The physician orders epinephrine. What are the nursing implications for Mr. Sobechenko's reaction to the antibiotic, and what assessment is needed relative to the adverse effects of epinephrine?

### Cardiopulmonary Resuscitation

Epinephrine is often administered during CPR. The most important action of epinephrine during cardiac arrest is constriction of peripheral blood vessels, which shunts blood to the central circulation and increases blood flow to the heart and brain. This beneficial effect comes at the expense of increased oxygen consumption by the myocardium, ventricular dysrhythmias, and myocardial dysfunction after resuscitation. Epinephrine was once considered the drug of choice in the treatment of all types of cardiac arrest. The most recent Advanced Cardiac Life Support (ACLS) guidelines for health professionals (2005) continue to support epinephrine for first use in pulseless sudden cardiac arrest, classifying it as class indeterminate for the treatment of defibrillation-resistant ventricular tachycardia and ventricular fibrillation during cardiac arrest. Class indeterminate refers to a promising treatment that lacks research evidence of benefit. Vasopressin may also be used as an alternative pressor to epinephrine during sudden pulseless cardiac arrest situations due to ventricular tachycardia or ventricular fibrillation (see Evidence-Based Practice Box 17-1). Epinephrine is still considered the drug of choice for the treatment of cardiac arrest in cases of nonventricular tachycardia/fibrillation such as asystole or pulseless electrical activity. Epinephrine is beneficial in these situations because it stimulates electrical and mechanical activity and produces myocardial contraction.

The specific effects of epinephrine depend largely on the dose and route of administration. The optimal dose in CPR has not been established. ACLS guidelines recommend epinephrine 1 milligram intravenously every 3 to 5 minutes. If this fails, higher doses of epinephrine may be given but are not recommended. Research has shown that high doses of epinephrine may produce significantly higher rates of resuscitation but no improvement on long-term survival or neurologic outcome. In addition, there is growing evidence that higher doses of epinephrine may be harmful to both adults and children.

## Evidence-Based Practice

### 17-1 Epinephrine Versus Vasopressin for Cardiac Arrest

There is ongoing debate and research regarding the pharmacologic approach to cardiac arrest that will produce the highest rate of restoration of spontaneous circulation and the highest neurologically intact survival rates post-resuscitation. Historically, epinephrine has been the drug of choice in cardiac arrest situations; however, the American Heart Association (AHA) guidelines (2000) recommended vasopressin as an alternate pressor, classifying it Class IIb (usefulness of the drug is supported by fair to good research).

In the most recent AHA guidelines (2005), changes were made with regard to the use of epinephrine versus vasopressin for cardiac arrest management. Epinephrine is still the recommended pressor in cardiac arrest due to asystole and pulseless electrical activity. Epinephrine is also recommended in pulseless sudden cardiac arrest due to ventricular tachycardia or ventricular fibrillation (Class IIb recommendation). However, the 2005 AHA guidelines state that one dose of vasopressin may replace either the first or second dose of epinephrine in all cardiac arrest algorithms, including asystole and pulseless electrical activity. Vasopressin has been reclassified in the 2005 AHA guidelines from Class IIb (AHA 2000 guidelines) to class indeterminate (promising treatment that lacks research evidence of benefit).

When used during resuscitation efforts, vasopressin is given as a single dose of 40 units intravenously or introsseously and onset of action may take up to 20 minutes (see Chap. 22). An advantage of vasopressin over epinephrine is the ability of vasopressin to increase coronary blood flow and the availability of oxygen to the myocardium during resuscitation efforts.

Both epinephrine and vasopressin have been shown to positively influence restoration of spontaneous circulation; however, no vasopressor has been shown to improve the rate of survival to discharge with an intact neurologic status after cardiac arrest. Further research is needed to determine the most effective treatment for cardiac arrest. It is imperative that nurses in critical care areas maintain current Advanced Cardiac Life Support (ACLS) certification and stay alert to research findings that may influence ACLS protocols for resuscitation in the future.

### Hypotension and Shock

In hypotension and shock, initial efforts involve identifying and treating the cause when possible. Such treatments include placing the patient in the recumbent position, blood transfusions, fluid and electrolyte replacement, treatment of infection, and use of positive inotropic drugs and other medications to treat heart failure. If these measures are ineffective in raising the blood pressure enough to maintain perfusion to vital organs such as the brain, kidneys, and heart, vasopressor drugs may be used. The usual goal of vasopressor drug therapy is to maintain tissue perfusion and a mean arterial pressure of at least 80 to 100 mm Hg.

### Nasal Congestion

Adrenergic drugs are given topically and systemically to constrict blood vessels in nasal mucosa and decrease the nasal congestion associated with the common cold, allergic rhinitis, and sinusitis. Topical agents are effective, undergo little systemic absorption, are available OTC, and are widely used. However,

overuse leads to decreased effectiveness (tolerance), irritation and ischemic changes in the nasal mucosa, and rebound congestion. These effects can be minimized by using small doses only when necessary and for no longer than 3 to 5 days.

Oral drugs have a slower onset of action than topical ones but may last longer. They also may cause more adverse effects, which may occur with usual therapeutic doses and are especially likely with high doses. The most problematic adverse effects are cardiac and CNS stimulation; the risks for hypertension and cerebral hemorrhage are greater in hypertensive people. Commonly used oral agents are pseudoephedrine and ephedrine.

## Toxicity of Adrenergics: Recognition and Management

Unlike catecholamines, which are quickly cleared from the body, excessive use of noncatecholamine adrenergic drugs (phenylephrine, ephedrine, and pseudoephedrine) can lead to overdose and toxicity. These drugs are an ingredient in OTC products such as nasal decongestants, cold preparations, and appetite suppressants. Phenylephrine and ephedrine have a narrow therapeutic index; toxic doses are only two to three times greater than the therapeutic dose. Pseudoephedrine toxicity occurs with doses four to five times greater than the normal therapeutic dose. Ephedrine and ephedra-containing herbal preparations (e.g., ma huang, herbal ecstasy) are often abused as an alternative to amphetamines. These substances were banned in the United States in 2003.

The primary clinical manifestation of noncatecholamine adrenergic drug toxicity is severe hypertension, which may lead to headache, confusion, seizures, and intracranial hemorrhage. Reflex bradycardia and atrioventricular block also have been associated with phenylephrine toxicity.

Treatment involves maintaining an airway and assisting with ventilation if needed. Activated charcoal may be administered early in treatment. Hypertension is aggressively treated with vasodilators such as phentolamine or nitroprusside. Beta blockers are not used alone to treat hypertension without first administering a vasodilator, to avoid a paradoxical increase in blood pressure. Dialysis and hemoperfusion are not effective in clearing these drugs from the body. Urinary acidification may enhance elimination of ephedrine and pseudoephedrine; however, this technique is not routinely used because of the risk of renal damage from myoglobin deposition in the kidney.

## Use in Special Populations

### Use in Children

Adrenergic agents are used to treat asthma, hypotension, shock, cardiac arrest, and anaphylaxis in children. However, guidelines for safe and effective use of adrenergic drugs in children are not well established. Children are very sensitive to drug effects, including cardiac and CNS stimulation, and recommended doses usually should not be exceeded.

Epinephrine is mainly used in children for treatment of bronchospasm due to asthma or allergic reactions. Parenteral epinephrine may cause syncope when given to asthmatic children. Isoproterenol is rarely given parenterally to children, but

if it is, the first dose should be approximately half the adult dose, and later doses should be based on the response to the first dose. There is little reason to use the inhalation route, because in children, as in adults, selective beta<sub>2</sub> agonists such as albuterol are preferred for bronchodilation in asthma.

Phenylephrine is most often used to relieve congestion of the upper respiratory tract and may be given topically, as nose drops. Doses must be carefully measured. Rebound nasal congestion occurs with overuse.

### Use in Older Adults

Adrenergic agents are used to treat asthma, hypotension, shock, cardiac arrest, and anaphylaxis in older adults. These drugs stimulate the heart to increase rate and force of contraction and blood pressure. Because older adults often have chronic cardiovascular conditions (e.g., angina, dysrhythmias, congestive heart failure, coronary artery disease, hypertension, peripheral vascular disease) that are aggravated by adrenergic drugs, careful monitoring by the nurse is required.

Adrenergic drugs are often prescribed as bronchodilators and decongestants in older adults. Therapeutic doses increase the workload of the heart and may cause symptoms of impaired cardiovascular function. Overdoses may cause severe cardiovascular dysfunction, including life-threatening dysrhythmias. The drugs also cause CNS stimulation. With therapeutic doses, anxiety, restlessness, nervousness, and insomnia often occur in older adults. Overdoses may cause hallucinations, convulsions, CNS depression, and death.

Adrenergics are ingredients in OTC asthma remedies, cold remedies, nasal decongestants, and appetite suppressants. Cautious use of these preparations is required in older adults. The drugs should not be taken concurrently with prescription adrenergic drugs because of the high risk of overdose and toxicity.

Ophthalmic preparations of adrenergic drugs also should be used cautiously. For example, phenylephrine is used as a vasoconstrictor and mydriatic. Applying larger-than-recommended doses to the normal eye or usual doses to the traumatized, inflamed, or diseased eye may result in sufficient systemic absorption of the drug to cause increased blood pressure and other adverse effects.

### Use in Patients With Renal Impairment

Adrenergic drugs exert effects on the renal system that may cause problems for patients with renal impairment. For example, adrenergic drugs with alpha<sub>1</sub> activity cause constriction of renal arteries, thereby diminishing renal blood flow and urine production. These drugs also constrict urinary sphincters, causing urinary retention and painful urination, especially in men with prostatic hyperplasia.

Many adrenergic drugs and their metabolites are eliminated by the renal system. In the presence of renal disease, these compounds may accumulate and cause increased adverse effects.

### Use in Patients With Hepatic Impairment

The liver is rich in the enzymes MAO and COMT, which are responsible for metabolism of circulating epinephrine and other adrenergic drugs (e.g., norepinephrine, dopamine,

isoproterenol). However, other tissues in the body also possess these enzymes and are capable of metabolizing natural and synthetic catecholamines. Any unchanged drug can be excreted in the urine. Many noncatecholamine adrenergic drugs are excreted largely unchanged in the urine. Therefore, liver disease is not usually considered a contraindication to administering adrenergic drugs.

### Use in Patients With Critical Illness

Adrenergic drugs are important emergency drugs. They are essential for treating hypotension, shock, asystole and other dysrhythmias, acute bronchospasm, and anaphylaxis. Although they may save the life of a critically ill patient, use of adrenergic drugs may result in secondary health problems that require monitoring and intervention. These health problems include

- Potential for the vasopressor action of adrenergic drugs to result in diminished renal perfusion and decreased urine output
- Potential for adrenergic drugs with beta<sub>1</sub> activity to induce irritable cardiac dysrhythmias
- Potential for adrenergic drugs with beta<sub>1</sub> activity to increase myocardial oxygen requirement
- Potential for adrenergic drugs with vasopressor action to decrease perfusion to the liver, with subsequent liver damage
- Hyperglycemia, hypokalemia, and hypophosphatemia due to beta<sub>1</sub>-adrenergic effects
- Severe hypertension and reflex bradycardia
- Tissue necrosis after extravasation
- Limb ischemia due to profound vasoconstriction

## Nursing Actions Adrenergic Drugs

### NURSING ACTIONS

#### 1. Administer accurately

- a. Check package inserts or other references if not absolutely sure about the preparation, concentration, or method of administration for an adrenergic drug.
- b. To give epinephrine subcutaneously, use a tuberculin syringe, aspirate, and massage the injection site.
- c. For inhalation, be sure to use the correct drug concentration, and use the nebulizing device properly.
- d. Do not give epinephrine and isoproterenol at the same time or within 4 hours of each other.
- e. Follow package insert guidelines carefully when diluting epinephrine for IV injection or IV infusion. Administer in an intensive care unit, when possible, using an infusion pump and a central IV line. Use parenteral solutions of epinephrine only if clear. Epinephrine is unstable in alkaline solutions.
- f. For IV infusion of isoproterenol and phenylephrine:
  - (1) Administer in an intensive care unit when possible.
  - (2) Use only clear drug solutions.
  - (3) Dilute isoproterenol in 5% dextrose injection. Phenylephrine can be diluted in 5% dextrose injection or 0.9% sodium chloride solution. Do not add the drug until ready to use.

### RATIONALE/EXPLANATION

The many different preparations and concentrations available for various routes of administration increase the risk of medication error unless extreme caution is used. Preparations for intravenous (IV), subcutaneous, inhalation, ophthalmic, or nasal routes must be used by the designated route only.

The tuberculin syringe is necessary for accurate measurement of the small doses usually given (often less than 0.5 mL). Aspiration is necessary to avoid inadvertent IV administration of the larger, undiluted amount of drug intended for subcutaneous use. Massaging the injection site accelerates drug absorption and thus relief of symptoms.

Inhalation medications are often administered by patients themselves or by respiratory therapists if intermittent positive-pressure breathing is used. The nurse may need to demonstrate and supervise self-administration initially. Both of these drugs are potent cardiac stimulants, and the combination could cause serious cardiac dysrhythmias. However, they have synergistic bronchodilating effects, and doses can be alternated and given safely if the drugs are given no more closely together than 4 hours.

Dilution increases safety of administration. A solution that is brown or contains a precipitate should not be used. Discoloration indicates chemical deterioration of epinephrine. Do not administer at the same time that sodium bicarbonate is being administered.

These drugs are given IV in emergencies, during which the patient's condition must be carefully monitored. Frequent recording of blood pressure and pulse and continuous electrocardiographic monitoring are needed. A brownish color or precipitate indicates deterioration, and such solutions should not be used. Mixing solutions when ready for use helps to ensure drug stability. Note that drug concentration varies with the amount of drug and the amount of IV solution to which it is added.

**NURSING ACTIONS**

- (4) Use an infusion device to regulate flow rate accurately.
- (5) Use a “piggyback” IV apparatus.
- (6) Start the adrenergic drug solution slowly and increase flow rate according to the patient’s response (e.g., blood pressure, color, mental status). Slow or discontinue the solution gradually as well.
- g. When giving adrenergic drugs as eye drops or nose drops, do not touch the dropper to the eye or nose.

**2. Observe for therapeutic effects**

- a. When the drug is used as a bronchodilator, observe for absence or reduction of wheezing, less labored breathing, and decreased rate of respirations.
- b. When epinephrine is given in anaphylactic shock, observe for decreased tissue edema and improved breathing and circulation.
- c. When isoproterenol or phenylephrine is given in hypotension and shock, observe for increased blood pressure, stronger pulse, and improved urine output, level of consciousness, and color.
- d. When a drug is given nasally for decongestant effects, observe for decreased nasal congestion and ability to breathe through the nose.
- e. When given as eye drops for vasoconstrictor effects, observe for decreased redness. When giving for mydriatic effects, observe for pupil dilation.

**3. Observe for adverse effects**

- a. Cardiovascular effects—cardiac dysrhythmias, hypertension
- b. Excessive central nervous system (CNS) stimulation—nervousness, anxiety, tremor, insomnia
- c. Rebound nasal congestion, rhinitis, possible ulceration of nasal mucosa

**4. Observe for drug interactions**

- a. Drugs that *increase* effects of adrenergic drugs:
  - (1) Anesthetics, general (e.g., halothane)
  - (2) Anticholinergics (e.g., atropine)
  - (3) Antidepressants, tricyclic (e.g., amitriptyline [Elavil])
  - (4) Antihistamines
  - (5) Cocaine
  - (6) Digoxin

**RATIONALE/EXPLANATION**

Flow rate usually requires frequent adjustment according to blood pressure measurements. An infusion device helps to regulate drug administration, so wide fluctuations in blood pressure are avoided.

Only one bottle contains an adrenergic drug, and it can be regulated or discontinued without disruption of the primary IV line.

To avoid abrupt changes in circulation and blood pressure

Contaminated droppers can be a source of bacterial infection.

These depend on the reason for use.

Indicates prevention or relief of bronchospasm. Acute bronchospasm is usually relieved within 5 minutes by injected or inhaled epinephrine or inhaled isoproterenol.

Epinephrine injection usually relieves laryngeal edema and bronchospasm within 5 minutes and lasts for approximately 20 minutes.

These are indicators of improved circulation.

The drugs act as vasoconstrictors to reduce engorgement of nasal mucosa.

Adverse effects depend to some extent on the reason for use. For example, cardiovascular effects are considered adverse reactions when the drugs are given for bronchodilation. Adverse effects occur with usual therapeutic doses and are more likely to occur with higher doses.

Tachycardia and hypertension are common; if severe or prolonged, myocardial ischemia or heart failure may occur. Premature ventricular contractions and other serious dysrhythmias may occur. Propranolol (Inderal) or another beta blocker may be given to decrease heart rate and hypertension resulting from overdose of adrenergic drugs. Phentolamine may be used to decrease severe hypertension.

These effects are more likely to occur with ephedrine or high doses of other adrenergic drugs. Sometimes, a sedative-type drug is given concomitantly to offset these effects.

These effects occur with excessive use of nasal decongestant drugs.

Most of these drugs increase incidence or severity of adverse reactions.

Increased risk of cardiac dysrhythmias. Potentially hazardous. Increased bronchial relaxation. Also increased mydriasis and therefore contraindicated with narrow-angle glaucoma.

Increased pressor response with IV epinephrine

May increase pressor effects

Increases pressor and mydriatic effects by inhibiting uptake of norepinephrine by nerve endings. Cardiac dysrhythmias, convulsions, and acute glaucoma may occur.

Sympathomimetics, especially beta-adrenergics like epinephrine and isoproterenol, increase the likelihood of cardiac dysrhythmias due to ectopic pacemaker activity.

## Nursing Actions Adrenergic Drugs (continued)

### NURSING ACTIONS

- (7) Doxapram (Dopram)
- (8) Ergot alkaloids
  
- (9) Monoamine oxidase (MAO) inhibitors (e.g., isocarboxazid [Marplan])
  
- (10) Methylphenidate (Ritalin)
- (11) Thyroid preparations (e.g., Synthroid)
- (12) Xanthines (in caffeine-containing substances, such as coffee, tea, cola drinks; theophylline)
- (13) Beta-adrenergic blocking agents (e.g., propranolol [Inderal])
- b. Drugs that *decrease* effects of adrenergics drugs:
  - (1) Anticholinesterases (e.g., neostigmine [Prostigmin], pyridostigmine [Mestinon]) and other cholinergic drugs
  - (2) Antihypertensives (e.g., methyl dopa)
  
  - (3) Antipsychotic drugs (e.g., haloperidol [Haldol])
  
  - (4) Beta-adrenergic blocking agents (e.g., propranolol [Inderal])
  - (5) Phentolamine

### RATIONALE/EXPLANATION

Increased pressor effect  
 Increased vasoconstriction. Extremely high blood pressure may occur. There also may be decreased perfusion of fingers and toes.

**CONTRAINDICATED. THE COMBINATION MAY CAUSE DEATH.** When these drugs are given concurrently with adrenergic drugs, there is danger of cardiac dysrhythmias, respiratory depression, and acute hypertensive crisis with possible intracranial hemorrhage, convulsions, coma, and death. Effects of a MAO inhibitor may not occur for several weeks after treatment is started and may last up to 3 weeks after the drug is stopped. Every patient taking a MAO inhibitor should be warned against taking any other medication without the advice of a physician or pharmacist.

Increased pressor and mydriatic effects. The combination may be hazardous in glaucoma.

Increased adrenergic effects, resulting in increased likelihood of dysrhythmias

Synergistic bronchodilating effect. Sympathomimetics with CNS-stimulating properties (e.g., ephedrine, isoproterenol) may produce excessive CNS stimulation with cardiac dysrhythmias, emotional disturbances, and insomnia. May augment hypertensive response to epinephrine (see also b[4] below)

Decrease mydriatic effects of adrenergics; thus, the two groups should not be given concurrently in ophthalmic conditions. Generally antagonize pressor effects of adrenergics, which act to increase blood pressure while antihypertensives act to lower it.

Block the vasopressor action of epinephrine. Therefore, epinephrine should not be used to treat hypotension induced by these drugs.

Decrease bronchodilating effects of adrenergics and may exacerbate asthma. Contraindicated with asthma. Antagonizes vasopressor effects of adrenergics

Occurrence of any of these adverse effects may complicate the already complex care of critically ill patients. Careful assessment and prompt nursing intervention are essential.

### Use in Home Care

Adrenergic drugs are often used in the home setting. Frequently prescribed drugs include bronchodilators and nasal decongestants. OTC drugs with the same effects are also commonly used to treat asthma, allergic rhinitis, cold symptoms, and appetite suppression for weight control. A major function

of the home care nurse is to teach patients to use the drugs correctly (especially metered-dose inhalers), to report excessive CNS or cardiac stimulation to a health care provider, and to not take OTC drugs or herbal preparations with the same or similar ingredients as prescription drugs.

Excessive adverse effects are probably most likely to occur in children and older adults. Older adults often have other illnesses that may be aggravated by adrenergic drugs or they may take other drugs whose effects may be altered by concomitant use of adrenergics.

## Key Concepts

- Adrenergic drugs produce effects similar to those produced by stimulation of the sympathetic nervous system.
- Specific effects of adrenergic medications depend mainly on the type of adrenergic receptor activated by the drug.
- Adrenergic drugs have three mechanisms of action: direct interaction with adrenergic receptors, indirect stimulation of adrenergic receptors by the neurotransmitter norepinephrine, or mixed acting, which is a combination of direct and indirect receptor stimulation.

- Because many body tissues have both alpha and beta receptors, the effect produced by an adrenergic drug depends on the type of receptor activated and the number of affected receptors in a particular body tissue.
- The *predominant* effect in response to activation of alpha<sub>1</sub> receptors by an adrenergic drug is vasoconstriction of blood vessels, increasing blood pressure. This is called a vasopressor or pressor effect.
- The *predominant* effect in response to activation of beta<sub>1</sub> receptors by an adrenergic drug is cardiac stimulation.
- The *predominant* effect in response to activation of beta<sub>2</sub> receptors is bronchodilation.
- The *predominant* effect in response to activation of beta<sub>3</sub> receptors is lipolysis and increased release of free fatty acids into the blood.
- Drugs that stimulate presynaptic alpha<sub>2</sub> receptors inhibit the release of norepinephrine into SNS synapses, thus exerting an *antiadrenergic response* in the body. Drugs that stimulate presynaptic alpha<sub>2</sub> receptors in the central nervous system are useful in treating hypertension.
- Adrenergic drugs are used as cardiac stimulants, vasopressors, bronchodilators, nasal decongestants, uterine relaxants, adjuncts to local anesthetics, and for hemostatic (topical) and mydriatic effects (topical).
- Epinephrine is the drug of choice to treat anaphylaxis.
- Individuals susceptible to severe allergic reactions should carry epinephrine in the form of an autoinjector such as EpiPen or EpiPen Jr for self-administration in emergency situations. Allergic individuals should also wear a medic alert tag or carry documentation of severe allergies.
- Use of beta-adrenergic blocking drugs (e.g., propranolol and others) may decrease the effectiveness of epinephrine in cases of anaphylaxis. Higher doses of epinephrine and use of intravenous fluids may be required to maintain a patent airway and restore blood pressure.
- Epinephrine is recommended as a vasopressor in cardiac arrest situations; however, current ACLS guidelines state vasopressin may replace either the first or second dose of epinephrine in all cardiac arrest algorithms. A benefit of epinephrine in arrest situations due to asystole or pulseless electrical activity is the added ability to stimulate electrical and mechanical activity and produce myocardial contraction.
- Contraindications to adrenergic drugs include cardiac dysrhythmias, angina, hypertension, hyperthyroidism, cerebrovascular disease, narrow-angle glaucoma, and hypersensitivity to sulfites. Local anesthetics containing adrenergics should not be used in any area of the body with a single blood supply (e.g., fingers, toes, nose, and ears).
- Epinephrine stimulates alpha<sub>1</sub> and beta receptors.
- Ephedrine stimulates alpha<sub>1</sub> and beta receptors.
- Pseudoephedrine stimulates alpha<sub>1</sub> and beta receptors.
- Isoproterenol stimulates beta<sub>1</sub> and beta<sub>2</sub> receptors.
- Phenylephrine stimulates alpha<sub>1</sub> receptors.
- Dietary supplements containing ephedrine alkaloids (ephedra) are prohibited in the United States.

## Review and Application Exercises

### Short Answer Exercises

1. How do adrenergic drugs act to relieve symptoms of acute bronchospasm, anaphylaxis, cardiac arrest, hypotension and shock, and nasal congestion?
2. Which adrenergic receptors are stimulated by administration of epinephrine?
3. Why is it important to have epinephrine and other adrenergic drugs readily available in all health care settings?
4. Which adrenergic drug is the drug of choice to treat acute anaphylactic reactions?
5. Why is inhaled epinephrine not a drug of choice for long-term treatment of asthma and other bronchoconstrictive disorders?
6. What are the major adverse effects of adrenergic drugs?
7. Why are patients with cardiac dysrhythmias, angina pectoris, hypertension, or diabetes mellitus especially likely to experience adverse reactions to adrenergic drugs?
8. For a patient who reports frequent use of OTC asthma remedies and cold remedies, what teaching is needed to increase patient safety?
9. Mentally rehearse nursing interventions for various emergency situations (anaphylaxis, acute respiratory distress, cardiac arrest) in terms of medications and equipment needed and how to obtain them promptly.
10. What signs and symptoms occur with overdose of noncatecholamine adrenergic drugs? What interventions are needed to treat the toxicity?

### NCLEX-Style Questions

11. You are caring for a patient with nasal congestion. His medical history includes depression. Which of the following medications would contraindicate the use of pseudoephedrine (Sudafed) to treat his nasal congestion?
  - a. fluoxetine (Prozac)
  - b. amitriptyline (Elavil)
  - c. isocarboxazid (Marplan)
  - d. lithium (Lithotab)

12. When giving a drug with beta<sub>2</sub> agonist activity, you know that the main therapeutic benefit is
  - a. vasoconstriction and elevation of the blood pressure
  - b. relaxation of bronchial smooth muscle and bronchodilation
  - c. elevated heart rate and improved force of myocardial contraction
  - d. uterine contraction and induction of labor
13. A patient with asthma tells the nurse he is using his metered-dose inhaler of epinephrine more frequently than prescribed to control wheezing. The nurse is concerned because this behavior may result in
  - a. drug tolerance
  - b. heart failure
  - c. drug toxicity
  - d. diabetes mellitus
14. The nurse teaches the diabetic patient using adrenergic medications to anticipate
  - a. no change in blood glucose levels
  - b. a decrease in blood glucose levels
  - c. an increase in blood glucose levels
  - d. more fluctuation in blood glucose levels
15. When the nurse responds to hypotension due to hypovolemic shock, which of the following should be administered first?
  - a. epinephrine (Adrenalin)
  - b. isoproterenol (Isuprel)
  - c. normal saline IV
  - d. ephedrine
16. Which of the following drugs is first administered by the nurse to treat an anaphylactic reaction to penicillin?
  - a. diphenhydramine (Benadryl)
  - b. epinephrine (Adrenalin)
  - c. isoproterenol (Isuprel)
  - d. dexamethasone (Decadron)

# Antiadrenergic Drugs

## KEY TERMS

- Agonist
- Alpha-adrenergic blocking drugs
- Antagonist
- Antiadrenergic drugs
- Cardioselective
- Chronotropy
- Dromotropy
- Floppy iris syndrome
- Inotropy
- Intrinsic sympathomimetic activity
- Membrane-stabilizing effect

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. List characteristics of antiadrenergic drugs in terms of effects on body tissues, indications for use, nursing process implications, principles of therapy, and observation of patient response.
2. Discuss alpha<sub>1</sub>-adrenergic blocking drugs and alpha<sub>2</sub>-adrenergic agonists in terms of indications for use, adverse effects, and other selected characteristics.
3. Compare and contrast beta-adrenergic blocking drugs in terms of cardioselectivity, indications for use, adverse effects, and other selected characteristics.
4. Teach patients about safe, effective use of antiadrenergic drugs.
5. Discuss principles of therapy and nursing process for using antiadrenergic drugs in special populations.

## Applying Your Knowledge

William Jones is a 58-year-old Caucasian man with a long history of hypertension. He has hyperlipidemia, type 2 diabetes mellitus, and coronary artery disease with a history of a myocardial infarction (MI) and triple coronary artery bypass graft. He is prescribed Lopressor 100 mg daily and clonidine transdermal patch every 7 days.

## Introduction

*Antiadrenergic drugs* decrease or block the effects of sympathetic nerve stimulation, endogenous catecholamines (e.g., epinephrine), and adrenergic drugs. The drugs are chemically diverse and have a wide spectrum of pharmacologic activity. Specific effects depend mainly on the patient's health status when a drug is given and the drug's binding with particular adrenergic receptors. Included in this chapter are centrally active antiadrenergic drugs such as clonidine, which are used primarily in the treatment of hypertension, and peripherally active alpha- and beta-adrenergic blocking agents, which are used to treat various cardiovascular and other disorders. A few uncommonly used antiadrenergic drugs for hypertension are included in Chapter 52.

A basal level of sympathetic tone is necessary to maintain normal body functioning, including regulation of blood pressure, blood glucose levels, and stress response. Therefore the goal of antiadrenergic drug therapy is to suppress pathologic stimulation—not the normal physiologic response to activity, stress, and other stimuli.

## General Characteristics of Antiadrenergic Drugs

### Mechanisms of Action

Antiadrenergic effects can occur either when  $\alpha_1$  or beta receptors are blocked by adrenergic antagonists or when presynaptic  $\alpha_2$  receptors are stimulated by agonist drugs. Most antiadrenergic drugs have *antagonist* or blocking effects when they bind with  $\alpha_1$ ,  $\beta_1$ ,  $\beta_2$ , or a combination of receptors in peripheral tissues, thus preventing adrenergic effects. Antiadrenergic drugs may be nonselective, exerting antiadrenergic effects on several adrenergic receptors simultaneously; or they may act selectively, blocking only one adrenergic receptor.

Clonidine and related drugs have *agonist* effects at presynaptic  $\alpha_2$  receptors in the brain. As stated in Chapter 17, this agonist effect results in a negative feedback type of mechanism that decreases the release of additional norepinephrine. Thus the overall effect is decreased sympathetic outflow from the brain and decreased activation of alpha and beta receptors by norepinephrine throughout the body.

### Alpha-Adrenergic Agonists and Blocking Drugs

$\alpha_2$ -adrenergic agonists such as clonidine (Catapres) inhibit the release of norepinephrine in the brain, thereby decreasing the effects of sympathetic nervous system stimulation throughout the body. A major clinical effect is decreased blood pressure. Although clinical effects are attributed mainly to drug action at presynaptic  $\alpha_2$  receptors in the brain, postsynaptic  $\alpha_2$  receptors in the brain and peripheral tissues (e.g., vascular smooth muscle) may also be involved. Activation of  $\alpha_2$  receptors in the pancreatic islets suppresses insulin secretion.

Some *alpha-adrenergic blocking drugs* may be selective for  $\alpha_1$  receptors in peripheral tissues such as smooth muscles and glands innervated by sympathetic nerve fibers. These drugs act primarily in the skin, mucosa, intestines, lungs, and kidneys to block or prevent alpha-mediated vasoconstriction. Specific effects of  $\alpha_1$ -adrenergic blocking drugs include dilation of arterioles and veins, increased local blood flow, decreased blood pressure, constriction of pupils, and increased motility of the gastrointestinal (GI) tract. Alpha-adrenergic antagonists often activate reflexes that oppose the decrease in blood pressure by increasing heart rate and cardiac output and by causing fluid retention.

Alpha<sub>1</sub>-adrenergic blocking drugs such as tamsulosin also can prevent alpha-mediated contraction of smooth muscle in nonvascular tissues. This action makes these drugs useful in the treatment of benign prostatic hyperplasia (BPH), a condition characterized by obstructed urine flow as the enlarged prostate gland presses on the urethra. Alpha<sub>1</sub>-blocking agents can decrease urinary retention and improve urine flow by relaxing muscles in the prostate and urinary bladder. Patients diagnosed with BPH should be evaluated for prostatic cancer before starting drug therapy because the signs

and symptoms of BPH and prostatic cancer are similar. The two conditions may also coexist.

Nonselective alpha-adrenergic blocking drugs such as phentolamine occupy peripheral  $\alpha_1$  receptors, causing vasodilation, and presynaptic  $\alpha_2$  receptors, causing cardiac stimulation. Consequently, decreased blood pressure is accompanied by tachycardia and perhaps other dysrhythmias.

### Beta-Adrenergic Blocking Drugs

Beta-adrenergic blocking agents occupy beta-adrenergic receptor sites and prevent the receptors from responding to sympathetic nerve impulses, circulating catecholamines, and beta-adrenergic drugs (Fig. 18-1).

Beta<sub>1</sub> receptor blockade has an inhibitory effect on the cardiovascular system, resulting in decreased heart rate (negative *chronotropy*), decreased force of myocardial contraction (negative *inotropy*), slowed conduction through the atrioventricular (AV) node (negative *dromotropy*), decreased automaticity of ectopic pacemakers, decreased cardiac output at rest and with exercise, and decreased blood pressure in supine and standing positions, especially in people with hypertension. Chronic use of beta blockers is associated with increased very-low-density lipoprotein (VLDL) and decreased high-density lipoprotein (HDL) cholesterol. These changes pose a potential risk for patients with cardiovascular disease. Beta<sub>1</sub> receptor blockade also results in decreased renin secretion from the kidneys, decreased production of aqueous humor in

**Figure 18-1** ■ Beta-adrenergic blocking agents prevent epinephrine and norepinephrine from occupying receptor sites on cell membranes. This action alters cell functions normally stimulated by epinephrine and norepinephrine, according to the number of receptor sites occupied by the beta-blocking drugs. (Adapted by J. Harley from *Encyclopedia Britannica Medical and Health Annual*. [1983]. Chicago: Encyclopedia Britannica.)

the eye, and diminished portal vein pressure in patients with cirrhosis.

Beta<sub>2</sub> receptor blockade produces bronchoconstriction of the smooth muscles in the respiratory tract, especially in people with asthma or other chronic lung diseases. Beta<sub>2</sub> receptor blockade also results in less effective metabolism of glucose (decreased glycogenolysis) when needed by the body, especially in people taking beta-blocking agents along with antidiabetic drugs. These diabetic patients may experience more severe and prolonged hypoglycemia. In addition, tachycardia, the early warning symptom of hypoglycemia, may be blocked by the medication, thereby delaying recognition and treatment. Beta<sub>2</sub> receptor blockade also increases the tone of smooth muscles in the GI tract, urinary bladder, and uterus.

## Indications for Use

### Alpha-Adrenergic Agonists and Blocking Drugs

Alpha<sub>2</sub> agonists are used in the treatment of hypertension. Clonidine, administered by the epidural route, is also approved for the relief of severe pain in cancer patients. A **BLACK BOX WARNING** alerts health care professionals that epidural administration of clonidine is not recommended for obstetrical, postpartum, or peri-operative pain management due to the risk for adverse effects resulting from hypotension and bradycardia. Investigational uses of clonidine include the treatment of tic disorders, postmenopausal hot flashes, migraine, attention deficit-hyperactivity disorder, drug-induced akathisia, and alcohol withdrawal and opioid dependence, as well as use as adjunct medication during anesthesia. Clonidine has not received approval by the U.S. Food and Drug Administration (FDA) for these purposes.

Selective alpha<sub>1</sub>-adrenergic blocking drugs are used in the treatment of hypertension, BPH, and vasospastic disorders. The use of selective alpha<sub>1</sub>-adrenergic blockers for the treatment of BPH was evaluated by an expert panel of the American Urological Association (AUA). The resulting clinical guidelines recommend alfuzosin, doxazosin, tamsulosin, and terazosin as equally effective in relieving the lower urinary tract symptoms of BPH, with only slight variations noted in the adverse effects profile of the individual alpha<sub>1</sub>-adrenergic blockers. The AUA guidelines note insufficient data to support a recommendation for the use of prazosin for treatment of lower urinary tract symptoms secondary to BPH.

Nonselective alpha-blocking drugs are used as antihypertensive drugs only when hypertension is caused by excessive catecholamines. Excessive catecholamines may result from overdoses of adrenergic drugs or from pheochromocytoma, a rare tumor of the adrenal medulla that secretes epinephrine and norepinephrine and causes hypertension, tachycardia, and cardiac dysrhythmias. Although the treatment of choice for pheochromocytoma is surgical excision, alpha-adrenergic blocking drugs are useful adjuncts. They are given before and during surgery, usually in conjunction with beta blockers

to block the sympathetic effect of excessive catecholamine secretion.

Nonselective alpha blockers also are used in vascular diseases characterized by vasospasm, such as Raynaud's disease and frostbite, in which they improve blood flow. Phentolamine also can be used to prevent tissue necrosis due to extravasation of potent vasoconstrictors such as norepinephrine and dopamine into subcutaneous tissues.

### Beta-Adrenergic Blocking Drugs

Clinical indications for use of beta-blocking agents are mainly cardiovascular disorders (e.g., angina pectoris, cardiac tachydysrhythmias, hypertension, myocardial infarction [MI], heart failure [HF]) and glaucoma.

In angina, beta blockers decrease myocardial contractility, cardiac output, heart rate, and blood pressure. These effects decrease myocardial oxygen demand (cardiac workload), especially in response to activity, exercise, and stress. In dysrhythmias, the drugs slow the sinus rate and prolong conduction through the AV node, thereby slowing the ventricular response rate to supraventricular tachydysrhythmias. In hypertension, the actions of beta blockers are unclear. Possible mechanisms include reduced cardiac output, inhibition of renin, and inhibition of sympathetic nervous system stimulation in the brain. However, the drugs effective in hypertension do not consistently demonstrate these effects; for example, a drug may lower blood pressure without reducing cardiac output or inhibiting renin.

After acute MI, beta blockers help protect the heart from reinfarction and decrease mortality rates over several years. Possible mechanisms include reduction in cardiac workload and prevention or reduction in the incidence of catecholamine-induced dysrhythmias. In HF, beta blockers play an important role but require careful monitoring on the part of the physician and the nurse. Administration of beta blockers may potentially worsen the condition of people with HF by blocking the sympathetic stimulation that helps maintain cardiac output. However, in many patients with HF, even those of advanced age and with advanced disease, the drugs are beneficial. For these patients, beta blockers decrease the risk of sudden cardiac death and may reduce ventricular remodeling that accompanies HF and leads to further deterioration of cardiac function.

In glaucoma, the drugs reduce intraocular pressure by binding to beta-adrenergic receptors in the ciliary body of the eye and decreasing formation of aqueous humor.

## Contraindications to Use

Alpha<sub>2</sub> agonists are contraindicated in patients with hypersensitivity to the drugs, and methyl dopa is also contraindicated in patients with active liver disease. Alpha-adrenergic blocking agents are contraindicated in angina pectoris, MI, HF, and stroke.

Beta-adrenergic blocking agents are contraindicated in bradycardia and heart block. Nonselective beta blockers are contraindicated with asthma and other allergic or pulmonary conditions characterized by bronchoconstriction; however, the

selective beta<sub>1</sub> blockers may be used in people with these disorders. Research has shown that beta blockers can be beneficial in selected patients with mild to moderate chronic HF; however, the drugs have not been proven safe for people older than 80 years of age or those with severe HF.

## Individual Drugs

Selected antiadrenergic medications are described in the following sections. Trade names, clinical indications, and dosage ranges are presented in Table 18-1 for alpha-adrenergic

agonists and blocking drugs and in Table 18-2 for beta-adrenergic blocking drugs.

### Alpha-Adrenergic Agonists and Blocking Drugs

Alpha<sub>2</sub>-adrenergic agonists include clonidine and methyldopa. These drugs produce similar therapeutic and adverse effects but differ in their pharmacokinetics and frequency of administration. Oral **clonidine** (Catapres) reduces blood pressure within 1 hour, reaches peak plasma levels in 3 to 5 hours, and has a plasma half-life of approximately 12 to 16 hours (longer with

Table 18-1

Drugs at a Glance: Alpha-Adrenergic Agonists and Blocking Drugs

GENERIC/TRADE NAME	CLINICAL INDICATIONS	ROUTES AND DOSAGE RANGES
<b>Alpha<sub>2</sub> Agonists</b>		
<b>Clonidine</b> (Catapres)	Hypertension	PO 0.1 mg 2 times daily initially, gradually increased if necessary. Average maintenance dose, 0.2–0.8 mg/d. Transdermal 0.1-mg patch every 7 d initially; increase every 7–14 d to 0.2 mg or 0.3 mg if necessary. Maximum dose, two 0.3-mg patches every 7 d
<b>Methyldopa</b>	Hypertension	<i>Adults:</i> PO 250 mg 2 or 3 times daily initially, increased gradually at intervals of not less than 2 d until blood pressure is controlled or a daily dose of 3 g is reached <i>Children:</i> PO 10 mg/kg/d in 2 to 4 divided doses initially, increased or decreased according to response. Maximal dose, 65 mg/kg/d or 3 g daily, whichever is less
<b>Selective Alpha<sub>1</sub>-Blocking Drugs</b>		
<b>Alfuzosin</b> (UroXatral)	BPH	PO 10 mg daily after same meal each day
<b>Doxazosin</b> (Cardura)	Hypertension BPH	PO 1 mg once daily initially, increased to 2 mg, then to 4, 8, and 16 mg if necessary
<b>Prazosin</b> (Minipress)	Hypertension BPH	PO 1 mg 2 to 3 times daily initially, increased if necessary to a total daily dose of 20 mg in divided doses. Average maintenance dose, 6–15 mg/d
<b>Tamsulosin HCl</b> (Flomax)	BPH	PO 0.4 mg/d after same meal each day. Dose may be increased if needed after 2–4 wk trial period.
<b>Terazosin</b> (Hytrin)	Hypertension  BPH	PO 1 mg at bedtime initially, increased gradually to maintenance dose, usually 1–5 mg once daily  1–5 mg once daily
<b>Nonselective Alpha-Blocking Drugs</b>		
<b>Phentolamine</b>	Hypertension caused by pheochromocytoma Prevention of tissue necrosis from extravasation of vasoconstrictive drugs	<i>Before and during surgery for pheochromocytoma:</i> IV, IM 5–20 mg as needed to control blood pressure <i>Prevention of tissue necrosis:</i> IV 10 mg in each liter of IV solution containing a potent vasoconstrictor <i>Treatment of extravasation:</i> Sub-Q 5–10 mg in 10 mL saline, infiltrated into the area within 12 h

BPH, benign prostatic hyperplasia.

Table 18-2

## Drugs at a Glance: Beta-Adrenergic Blocking Agents

GENERIC/TRADE NAME	CLINICAL INDICATIONS	ROUTES AND DOSAGE RANGES
<b>Nonselective Blocking Agents</b>		
<b>Levobunolol</b> (Betagan)	Glaucoma	Topically to affected eye, 1 drop twice daily
<b>Metipranolol</b> (OptiPranolol)	Glaucoma	Topically to each eye, 1 drop once or twice daily
<b>Propranolol</b> (Inderal)	Hypertension	PO 40 mg twice daily initially, may be increased to 120–240 mg daily in divided doses Sustained-release capsules, PO 80 mg once daily, may be increased to 120–160 mg once daily Maximal daily dose, 640 mg
	Angina pectoris	PO 80–320 mg in 2–4 divided doses Sustained release, PO 80–160 mg once daily Maximal daily dose, 320 mg
	Dysrhythmias	PO 10–30 mg, q6–8h Life-threatening dysrhythmias, IV 1–3 mg at a rate not to exceed 1 mg/min with electrocardiographic and blood-pressure monitoring
	Myocardial infarction	PO 180–240 mg daily in 3 or 4 divided doses Maximal daily dose, 240 mg
	Hypertrophic subaortic stenosis	PO 20–40 mg daily in 3 or 4 divided doses Sustained release, PO 80–160 mg once daily
	Migraine prophylaxis	PO 80–240 mg daily in divided doses Sustained release, PO 80 mg once daily
	<b>Pindolol</b> (Visken)*	Hypertension
<b>Nadolol</b> (Corgard)	Hypertension	Hypertension, PO 40 mg once daily initially, gradually increased. Usual daily maintenance dose, 80–320 mg
	Angina pectoris	Angina, PO 40 mg once daily initially, increased by 40–80 mg at 3- to 7-d intervals. Usual daily maintenance dose, 80–240 mg
<b>Sotalol</b> (Betapace, Betapace AF)	Cardiac dysrhythmias	PO 80–160 mg twice daily
<b>Timolol</b> (Blocadren, Timoptic)	Hypertension	Hypertension, PO 10 mg twice daily initially, increased at 7-d intervals to a maximum of 60 mg/d in 2 divided doses; usual maintenance dose, 20–40 mg daily
	Myocardial infarction	Myocardial infarction, PO 10 mg twice daily
	Glaucoma	Glaucoma, topically to eye, 1 drop of 0.25% or 0.5% solution (Timoptic) in each eye twice daily
<b>Cardioselective Blocking Agents</b>		
<b>Acebutolol</b> (Sectral)*	Hypertension	Hypertension, PO 400 mg daily in 1 or 2 doses; usual maintenance dose, 400–800 mg daily
	Ventricular dysrhythmias	Dysrhythmias, PO 400 mg daily in 2 divided doses; usual maintenance dose, 600–1200 mg daily

(continued on page 300)

Table 18-2

**Drugs at a Glance: Beta-Adrenergic Blocking Agents** (continued)

GENERIC/TRADE NAME	CLINICAL INDICATIONS	ROUTES AND DOSAGE RANGES
<b>Atenolol</b> (Tenormin)	Hypertension Angina pectoris Myocardial infarction	Hypertension, PO 50–100 mg daily Angina, PO 50–100 mg daily, increased to 200 mg daily if necessary Myocardial infarction, IV 5 mg over 5 min, then 5 mg 10 min later, then 50 mg PO 10 min later, then 50 mg 12 h later. Thereafter, PO 100 mg daily, in 1 or 2 doses, for 6–9 d or until discharge from hospital
<b>Betaxolol</b> (Betoptic, Kerlone)	Glaucoma Hypertension	Topically to each eye, 1 drop twice daily Hypertension, PO 10–20 mg daily
<b>Bisoprolol</b> (Zebeta)	Hypertension	PO 5–20 mg once daily
<b>Esmolol</b> (Brevibloc)	Supraventricular tachyarrhythmias	IV 50–200 mcg/kg/min; average dose, 100 mcg/kg/min, titrated to effect with close monitoring of client's condition
<b>Metoprolol</b> (Lopressor)	Hypertension Myocardial infarction	Hypertension, PO 100 mg daily in single or divided doses, increased at 7-d or longer intervals; usual maintenance dose, 100–450 mg/d Myocardial infarction, early treatment, IV 5 mg every 2 min for total of 3 doses (15 mg), then 50 mg PO q6h for 48 h, then 100 mg PO twice daily. Myocardial infarction, late treatment, PO 100 mg twice daily, for at least 3 months, up to 1–3 y
<b>Alpha-Beta-Blocking Agents</b>		
<b>Carvedilol</b> (Coreg)*	Hypertension Congestive heart failure	PO 6.25 mg twice daily for 7–14 d, then increase to 12.5 mg twice daily if necessary for 7–14 d, then increase to 25 mg twice daily if necessary (maximum dose)
<b>Labetalol</b> (Trandate, Normodyne)	Hypertension, including hypertensive emergencies	PO 100 mg twice daily IV 20 mg over 2 min then 40–80 mg every 10 min until desired blood pressure achieved or 300 mg given IV infusion 2 mg/min (e.g., add 200 mg of drug to 250 mL 5% dextrose solution for a 2 mg/3 mL concentration)

\* These drugs also have intrinsic sympathomimetic activity (ISA).

renal impairment). Approximately half the oral dose is metabolized in the liver, and the remainder is excreted unchanged in urine. When transdermal clonidine is given, therapeutic plasma levels are reached in 2 to 3 days and last 1 week.

**Methyldopa** (Aldomet) is an older drug with low to moderate absorption. With oral drug, peak plasma levels are reached in 2 to 4 hours, and peak antihypertensive effects occur in approximately 2 days. When discontinued, blood pressure increases in approximately 2 days. Intravenous (IV) administration reduces blood pressure in 4 to 6 hours and lasts 10 to 16 hours. Methyldopa is metabolized to some extent in the liver but is largely excreted in urine. In patients with renal impair-

ment, blood pressure-lowering effects may be pronounced and prolonged because of slower excretion. In addition to the adverse effects that occur with all these drugs, methyldopa also may cause hemolytic anemia and hepatotoxicity (e.g., jaundice, hepatitis).

Alpha<sub>1</sub>-adrenergic antagonists include alfuzosin, doxazosin, prazosin, terazosin, and tamsulosin. **P Prazosin** (Mini-press), the prototype, is well absorbed after oral administration and reaches peak plasma concentrations in 1 to 3 hours; action lasts approximately 4 to 6 hours. The drug is highly bound to plasma proteins, and the plasma half-life is approximately 2 to 3 hours. It is extensively metabolized in the

liver, and its metabolites are excreted by the kidneys. **Doxazosin** (Cardura) and **terazosin** (Hytrin) are similar to prazosin but have longer half-lives (doxazosin, 10–20 hours; terazosin, approximately 12 hours) and durations of action (doxazosin, up to 36 hours; terazosin, 18 hours or longer). Prazosin must be taken in multiple doses. Doxazosin and terazosin may usually be taken once daily to control hypertension or symptoms of BPH.

**Tamsulosin** (Flomax) is the first  $\alpha_1$  antagonist designed specifically to treat BPH. Tamsulosin blocks  $\alpha_1$  receptors in the male genitourinary system, producing smooth-muscle relaxation in the prostate gland and urinary bladder neck. Urinary flow rate is improved, and symptoms of BPH are reduced. Because of the specificity of tamsulosin for receptors in the genitourinary system, this drug causes less orthostatic hypotension than other  $\alpha_1$  antagonists.

After oral administration, more than 90% of tamsulosin is absorbed. Administration with food decreases bioavailability by 30%. Tamsulosin is highly protein bound and is metabolized by the liver. Approximately 10% of the drug is excreted unchanged in the urine. An advantage of tamsulosin is the ability to start the drug at the recommended dosage. Most of the  $\alpha_1$  antagonists must be gradually increased to the recommended dosage. Common adverse effects include abnormal ejaculation and dizziness.

**Alfuzosin** (UroXatral) is another  $\alpha_1$ -blocking drug specifically indicated for BPH. This moderately protein bound, extended-release medication is similar to prazosin but has the advantage of once-a-day dosing. It has a half-life of 10 hours and a duration of action of 24 hours. Alfuzosin should be taken after meals to promote absorption. It is metabolized extensively in the liver by cytochrome P450 3A4 enzymes and should not be given with potent inhibitors of this enzyme such as ketoconazole, itraconazole, or ritonavir or in the presence of moderate to severe liver insufficiency, because drug toxicity will occur. In addition, alfuzosin can prolong the Q–T interval and therefore should be used with caution in people with congenital or acquired Q–T prolongation. Common adverse effects include dizziness, headache, fatigue, and increased incidence of upper respiratory infections.

Of the alpha-adrenergic blocking drugs, **phenoxybenzamine** (Dibenzylin) is an old drug that exerts its action by binding permanently to alpha receptors and producing drug effects until the body builds new receptors. Therefore the drug action of phenoxybenzamine is long acting, persisting for 3 to 4 days. **Phentolamine** (Regitine) is similar to phenoxybenzamine but more useful clinically. Phentolamine acts competitively at alpha receptors and is therefore short acting; effects last only a few hours and can be reversed by an alpha-adrenergic stimulant drug such as norepinephrine.

## Beta-Adrenergic Blocking Drugs

Numerous beta-blocking drugs are marketed in the United States. Although they produce similar effects, they differ from the prototype **P** **propranolol** (Inderal) with respect to several properties.

## Clinical Indications

**Propranolol** is the oldest and most extensively studied beta blocker. In addition to its use in the treatment of hypertension, dysrhythmias, angina pectoris, and MI, propranolol is used to treat a wide variety of other conditions. In hypertrophic obstructive cardiomyopathy, it is used to improve exercise tolerance by increasing stroke volume. In pheochromocytoma, it is used in conjunction with an alpha-blocking drug to counter the effect of excessive catecholamine secretion, thereby preventing tachycardia and dysrhythmias. In dissecting aortic aneurysms, it is used to decrease systolic blood pressure. In hyperthyroidism, it decreases heart rate, cardiac output, and tremor.

Propranolol is also useful, by an unknown mechanism, for the prevention of migraine headache. However, it is not helpful in acute attacks of migraine headache. It also relieves palpitation and tremor associated with anxiety and stage fright, but it is not approved for clinical use as an anti-anxiety drug. Some people experiencing alcohol withdrawal may also benefit from administration of propranolol.

Research indicates that propranolol may be useful in treating cirrhosis of the liver. The drug may decrease the incidence of the initial episode of bleeding esophageal varices, prevent rebleeding episodes, and decrease the mortality rate due to hemorrhage.

Most beta blockers are approved for the treatment of hypertension. A beta blocker may be used alone or with another antihypertensive drug, such as a diuretic. **Labetalol** (Trandate, Normodyne) is also approved for treatment of hypertensive emergencies. **Atenolol** (Tenormin), metoprolol (Lopressor), **nadolol** (Corgard), and **propranolol** are approved as antianginal agents. **Betaxolol** (Betoptic, Kerlone) and **timolol** are used for hypertension and glaucoma. **Levobunolol** (Betagan) and **metipranolol** (OptiPranolol) are used only for glaucoma.

**Acebutolol** (Sectral), **esmolol** (Brevibloc), **propranolol**, and **sotalol** (Betapace and Betapace AF) are approved as antidysrhythmic agents. **Atenolol**, **metoprolol**, **propranolol**, and **timolol** (Blocadren, Timoptic) are used to prevent MI or reinfarction.

A growing number of studies demonstrate that **carvedilol** (Coreg), a *cardioselective* alpha–beta blocker, is useful not only in treating mild to moderate cases of chronic HF but also in reducing the risk of sudden death. Carvedilol has been shown to reduce risk of death or hospitalization in patients with mild to moderate HF by 38%. Despite concern that people who have severe HF or are more advanced in age would not be able to tolerate beta blockers, carvedilol appears to be well tolerated, even if the HF is advanced. Exactly how beta blockers benefit patients with HF is unclear. Possible mechanisms of action include blockade of the damaging effects of sympathetic stimulation on the heart, beta receptor up-regulation, decreased sympathetic stimulation due to decreased plasma norepinephrine and antidysrhythmic effects, and improved diastolic function by lengthening diastolic filling time. Research has shown that carvedilol demonstrates antioxidant

activity. The clinical significance of this finding for patients with HF is not yet clear. **Metoprolol**, a cardioselective beta blocker, is also indicated for the treatment of stable heart failure along with an ACE inhibitor, a diuretic, and digoxin. Studies show metoprolol reduces hospitalizations for exacerbation of heart failure and reduces cardiovascular mortality.

### Applying Your Knowledge 18-1

What is the potential benefit of using Lopressor for Mr. Jones' hypertension and his coronary history?

### Receptor Selectivity

Levobunolol, metipranolol, penbutolol, nadolol, pindolol, propranolol, sotalol, and timolol are nonselective beta blockers. The term *nonselective* means that the drugs block both beta<sub>1</sub> (cardiac) and beta<sub>2</sub> (mainly smooth muscle in the bronchi and blood vessels) receptors. Blockade of beta<sub>2</sub> receptors is associated with adverse effects such as bronchoconstriction, peripheral vasoconstriction, and interference with glycogenolysis.

Acebutolol, atenolol, betaxolol, bisoprolol, esmolol, and metoprolol are cardioselective agents, which means they have more effect on beta<sub>1</sub> receptors than on beta<sub>2</sub> receptors. As a result, they may cause less bronchospasm, less impairment of glucose metabolism, and less peripheral vascular insufficiency. These drugs are preferred when beta blockers are needed by patients with diabetes mellitus, peripheral vascular disorders, or asthma or other bronchospastic pulmonary disorders (see Evidence-Based Practice Box 18-1). However, cardioselectivity is lost at higher doses because most organs have both beta<sub>1</sub> and beta<sub>2</sub> receptors rather than one or the other exclusively.

Labetalol and carvedilol block alpha<sub>1</sub> receptors to cause vasodilation and beta<sub>1</sub> and beta<sub>2</sub> receptors to cause all the effects of the nonselective agents. Both alpha- and beta-adrenergic blocking actions contribute to antihypertensive effects, but it is unclear whether these drugs have any definite advantage over other beta blockers. They may cause less bradycardia but more postural hypotension than other beta-blocking agents, and they may cause less reflex tachycardia than other vasodilators.

### Intrinsic Sympathomimetic Activity

Drugs with *intrinsic sympathomimetic activity* (ISA) (acebutolol, carvedilol, penbutolol, and pindolol) have a chemical structure similar to that of catecholamines. As a result, they can block some beta receptors and stimulate others. It was once thought that these drugs would produce fewer adverse effects than other beta blockers; however, this has not occurred clinically. The primary use for medications with intrinsic sympathomimetic activity is to treat people who experience bradycardia with other beta blockers. These medications should not be used to prevent recurrent MI because of their potential to increase dysrhythmias and oxygen consumption by the myocardium.

## Evidence-Based Practice

### 18-1 Cardioselective Beta Blockers in Patients With Asthma or Chronic Obstructive Pulmonary Disease

Beta blockers have been shown to benefit patients with hypertension, heart failure, and myocardial infarction. However, they have traditionally been considered contraindicated in patients with obstructive airway disorders because of the bronchoconstrictive effects of beta blockade. This Cochrane review (which included a meta-analysis of 19 randomized, blinded, controlled trials on single-dose treatment with beta blockers and 10 studies on continued treatment with beta blockers) sought to assess the effect of cardioselective beta blockers on respiratory function in patients with asthma or chronic obstructive pulmonary disease (COPD) by assessing the effect of the beta blocker on the forced expiratory volume in 1 second (FEV<sub>1</sub>). The reviewers divided beta blockers into those with or without ISA for this analysis and looked at the effect of a single dose as well as continued beta<sub>1</sub> blocker therapy. Cardioselective beta blockers produced no significant change in FEV<sub>1</sub> or respiratory symptoms compared with a placebo when given as a single dose or for longer duration. There was no significant difference in FEV<sub>1</sub> with beta-blocker therapy based on presence or absence of ISA properties. In view of this review and the demonstrated benefits of beta blockers in conditions such as heart failure, coronary artery disease, and hypertension, the reviewers concluded that cardioselective beta blockers are safe for short-term use in patients with mild to moderate asthma or COPD. Further research is needed to establish long-term safety.

### Membrane-Stabilizing Activity

Several beta blockers have a *membrane-stabilizing effect* that is sometimes described as quinidine-like (i.e., producing myocardial depression). Because the doses required to produce this effect are much higher than those used for therapeutic effects, this characteristic is considered clinically insignificant.

### Potassium Channel Blockade

Unique among beta blockers, sotalol exerts an antidysrhythmic effect by blocking potassium channels in cell membranes, thereby prolonging repolarization and the refractory period of the heart. At low doses, beta-blocking effects predominate, and at high doses, antidysrhythmic effects predominate. Sotalol is used to treat life-threatening ventricular dysrhythmias and to maintain normal sinus rhythm in patients who frequently revert to atrial fibrillation/flutter (see Chap. 49). A **BLACK BOX WARNING** alerts health care professionals that appropriate use of sotalol (Betapace and Betapace AF) requires continuous ECG monitoring for 3 days after the patient is stabilized on a maintenance dose to minimize risk from drug-induced dysrhythmias. Calculation of creatinine clearance is necessary before initiating sotalol therapy to prevent drug accumulation and toxicity. Furthermore, substitution of Betapace for Betapace AF should be avoided due to significant differences in labeling, including patient package insert, dosing administration, and safety information.

## Lipid Solubility

The more lipid-soluble beta blockers were thought to penetrate the central nervous system (CNS) more extensively and cause adverse effects such as confusion, depression, hallucinations, and insomnia. Some clinicians state that this characteristic is important only in terms of drug usage and excretion in certain disease states. Thus a water-soluble, renally excreted beta blocker may be preferred in patients with liver disease and a lipid-soluble, hepatically metabolized drug may be preferred in patients with renal disease.

## Routes of Elimination

Most beta-blocking drugs are metabolized in the liver. Atenolol, nadolol, and an active metabolite of acebutolol are excreted by the kidneys; dosage must be reduced in the presence of renal failure.

## Routes of Administration

Most beta blockers can be given orally. Atenolol, esmolol, labetalol, metoprolol, and propranolol also can be given IV, and ophthalmic solutions are applied topically to the eye. Betaxolol and timolol are available in oral and ophthalmic forms.

## Duration of Action

Acebutolol, atenolol, bisoprolol, penbutolol, and nadolol have long serum half-lives and can usually be given once daily. Carvedilol, labetalol, metoprolol, pindolol, sotalol, and timolol are usually given twice daily. Propranolol required administration several times daily until development of a sustained-release capsule allowed once-daily dosing.

## Nursing Process

### Assessment

- Assess the patient's condition in relation to disorders in which antiadrenergic drugs are used. Because most of the drugs are used to treat hypertension, assess blood-pressure patterns over time, when possible, including antihypertensive drugs used and the response obtained. With other cardiovascular disorders, check blood pressure for elevation and pulse for tachycardia or dysrhythmia, and determine the presence or absence of chest pain, migraine headache, or hyperthyroidism. If the client reports or medical records indicate one or more of these disorders, assess for specific signs and symptoms. With BPH, assess for signs and symptoms of urinary retention and difficulty voiding.
- Assess for conditions that contraindicate the use of antiadrenergic drugs.
- Assess vital signs to establish a baseline for later comparisons.
- Assess for use of prescription and nonprescription drugs that are likely to increase or decrease effects of antiadrenergic drugs.

- Assess for lifestyle habits that are likely to increase or decrease effects of antiadrenergic drugs (e.g., ingestion of caffeine or nicotine).

## Nursing Diagnoses

- Decreased Cardiac Output related to drug-induced postural hypotension (alpha<sub>2</sub> agonists, alpha<sub>1</sub>-blocking agents, nonselective alpha-blocking agents, and beta blockers) and worsening HF (beta blockers)
- Impaired Gas Exchange related to drug-induced bronchoconstriction with beta blockers
- Sexual Dysfunction in men related to impotence and decreased libido
- Fatigue related to decreased cardiac output
- Noncompliance with drug therapy related to adverse drug effects or inadequate understanding of drug regimen
- Risk for Injury related to hypotension, dizziness, sedation
- Deficient Knowledge of drug effects and safe usage

## Planning/Goals

### The patient will

- Receive or self-administer drugs accurately
- Experience relief of symptoms for which antiadrenergic drugs are given
- Comply with instructions for safe drug usage
- Avoid stopping antiadrenergic drugs abruptly
- Demonstrate knowledge of adverse drug effects to be reported
- Avoid preventable adverse drug effects
- Keep appointments for blood pressure monitoring and other follow-up activities

## Interventions

Use measures to prevent or decrease the need for antiadrenergic drugs. Because the sympathetic nervous system is stimulated by physical and emotional stress, efforts to decrease stress may indirectly decrease the need for drugs to antagonize sympathetic effects. Such efforts may include the following:

- Helping the patient stop or decrease cigarette smoking. Nicotine stimulates the CNS and the sympathetic nervous system to cause tremors, tachycardia, and elevated blood pressure.
- Teaching measures to relieve pain, anxiety, and other stresses
- Counseling regarding relaxation techniques
- Helping the patient avoid temperature extremes
- Helping the patient avoid excessive caffeine in coffee or other beverages
- Helping the patient develop a reasonable balance among rest, exercise, work, and recreation

*Nursing Process continues on page 304*

- Recording vital signs at regular intervals in hospitalized clients to monitor for adverse effects
- Helping with activity or ambulation as needed to prevent injury from dizziness

In addition, teaching guidelines are included in the accompanying display.

### Evaluation

- Observe for decreased blood pressure when antiadrenergic drugs are given for hypertension.
- Interview regarding decreased chest pain when beta blockers are given for angina.
- Interview and observe for signs and symptoms of adverse drug effects (e.g., edema, tachycardia with alpha agonists and blocking agents; bradycardia, congestive HF, bronchoconstriction with beta blockers).
- Interview regarding knowledge and use of drugs.

## Principles of Therapy

### Drug Selection and Administration

#### Alpha-Adrenergic Agonists and Blocking Drugs

When an  $\alpha_1$ -blocking agent (doxazosin, prazosin, terazosin) is given for hypertension, “first-dose syncope” may occur due to hypotension. This reaction can be prevented or minimized by starting with a low dose, increasing the dose gradually, and giving the first dose at bedtime. The decreased blood pressure also stimulates reflex mechanisms to raise blood pressure

(increase heart rate and cardiac output, fluid retention), and a diuretic may be necessary.

When an  $\alpha_2$  agonist is given for hypertension, it is very important not to stop the drug abruptly because of the risk of rebound hypertension. For example, to discontinue clonidine, the dosage should be gradually reduced over 2 to 4 days.

#### Beta-Adrenergic Blocking Drugs

For most people, a nonselective beta blocker that can be taken once or twice daily is acceptable. For others, the choice of a beta blocker depends largely on the patient’s condition and response to the drugs. For example, cardioselective drugs are preferred for patients who have pulmonary disorders and diabetes mellitus, and drugs with intrinsic sympathomimetic activity may be preferred for those who experience significant bradycardia with beta blockers lacking this property.

Dosage of beta blockers must be individualized because of wide variations in plasma levels from comparable doses. Variations are attributed to the initial metabolism in the liver, the extent of binding to plasma proteins, and the degree of beta-adrenergic stimulation that the drugs must overcome. In general, low doses should be used initially and increased gradually until therapeutic or adverse effects occur. Adequacy of dosage or extent of beta blockade can be assessed by determining whether the heart rate increases in response to exercise.

Metoprolol and carvedilol are indicated for treatment of HF. Treatment should begin with a low dose of the beta blocker, often administered concurrently with an angiotensin-converting enzyme (ACE) inhibitor, a diuretic, and digoxin. The purpose of the ACE inhibitor is to counteract any initial aggravation of the HF symptoms due to the beta blocker.

## Patient Teaching Guidelines

### Alpha<sub>2</sub> Agonists and Alpha-Blocking Drugs

#### General Considerations

- Have your blood pressure checked regularly. Report high or low values to your health care provider.
- The adverse reactions of palpitations, weakness, and dizziness usually disappear with continued use. However, they may recur with conditions promoting vasodilation (dosage increase, exercise, high environmental temperatures, ingesting alcohol or a large meal).
- To prevent falls and injuries, if the above reactions occur, sit down or lie down immediately and flex arms and legs. Change positions slowly, especially from supine to standing.
- Do not drive a car or operate machinery if drowsy or dizzy from medication.
- Do not stop the drugs abruptly. Hypertension, possibly severe, may develop.
- With methyl dopa, report any signs of abdominal pain, nausea, vomiting, diarrhea, or jaundice to your health

care provider. Regular blood tests are needed to make sure the medication is working as it should.

- Do not take over-the-counter or other medications without the physician’s knowledge. Many drugs interact to increase or decrease the effects of antiadrenergic drugs.

#### Self-Administration

- Sedation and first-dose syncope may be minimized by taking all or most of the prescribed dose at bedtime.
- When using the clonidine transdermal patch, select a hairless area on the upper arm or torso for the application. The patch is changed once a week.
- Avoid alcohol use with these medications because excessive drowsiness may occur.
- With extended-release medications such as alfuzosin (UroXatral), do not crush, split, or chew the tablets, because overdose may occur.
- Take alfuzosin (UroXatral) and tamsulosin (Flomax) after a meal.

## Patient Teaching Guidelines Beta-Blocking Drugs

### General Considerations

- Count your pulse daily and report to a health care provider if under 50 for several days in succession. This information helps to determine if the drug therapy needs to be altered to avoid more serious adverse effects.
- Report weight gain (more than 2 lb within a week), ankle edema, shortness of breath, or excessive fatigue. These are signs of heart failure. If they occur, the drug may be stopped.
- Report fainting spells, excessive weakness, or difficulty in breathing. Beta-blocking drugs decrease the usual adaptive responses to exercise or stress. Syncope may result from hypotension, bradycardia, or heart block; its occur-

rence probably indicates stopping or decreasing the dose of the drug.

- Do not stop taking the drugs abruptly. Stopping the drugs suddenly may cause or aggravate chest pain (angina).
- Do not take over-the-counter or other medications without the physician's knowledge. Many drugs interact to increase or decrease the effects of beta-blocking agents.

### Self-Administration

- Consistently take the drug at the same time each day with or without food. This maintains consistent therapeutic blood levels.
- Do not crush or chew long-acting forms of these medications.

The purpose of the diuretic is to manage fluid retention. The purpose of digoxin is to improve cardiac output. The patient should be closely monitored for adverse effects such as worsening HF.

Current evidence based practice guidelines by the American Heart Association and the American College of Cardiology recommend early use of an oral beta blocker with or without reperfusion therapy after an acute MI along with oxygen, aspirin, nitroglycerin, and an anticoagulant (heparin or low-molecular weight heparin). Adjunctive medications may include clopidogrel and a glycoprotein IIb/IIIa receptor blocker. Intravenous beta-blocker therapy is appropriate for patients with acute MI accompanied by tachyarrhythmias or high blood pressures; however, there is a higher risk of early cardiogenic shock in more hemodynamically at-risk patients. Patients with acute MI that have documented heart failure or high risk for shock may not be candidates for early beta-blocker treatment; it is important to individualize treatment in these cases. Beta-blocker therapy should be continued for at least 2 years post-MI. (A beta blocker with intrinsic sympathomimetic activity should not be used for this purpose.) Studies have shown that such use of a beta blocker may reduce mortality by as much as 25%. Accompanying post-MI beta-blocker therapy, most patients will also receive aspirin and an angiotensin-converting enzyme inhibitor for secondary prevention of death stroke and recurrent MI. Adjunctive medications may include statins for hyperlipidemia and anticoagulation with warfarin.

A **BLACK BOX WARNING** alerts health care providers that beta blockers should not be discontinued abruptly. Long-term blockade of beta-adrenergic receptors increases the receptors' sensitivity to epinephrine and norepinephrine when the drugs are discontinued. There is a risk of severe hypertension, angina, dysrhythmias, and MI from the increased or excessive sympathetic nervous system stimulation. Thus the dosage should be tapered and gradually discontinued to allow beta-adrenergic receptors to return to predrug density and sensitivity. An optimal tapering period has not been defined.

Some authorities recommend 1 to 2 weeks, and others recommend reducing the dosage over approximately 10 days to 30 milligrams per day of propranolol (or an equivalent amount of other drugs) and continuing this amount at least 2 weeks before the drug is stopped completely. Treatment with beta blockers should be restarted if angina worsens or acute coronary insufficiency develops during the tapering process.

Beta blockers are indicated to reduce hemodynamic complications during the perioperative period. Esmolol is often the beta blocker of choice in this situation because it is cardioselective, can be given IV, and has a rapid onset of action. Cardiac output may be an important factor in determining the amount of IV anesthetic needed for induction, and esmolol is known to reduce cardiac output. A recent study found that propofol requirements for induction were reduced by 25% after pretreatment with esmolol. During the intraoperative and postoperative periods, esmolol is useful for controlling tachycardia and hypertension. With some types of anesthesia such as desflurane, intraoperative administration of esmolol promotes more rapid awakening after anesthesia and reduced need for opioid analgesics. Postoperatively, esmolol may also be useful in preventing myocardial ischemia.

Various drugs may be used to treat adverse effects of beta blockers. Atropine can be given for bradycardia, digoxin and diuretics for HF, vasopressors for hypotension, and bronchodilator drugs for bronchoconstriction.

It is important to note that bronchodilation does not occur in a patient taking beta blockers when given epinephrine to treat an allergic reaction to an allergen or during allergy testing. This absence of the normal response to epinephrine is due to drug-induced beta<sub>2</sub> blockade.

### Applying Your Knowledge 18-2

What explanation do you give Mr. Jones when he asks what the patch does for his condition?

.....

## Use in Special Populations

### Use in Children

Most alpha-adrenergic agonists and blocking agents have not been established as safe and effective in children.

Beta-adrenergic blocking drugs are used in children for disorders similar to those in adults. However, safety and effectiveness have not been established, and manufacturers of most of the drugs do not recommend pediatric use or suggest dosages. The drugs are probably contraindicated in young children with resting heart rates of less than 60 beats per minute.

When beta blockers are given, general guidelines include the following:

- Adjust dosage for body weight.
- Monitor responses closely. Children are more sensitive to adverse drug effects than adults.
- Remember that if beta blockers are given to infants (up to 1 year of age) with immature liver function, blood levels may be higher and accumulation is more likely even when doses are based on weight.
- When monitoring responses, remember that heart rate and blood pressure vary among children according to age and level of growth and development. They also differ from those of adults.
- Recall that children are more likely to have asthma than adults. Thus they may be at greater risk of drug-induced bronchoconstriction.

Propranolol is probably the most frequently used beta blocker in children. The drug is given orally for hypertension, and dosage should be individualized. The usual dosage range is 2 to 4 milligrams per kilogram of body weight per day, in two equal doses. Calculation of the dosage on the basis of body surface area is not recommended because of possible excessive blood levels of drug and greater risk of toxicity. As with adults, the drug should not be stopped abruptly and should be tapered gradually over 1 to 3 weeks.

### Use in Older Adults

Alpha<sub>2</sub>-adrenergic agonists may be used to treat hypertension in older adults, and alpha<sub>1</sub>-adrenergic antagonists may be used to treat hypertension and BPH. Dosage of these drugs should be reduced because older adults are more likely to experience adverse drug effects, especially with impaired renal or hepatic function. As with other populations, these drugs should not be stopped suddenly. Instead, they should be tapered in dosage and discontinued gradually, over 1 to 2 weeks.

Older adults undergoing cataract surgery are at risk of a surgical complication, intraoperative *floppy iris syndrome*, if they are taking selective alpha<sub>1</sub>-blockers for BPH or hypertension. Pupil dilation is necessary for cataract surgery. Alpha<sub>1</sub> blockers may cause the pupil to constrict and the iris to relax, complicating the surgical procedure. It is important for individuals to alert eye surgeons of alpha<sub>1</sub> blockers therapy so

special precautions during surgery can be implemented to reduce potential complications.

Beta-adrenergic blocking drugs are commonly used in older adults for angina, dysrhythmias, hypertension, HF, prevention of recurrent MI, and glaucoma. Several recent clinical trials and research studies demonstrated that older adults can tolerate and benefit from use of beta blockers in the treatment of HF. In hypertension, beta blockers are not recommended for monotherapy because older adults may be less responsive than younger adults. Thus the drugs are probably most useful as second drugs (with diuretics) in patients who require multidrug therapy and patients who also have angina pectoris or another disorder for which a beta blocker is indicated.

Whatever the indications for beta blockers in older adults, the drugs should be used cautiously and patients' responses should be monitored closely. Older adults are likely to have disorders that put them at higher risk of adverse drug effects, such as HF and other cardiovascular conditions, renal or hepatic impairment, and chronic pulmonary disease. Thus they may experience bradycardia, bronchoconstriction, and hypotension to a greater degree than younger adults. Dosage usually should be reduced because of decreased hepatic blood flow and subsequent slowing of drug metabolism. As in other populations, beta blockers should be tapered in dosage and discontinued over 1 to 3 weeks to avoid myocardial ischemia and other potentially serious adverse cardiovascular effects.

## Applying Your Knowledge 18-3

### How Can You Avoid This Medication Error?

You are preparing medication for Mr. Jones. The pharmacy has substituted Lopressor with a generic drug. Mr. Jones informs you that he cannot take another form of the drug, so you hold the dose and do not administer today's metoprolol.

.....

### Use in Various Ethnic Groups

Most studies involve adults with hypertension and compare drug therapy responses between African Americans and Caucasians. Findings indicate that monotherapy with alpha<sub>1</sub> blockers and combination therapy with alpha and beta blockers is equally effective in the two groups. However, monotherapy with beta blockers is less effective in African Americans than in Caucasians. When beta blockers are used in African Americans, they should usually be part of a multidrug treatment regimen, and higher doses may be required. In addition, labetalol, an alpha and beta blocker, has been shown to be more effective in the African-American population than propranolol, timolol, or metoprolol. According to the U.S. Carvedilol Heart Failure Trials Program and the COPERNICUS trials, African Americans with HF responded favorably

to a combination of carvedilol plus ACE inhibitors, even when their condition was advanced.

Several studies indicate that Asians achieve higher blood levels of beta blockers with given doses and, in general, need much smaller doses than Caucasians. This increased sensitivity to the drugs may result from slower metabolism and excretion.

### Use in Patients With Renal Impairment

Centrally acting  $\alpha_2$  agonists such as clonidine and methyldopa are eliminated by a combination of liver metabolism and renal excretion. Renal impairment may result in slower excretion of these medications, with subsequent accumulation and increased adverse effects.

$\alpha_1$ -adrenergic antagonists such as prazosin, terazosin, alfuzosin, doxazosin, and tamsulosin are eliminated primarily by liver metabolism and biliary excretion. Therefore renal impairment is not a contraindication to use of these medications. However, the kidneys excrete tolazoline, and reduced dosage should be considered in the presence of renal impairment.

Many beta blockers are eliminated primarily in the urine and pose potentially serious problems for patients with renal failure. In renal failure, dosage of acebutolol, atenolol, and nadolol must be reduced because they are eliminated mainly through the kidneys. The dosage of acebutolol and nadolol should be reduced if creatinine clearance is less than 50 milliliters per minute, and the dosage of atenolol should be reduced if the creatinine clearance is less than 35 milliliters per minute.

### Use in Patients With Liver Impairment

Caution must be used when administering centrally acting  $\alpha_2$ -adrenergic agonists such as clonidine and methyldopa to patients with liver impairment. These medications rely on hepatic metabolism as well as renal elimination to clear the body. Furthermore, methyldopa has been associated with liver disorders such as hepatitis and hepatic necrosis.

$\alpha_1$ -adrenergic medications such as prazosin, alfuzosin, terazosin, doxazosin, and tamsulosin rely heavily on liver metabolism and biliary excretion to clear the body. Liver impairment may result in increased drug levels and adverse effects.

In the presence of hepatic disease (e.g., cirrhosis) or impaired blood flow to the liver (e.g., reduced cardiac output from any cause), dosage of some beta blockers such as propranolol, metoprolol, and timolol should be substantially reduced because these drugs are extensively metabolized in the liver. The use of atenolol or nadolol is preferred in liver disease because both are eliminated primarily by the kidneys.

### Use in Patients With Critical Illness

Antiadrenergic drugs are one of several families of medications that may be used to treat urgent or malignant hypertension. An  $\alpha_2$  agonist such as clonidine might be prescribed under such conditions. A loading dose of clonidine 0.2 milligrams,

followed by 0.1 milligram per hour until the diastolic pressure falls below 110 mm Hg, may be administered. A dose of 0.7 milligrams should not be exceeded when using clonidine to treat malignant hypertension.

Beta blockers may be used in the treatment of acute MI. Early administration of a beta blocker after an acute MI results in a lower incidence of reinfarction, ventricular dysrhythmias, and mortality. These results have been demonstrated with several different agents; however, those with intrinsic sympathomimetic activity are not prescribed for this purpose. Patients must be carefully monitored for hypotension and HF when receiving beta blockers after an MI.

### Use in Home Care

Antiadrenergic drugs are commonly used in the home setting, mainly to treat chronic disorders in adults. With  $\alpha_1$ -adrenergic blocking drugs, the home care nurse may need to teach patients ways to avoid orthostatic hypotension. Most patients probably take these medications for hypertension. However, some older men with BPH take one of these drugs to aid urinary elimination. For an older man taking one of these drugs, the home care nurse must assess the reason for use to teach the patient and monitor for drug effects.

With beta-adrenergic blocking drugs, the home care nurse may need to assist patients and caregivers in assessing for therapeutic and adverse drug effects. It is helpful to have the patient or someone else in the household count and record the radial pulse daily, preferably about the same time interval before or after taking a beta blocker. Several days of a slow pulse should probably be reported to the health care provider who prescribed the beta blocker, especially if the patient also has excessive fatigue or signs of HF.

If wheezing respirations (indicating bronchoconstriction) develop in a patient taking a nonselective beta blocker, the patient or the home care nurse must consult the prescribing physician about changing to a cardioselective beta blocker. If a patient has diabetes mellitus, the home care nurse must interview and observe the patient for alterations in blood sugar control, especially increased episodes of hypoglycemia. If a patient has hypertension, the home care nurse must teach the patient to avoid over-the-counter (OTC) asthma and cold remedies, decongestants, appetite suppressants, and herbal preparations such as ma huang, black cohosh, and St. John's wort because these drugs act to increase blood pressure and may reduce the benefits of antiadrenergic medications. In addition, OTC analgesics such as ibuprofen, ketoprofen, and naproxen may raise blood pressure by causing retention of sodium and water.

### Applying Your Knowledge 18-4

Mr. Jones has diabetes and is therefore at increased risk of what complication from Lopressor?

.....

## Nursing Actions Antiadrenergic Drugs

### NURSING ACTIONS

#### 1. Administer accurately

##### a. With $\alpha_2$ agonists:

- (1) Give all or most of a dose at bedtime, when possible.
- (2) Apply the clonidine skin patch to a hairless, intact area on the upper arm or torso; then apply adhesive overlay securely. Do not cut or alter the patch. Remove a used patch and fold its adhesive edges together before discarding. Apply a new patch in a new site.

To minimize daytime drowsiness and sedation  
To promote effectiveness and safe usage

##### b. With $\alpha_1$ -blocking drugs:

- (1) Give the first dose of doxazosin, prazosin, or terazosin at bedtime.
- (2) Give alfuzosin and tamsulosin after the same meal each day.

To prevent fainting from severe orthostatic hypotension

Drug absorption is delayed in fasting conditions.

##### c. With beta-adrenergic blocking drugs:

- (1) Check blood pressure and pulse frequently, especially when dosage is being increased.
- (2) See Table 18–2 and manufacturers' literature regarding intravenous (IV) administration.

To monitor therapeutic effects and the occurrence of adverse reactions. Some patients with heart rates between 50 and 60 beats per minute may be continued on a beta blocker if hypotension or escape dysrhythmias do not develop. Specific instructions vary with individual drugs.

#### 2. Observe for therapeutic effects

##### a. With $\alpha_2$ agonists and alpha-blocking drugs:

- (1) With hypertension, observe for decreased blood pressure.
- (2) With benign prostatic hyperplasia, observe for improved urination.
- (3) In pheochromocytoma, observe for decreased pulse rate, blood pressure, sweating, palpitations, and blood sugar.
- (4) In Raynaud's disease or frostbite, observe affected areas for improvement in skin color and temperature and in the quality of peripheral pulses.

With most of the drugs, blood pressure decreases within a few hours. However, antihypertensive effects with clonidine skin patches occur 2–3 days after initial application (overlap with oral clonidine or other antihypertensive drugs may be needed) and persist 2–3 days when discontinued.

The patient may report a larger stream, less nocturnal voiding, and more complete emptying of the bladder.

Because symptoms of pheochromocytoma are caused by excessive sympathetic nervous system stimulation, blocking stimulation with these drugs produces a decrease or absence of symptoms.

These conditions are characterized by vasospasm, which diminishes blood flow to the affected part. The drugs improve blood flow by vasodilation.

##### b. With beta-blocking drugs:

- (1) With hypertension, observe for decreasing blood pressure.
- (2) With angina, observe for absence of chest pain, nausea, vomiting, sweating, and anxiety.
- (3) With dysrhythmias, observe for regular pulse and signs of adequate cardiac output.

Blood pressure is lowered when sympathetic nervous system activity is inhibited.

Angina is characterized by inadequate blood flow and oxygenation to the myocardium. The drugs reduce cardiac workload and therefore reduce oxygen demand.

Rhythm disturbances decrease cardiac output.

#### 3. Observe for adverse effects

##### a. With $\alpha_2$ agonists and alpha-blocking drugs:

- (1) Hypotension
- (2) Sedation, drowsiness
- (3) Tachycardia
- (4) Edema
- (5) Impaired ejaculation

Adverse effects are usually extensions of therapeutic effects.

Hypotension may range from transient postural hypotension to a more severe hypotensive state resembling shock. "First-dose syncope" may occur with prazosin and related drugs. Sedation can be minimized by increasing dosage slowly and giving all or most of the daily dose at bedtime.

Tachycardia occurs as a reflex mechanism to increase blood supply to body tissues in hypotensive states.

These drugs promote retention of sodium and water. Concomitant diuretic therapy may be needed to maintain antihypertensive effects with long-term use.

Blockade of the sympathetic nervous system impedes efferent nerve conduction to the seminal vesicles.

## NURSING ACTIONS

- (6) Prolonged Q-T interval and dysrhythmias with alfuzosin
- b. With beta-blocking drugs:
- (1) Bradycardia and heart block
  - (2) Congestive heart failure—edema, dyspnea, fatigue
  - (3) Bronchospasm—dyspnea, wheezing
  - (4) Fatigue and dizziness, especially with activity or exercise
  - (5) Central nervous system (CNS) effects—depression, insomnia, vivid dreams, and hallucinations

## 4. Observe for drug interactions

- a. Drugs that *increase* effects of alpha-antiadrenergic drugs:
- (1) Other antihypertensive drugs
  - (2) CNS depressants
  - (3) Nonsteroidal anti-inflammatory drugs
  - (4) Epinephrine
  - (5) Ketoconazole, itraconazole, and ritonavir (with alfuzosin)
- b. Drugs that *decrease* effects of alpha-antiadrenergic drugs:
- (1) Alpha adrenergics (e.g., norepinephrine)
  - (2) Estrogens, oral contraceptives, nonsteroidal anti-inflammatory drugs
- c. Drugs that *increase* effects of beta-adrenergic blocking drugs (e.g., propranolol):
- (1) Other antihypertensives
  - (2) Phentolamine
  - (3) Cimetidine, furosemide
  - (4) Digoxin
  - (5) Phenytoin
  - (6) Quinidine
  - (7) Verapamil, IV
- d. Drugs that *decrease* effects of beta-adrenergic blocking drugs:
- (1) Antacids
  - (2) Atropine
  - (3) Isoproterenol
  - (4) Cocaine

## RATIONALE/EXPLANATION

Prolongation of the Q-T interval increases the risk of ventricular dysrhythmias such as torsades de pointes.

These are extensions of the therapeutic effects, which slow conduction of electrical impulses through the atrioventricular node, particularly in patients with compromised cardiac function.

Caused by reduced force of myocardial contraction  
Caused by drug-induced constriction of bronchi and bronchioles. It is more likely to occur in people with bronchial asthma or other obstructive lung disease.

These symptoms occur because the usual sympathetic nervous system stimulation in response to activity or stress is blocked by drug action.

The mechanism by which these effects are produced is unknown.

Additive antihypertensive effects

Additive sedation and drowsiness

Additive sodium and water retention, possible edema

Epinephrine increases the hypotensive effects of phentolamine and should not be given to treat shock caused by these drugs. Because epinephrine stimulates both alpha- and beta-adrenergic receptors, the net effect is vasodilation and a further drop in blood pressure.

These drugs inhibit the enzyme CYP3A4, which is responsible for the metabolism of alfuzosin.

Norepinephrine is a strong vasoconstricting agent and is the drug of choice for treating shock caused by overdose of, or hypersensitivity to, phentolamine or phentalamine.

These drugs may cause sodium and fluid retention and thereby decrease antihypertensive effects of alpha-antiadrenergic drugs.

Synergistic antihypertensive effects. Patients who do not respond to beta blockers or vasodilators alone may respond well to the combination. Also, beta blockers prevent reflex tachycardia, which usually occurs with vasodilator antihypertensive drugs.

Synergistic effects to prevent excessive hypertension before and during surgical excision of pheochromocytoma

Increase plasma levels by slowing hepatic metabolism

Additive bradycardia, heart block

Potentiates cardiac depressant effects of propranolol

The combination may be synergistic in treating cardiac arrhythmias. However, additive cardiac depressant effects also may occur (bradycardia, decreased force of myocardial contraction [negative inotropy], decreased cardiac output). IV verapamil and IV propranolol should never be used in combination because of additive bradycardia and hypotension.

Decrease absorption of several oral beta blockers

Increases heart rate and may be used to counteract excessive bradycardia caused by beta blockers

Stimulates beta-adrenergic receptors and therefore antagonizes effects of beta-blocking agents. Isoproterenol also can be used to counteract excessive bradycardia.

May reduce or cancel the effects of beta-blocking drugs

## Key Concepts

- Antiadrenergic drugs decrease or block the effects of sympathetic nerve stimulation, endogenous catecholamines (e.g., epinephrine), and adrenergic drugs.
- Antiadrenergic effects can occur either when  $\alpha_1$  or beta receptors are blocked by adrenergic antagonists or when presynaptic  $\alpha_2$  receptors are stimulated by agonist drugs.
- Most antiadrenergic drugs have antagonist or blocking effects when they bind with  $\alpha_1$ ,  $\beta_1$ ,  $\beta_2$ , or a combination of receptors in peripheral tissues, thus preventing adrenergic effects.
- $\alpha_2$ -adrenergic agonists such as clonidine (Catapres) inhibit the release of norepinephrine in the brain, thereby decreasing the effects of sympathetic nervous system stimulation throughout the body.
- $\alpha_2$  agonists are used in the treatment of hypertension
- Selective  $\alpha_1$ -adrenergic blocking drugs are used in the treatment of hypertension, BPH, and vasospastic disorders.
- Clinical indications for beta-blocking agents are mainly cardiovascular disorders (e.g., angina pectoris, cardiac tachydysrhythmias, hypertension, myocardial infarction [MI], heart failure [HF]) and glaucoma.
- Antiadrenergic drugs should not be abruptly discontinued.

## Review and Application Exercises

### Short Answer Exercises

1. How do  $\alpha_2$  agonists and  $\alpha_1$ -blocking drugs decrease blood pressure?
2. What are safety factors in administering and monitoring the effects of  $\alpha_2$  agonists and  $\alpha_1$ -blocking drugs?
3. Why should a patient be cautioned against stopping  $\alpha_2$  agonists and  $\alpha_1$ -blocking drugs abruptly?
4. What are the main mechanisms by which beta blockers relieve angina pectoris?
5. How are beta blockers thought to be “cardioprotective” in preventing repeat MIs?
6. What are some noncardiovascular indications for the use of propranolol?
7. What are the main differences between cardioselective and nonselective beta blockers?
8. Why are cardioselective beta blockers preferred for patients with asthma or diabetes mellitus?
9. List at least five adverse effects of beta blockers.
10. Explain the drug effects that contribute to each adverse reaction.
11. What signs, symptoms, or behaviors would lead you to suspect adverse drug effects?
12. Do the same adverse effects occur with beta-blocker eye drops that occur with systemic drugs? If so, how may they be prevented or minimized?
13. What information needs to be included in teaching patients about beta-blocker therapy?
14. What is the risk of abruptly stopping a beta-blocker drug rather than tapering the dose and gradually discontinuing the drug, as recommended?
15. How can beta blockers be both therapeutic and nontherapeutic for HF?

### NCLEX-Style Questions

16. A patient with a history of emphysema is prescribed propranolol (Inderal) to treat hypertension. In this situation, the nurse should assess for the presence of
  - a. hyperglycemia
  - b. tachycardia
  - c. bronchoconstriction
  - d. respiratory depression
17. Your diabetic patient requires a beta blocker to treat a tachydysrhythmia. Due to the beta-blocker therapy, you should teach this patient not to rely on which of the following signs of developing hypoglycemia?
  - a. increased thirst
  - b. irritability
  - c. tachycardia
  - d. hunger
18. A patient is taking clonidine (Catapres), an  $\alpha_2$  blocker, for hypertension. It is important for the nurse to give this patient which of the following instructions?
  - a. Change from lying to standing positions slowly.
  - b. Rest often to avoid exercise intolerance.
  - c. Promptly report episodes of wheezing and difficulty breathing.
  - d. Take the medication in the morning to avoid insomnia.

19. You are taking care of a patient receiving intravenous dopamine (Intropin), a vasoconstrictor. What must you be prepared to administer if extravasation occurs?
- phentolamine (Regitine)
  - propranolol (Inderal)
  - esmolol (Brevibloc)
  - tamsulosin (Flomax)
20. The nurse should monitor which of the following tests in a hypertensive patient taking methyldopa (Aldomet)?
- prostate-specific antigen
  - serum electrolytes
  - blood glucose
  - liver studies
21. Which of the following instructions should be given to the patient with benign prostatic hyperplasia before taking his first dose of prazosin (Minipress)?
- Take your medication in the morning after meals.
  - Take your medication at bedtime.
  - Take your medication on an empty stomach.
  - Take your medication with a glass of milk.

# Cholinergic Drugs

## KEY TERMS

- Acetylcholinesterase
- Alzheimer's disease
- Anticholinesterase
- Cholinergic
- Myasthenia gravis

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Describe effects and indications for use of selected cholinergic drugs.
2. Discuss drug therapy for myasthenia gravis.
3. Discuss the use of cholinergic drug therapy for paralytic ileus and urinary retention.
4. Discuss drug therapy for Alzheimer's disease.
5. Describe major nursing care needs of patients receiving cholinergic drugs.
6. Describe signs, symptoms, and treatment of overdose with cholinergic drugs.
7. Discuss atropine and pralidoxime as antidotes for cholinergic drugs.
8. Discuss principles of therapy for using cholinergic drugs in special populations.
9. Teach patients about safe, effective use of cholinergic drugs.

## Applying Your Knowledge

Betty Humbarger is a 39-year-old woman who has myasthenia gravis. The use of neostigmine 30 mg three to four times a day has controlled her symptoms.

## Introduction

*Cholinergic* drugs stimulate the parasympathetic nervous system in the same manner as acetylcholine (see Chap. 16). Some drugs act directly to stimulate cholinergic receptors; others act indirectly by inhibiting the enzyme *acetylcholinesterase*, thereby slowing acetylcholine metabolism at autonomic nerve synapses. Selected drugs are discussed here in relation to their use in *myasthenia gravis*, *Alzheimer's disease*, and atony of the smooth muscle of the gastrointestinal (GI) and urinary systems, which results in paralytic ileus and urinary retention, respectively.

In normal neuromuscular function, acetylcholine is released from nerve endings and binds to nicotinic receptors on cell membranes of muscle cells to cause muscle contraction. Myasthenia gravis is an autoimmune disorder in which autoantibodies are thought to destroy nicotinic receptors for acetylcholine on skeletal muscle. As a result, acetylcholine is less able to stimulate muscle contraction, and muscle weakness occurs.

In normal brain function, acetylcholine is an essential neurotransmitter and plays an important role in cognitive functions, including memory storage and retrieval. Alzheimer's disease, the most common type of dementia in adults, is characterized by abnormalities in the cholinergic,

serotonergic, noradrenergic, and glutamatergic neurotransmission systems (see Chap. 5). In the cholinergic system, there is a substantial loss of neurons that secrete acetylcholine in the brain and decreased activity of choline acetyltransferase, the enzyme required for synthesis of acetylcholine.

Acetylcholine stimulates cholinergic receptors in the gut to promote normal secretory and motor activity. Cholinergic stimulation results in increased peristalsis and relaxation of the smooth muscle in sphincters to facilitate movement of flatus and feces. The secretory functions of the salivary and gastric glands are also stimulated.

Acetylcholine stimulates cholinergic receptors in the urinary system to promote normal urination. Cholinergic stimulation results in contraction of the detrusor muscle and relaxation of the urinary sphincter to facilitate emptying the urinary bladder.

## General Characteristics of Cholinergic Drugs

### Mechanisms of Action and Effects

Direct-acting cholinergic drugs are synthetic derivatives of choline. Most direct-acting cholinergic drugs are quaternary amines, carry a positive charge, and are lipid insoluble. They do not readily enter the central nervous system; thus their effects occur primarily in the periphery. Direct-acting cholinergic drugs are highly resistant to metabolism by acetylcholinesterase, the enzyme that normally metabolizes acetylcholine. This allows the drugs to have a longer duration of action than acetylcholine would produce. Direct-acting cholinergic drugs have widespread systemic effects when they activate muscarinic receptors in cardiac muscle, smooth muscle, exocrine glands, and the eye (Fig. 19-1).

Specific effects of direct-acting cholinergic drugs include

- Decreased heart rate, vasodilation, and unpredictable changes in blood pressure
- Increased tone and contractility in GI smooth muscle, relaxation of sphincters, and increased salivary-gland and GI secretions
- Increased tone and contractility of smooth muscle (detrusor) in the urinary bladder and relaxation of the sphincter
- Increased tone and contractility of bronchial smooth muscle
- Increased respiratory secretions
- Constriction of pupils (miosis) and contraction of ciliary muscle, resulting in accommodation for near vision

Indirect-acting cholinergic, or *anticholinesterase*, drugs decrease the inactivation of acetylcholine in the synapse by the enzyme acetylcholinesterase. Acetylcholine can then accumulate in the synapse and enhance the activation of postsynaptic muscarinic as well as nicotinic receptors (Fig. 19-2). In addition to the cholinergic drug effects described above, the added effect of indirect-acting cholinergic drugs on nicotinic

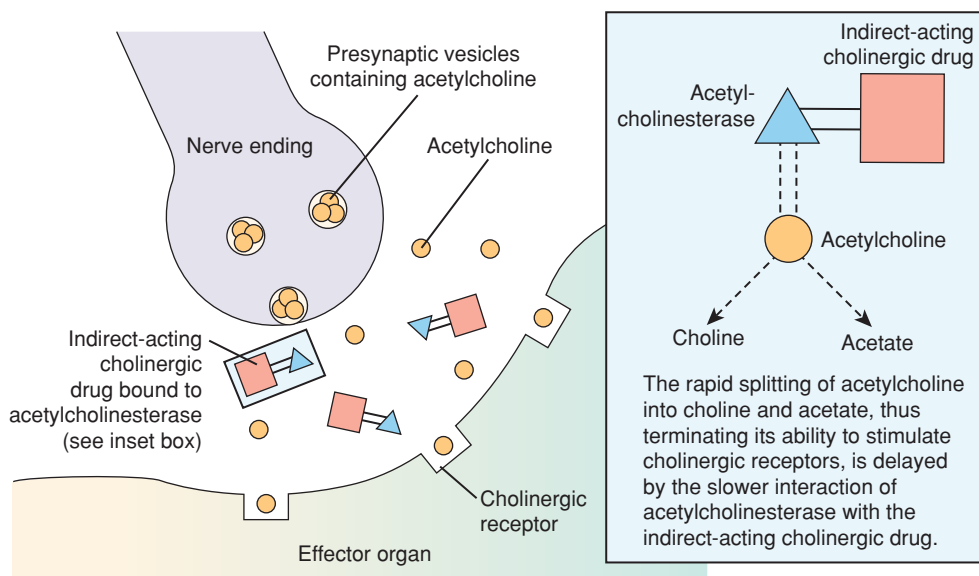

**Figure 19-1** ■ Mechanism of direct cholinergic drug action. Direct-acting cholinergic drugs interact with postsynaptic cholinergic receptors on target effector organs, activating the organ in a similar fashion as the neurotransmitter acetylcholine.

receptors in skeletal muscles results in improved skeletal muscle tone and strength. Indirect-acting cholinergic medications for Alzheimer's disease are widely distributed, including to the central nervous system. Thus indirect-acting cholinergic drugs are able to improve cholinergic neurotransmission in the brain.

Anticholinesterase drugs are classified as either reversible or irreversible inhibitors of acetylcholinesterase. The reversible inhibitors exhibit a moderate duration of action and have several therapeutic uses, such as for Alzheimer's disease and myasthenia gravis, as described later. The irreversible inhibitors produce prolonged effects and are highly toxic. These agents are used primarily as poisons (i.e., insecticides and nerve gases); management of the toxicity caused by these agents is discussed later in this chapter. The only therapeutic use of these drugs is in the treatment of glaucoma (see Chap. 63).

### Indications for Use

Cholinergic drugs have limited but varied uses. A direct-acting drug, bethanechol, is used to treat urinary retention due to urinary bladder atony and postoperative abdominal distention due to paralytic ileus. The anticholinesterase agents are used in the diagnosis and treatment of myasthenia gravis. They are also used to reverse the action of nondepolarizing neuromuscular blocking agents, such as tubocurarine, used in surgery (see Appendix C). Anticholinesterase agents do not reverse the neuromuscular blockade produced by depolarizing neuromuscular blocking agents, such as succinylcholine. In addition, donepezil, rivastigmine, and galantamine are anticholinesterase agents approved for treatment of Alzheimer's disease. Rivastigmine is also approved for treatment of mild to moderate dementia due to Parkinson's disease. Cholinergic drugs may also be used to treat glaucoma (see Chap. 63).

**Figure 19-2** ■ Mechanism of indirect cholinergic drug action. Indirect-acting cholinergic drugs prevent the enzymatic breakdown of the neurotransmitter acetylcholine. The acetylcholine remains in the synapse and continues to interact with cholinergic receptors on target effector organs, producing a cholinergic response.

## Contraindications to Use

Cholinergic drugs are contraindicated in urinary or GI tract obstruction because they increase the contractility of smooth muscle in the urinary and GI systems and may result in injury to structures proximal to the obstruction. Cholinergic drugs are contraindicated in individuals with asthma because they may cause bronchoconstriction and increased respiratory secretions. Individuals with peptic ulcer disease should not use cholinergic drugs because they increase gastric acid secretion. These drugs are also contraindicated in patients with inflammatory abdominal conditions and recent bowel surgery, because the drugs cause increased tone and motility of the intestinal smooth muscle and may lead to rupture of the bowel. Individuals with coronary artery disease should not take cholinergics because they can result in bradycardia, vasodilation, and hypotension.

Patients with hyperthyroidism should avoid cholinergic drugs. In the individual with hyperthyroidism, the initial response to cholinergic medications (bradycardia and hypotension) triggers the baroreceptor reflex. As this reflex attempts to resolve the hypotension, norepinephrine is secreted from sympathetic nerves regulating the heart. Norepinephrine may trigger reflex tachycardia and other cardiac dysrhythmias.

Pregnant women should not take cholinergic medications.

## Individual Drugs

Cholinergic drugs are described in the following sections. Trade names, clinical indications, and dosage ranges are listed in Table 19-1.

### Direct-Acting Cholinergics

**Bethanechol** (Urecholine) is a synthetic derivative of choline. Because the drug produces smooth-muscle contractions, it

should not be used in obstructive conditions of the urinary or GI tracts.

### Reversible Indirect-Acting Cholinergics (Anticholinesterases)

**P Neostigmine** (Prostigmin) is the prototype anticholinesterase agent. It is used for long-term treatment of myasthenia gravis and as an antidote for tubocurarine and other nondepolarizing skeletal muscle relaxants used in surgery. Neostigmine, like bethanechol, is a quaternary amine and carries a positive charge. This reduces its lipid solubility and results in poor absorption from the GI tract. Consequently, oral doses are much larger than parenteral doses. When it is used for long-term treatment of myasthenia gravis, resistance to its action may occur and larger doses may be required.

**Edrophonium** (Tensilon) is a short-acting cholinergic drug used to diagnose myasthenia gravis, to differentiate between myasthenic crisis and cholinergic crisis, and to reverse the neuromuscular blockade produced by nondepolarizing skeletal muscle relaxants. It is given IM or IV by a physician who remains in attendance. Atropine, an antidote, and life-support equipment, such as ventilators and endotracheal tubes, must be available when the drug is given.

**Physostigmine salicylate** (Antilirium) is the only anticholinesterase capable of crossing the blood–brain barrier. Unlike other drugs in this group, physostigmine is not a quaternary amine, does not carry a positive charge, and therefore is more lipid soluble. It is sometimes used as an antidote for overdosage of anticholinergic drugs, including atropine, antihistamines, tricyclic antidepressants, and phenothiazine antipsychotics. However, its potential for causing serious adverse effects limits its usefulness. Some preparations of physostigmine are also used in the treatment of glaucoma (see Chap. 63).

**Pyridostigmine** (Mestinon) is similar to neostigmine in actions and uses and in adverse effects. It may have a longer

Table 19-1

## Drugs at a Glance: Selected Cholinergic Drugs

Generic/Trade Name	ROUTES AND DOSAGE RANGES	
	Adults	Children
<b>Direct-Acting Cholinergics</b>		
<b>Bethanechol</b> (Urecholine)	PO 10–50 mg 2 to 4 times daily, maximum single dose not to exceed 50 mg	Safety and efficacy not established <8 y. PO: 0.6 mg/kg 3 to 4 times daily.
<b>Indirect-Acting Cholinergics (Anticholinesterase Drugs)</b>		
<b>Edrophonium</b> (Tensilon)	<p><i>Diagnosis of myasthenia gravis:</i>            IV route preferred: 2 mg IV over 15–30 sec; 8 mg IV given 45 sec later if no response            Test dose may be repeated in 30 min.            IM route: 10 mg; may follow up with an additional 2 mg 30 min later if no response</p> <p><i>Differentiation of myasthenic crisis from cholinergic crisis:</i>            2 mg IV, observe response for 60 sec            May repeat with subsequent doses of 3 mg and 5 mg if no response to initial dose. BE PREPARED to intubate.</p>	<p><i>Diagnosis of myasthenia gravis:</i>            Infants: 0.5 mg IV. &lt;34 kg: 1 mg IV; may titrate up to 5 mg if no response. &gt;34 kg: 2 mg IV; may titrate up to 10 mg if no response            Children &lt;34 kg: 2 mg IM            Children &gt;34 kg: 5 mg, IM</p>
<b>Neostigmine</b> (Prostigmin)	<p><i>Prevention/treatment of postoperative distention and urinary retention:</i>            0.25–0.5 mg IM or Sub-Q q 4–6 h for 2–3 d.</p> <p><i>Treatment of myasthenia gravis:</i>            Dosage individualized to patient needs.            PO 15–375 mg/day in 3 or 4 divided doses. Sub-Q, IV, or IM 0.5 mg initially. Individualize subsequent doses.</p> <p><i>Diagnosis of myasthenia gravis:</i>            0.022 mg/kg IM</p> <p><i>Antidote for nondepolarizing neuromuscular blockers:</i>            Give atropine sulfate 0.6–1.2 mg IV several min before slow IV injection of neostigmine 0.5–2 mg. Repeat as needed; total dose not to exceed 5 mg</p>	<p><i>Prevention/treatment of postoperative distention and urinary retention</i>            Safety and efficacy not established  <i>Treatment of myasthenia gravis:</i>            PO 0.3–0.6 mg/kg q3–4h Sub-Q, IV, IM 0.01–0.04 mg/kg/dose q2–3h as needed</p> <p><i>Diagnosis of myasthenia gravis:</i>            0.04 mg/kg IM</p> <p><i>Antidote for nondepolarizing neuromuscular blockers</i>            Give 0.008–0.025 mg/kg atropine sulfate IV several min before slow IV injection of neostigmine 0.07–0.08 mg/kg.</p>
<b>Physostigmine</b> (Antilirium)	IM, IV 0.5–2 mg. Give IV slowly, no faster than 1 mg/min to avoid adverse effects of bradycardia, respiratory distress, and seizures.	
<b>Pyridostigmine</b> (Mestinon)	PO 60 mg 3 times daily initially; individualize dose to control symptoms. Average dose in 24 h: 600 mg. Range in 24 h: 60–1500 mg. IM, IV slowly: 1/30th the oral dose	PO 7 mg/kg/d divided into 5 or 6 doses  Neonates of mothers with myasthenia gravis, who have difficulty with sucking/breathing/swallowing: 0.05–0.15 mg/kg IM. Change to syrup as soon as possible.
<b>Indirect-Acting Cholinergics for Alzheimer's Disease (Anticholinesterase Drugs)</b>		
<b>Donepezil</b> (Aricept)	PO 5 mg daily at bedtime for 4–6 wk, then increase to 10 mg daily if needed.	

Generic/Trade Name	ROUTES AND DOSAGE RANGES	
	Adults	Children
<b>Galantamine</b> (Razadyne, Razadyne ER).	PO 8 mg/d initially, with food; increase to 16 mg/d after 4 wks if needed. May continue to increase q 4 wk up to maximum dose of 24 mg/d.	
<b>Rivastigmine</b> (Exelon), (Exelon Patch)	PO 1.5 mg twice daily with food initially. May titrate to higher doses at 1.5-mg intervals q 2 wk to a maximum dose of 12 mg/d. TDS initially 4–6 mg/24 h patch. Increase to 9.5 mg/24 h patch after 4 weeks. Maximum dose 9.5 mg/24 h patch.	
<b>Tacrine</b> (Cognex)	PO 40 mg/d (10 mg 4 times daily) for 6 wk. If aminotransferase levels are satisfactory after weekly monitoring, may increase the dose to 80 mg/d (20 mg 4 times daily). If liver function remains normal, may increase daily dose by 10 mg q 6 wk to a total of 120–160 mg/d.	

TDS, transdermal delivery system.

duration of action and lower incidence of side effects than neostigmine, and it is the maintenance drug of choice for patients with myasthenia gravis. An added advantage is the availability of a slow-release form, which is effective for 8 to 12 hours. When this form is taken at bedtime, the patient does not have to take other medications during the night and does not awaken too weak to swallow.

### Reversible Indirect-Acting Cholinergics (Anticholinesterases) for Alzheimer's Disease

**Donepezil** (Aricept) is used to treat mild to moderate Alzheimer's disease. In long-term studies, donepezil delayed the progression of the disease for up to 55 weeks. Donepezil increases acetylcholine in the brain by inhibiting its metabolism. Donepezil is well absorbed after oral administration, and absorption is unaffected by food. The drug is highly bound (96%) to plasma proteins. It is metabolized in the liver to several metabolites, some of which are pharmacologically active; metabolites and some unchanged drug are excreted mainly in urine. Adverse effects include nausea, vomiting, diarrhea, bradycardia, and possible aggravation of asthma, peptic ulcer disease, and chronic obstructive pulmonary disease.

**Galantamine** (Razadyne) is a newer long-acting anticholinesterase agent approved by the U.S. Food and Drug Administration (FDA) for the treatment of Alzheimer's disease. Its pharmacokinetics and adverse-effect profile are similar to donepezil and rivastigmine.

**Rivastigmine** (Exelon) is a long-acting central anticholinesterase agent approved for the treatment of mild to moderate dementia due to Alzheimer's disease and Parkinson's disease. Oral rivastigmine lasts 12 hours, making twice-a-day dosing possible. Rivastigmine transdermal is applied as a patch once a day. Like other drugs in this class, it is not a cure for Alzheimer's disease but does slow the progression of symptoms. Rivastigmine is metabolized by the liver and excreted in the feces. It has an adverse-effect profile similar to donepezil. Dosages are typically increased slowly until therapeutic dosage is reached to minimize certain side effects (e.g., nausea, vomiting, loss of appetite). It may be taken with food to decrease GI distress.

## Nursing Process

### Assessment

Assess the patient's condition in relation to disorders for which cholinergic drugs are used.

- In patients known to have myasthenia gravis, assess for muscle weakness. This may be manifested by ptosis (drooping) of the upper eyelid and diplopia (double vision) caused by weakness of the eye muscles. More severe disease may be indicated by difficulty in chewing, swallowing, and speaking; accumulation of oral secretions,

*Nursing Process continues on page 318*

which the patient may be unable to expectorate or swallow; decreased skeletal muscle activity, including impaired chest expansion; and eventual respiratory failure.

- In patients with possible urinary retention, assess for bladder distention, time and amount of previous urination, and fluid intake.
- In patients with possible paralytic ileus, assess for presence of bowel sounds, abdominal distention, and elimination pattern.
- In patients with Alzheimer's disease, assess for abilities and limitations in relation to memory, cognitive functioning, self-care activities, and pre-existing conditions that may be aggravated by a cholinergic drug.

### Nursing Diagnoses

- Impaired Gas Exchange related to increased respiratory secretions, bronchospasm, and/or respiratory paralysis
- Ineffective Breathing Pattern related to bronchoconstriction
- Ineffective Airway Clearance related to increased respiratory secretions
- Self-Care Deficit related to muscle weakness, cognitive impairment, or diplopia
- Deficient Knowledge: Drug administration and effects

### Planning/Goals

#### The patient will

- Verbalize or demonstrate correct drug administration
- Improve in self-care abilities
- Regain usual patterns of urinary and bowel elimination
- Maintain effective oxygenation of tissues
- Report adverse drug effects
- For patients with myasthenia gravis, at least one family member will verbalize or demonstrate correct drug administration, symptoms of too much or too little drug, and emergency care procedures.
- For patients with dementia, a caregiver will verbalize or demonstrate correct drug administration and knowledge of adverse effects to be reported to a health care provider.

### Interventions

- Use measures to prevent or decrease the need for cholinergic drugs. Ambulation, adequate fluid intake, and judicious use of opioid analgesics or other sedative-type drugs help prevent postoperative urinary retention. In myasthenia gravis, muscle weakness is aggravated by exercise and improved by rest. Therefore, scheduling activities to avoid excessive fatigue and to allow adequate rest periods may be beneficial.
- With drug therapy for Alzheimer's disease, assist and teach caregivers to:

- Maintain a quiet, stable environment and daily routines to decrease confusion (e.g., verbal or written reminders, simple directions, adequate lighting, calendars, personal objects within view and reach).
- Avoid altering dosage or stopping the drug without consulting the prescribing physician.
- Be sure that the patient keeps appointments for supervision and blood tests.
- Report signs and symptoms (i.e., skin rash, jaundice, light-colored stools) that may indicate hepatotoxicity for patients taking tacrine.
- Notify surgeons about tacrine therapy. Exaggerated muscle relaxation may occur if succinylcholine-type drugs are given.
- Do not give cholinergic drugs for bladder atony and urinary retention or for paralytic ileus in the presence of an obstruction.
- For long-term use, assist patients and families to establish a schedule of drug administration that best meets the patient's needs.
- With myasthenia gravis, recommend that one or more family members be trained in cardiopulmonary resuscitation.

In addition, teaching guidelines are given in the accompanying display.

### Evaluation

- Observe and interview about the adequacy of urinary elimination.
- Observe abilities and limitations in self-care.
- Question the patient and at least one family member of the patient with myasthenia gravis about correct drug usage, symptoms of underdosage and overdosage, and emergency care procedures.
- Question caregivers of patients with dementia about the patient's level of functioning and response to medication.

## Principles of Therapy

### Use in Myasthenia Gravis

Guidelines for the use of anticholinesterase drugs in myasthenia gravis include the following:

- Drug dosage should be increased gradually until maximal benefit is obtained. Larger doses are often required with increased physical activity, emotional stress, infections, and sometimes premenstrually.
- Some patients with myasthenia gravis cannot tolerate optimal doses of anticholinesterase drugs unless atropine is given to decrease the severity of adverse reactions due to

muscarinic activation. However, atropine should be given only if necessary because it may mask the sudden increase of adverse effects. Such an increase is the first sign of overdose.

- Drug dosage in excess of the amount needed to maintain muscle strength and function can produce a cholinergic crisis. A cholinergic crisis is characterized by excessive stimulation of the parasympathetic nervous system. If early symptoms are not treated, hypotension and respiratory failure may occur. At high doses, anticholinesterase drugs weaken rather than strengthen skeletal muscle contraction because excessive amounts of acetylcholine accumulate at motor endplates and reduce nerve impulse transmission to muscle tissue.
- Some people acquire partial or total resistance to anticholinesterase drugs after taking them for months or years. Therefore do not assume that drug therapy that is effective initially will continue to be effective over the long-term course of the disease.

- All anticholinesterase drugs should be taken with food or milk to decrease the risk of gastric distress and ulceration.

### Applying Your Knowledge 19-1

Ms. Humbarger tells you that she usually increases the dose of her medication according to her symptoms and that she usually requires less medication when she is in the hospital. What is your most appropriate action/response?

### Cholinergic vs. Myasthenic Crisis: Recognition and Management

Differentiating myasthenic crisis from cholinergic crisis may be difficult because both are characterized by respiratory difficulty or failure. It is necessary to differentiate between them, however, because they require opposite treatment measures. Myasthenic crisis is an exacerbation of the disease process

## Patient Teaching Guidelines

## Cholinergic Drugs

### General Considerations

- Because cholinergic drugs used for urinary retention usually act within 60 minutes after administration, be sure bathroom facilities are available.
- Wear a medical alert identification device if taking long-term cholinergic drug therapy for myasthenia gravis, hypotonic bladder, or Alzheimer's disease.
- Atropine 0.6 mg IV may be administered for overdose of cholinergic drugs.
- Record symptoms of myasthenia gravis and effects of drug therapy, especially when drug therapy is initiated and medication doses are being titrated. The amount of medication required to control symptoms of myasthenia gravis varies greatly and the physician needs this information to adjust the dosage correctly.
- Do not overexert yourself if you have myasthenia gravis. Rest between activities. Although the dose of medication may be increased during periods of increased activity, it is desirable to space activities to obtain optimal benefit from the drug, at the lowest possible dose, with the fewest adverse effects.
- Report increased muscle weakness, difficulty breathing, or recurrence of myasthenic symptoms to the physician. These are signs of drug underdosage (myasthenic crisis) and indicate a need to increase or change drug therapy.
- Report adverse reactions, including abdominal cramps, diarrhea, excessive oral secretions, difficulty in breathing, and muscle weakness. These are signs of drug overdosage (cholinergic crisis) and require immediate discontinuation of drugs and treatment by the physician. Respiratory failure can result if this condition is not recognized and treated properly.
- Patients taking tacrine need weekly monitoring of liver aminotransferase levels for 18 weeks when initiating therapy and weekly monitoring for 6 weeks after any increase in dose. Caregivers should report any signs or symptoms of adverse drug reactions such as nausea, vomiting, diarrhea, rash, jaundice, or change in the color of stools. The drug should not be suddenly discontinued.
- If dizziness or syncope occurs when taking tacrine, donepezil, or other anticholinesterase drugs, ambulation should be supervised to avoid injury.
- Caregivers should record observed effects of anticholinesterase medications given to treat Alzheimer's disease. These medications are often titrated upward to improve cognitive function and delay symptom progression, and this information will be helpful to the prescriber.

### Self- or Caregiver Administration

- Take drugs as directed on a regular schedule to maintain consistent blood levels and control of symptoms.
- Do not chew or crush sustained-release medications.
- Take oral cholinergics on an empty stomach to lessen nausea and vomiting. Also, food decreases absorption of tacrine by up to 40%.
- Ensure adequate fluid intake if vomiting or diarrhea occurs as a side effect of cholinergic medications.
- Avoid taking St. John's wort because concurrent use may reduce blood levels of donepezil.
- Remove Exelon Patch from sealed pouch immediately before application. Apply Exelon Patch to clean dry intact skin on upper or lower back, upper arm, or chest. Select a new site with each patch application and do not re-use a site within 14 days. Do not cut or tear patch. Remove the patch after 24 hours. You may bath, swim, or shower while wearing the patch.

and its clinical manifestations, requiring more anticholinesterase drug. Cholinergic crisis is a drug-induced overstimulation of the parasympathetic nervous system, requiring discontinuation of any anticholinesterase drug that the patient has been receiving.

An accurate diagnosis may be determined from signs and symptoms and their timing in relation to medication; that is, signs and symptoms having their onset within approximately 1 hour after a dose of anticholinesterase drug are more likely to be caused by cholinergic crisis (too much drug). Signs and symptoms beginning 3 hours or more after a drug dose are more likely to be caused by myasthenic crisis (too little drug).

If the differential diagnosis cannot be made on the basis of signs and symptoms, the patient can be intubated, mechanically ventilated, and observed closely until a diagnosis is possible. Still another way to differentiate between the two conditions is for the physician to inject a small dose of IV edrophonium (Tensilon). The ideal test dose of edrophonium has not been determined. An incremental dosing schedule begins with 2 milligrams IV, followed by a 60-second period of time during which the response of the individual is observed. Subsequent doses of 3 and 5 milligrams may be given if indicated by a lack of response. If the edrophonium test causes a dramatic improvement in breathing, the test is considered positive and the diagnosis is myasthenic crisis. If the edrophonium test makes the patient even weaker, the diagnosis is cholinergic crisis. Edrophonium or any other diagnostic pharmacologic agent should be administered only after endotracheal intubation and controlled ventilation have been instituted.

Treatment for cholinergic crisis includes withdrawal of anticholinesterase drugs; administration of atropine, an anticholinergic drug (see Chap. 20); and measures to maintain respiration. It is important to understand that atropine reverses only the muscarinic effects of cholinergic crisis, having no effect on reversing nicotinic receptor-mediated skeletal muscle weakness. Endotracheal intubation and mechanical ventilation may be necessary due to this profound skeletal muscle weakness, including muscles of respiration.

Treatment for myasthenic crisis includes administration of additional anticholinesterase medications and measures to maintain respirations until the medications are effective in improving muscle strength.

### Use in Alzheimer's Disease

The goal of drug therapy for Alzheimer's disease is to slow the loss of memory and cognition, thus preserving the independence of the individual for as long as possible. Practice guidelines developed by the American Academy of Neurology (2001, reviewed 2003) recommend early diagnosis and treatment of Alzheimer's disease with cholinesterase inhibitors for all patients with mild to moderate symptoms. Although these drugs do not cure Alzheimer's disease, they do delay the onset of the disease somewhat and bring about a slight improvement in cognition and function. Additional medications that may be beneficial in slowing the progression of

## Evidence-Based Practice

### 19-1 The Role of Inflammation and NSAIDs in Alzheimer's Disease

There is research evidence that brain inflammation may contribute to the changes in the brain associated with Alzheimer's disease. Some studies have indicated that the long-term use of nonsteroidal anti-inflammatory drugs (NSAIDs), such as ibuprofen, naproxen, and aspirin, before the onset of symptoms of Alzheimer's disease may help prevent the disorder. Other researchers have suggested that NSAIDs may help slow the progression of the disease. A clinical trial tested two NSAIDs, rofecoxib (Vioxx) and naproxen (Aleve), and found these drugs did not delay the progression of Alzheimer's disease in those previously diagnosed with the disorder. The Alzheimer's Disease Anti-inflammatory Prevention Trial (ADAPT) was designed to test celecoxib (Celebrex) and naproxen to determine if NSAIDs are beneficial in preventing Alzheimer's disease in healthy older people. However, the ADAPT study was suspended because of concerns over increased adverse cardiovascular events associated with the use of NSAIDs (see Chap. 7). At this time, NSAIDs are not recommended for the prevention or treatment of Alzheimer's disease.

Alzheimer's disease include high-dose vitamin E therapy, selegiline, and memantine (Namenda), an *N*-methyl D-aspartate (NMDA) antagonist. Estrogen is not recommended as a treatment for Alzheimer's disease. Although some studies suggest that inflammation may play a role in Alzheimer's disease, anti-inflammatory drugs such as prednisone or NSAIDs are not recommended for treatment at this time (see Evidence-Based Practice Box 19-1).

### Toxicity of Cholinergic Drugs: Recognition and Management

Atropine, an anticholinergic, antimuscarinic drug, is a specific antidote to cholinergic agents. The drug and equipment for its injection should be readily available whenever cholinergic drugs are given. It is important to note that atropine reverses only the muscarinic effects of cholinergic drugs, primarily in the heart, smooth muscle, and glands. Atropine does not interact with nicotinic receptors and therefore cannot reverse the nicotinic effects of skeletal-muscle weakness or paralysis due to overdose of the indirect cholinergic drugs.

### Management of Mushroom Poisoning

Muscarinic receptors in the parasympathetic nervous system were given their name because they can be stimulated by muscarine, an alkaloid that is found in small quantities in the *Amanita muscaria* mushroom. Some mushrooms found in North America, such as the *Clitocybe* and *Inocybe* mushrooms, however, contain much larger quantities of muscarine. Accidental or intentional ingestion of these mushrooms results in intense cholinergic stimulation (cholinergic crisis) and is potentially fatal. Atropine is the specific antidote for mushroom poisoning.

## Toxicity of Irreversible Anticholinesterase Agents: Recognition and Management

Most irreversible anticholinesterase agents are highly lipid soluble and can enter the body by a variety of routes, including the eye, skin, respiratory system, and GI tract. Because they readily cross the blood–brain barrier, their effects are seen peripherally as well as centrally.

Exposure to toxic doses of irreversible anticholinesterase agents, such as organophosphate insecticides (malathion, parathion) or nerve gases (sarin, tabun, soman), produces a cholinergic crisis characterized by excessive cholinergic (muscarinic) stimulation and neuromuscular blockade. This cholinergic crisis occurs because the irreversible anticholinesterase poison binds to the enzyme acetylcholinesterase and inactivates it. Consequently, acetylcholine remains in cholinergic synapses and causes excessive stimulation of muscarinic and nicotinic receptors.

Emergency treatment includes decontamination procedures such as removing contaminated clothing, flushing the poison from skin and eyes, and using activated charcoal and lavage to remove ingested poison from the GI tract. Pharmacologic treatment includes administering atropine to counteract the muscarinic effects of the poison (e.g., salivation, urination, defecation, bronchial secretions, laryngospasm, bronchospasm).

To relieve the neuromuscular blockade produced by nicotinic effects of the poison, a second drug, pralidoxime, is needed. Pralidoxime (Protopam), a cholinesterase reactivator, is a specific antidote for overdose with irreversible anticholinesterase agents. Pralidoxime treats toxicity by causing the anticholinesterase poison to release the enzyme acetylcholinesterase. The reactivated acetylcholinesterase can then degrade excess acetylcholine at the cholinergic synapses, including the neuromuscular junction. Because pralidoxime cannot cross the blood–brain barrier, it is effective only in the peripheral areas of the body. Pralidoxime must be given as soon after the poisoning as possible. If too much time passes, the bond between the irreversible anticholinesterase agent and acetylcholinesterase becomes stronger and pralidoxime is unable to release the enzyme from the poison.

Treatment of anticholinesterase overdose may also require diazepam or lorazepam to control seizures. Mechanical ventilation may be necessary to treat respiratory paralysis.

## Use in Special Populations

### Use in Children

Bethanechol is occasionally used to treat urinary retention and paralytic ileus, but safety and effectiveness for children younger than 8 years of age have not been established. Neostigmine is used to treat myasthenia gravis and to reverse neuromuscular blockade after general anesthesia but is not recommended for urinary retention. Pyridostigmine may be used in the neonate of a mother with myasthenia gravis to treat difficulties with sucking, swallowing, and breathing.

Although galantamine and donepezil are approved only for the treatment of Alzheimer's disease, these medications are currently under investigation to treat attention deficit-hyperactivity disorder (ADHD). Some studies have shown that these medications may be useful in treating the child with ADHD by improving cognition relative to executive functioning, including planning, time-management, and organizational skills.

Precautions and adverse effects for cholinergic drugs are the same for children as for adults.

### Use in Older Adults

Indirect-acting cholinergic drugs may be used in patients with myasthenia gravis or Alzheimer's disease or to treat overdoses of atropine and other centrally acting anticholinergic drugs (e.g., those used for parkinsonism). Older adults are more likely to experience adverse drug effects because of age-related physiologic changes and superimposed pathologic conditions.

### Use in Patients With Renal Impairment

Because bethanechol and other cholinergic drugs increase pressure in the urinary tract by stimulating detrusor muscle contraction and relaxation of urinary sphincters, they are contraindicated for patients with urinary tract obstructions or weaknesses in the bladder wall. Administering a cholinergic drug to these people might result in rupture of the bladder.

Some aspects of the pharmacokinetics of cholinergic drugs are unknown. Many of the drugs are degraded enzymatically by cholinesterases. However, a few (e.g., neostigmine, pyridostigmine) undergo hepatic metabolism and tubular excretion in the kidneys. Renal impairment may result in accumulation and increased adverse effects, especially with chronic use.

### Use in Patients With Hepatic Impairment

The hepatic metabolism of neostigmine and pyridostigmine may be impaired by liver disease, resulting in increased adverse effects.

### Use in Critical Illness

Cholinergic drugs have several specific uses in critical illness:

- Neostigmine, pyridostigmine, and edrophonium to reverse neuromuscular blockade (skeletal muscle paralysis) caused by nondepolarizing muscle relaxants
- Anticholinesterase drugs to treat myasthenic crisis and improve muscle strength
- Physostigmine in severe cases as an antidote to anticholinergic poisoning with drugs such as atropine or tricyclic antidepressants

### Use in Home Care

Medications to treat long-term conditions such as myasthenia gravis or Alzheimer's disease are often administered in the home setting. The person using the drugs may have difficulty

with self-administration. The patient with myasthenia gravis may have diplopia or diminished muscle strength that makes it difficult to self-administer medications. Strict adherence to timely medication administration promotes optimal blood levels of drugs and optimal symptom control. The patient with Alzheimer's disease may have problems with remembering to take medications and may easily underdose or overdose him- or herself. It is important to work with responsible family members in such cases to ensure accurate drug administration.

## Applying Your Knowledge 19-2

### How Can You Avoid This Medication Error?

After administering her medication, you leave Ms. Humbarger's room to tend to other patients. When you return 4 hours later, Ms. Humbarger complains that she is having increased difficulty breathing. You recognize this as a cholinergic crisis and prepare to administer the antidote atropine.

## Nursing Actions Cholinergic Drugs

### NURSING ACTIONS

#### 1. Administer accurately

- a. Give oral bethanechol before meals.
- b. With pyridostigmine and other drugs for myasthenia gravis, give at regularly scheduled intervals with food or milk.
- c. Give tacrine on an empty stomach, 1 hour before or 2 hours after a meal, if possible, at regular intervals around the clock (e.g., q6h). Give with meals if GI upset occurs.
- d. Give donepezil at bedtime.
- e. Give galantamine and rivastigmine with food.

#### 2. Observe for therapeutic effects

- a. When the drug is given for postoperative hypoperistalsis, observe for bowel sounds, passage of flatus through the rectum, or a bowel movement.
- b. When bethanechol or neostigmine is given for urinary retention, micturition usually occurs within approximately 60 minutes. If it does not, urinary catheterization may be necessary.
- c. When the drug is given to clients with myasthenia gravis, observe for increased muscle strength as shown by:
  - (1) Decreased or absent ptosis of eyelids
  - (2) Decreased difficulty with chewing, swallowing, and speech
  - (3) Increased skeletal muscle strength, increased tolerance of activity, less fatigue
- d. With cholinergic drugs to treat Alzheimer's disease (tacrine, donepezil, galantamine, and rivastigmine) observe for improvement in memory and cognitive functioning in activities of daily living.

#### 3. Observe for adverse effects

- a. Central nervous system effects—convulsions, dizziness, drowsiness, headache, loss of consciousness
- b. Respiratory effects—increased secretions, bronchospasm, laryngospasm, respiratory failure
- c. Cardiovascular effects—dysrhythmias (bradycardia, tachycardia, atrioventricular block), cardiac arrest, hypotension, syncope

### RATIONALE/EXPLANATION

If these drugs are given after meals, nausea and vomiting may occur because the drug stimulates contraction of muscles in the gastrointestinal (GI) tract.

For consistent blood levels and control of symptoms. These drugs increase the risk of GI distress and ulceration.

Food decreases absorption and decreases serum drug levels by 30% or more.

Regular intervals increase therapeutic effects and decrease adverse effects.

Manufacturer's recommendation

To decrease GI distress

These are indicators of increased GI muscle tone and motility.

With neostigmine, onset of action is 2–4 hours after oral administration and 10–30 minutes after injection. Duration is approximately 3–4 hours. With pyridostigmine, onset of action is approximately 30–45 minutes after oral use, 15 minutes after IM injection, and 2–5 minutes after IV injection. Duration is approximately 4–6 hours. The long-acting form of pyridostigmine lasts 8–12 hours.

Improved functioning is most likely to occur in patients with mild to moderate dementia.

Adverse effects occur with usual therapeutic doses but are more likely with large doses. They are caused by stimulation of the parasympathetic nervous system.

These may be detected early by regular assessment of blood pressure and heart rate.

Bradycardia is probably the most likely dysrhythmia to occur. GI effects commonly occur. Tacrine may be hepatotoxic.

NURSING ACTIONS	RATIONALE/EXPLANATION
<p>d. GI effects—nausea and vomiting, diarrhea, increased peristalsis, abdominal cramping, increased secretions (i.e., saliva, gastric and intestinal secretions). With tacrine, observe for signs of hepatotoxicity (e.g., jaundice, elevated liver enzymes).</p> <p>e. Other effects—increased frequency and urgency of urination, increased sweating, miosis, skin rash</p>	<p>Skin rashes are most likely to occur from formulations of neostigmine or pyridostigmine that contain bromide.</p>

## Key Concepts

- Cholinergic drugs stimulate the parasympathetic nervous system directly by stimulating cholinergic receptors or indirectly by inhibiting the enzymatic metabolism of acetylcholine in synapses.
- Both direct-acting cholinergic drugs and indirect-acting cholinergic drugs (or anticholinesterase drugs) have widespread parasympathetic effects when they activate muscarinic receptors in cardiac muscle, smooth muscle, exocrine glands, and the eye.
- Indirect-acting cholinergic drugs also stimulate nicotinic receptors in skeletal muscles, resulting in improved skeletal muscle tone and strength.
- The direct-acting cholinergic drug, bethanechol, is used to treat urinary retention due to urinary bladder atony and postoperative abdominal distention due to paralytic ileus.
- Indirect-acting cholinergic or anticholinesterase drugs are indicated to treat myasthenia gravis and Alzheimer's disease.
- Edrophonium is used to differentiate between myasthenic crisis (too little cholinergic medication) and cholinergic crisis (too much cholinergic medication).
- Atropine reverses muscarinic effects due to overdose of cholinergic drugs but does not reverse the nicotinic effects of skeletal-muscle weakness or paralysis due to overdose of indirect cholinergic drugs.
- Pralidoxime, a cholinesterase reactivator, is the specific treatment for neuromuscular blockade due to overdose with irreversible indirect cholinergic drugs.

## Review and Application Exercises

### Short Answer Exercises

1. What are the actions of cholinergic drugs?
2. Which neurotransmitter is involved in cholinergic (parasympathetic) stimulation?
3. When a cholinergic drug is given to treat myasthenia gravis, what is the expected effect?
4. What is the difference between cholinergic crisis and myasthenic crisis? How are they treated?
5. When indirect-acting cholinergic drugs are used to treat Alzheimer's disease, what is the desired effect?
6. Is a cholinergic drug the usual treatment of choice for urinary bladder atony? Why or why not?
7. What are the adverse effects of cholinergic drugs?
8. How are overdoses of cholinergic drugs treated?

### NCLEX-Style Questions

9. A patient with myasthenia gravis is admitted to the emergency department with complaints of muscle weakness and respiratory distress. You give an ordered "test dose" of edrophonium (Tensilon) and the patient ceases to breathe, requiring mechanical ventilation. The results of this test dose indicate
  - a. The patient is underdosed on his medications and is in myasthenic crisis.
  - b. The patient is allergic to edrophonium and is having an anaphylactic reaction.
  - c. The patient is overdosed on his medications and is in cholinergic crisis.
  - d. The patient's condition is not due to myasthenia gravis because edrophonium did not improve the symptoms.
10. A 65-year-old patient has been admitted with a diagnosis of benign prostatic hyperplasia. How should the nurse respond to an order for bethanechol (Urecholine) to treat urinary retention in this situation?
  - a. Give the medication as ordered.
  - b. Insert a Foley catheter before administering the medication.
  - c. Provide a urinal because urinary frequency will increase after drug administration.
  - d. Question this order because the patient's urinary retention is due to an obstructive process.
11. The nurse should be prepared to administer which of the following drugs as an antidote to cholinergic drug overdose?
  - a. epinephrine (Adrenalin)
  - b. diphenhydramine (Benadryl)
  - c. atropine (AtroPen)
  - d. propranolol (Inderal)
12. You are teaching family members how to administer galantamine for Alzheimer's disease. Your instructions should include which of the following?
  - a. Take this medication with food.
  - b. Take this medication on an empty stomach.
  - c. Take this medication at bedtime.
  - d. Take this medication at the start of each day.
13. When treating a patient in cholinergic crisis due to exposure to an organophosphate insecticide, the nurse must be prepared to administer which drug to relieve neuromuscular blockade?
  - a. atropine (AtroPen)
  - b. pralidoxime (Protopam)
  - c. epinephrine (Adrenalin)
  - d. physostigmine (Antilirium)

# Anticholinergic Drugs

## KEY TERMS

- Antimuscarinic drugs
- Cycloplegia
- Muscarinic receptors
- Mydriasis
- Nicotinic receptors
- Quaternary amines
- Tertiary amines

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. List characteristics of anticholinergic drugs in terms of effects on body tissues, indications for use, nursing process implications, observation of patient response, and teaching patients.
2. Discuss atropine as the prototype of anticholinergic drugs.
3. Discuss clinical disorders or symptoms for which anticholinergic drugs are used.
4. Describe the mechanism by which atropine relieves bradycardia.
5. Review anticholinergic effects of antipsychotics, tricyclic antidepressants, and antihistamines.
6. Discuss principles of therapy and nursing process for using anticholinergic drugs in special populations.
7. Describe the signs and symptoms of atropine or anticholinergic drug overdose and its treatment.
8. Teach patients about the safe, effective use of anticholinergic drugs.

## Applying Your Knowledge

J. E. Smoot is a 77-year-old man who has chronic obstructive pulmonary disease and experiences a syncopal episode. He is admitted to your unit with stable vital signs. The physician orders ipratropium two puffs four times a day and places Mr. Smoot on a cardiac monitor.

## Introduction

Anticholinergic drugs block the action of acetylcholine on the parasympathetic nervous system. Most anticholinergic drugs interact with muscarinic cholinergic receptors in the brain, secretory glands, heart, and smooth muscle and are sometimes called *antimuscarinic drugs*. When given at high doses, a few anticholinergic drugs are also able to block *nicotinic receptors* in autonomic ganglia and skeletal muscles. Glycopyrrolate is an example of such a medication. This drug class includes belladonna alkaloids and their derivatives, such as atropine, and many synthetic substitutes.

Most anticholinergic medications are either *tertiary amines* or *quaternary amines* (Table 20-1). Tertiary amines are uncharged lipid-soluble molecules. Atropine and scopolamine are tertiary amines and therefore are able to cross cell membranes readily. They are well absorbed from the gastrointestinal (GI) tract and conjunctiva, and they cross the blood–brain barrier. Tertiary amines are excreted in the urine.

Some belladonna derivatives and synthetic anticholinergics are quaternary amines. These drugs carry a positive charge and are lipid insoluble. Consequently, they do not readily cross cell

Table 20-1

## Common Tertiary Amine and Quaternary Amine Anticholinergic Drugs

## TERTIARY AMINES

Atropine  
 Bzotropine (Cogentin)  
 Darifenacin hydrobromide (Enablex)  
 Dicyclomine hydrochloride (Bentyl)  
 Flavoxate (Urispas)  
 l-Hyoscyamine (Anaspaz)  
 Oxybutynin (Ditropan)  
 Scopolamine  
 Solifenacin succinate (Vesicare)  
 Tolterodine (Detrol, Detrol LA, and Oxytrol)  
 Trihexyphenidyl (Trihexy)

## QUATERNARY AMINES

Glycopyrrolate (Robinul)  
 Ipratropium (Atrovent)  
 Methscopolamine (Pamine)  
 Tiotropium (Spiriva)  
 Trospium chloride (Sanctura)

membranes. They are poorly absorbed from the GI tract and do not cross the blood–brain barrier. Quaternary amines are excreted largely in the feces.

## General Characteristics of Anticholinergic Drugs

### Mechanism of Action and Effects

These drugs act by occupying receptor sites on target organs innervated by the parasympathetic nervous system, thereby leaving fewer receptor sites free to respond to acetylcholine (Fig. 20-1). Parasympathetic response is absent or decreased, depending on the number of receptors blocked by anticholinergic drugs and the underlying degree of parasympathetic activity. Because cholinergic *muscarinic receptors* are widely distributed in the body, anticholinergic drugs produce effects in a variety of locations, including the central nervous system (CNS), heart, smooth muscle, glands, and the eye.

Specific effects on body tissues and organs include the following:

- CNS stimulation followed by depression, which may result in coma and death. This is most likely to occur with large doses of anticholinergic drugs that cross the blood–brain barrier (atropine, scopolamine, and antiparkinson agents).
- Decreased cardiovascular response to parasympathetic (vagal) stimulation that slows heart rate. Atropine is the anticholinergic drug most often used for its cardiovascular effects. According to Advanced Cardiac Life Support (ACLS) protocol, atropine is the drug of choice to treat symptomatic sinus bradycardia. Low doses (<0.5 mg) may

**Figure 20-1** ■ Mechanism of action of anticholinergic drugs. Anticholinergic (antimuscarinic) drugs prevent acetylcholine from interacting with muscarinic receptors on target effector organs, thus blocking or decreasing a parasympathetic response in these organs.

produce a slight and temporary decrease in heart rate; however, moderate to large doses (0.5–1 mg) increase heart rate by blocking parasympathetic vagal stimulation. Although the increase in heart rate may be therapeutic in bradycardia, it can be an adverse effect in patients with other types of heart disease because atropine increases the myocardial oxygen demand. Atropine usually has little or no effect on blood pressure. Large doses cause facial flushing because of dilation of blood vessels in the neck.

- Bronchodilation and decreased respiratory tract secretions. Anticholinergics block the action of acetylcholine in bronchial smooth muscle when given by inhalation. This action reduces intracellular GMP, a bronchoconstrictive substance. When anticholinergic drugs are given systemically, respiratory secretions decrease and may become viscous, resulting in mucous plugging of small respiratory passages. Administering the medications by inhalation decreases this effect while preserving the beneficial bronchodilation effect.
- Antispasmodic effects in the GI tract due to decreased muscle tone and motility. The drugs have little inhibitory effect on gastric acid secretion with usual doses and insignificant effects on pancreatic and intestinal secretions.
- *Mydriasis* and *cycloplegia* in the eye. Normally, anticholinergics do not change intraocular pressure, but with narrow-angle glaucoma, they may increase intraocular pressure and precipitate an episode of acute glaucoma. When the pupil is fully dilated, photophobia may be uncomfortable, and reflexes to light and accommodation may disappear.

- Miscellaneous effects include decreased secretions from salivary and sweat glands; relaxation of ureters, urinary bladder, and the detrusor muscle; and relaxation of smooth muscle in the gallbladder and bile ducts.

The clinical usefulness of anticholinergic drugs is limited by their widespread effects. Consequently, several synthetic drugs have been developed in an effort to increase selectivity of action on particular body tissues, especially to retain the antispasmodic and antisecretory effects of atropine while eliminating its adverse effects. This effort has been less than successful—all the synthetic drugs produce atropine-like adverse effects when given in sufficient dosage.

Some synthetic drugs are used for antispasmodic effects in GI disorders and overactive urinary bladder. Another group of synthetic drugs includes centrally active anticholinergics used in the treatment of Parkinson's disease (see Chap. 12). They balance the relative cholinergic dominance that causes the movement disorders associated with parkinsonism.

## Indications for Use

Anticholinergic drugs are used for disorders in many body systems. Clinical indications include the following.

**GI Disorders.** Anticholinergics have been used for peptic ulcer disease, gastritis, pylorospasm, and diverticulitis. These conditions are often characterized by excessive gastric acid and abdominal pain because of increased motility and spasm of GI smooth muscle. However, anticholinergics are weak inhibitors of gastric acid secretion, even in maximal doses that usually produce intolerable adverse effects, making them a second choice for treatment of peptic ulcers. Although the drugs do not heal peptic ulcers, they may relieve abdominal pain by relaxing GI smooth muscle. In addition, anticholinergics may be helpful in reducing the frequency of bowel movements and abdominal discomfort associated with irritable colon or colitis. Anticholinergics are not usually prescribed for chronic inflammatory disorders (e.g., diverticulitis, ulcerative colitis) or acute intestinal infections (e.g., bacterial, viral, amebic). Other drugs are more useful in treating the diarrhea and increased intestinal motility that occurs in these conditions.

**Genitourinary Disorders.** Anticholinergic drugs are the drugs of choice for their antispasmodic effects on smooth muscle to relieve the symptoms of urinary incontinence and frequency that accompany an overactive bladder. In infections such as cystitis, urethritis, and prostatitis, the drugs decrease the frequency and pain of urination. The drugs are also given to increase bladder capacity in enuresis, paraplegia, or neurogenic bladder.

**Ophthalmology.** Anticholinergic drugs are applied topically for mydriatic and cycloplegic effects to aid examination or surgery. They are also used to treat some inflammatory disorders. Anticholinergic preparations used in ophthalmology are discussed further in Chapter 63.

**Respiratory Disorders.** Anticholinergic drugs are used for respiratory disorders characterized by bronchoconstriction

(i.e., asthma, chronic bronchitis). Ipratropium or tiotropium bromide may be given by inhalation for bronchodilating effects (see Chap. 44).

**Cardiac Disorders.** Atropine may be given to increase heart rate in bradycardia and heart block characterized by hypotension and shock.

**Parkinson's Disease.** Anticholinergic drugs are given for their central effects in decreasing salivation, spasticity, and tremors. They are used mainly in patients who have minimal symptoms, who do not respond to levodopa, or who cannot tolerate levodopa because of adverse reactions or contraindications. An additional use of anticholinergic drugs is to relieve Parkinson-like symptoms that occur with older antipsychotic drugs.

**Preoperative Use.** Anticholinergics are given to prevent vagal stimulation and potential bradycardia, hypotension, and cardiac arrest. They are also given to reduce respiratory tract secretions, especially in head and neck surgery and bronchoscopy.

**Toxicity and Poisoning.** Anticholinergics are used to treat anticholinesterase toxicity, mushroom poisoning, or organophosphate pesticide poisoning (see Chap. 19). Atropine is given to treat excessive cholinergic stimulation.

## Contraindications to Use

Contraindications to the use of anticholinergic drugs include any condition characterized by symptoms that would be aggravated by the drugs. Some of these are prostatic hypertrophy, myasthenia gravis, hyperthyroidism, glaucoma, tachydysrhythmia, myocardial infarction, and heart failure unless bradycardia is present. Anticholinergic drugs should not be given in hiatal hernia or other conditions contributing to reflux esophagitis because the drugs delay gastric emptying, relax the cardioesophageal sphincter, and increase esophageal reflux.

## Individual Drugs

The therapeutic uses, dosages, and routes of administration for selected anticholinergic drugs are presented in Table 20-2.

### Belladonna Alkaloids and Derivatives

**P Atropine**, the prototype of anticholinergic drugs, is a naturally occurring belladonna alkaloid that can be extracted from the belladonna plant or prepared synthetically. It is usually prepared as atropine sulfate, a salt that is very soluble in water. It is well absorbed from the GI tract and distributed throughout the body. It crosses the blood-brain barrier to enter the CNS, where large doses produce stimulant effects and toxic doses produce depressant effects. Atropine is also absorbed systemically when applied locally to mucous membranes. The drug is rapidly excreted in the urine. Pharmacologic effects are of short duration except for ocular effects, which may last for several days.

Table 20-2

## Drugs at a Glance: Selected Anticholinergic Drugs

Generic/TradeName	Use	ROUTES AND DOSAGE RANGES	
		Adults	Children
<b>Belladonna Alkaloids and Derivatives</b>			
<b>Atropine</b>	Systemic use	PO, IM, Sub-Q, IV 0.4–0.6 mg	PO, IM, Sub-Q, IV: 7–16 lb: 0.1 mg 16–24 lb: 0.15 mg 24–40 lb: 0.2 mg 40–65 lb: 0.3 mg 65–90 lb: 0.4 mg under 90 lb: 0.4–0.6 mg
	Surgery	IM, Sub-Q, or IV 0.4–0.6 mg prior to induction. Use 0.4-mg dose with cyclopropane anesthesia.	0.1 mg (newborn) to 0.6 mg (12 y) given Sub-Q 30 min prior to surgery
	Bradycarrhythmias	IV 0.5 mg (up to 3 mg) q 3–5 min PRN	
	Antidote for cholinergic poisoning	IV Titrate large doses of 2–3 mg as needed until signs of atropine toxicity appear and cholinergic crisis is controlled.	
<b>Ophthalmic atropine</b> (Isopto-Atropine)	Mydriatic/cycloplegia/inflammation of uveal tract	<i>For refraction:</i> Instill 1 or 2 drops of 1% solution into eye(s) 1 h before refraction. <i>For uveitis:</i> Instill 1–2 drops of 1% solution into eye(s) 4 times daily.	<i>For refraction:</i> Instill 1–2 drops of 0.5% solution twice daily for 1–3 d before procedure.
<b>Homatropine</b> (Isopto-Homatropine)	Mydriatic/cycloplegia/inflammation of uveal tract	<i>For refraction:</i> Instill 1–2 drops of 2% solution or 1 drop of 5% solution into eye before procedure. May repeat at 5–10 min intervals as needed. <i>For uveitis:</i> Instill 1 or 2 drops of 2% or 5% solution 2–4 times daily or every 3–4 h as needed.	<i>For refraction:</i> Instill 1 drop of 2% solution into eye before procedure. May repeat q 10 min as needed. <i>For uveitis:</i> Instill 1 drop of 2% solution 2–4 times daily
<b>Hyoscyamine</b> (Anaspaz)	Antispasmodic/antisecretory for gastrointestinal (GI) and genitourinary (GU) disorders	PO, SL 0.125–0.25 mg 3 or 4 times daily before meals and at bedtime. PO (timed-release formula): 0.375–0.75 mg q12h. IM, IV, Sub-Q: 0.25–0.5 mg q6h	<i>Children 2–10 y:</i> PO 0.062–0.125 mg q 6–8h. <i>Children under 2 y:</i> half of the previous dose
<b>Ipratropium</b> (Atrovent)	Bronchodilation	2 puffs (36 mcg) of aerosol 4 times daily. Additional inhalations may be needed. Do not exceed 12 puffs/24h. Solution for inhalation: 500 mcg, 3 or 4 times daily.	
	Nasal spray for rhinorrhea	2 sprays/nostril of 0.03% spray 2 or 3 times daily. 2 sprays/nostril of 0.06% spray 3–4 times daily.	2 sprays/nostril of 0.03% spray 2 or 3 times daily
<b>Scopolamine</b>	Systemic use	PO 0.4–0.8 mg daily. Sub-Q, IM 0.32–0.65 mg IV 0.32–0.65 mg diluted in sterile water for injection	Not approved for PO use under 6 y <i>Parenteral:</i> 0.006 mg/kg <i>Maximum dose:</i> 0.3 mg

Generic/TradeName	Use	ROUTES AND DOSAGE RANGES	
		Adults	Children
	Antiemetic	Transdermal: Apply disk 4 h before antiemetic effect is needed. Replace q3d.	Not approved in children
	Mydriatic/cycloplegia/inflammation of uveal tract	For refraction: Instill 1 or 2 drops into eye 1 h before refracting. For uveitis: Instill 1 or 2 drops into eye(s) up to 3 times daily.	Same as adult dose
<b>Tiotropium bromide</b> (Spiriva)	Bronchodilation	Inhalation of contents of one capsule (18 mcg) daily using the HandiHaler inhalation device	Safety and efficacy not established
<b>Antisecretory/Antispasmodic Anticholinergics for Gastrointestinal Disorders</b>			
<b>Dicyclomine hydrochloride</b> (Bentyl)	Antisecretory/antispasmodic	PO 20–40 mg before meals and at bedtime IM 20 mg before meals and at bedtime	
<b>Glycopyrrolate</b> (Robinul)	Antisecretory/antispasmodic Preanesthetic	PO 1–2 mg 2 or 3 times daily IM, IV 0.1–0.2 mg IM 0.004 mg/kg 30–60 min before anesthesia	<i>under 12 y</i> : Not recommended <i>under 2 y</i> : 0.004 mg/lb IM 30–60 min before anesthesia <i>2–12 y</i> : 0.002–0.004 mg/lb IM 30–60 min before anesthesia
<b>Anticholinergics Used in Parkinson's Disease</b>			
<b>Benztropine</b> (Cogentin)	Parkinsonism	PO, IM, IV 0.5–1 mg at bedtime. May increase up to 6 mg given at bedtime or in 2–4 divided doses.	
	Drug-induced extrapyramidal symptoms	For acute dystonia: IM, IV 1–2 mg. May repeat if needed. For prevention: PO 1–2 mg.	
<b>Trihexyphenidyl</b> (Trihexy)	Parkinsonism	PO 1–2 mg. Increase by 2-mg increments at 3- to 5-d intervals until a total of 6–10 mg is given daily in divided doses 3–4 times daily at mealtimes and bedtimes.	
	Drug-induced extrapyramidal symptoms	PO 1 mg initially. Increase as needed to control symptoms.	
<b>Urinary Antispasmodics</b>			
<b>Darifenacin hydrobromide</b> (Enablex)	Overactive bladder	PO 7.5 mg once daily. May increase to 15 mg if needed to control symptoms.	Safety and efficacy not established
<b>Flavoxate</b> (Urispas)	Overactive bladder	PO 100–200 mg 3 or 4 times daily. Reduce when symptoms improve.	<i>under 12 y</i> : Safety and efficacy not established
<b>Oxybutynin</b> (Ditropan and Ditropan XL, Oxytrol transdermal system)	Overactive bladder	PO 5 mg 2 or 3 times daily. Maximum dose 5 mg 4 times daily. <i>Extended-release</i> 5 mg PO daily up to 30 mg/daily. TDS: Apply TDS every 3–4 days.	<i>older than 5 y</i> : 5 mg PO twice daily. Maximum dose 5 mg 3 times daily

(continued on page 330)

Table 20-2

### Drugs at a Glance: Selected Anticholinergic Drugs (continued)

Generic/TradeName	Use	ROUTES AND DOSAGE RANGES	
		Adults	Children
<b>Solifenacin succinate</b> (VESIcare)	Overactive bladder	PO 5 mg once daily. May increase to 10 mg once daily if needed to control symptoms.	Safety and efficacy not established
<b>Tolterodine</b> (Detrol and Detrol LA)	Overactive bladder	PO 2 mg twice daily. May decrease to 1 mg when symptoms improve. Reduce doses to 1 mg PO twice daily in presence of hepatic impairment.	Safety and efficacy not established
<b>Tropium chloride</b> (Sanctura)	Overactive bladder	PO 20 mg twice daily at least 1 h before meals or on an empty stomach	Safety and efficacy not established

PRN, as needed; SL, sublingual; TDS, transdermal system.

**Belladonna tincture** is a mixture of alkaloids in an aqueous–alcohol solution. It is most often used in GI disorders because of its antispasmodic effect. It is an ingredient in several drug mixtures.

**Homatropine hydrobromide** is a semisynthetic derivative of atropine used as eye drops to produce mydriasis and cycloplegia. Compared with atropine, homatropine may be preferable, because ocular effects do not last as long.

**Hyoscyamine** (Anaspaz) is a belladonna alkaloid used in GI and genitourinary disorders characterized by spasm, increased secretion, and increased motility. It has the same effects as other atropine-like drugs.

**Ipratropium** (Atrovent) is an anticholinergic drug chemically related to atropine. When given as a nasal spray, it is useful in treating rhinorrhea due to allergy or the common cold. When given as an inhalation treatment or aerosol to patients with chronic obstructive pulmonary disease (COPD), it is beneficial as a bronchodilator. An advantage of administration of anticholinergic drugs by the respiratory route over the systemic route is less thickening of respiratory secretions and therefore a reduced incidence of mucous-plugged airways.

**Scopolamine** is similar to atropine in terms of uses, adverse effects, and peripheral effects but different in central effects. When it is given parenterally, scopolamine depresses the CNS and causes amnesia, drowsiness, euphoria, relaxation, and sleep. Effects of the drug appear more quickly and disappear more readily than those of atropine. Scopolamine also is used in motion sickness. It is available as oral tablets and as a transdermal adhesive disk that is placed behind the ear. The disk (Transderm-V) protects against motion sickness for 72 hours.

**Tiotropium bromide** (Spiriva HandiHaler) is a dry powder in capsule form intended for oral inhalation with the HandiHaler inhalation device. This long-acting, antimuscarinic, anticholinergic, quaternary ammonium compound inhibits M<sub>3</sub> receptors in smooth muscle, resulting in bronchodilation. Tiotropium is indicated for daily maintenance treatment of bronchospasm associated with COPD. It is not indicated for

acute episodes of bronchospasm (i.e., rescue therapy). Tiotropium is eliminated via the renal system, and patients with moderate to severe renal dysfunction should be carefully monitored for drug toxicity. No dosage adjustments are required for older patients or patients with hepatic impairment or mild renal impairment.

### Antisecretory/Antispasmodic Anticholinergics Used in Gastrointestinal Disorders

**Dicyclomine** and **glycopyrrolate** are older medications, previously commonly used to treat peptic ulcer disease. With the introduction of medications such as proton pump inhibitors and other drugs that more effectively treat hyperacidity with fewer adverse effects (see Chap. 59), anticholinergics are infrequently prescribed today. Dicyclomine is also useful as an antispasmodic agent for treatment of irritable bowel syndrome.

### Centrally Acting Anticholinergics Used in Parkinson's Disease

Older anticholinergic drugs such as atropine are rarely used to treat Parkinson's disease because of their undesirable peripheral effects (e.g., dry mouth, blurred vision, photophobia, constipation, urinary retention, tachycardia). Newer, centrally acting synthetic anticholinergic drugs are more selective for muscarinic receptors in the CNS and are designed to produce fewer adverse effects.

**Trihexyphenidyl** (Trihexy) is used in the treatment of parkinsonism and extrapyramidal reactions caused by some antipsychotic drugs. Trihexyphenidyl relieves smooth muscle spasm by a direct action on the muscle and by inhibiting the parasympathetic nervous system. The drug supposedly has fewer adverse effects than atropine, but approximately half the recipients report mouth dryness, blurring of vision, and other adverse effects common to anticholinergic drugs. Trihexyphenidyl requires the same precautions as other anticholinergic drugs and is contraindicated in glaucoma.

**Benztropine** (Cogentin) is a synthetic drug with both anticholinergic and antihistaminic effects. Its anticholinergic activity approximates that of atropine. A major clinical use is to treat acute dystonic reactions caused by antipsychotic drugs and to prevent their recurrence in patients receiving long-term antipsychotic drug therapy. It also may be given in small doses to supplement other antiparkinson drugs. In full dosage, adverse reactions are common.

## Urinary Antispasmodics

**Darifenacin** (Enablex) is a competitive, antimuscarinic, anticholinergic agent with selective affinity for M<sub>3</sub> receptors involved in contraction of the urinary bladder. Darifenacin is indicated for the treatment of overactive bladder, reducing symptoms of urge incontinence, urgency, and frequency. After oral administration, darifenacin is 98% protein bound and extensively metabolized in the liver by CYP3A4 and CYP2D6 enzymes. A small group of individuals (approximately 7% Caucasian and 2% African American) are poor metabolizers of the drug and may require reduced dosages to avoid adverse effects. Dosage should also be reduced in individuals with moderate liver dysfunction and avoided in those individuals with severe liver impairment.

**Flavoxate** (Urispas) was developed specifically to counteract spasm in smooth muscle tissue of the urinary tract. It has anticholinergic, local anesthetic, and analgesic effects. Thus, the drug relieves dysuria, urgency, frequency, and pain with genitourinary infections, such as cystitis and prostatitis.

**Oxybutynin** (Ditropan, Ditropan XL, and Oxytrol transdermal system) has direct antispasmodic effects on smooth muscle and anticholinergic effects. It increases bladder capacity and decreases frequency of voiding in patients with neurogenic bladder. Oxybutynin is available in an extended-release form for once-daily dosing and a transdermal system that can be administered every 3 to 4 days.

**Solifenacin** (VESIcare) is a competitive, antimuscarinic, anticholinergic agent indicated for the treatment of overactive bladder with symptoms of urgency, urge incontinence, and frequency. Solifenacin is well absorbed after oral administration, 98% bound to plasma proteins, and extensively metabolized in the liver by CYP3A4 enzymes. Dosages should be reduced in individuals with moderate renal or liver impairment, and solifenacin is not recommended for those with severe liver impairment. Solifenacin may prolong QT intervals, especially at higher dosages, potentially resulting in dysrhythmias.

**Tolterodine** (Detrol and Detrol LA) is a competitive antimuscarinic, anticholinergic agent that inhibits bladder contraction, decreases detrusor muscle pressure, and delays the urge to void. It is used to treat urinary frequency, urgency, and urge incontinence. Tolterodine is more selective for muscarinic receptors in the urinary bladder than in other areas of the body, such as the salivary glands, and therefore anticholinergic adverse effects are less marked. Reduced doses (1 mg) are recommended for patients with hepatic dysfunction. Tolterodine is also available in an extended-release form.

**Tropium chloride** (Sanctura) is an antimuscarinic, anticholinergic drug for treatment of urgency, urge incontinence,

and urinary frequency associated with overactive bladder. Tropium reduces the tone of smooth muscle in the bladder, exerting an antispasmodic effect. Because of its quaternary structure, less than 10% of an orally administered dose is absorbed, and food further delays absorption. Therefore, it is recommended that the medication be taken at least 1 hour before meals or on an empty stomach. Absorbed tropium is eliminated by a combination of glomerular filtration and active tubular secretion. Tropium has the potential for interaction with other drugs that are eliminated by active tubular secretion (e.g., digoxin, procainamide, pancuronium, morphine, vancomycin, metformin, tenofovir), resulting in increased serum concentration of either tropium or the co-administered drug because of competition for the urinary tubular pump. Reduced dosages of tropium are recommended for patients with renal insufficiency and those older than 75 years of age who may be less able to tolerate the adverse effects of anticholinergic drugs.

## Nursing Process

### Assessment

- Assess the patient's condition in relation to disorders for which anticholinergic drugs are used (i.e., check for bradycardia or heart block, diarrhea, dysuria, abdominal pain, and other disorders). If the patient reports or medical records indicate a specific disorder, assess for signs and symptoms of that disorder (e.g., Parkinson's disease).
- Assess for disorders in which anticholinergic drugs are contraindicated (e.g., glaucoma, prostatic hypertrophy, reflux esophagitis, myasthenia gravis, hyperthyroidism).
- Assess use of other drugs with anticholinergic effects, such as antihistamines (histamine<sub>1</sub> receptor antagonists [see Chap. 45]), antipsychotic agents, and tricyclic antidepressants.

### Nursing Diagnoses

- Impaired Urinary Elimination: Decreased bladder tone and urine retention
- Constipation related to slowed GI function
- Disturbed Thought Processes: Confusion, disorientation, especially in older adults
- Deficient Knowledge: Drug effects and accurate usage
- Risk for Injury related to drug-induced blurred vision and photophobia
- Risk for Noncompliance related to adverse drug effects
- Risk for Altered Body Temperature: Hyperthermia

### Planning/Goals

#### The patient will

- Receive or self-administer the drugs correctly
- Experience relief of symptoms for which anticholinergic drugs are given

- Be assisted to avoid or cope with adverse drug effects on vision, thought processes, bowel and bladder elimination, and heat dissipation

## Interventions

Use measures to decrease the need for anticholinergic drugs. For example, with peptic ulcer disease, teach the client to avoid factors known to increase gastric secretion and GI motility (alcohol; cigarette smoking; caffeine-containing beverages, such as coffee, tea, and cola drinks; ulcerogenic drugs, such as aspirin). Late evening snacks also should be avoided because increased gastric acid secretion occurs approximately 90 minutes after eating and may cause pain and awakening from sleep. Although milk was previously considered an “ulcer food,” it contains protein and calcium, which promote acid secretion, and is a poor buffer of gastric acid. Thus, drinking large amounts of milk should be avoided.

Patient Guidelines for Anticholinergic Drugs are presented in the accompanying display.

## Evaluation

- Interview and observe in relation to safe, accurate drug administration.
- Interview and observe for relief of symptoms for which the drugs are given.
- Interview and observe for adverse drug effects.

## Applying Your Knowledge 20-1

Mr. Smoot experiences symptomatic bradycardia, with a heart rate in the range of 40 to 50 beats per minute. The standing order is to give atropine 1 mg IV. You administer the medication. What response is expected?

.....

## Principles of Therapy

### Treatment of Specific Disorders

#### Renal or Biliary Colic

Atropine is sometimes given with morphine or meperidine to relieve the severe pain of renal or biliary colic. It acts mainly to decrease the spasm-producing effects of the opioid analgesics. It has little antispasmodic effect on the involved muscles and is not used alone for this purpose.

#### Overactive Urinary Bladder

Urinary antispasmodics are useful in relieving the urgency, frequency, and urge incontinence associated with overactive bladder. Although these medications are formulated to be more selective for the muscarinic receptors in the smooth muscle of the urinary bladder, unwanted anticholinergic effects such as dry mouth, constipation, and mydriasis may occur.

### Preoperative Use in Patients With Glaucoma

Glaucoma is usually listed as a contraindication to anticholinergic drugs because the drugs impair outflow of aqueous humor and may cause an acute attack of glaucoma (increased intraocular pressure). However, anticholinergic drugs can be given safely before surgery to patients with open-angle glaucoma (80% of patients with primary glaucoma) if they are receiving miotic drugs such as pilocarpine. If anticholinergic preoperative medication is needed in patients predisposed to angle closure, the hazard of causing acute glaucoma can be minimized by also giving pilocarpine eye drops and acetazolamide.

### Gastrointestinal Disorders

In peptic ulcer disease, more effective drugs have been developed, and anticholinergics are rarely used. When anticholinergic drugs are given for GI disorders, larger doses may be given at bedtime to prevent pain and awakening during sleep.

### Parkinson's Disease

When anticholinergic drugs are used in parkinsonism, small doses are given initially and gradually increased. This regimen decreases adverse reactions.

### Extrapyramidal Reactions

When anticholinergic drugs are used in drug-induced extrapyramidal reactions (Parkinson-like symptoms), they should be prescribed only if symptoms occur. They should not be used routinely to prevent extrapyramidal reactions, because fewer than half of patients taking antipsychotic drugs experience such reactions. Most drug-induced reactions last approximately 3 months and do not recur if anticholinergic drugs are discontinued at that time. (An exception is tardive dyskinesia, which does not respond to anticholinergic drugs and may be aggravated by them.)

### Muscarinic Agonist Poisoning

Atropine is the antidote for poisoning by cholinergic (muscarinic) agonists such as certain species of mushrooms, cholinergic agonist drugs, cholinesterase inhibitor drugs, and insecticides containing organophosphates. Symptoms of muscarinic poisoning include salivation, lacrimation, visual disturbances, bronchospasm, diarrhea, bradycardia, and hypotension. Atropine prevents the poison from interacting with the muscarinic receptor, thus reversing the toxic effects.

### Asthma and Other Chronic Obstructive Lung Diseases

Oral anticholinergics are not used to treat asthma and other COPDs because of the possibility of thickened respiratory secretions and formation of mucous plugs in airways. Administration of ipratropium or tiotropium by inhalation causes the beneficial bronchodilating effect.

### Toxicity of Anticholinergics: Recognition and Management

Overdose of atropine or other anticholinergic drugs produces the usual pharmacologic effects in a severe and exaggerated

## Patient Teaching Guidelines Anticholinergic Drugs

### General Considerations

- Do not take other drugs without the physician's knowledge. In addition to some prescribed antiparkinson drugs, antidepressants, antihistamines, and antipsychotic drugs with anticholinergic properties, over-the-counter sleeping pills and antihistamines have anticholinergic effects. Taking any of these concurrently could cause overdose or excessive anticholinergic effects.
- Use measures to minimize risks of heat exhaustion and heat stroke:
  - Wear light, cool clothing in warm climates or environments.
  - Maintain fluid and salt intake if not contraindicated.
  - Limit exposure to direct sunlight.
  - Limit physical activity.
  - Take frequent cool baths.
  - Ensure adequate ventilation, with fans or air conditioners if necessary.
  - Avoid alcoholic beverages.
- Use sugarless chewing gum and hard candy, if not contraindicated, to relieve mouth dryness.
- Carry out good dental hygiene practices (e.g., regular brushing of teeth) to prevent dental caries and loss of teeth that may result from drug-induced xerostomia (dry mouth from decreased saliva production). This is more likely to occur with long-term use of these drugs.
- To prevent injury due to blurring of vision or drowsiness, avoid potentially hazardous activities (e.g., driving or operating machinery).
- To reduce sensitivity to light (photophobia), dark glasses can be worn outdoors in strong light.
- If you wear contact lenses and experience dry eyes, use an ophthalmic lubricating solution.

- When using anticholinergic ophthalmic preparations, if eye pain occurs, stop using the medication and contact your physician or health care provider. This may be a warning sign of undiagnosed glaucoma.
- Notify your physician or health care provider if urinary retention or constipation occurs.
- Tell your physician or health care provider if you are pregnant or breast-feeding or allergic to sulfite preservatives or any other atropine compound.

### Self-Administration

- Take anticholinergic drugs for gastrointestinal disorders 30 minutes before meals and at bedtime.
- Safeguard anticholinergic medications from children because they are especially sensitive to atropine poisoning.
- To prevent constipation, eat a diet high in fiber. Include whole grains, fruits, and vegetables in your daily menu. Also, drink 2 to 3 quarts of fluid a day and exercise regularly.
- Take trospium at least 1 hour before meals or on an empty stomach.
- To take tiotropium, follow the manufacturer's guidelines for using the HandiHaler to self-administer the drug by inhalation. Place a capsule into the center of the HandiHaler inhalation device. Pierce the capsule by pressing and releasing the button on the side of the inhalation device. Inhale through the mouthpiece to disperse the drug. Do not swallow tiotropium capsules. Avoid allowing tiotropium powder to enter the eyes.
- Rotate sites on the hips, abdomen, or buttocks and apply Oxytrol transdermal system to clean, dry skin.
- Do not crush or chew extended-release anticholinergic medications. Swallow whole with liquid.

form. The anticholinergic overdose syndrome is characterized by hyperthermia; hot, dry, flushed skin; dry mouth; mydriasis; delirium; tachycardia; paralytic ileus; and urinary retention. Myoclonic movements and choreoathetosis may be seen. Seizures, coma, and respiratory arrest may also occur. Treatment involves use of activated charcoal to absorb ingested poison. Hemodialysis, hemoperfusion, peritoneal dialysis, and repeated doses of charcoal are not effective.

**Physostigmine salicylate** (Antilirium), an acetylcholinesterase inhibitor, is a specific antidote for overdose of anticholinergics. It is usually given intravenously (IV) at a slow rate of injection, because rapid administration may cause bradycardia, hypersalivation (with subsequent respiratory distress), and seizures. The adult dose is 2 milligrams (no more than 1 mg/min), and the pediatric dose is 0.5 to 1 milligrams (no more than 0.5 mg/min). Repeated doses may be given if life-threatening dysrhythmias, convulsions, or coma occur with anticholinergic overdose. However, the benefit of repeat dosing must be balanced against the risk of physostigmine overdose. Excessive administration of physostigmine can precipitate a cholinergic crisis, leading to seizures and dysrhythmias. Atropine is the antidote for physostigmine overdose.

Diazepam or a similar drug may be given for excessive CNS stimulation (e.g., delirium, excitement) that accompanies anticholinergic toxicity. Ice bags, cooling blankets, and tepid sponge baths may help reduce fever. Artificial ventilation and cardiopulmonary resuscitative measures are used if excessive depression of the CNS causes coma and respiratory failure. Infants, children, and the elderly are especially susceptible to the toxic effects of anticholinergic drugs.

Anticholinergic drugs have potential intoxicating effects. Abuse of these drugs may produce euphoria, disorientation, hallucinations, and paranoia in addition to the classic anticholinergic adverse reactions.

## Use in Special Populations

### Use in Children

Systemic anticholinergics, including atropine, glycopyrrolate, and scopolamine, are given to children of all ages for essentially the same effects as for adults. Most of the antisecretory, antispasmodic drugs for GI disorders are not recommended for children. With the urinary antispasmodics, flavoxate is not recommended for children younger than 12 years of age; oxybutynin is not recommended for children younger than 5 years

of age; and the safety and efficacy of darifenacin, solifenacin, tolterodine, and trospium are not established in children. Similarly, the safety and efficacy of ipratropium and tiotropium, which are used for bronchodilation in chronic lung disorders, are not established in children.

Anticholinergic drugs cause the same adverse effects in children as in adults. However, the effects may be more severe in children, who are especially sensitive to these drugs. Facial flushing is common, and skin rashes may occur.

Ophthalmic anticholinergic drugs should be used only with close medical supervision. Cyclopentolate and tropicamide have been associated with behavioral disturbances and psychotic reactions in children. Tropicamide also has been associated with cardiopulmonary collapse.

### Use in Older Adults

Anticholinergic drugs are given in older adults for the same purposes as in younger adults. In addition to the primary anticholinergic drugs, many others are commonly prescribed for older adults have high anticholinergic activity, including many antihistamines (histamine<sub>1</sub> receptor antagonists), tricyclic antidepressants, and antipsychotic drugs.

Older adults are especially likely to have significant adverse reactions because of slowed drug metabolism and the frequent presence of several disease processes. Some common adverse effects, with suggestions for reducing their impact, are

- Blurred vision. Patients may need help with ambulation, especially with stairs or in other potentially hazardous environments. Remove obstacles and hazards when possible.
- Confusion. Provide whatever assistance is needed to prevent falls and other injuries.
- Heat stroke. Help avoid precipitating factors, such as strenuous activity and high environmental temperatures.
- Constipation. Encourage or assist with an adequate intake of high-fiber foods and fluids and adequate exercise when feasible.
- Urinary retention. Encourage adequate fluid intake and avoid high doses of the drugs. Men should be examined for prostatic hypertrophy.
- Hallucinations and other psychotic symptoms. These are most likely to occur with the centrally active anticholinergics given for Parkinson's disease or drug-induced extrapyramidal effects, such as trihexyphenidyl or benztropine. Regulate and supervise dosage of these drugs carefully.

### Applying Your Knowledge 20-2

Mr. Smoot complains about being unable to move his bowels and is having difficulty with urination. How should the nurse respond?

.....

### Use in Patients With Renal Impairment

Anticholinergic drugs that have a tertiary amine structure, such as atropine, are eliminated by a combination of hepatic metabolism and renal excretion. In the presence of renal impairment, they may accumulate and cause increased adverse effects. Quaternary amines are eliminated largely in the feces and are less affected by renal impairment.

### Use in Patients With Hepatic Impairment

Some anticholinergic drugs are metabolized by the liver. Therefore, in the presence of hepatic impairment, they may accumulate and cause adverse effects. Darifenacin, solifenacin, and tolterodine are examples of such medications. Dosages should be reduced and/or given less frequently in the presence of liver impairment.

### Use in Patients With Critical Illness

Atropine is an important drug in the emergency drug box. According to ACLS guidelines, atropine is the first drug to be administered in the emergency treatment of bradydysrhythmias. Atropine 0.5 milligrams should be administered IV every 3 to 5 minutes and may be repeated up to 3 milligrams (0.03–0.04 mg/kg total dose). For patients with asystole, 1 milligram of atropine is administered IV or IO and repeated every 3 to 5 minutes if asystole persists, up to 0.04 milligrams per kilogram of body weight. Administration of atropine in doses less than 0.5 milligrams should be avoided, because this may result in a paradoxical bradycardia. Atropine may be administered by endotracheal tube in patients without IV access. The recommended dose is 2 to 3 milligrams diluted in 10 milliliters of normal saline.

### Use in Home Care

Anticholinergic drugs are commonly used in home care with children and adults. Children and older adults are probably most likely to experience adverse effects of these drugs and should be monitored carefully. With older patients, the home care nurse needs to assess medication regimens for combinations of drugs with anticholinergic effects, especially if mental confusion develops or worsens. The home care nurse may also need to teach older patients or caregivers that the drugs prevent sweating and heat loss and increase risks of heat stroke if precautions to avoid overheating are not taken.

### Applying Your Knowledge 20-3

#### How Can You Avoid This Medication Error?

Mr. Bing is another patient of yours on the unit. He is a 50-year-old man with a medical history of cholelithiasis, glaucoma, and hypertension. He has had surgery today to remove his gallbladder. You assess Mr. Bing and find that he is experiencing nausea. The resident on call orders a scopolamine patch. You follow the order and apply the patch.

.....

## Nursing Actions Anticholinergic Drugs

### NURSING ACTIONS

#### 1. Administer accurately

- a. For gastrointestinal disorders, give most oral anticholinergic drugs approximately 30 min before meals and at bedtime.
- b. When given before surgery, parenteral preparations of atropine can be mixed in the same syringe with several other common preoperative medications, such as meperidine (Demerol), morphine, oxymorphone (Numorphan), and promethazine (Phenergan).
- c. When applying topical atropine solutions or ointment to the eye, be sure to use the correct concentration and blot any excess from the inner canthus.
- d. Parenteral glycopyrrolate can be given through the tubing of a running intravenous infusion of physiologic saline or lactated Ringer's solution.
- e. Do not crush extended-release or long-acting forms of anticholinergic drugs such as Detrol LA, Ditropan XL, VESIcare, and Enablex.
- f. Take trospium (Sanctura) on an empty stomach.
- g. Follow the manufacturer's guidelines for administration of tiotropium using the HandiHaler inhalation device. Use the drug immediately after opening. Do not allow the powder to enter the eyes.

#### 2. Observe for therapeutic effects

- a. When a drug is given for *peptic ulcer disease* or other gastrointestinal disorders, observe for decreased abdominal pain.
- b. When the drug is given for *diagnosing or treating eye disorders*, observe for pupil dilation (mydriasis) and blurring of vision (cycloplegia).
- c. When the drug is given for *symptomatic bradycardia*, observe for increased pulse rate.
- d. When the drug is given for *urinary-tract disorders*, such as cystitis or enuresis, observe for decreased frequency of urination. When the drug is given for *renal colic due to stones*, observe for decreased pain. When the drug is given for *overactive bladder*, observe for fewer symptoms of urgency, urge incontinence, and frequency.
- e. When the centrally acting anticholinergics are given for *Parkinson's disease*, observe for decrease in tremor, salivation, and drooling.

#### 3. Observe for adverse effects

- a. Tachycardia

### RATIONALE/EXPLANATION

To allow the drugs to reach peak antisecretory effects by the time ingested food is stimulating gastric acid secretion. Bedtime administration helps prevent awakening with abdominal pain. The primary reason for mixing medications in the same syringe is to decrease the number of injections and thus decrease patient discomfort. Note, however, that extra caution is required when mixing drugs to be sure that the dosage of each drug is accurate. Also, if any question exists regarding compatibility with another drug, it is safer not to mix the drugs, even if two or three injections are required. Atropine ophthalmic preparations are available in several concentrations (usually 1%, 2%, and 3%). Excess medication should be removed so the drug will not enter the nasolacrimal (tear) ducts and be absorbed systemically through the mucous membrane of the nasopharynx or be carried to the throat and swallowed.

Crushing long-acting medications may result in high blood levels of the medication and increased adverse effects.

Food interferes with absorption.

This ensures proper dosage and prevents reduced effectiveness. Drug powder in the eyes may cause blurred vision and pupil dilation.

Therapeutic effects depend primarily on the reason for use. Thus, a therapeutic effect in one condition may be an adverse effect in another condition.

Relief of abdominal pain is due to the smooth muscle relaxant or antispasmodic effect of the drug.

Note that these ocular effects are considered adverse effects when the drugs are given for problems not related to the eyes.

These drugs increase heart rate by blocking action of the vagus nerve.

Anticholinergic drugs decrease muscle tone and spasm in the smooth muscle of the ureters and urinary bladder.

Decreased salivation is a therapeutic effect with parkinsonism but an adverse reaction in most other conditions.

These depend on reasons for use and are dose related.

Tachycardia may occur with usual therapeutic doses because anticholinergic drugs block vagal action, which normally slows heart rate. Tachycardia is not likely to be serious except in patients with underlying heart disease. For example, in patients with angina pectoris, prolonged or severe tachycardia may increase myocardial ischemia to the point of causing an acute attack of angina (chest pain) or even myocardial infarction. In patients with congestive heart failure, severe or prolonged tachycardia can increase the workload of the heart to the point of causing acute heart failure or pulmonary edema.

## Nursing Actions Anticholinergic Drugs (continued)

### NURSING ACTIONS

- b. Excessive central nervous system (CNS) stimulation (tremor, restlessness, confusion, hallucinations, delirium) followed by excessive CNS depression (coma, respiratory depression)
- c. Sedation and amnesia with scopolamine or benztropine (Cogentin)
- d. Constipation or paralytic ileus
- e. Decreased oral and respiratory tract secretions, which cause mouth dryness and thick respiratory secretions
- f. Paradoxical bronchospasm
- g. Urinary retention
- h. Hot, dry skin; fever; heat stroke
- i. Ocular effects—mydriasis, blurred vision, photophobia
- j. Angioedema with tiotropium

### 4. Observe for drug interactions

- a. Drugs that *increase* effects of anticholinergic drugs: antihistamines, disopyramide, phenothiazines, thioxanthene agents, tricyclic antidepressants, amantadine
- b. Drugs that *decrease* effects of anticholinergic drugs: cholinergic drugs
- c. For trospium, use caution when administering concurrently with drugs that are eliminated by active tubular secretion (e.g., digoxin, metformin, morphine, pancuronium, procainamide, tenofovir, vancomycin).
- d. For solifenacin and darifenacin: ketoconazole and other inhibitors of CYP3A4 enzymes increase the effect of anticholinergic drugs.

### RATIONALE/EXPLANATION

- These effects are more likely to occur with large doses of atropine because atropine crosses the blood-brain barrier. Large doses of trihexyphenidyl (Trihexy) also may cause CNS stimulation.
- This may be a therapeutic effect but becomes an adverse reaction if severe or if the drug is given for another purpose. Benztropine has anticholinergic and antihistaminic properties. Apparently, drowsiness and sedation are caused by the antihistaminic component.
- These effects are the result of decreased gastrointestinal motility and muscle tone. Constipation is more likely with large doses or parenteral administration. Paralytic ileus is not likely unless the drugs are given to patients who already have decreased gastrointestinal motility.
- Mouth dryness is more annoying than serious in most cases and is caused by decreased salivation. However, patients with chronic lung disease, who usually have excessive secretions, tend to retain them with the consequence of frequent respiratory tract infections.
- This effect is detrimental and requires that the drug be discontinued.
- This reaction is caused by loss of bladder tone and is most likely to occur in elderly men with enlarged prostate glands. Thus, the drugs are usually contraindicated with prostatic hypertrophy.
- These effects are due to decreased sweating and impairment of the normal heat-loss mechanism. Fever may occur with any age group. Heat stroke is more likely to occur with cardiovascular disease, strenuous physical activity, and high environmental temperatures, especially in older people.
- These are adverse effects when anticholinergic drugs are given for conditions not related to the eyes.
- This effect requires that the drug be discontinued.
- These drugs have anticholinergic properties and produce additive anticholinergic effects.
- These drugs counteract the inhibition of gastrointestinal motility and tone induced by atropine. They are sometimes used in atropine overdose.
- As these drugs compete for urinary tubular pumps, increased serum concentration of trospium or the co-administered drug may occur.
- Ketoconazole inhibits the metabolism of solifenacin and darifenacin, increasing effects.

## Key Concepts

- Anticholinergic drugs block the action of acetylcholine on the parasympathetic nervous system.
- Most anticholinergic drugs interact with muscarinic cholinergic receptors in the brain, secretory glands, heart, and smooth muscle and are sometimes called antimuscarinic drugs.
- Cholinergic (muscarinic) receptors are widespread throughout the body, producing effects in a variety of locations including the central nervous system, heart, smooth muscle, glands, and the eye.
- Synthetic anticholinergics were developed to exert more selective effects on particular body tissues.
- Anticholinergic drugs (e.g., dicyclomine or glycopyrrolate) are indicated for antispasmodic effects in GI disorders. Historically, they have also been used to treat peptic ulcer disease; however, they are weak inhibitors of gastric acid secretion and have been largely replaced other more effective medications (e.g., proton pump inhibitors)
- Urinary antispasmodic anticholinergic drugs are the drugs of choice for treatment of symptoms of overactive bladder.
- Ophthalmic anticholinergic preparations are indicated for mydriatic and cycloplegic effects to aid in eye examination and surgery.
- Ipratropium and tiotropium are anticholinergic medications given by inhalation for bronchodilation effects in the treatment of asthma and chronic bronchitis.
- Atropine is the drug of choice to treat bradycardia.
- Anticholinergic medications are indicated in the relief of central nervous system symptoms of Parkinson's disease or extrapyramidal symptoms associated with some antipsychotic drugs.
- Anticholinergic drugs are given preoperatively to prevent anesthesia-associated complications such as bradycardia, excessive respiratory secretions, and hypotension.
- Anticholinergic drugs are contraindicated for patients with benign prostatic hypertrophy, myasthenia gravis, hyperthyroidism, narrow-angle glaucoma, tachydysrhythmias, myocardial infarction, heart failure, or conditions associated with esophageal reflux.
- Anticholinergic overdose is characterized by hyperthermia; hot, dry, flushed skin; dry mouth; mydriasis; delirium; tachycardia; paralytic ileus; urinary retention; myoclonic movements; seizures; coma; and respiratory arrest. Physostigmine is the specific antidote for anticholinergic overdose.
- Atropine is the antidote for muscarinic agonist poisoning.

## Review and Application Exercises

### Short Answer Exercises

1. How do anticholinergic drugs exert their therapeutic effects?
2. What are the indications and contraindications for use of anticholinergic drugs?
3. What is the effect of anticholinergic drugs on heart rate, and what is the mechanism for this effect?
4. Under what circumstances is it desirable to administer atropine before surgery, and why?
5. What are adverse effects of anticholinergic drugs?
6. What treatment measures are indicated for a patient with an overdose of a drug with anticholinergic effects?
7. Name two other commonly used drug groups that have anticholinergic effects.
8. What nursing observations and interventions are needed to increase patient safety and comfort during anticholinergic drug therapy?

### NCLEX-Style Questions

9. Your 62-year-old patient has a sinus bradycardia with a rate of 48 beats per minute. He is confused, and his skin is cool and clammy. What is the drug of choice in this situation?
  - a. atropine sulfate
  - b. epinephrine (Adrenalin)
  - c. isoproterenol (Isuprel)
  - d. dopamine (Intropin)
10. Your patient is taking an anticholinergic medication. Which of the following instructions would be appropriate for this patient?
  - a. Limit oral intake because these medications cause fluid retention.
  - b. Be sure a bathroom is near because these medications may cause diarrhea.
  - c. Avoid overheating and wear cool, loose clothing because these medications impair sweating.
  - d. Change positions slowly because these medications may cause orthostatic hypotension.

11. Shortly after administration of the first dose of atropine, your patient complains of acute eye pain. The nurse should
  - a. Administer a PRN (as needed) dose of analgesic, such as acetaminophen.
  - b. Place a cool, damp cloth over the patient's eyes for comfort.
  - c. Hold further doses of atropine and notify the physician immediately.
  - d. Prepare to treat an allergic reaction to atropine with epinephrine (Adrenalin).
12. Your patient with chronic lung disease is in respiratory distress due to acute bronchospasm. Which of the following orders for treatment of this condition would you question?
  - a. epinephrine (Adrenalin)
  - b. albuterol (Ventolin)
  - c. aminophylline (Truphylline)
  - d. tiotropium (Spiriva)

- 28 ■ Androgens and Anabolic Steroids

# Physiology of the Endocrine System

## KEY TERMS

- Down-regulation
- Hormones
- Hypothalamic–pituitary–adrenocortical (HPA) axis
- Hypothalamus
- Negative feedback system
- Phospholipids
- Second-messenger systems
- Up-regulation

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Examine the relationship between the endocrine system and the central nervous system.
2. Describe general characteristics and functions of hormones.
3. Compare steroid and protein hormones in relation to site of action and pharmacokinetics.
4. Examine hormonal action at the cellular level.
5. Describe the second-messenger roles of cyclic adenosine monophosphate and calcium within body cells.
6. Differentiate between physiologic and pharmacologic doses of hormonal drugs.

## Introduction

The endocrine system participates in the regulation of essentially all body activities, including metabolism of nutrients and water, reproduction, growth and development, and adapting to changes in internal and external environments. The major elements of the endocrine system are the *hypothalamus*, pituitary gland, thyroid gland, parathyroid glands, pancreas, adrenal glands, ovaries, and testes. These tissues function through *hormones*, substances that are synthesized and secreted into body fluids by one group of cells and have physiologic effects on other body cells. Hormones act as chemical messengers to transmit information between body cells and organs. Most hormones from the traditional endocrine glands are secreted into the bloodstream and act on distant organs.

In addition to the major endocrine organs, other tissues also produce hormones. These endocrine-like cells intermingle with nonendocrine cells in various organs. Their hormones are secreted into tissue fluids and act locally on nearby cells, as in the following examples:

- The gastrointestinal mucosa produces hormones that are important in the digestive process (e.g., gastrin, enterogastrone, secretin, cholecystokinin).
- The kidneys produce erythropoietin, a hormone that stimulates the bone marrow to produce red blood cells.
- White blood cells produce cytokines that function as messengers among leukocytes in inflammatory and immune processes.
- Many body tissues produce prostaglandins and leukotrienes, which have a variety of physiologic effects.

Neoplasms also may produce hormones. In endocrine tissues, neoplasms may be an added source of the hormone normally produced by the organ. In nonendocrine tissues, various hormones may be produced. For example, lung tumors may produce corticotropin (adrenocorticotropic hor-

mone [ACTH]), antidiuretic hormone, or parathyroid hormone; kidney tumors may produce parathyroid hormone. The usual effects are those of excess hormone secretion.

This chapter focuses on the traditional endocrine organs and their hormones. Specific organs are discussed in the following chapters; general characteristics of the endocrine system and hormones are described in the following sections and in Box 21-1.

## Endocrine System–Nervous System Interactions

The endocrine and nervous systems are closely connected, anatomically and physiologically, and work in harmony to inte-

### Box 21-1

### Major Hormones and Their General Functions

**Anterior pituitary hormones** are growth hormone (also called somatotropin), corticotropin, thyroid-stimulating hormone, follicle-stimulating hormone, luteinizing hormone, and prolactin. Most of these hormones function by stimulating secretion of other hormones.

**Posterior pituitary hormones** are antidiuretic hormone (ADH or vasopressin) and oxytocin. ADH helps maintain fluid balance; oxytocin stimulates uterine contractions during childbirth.

**Adrenal cortex hormones**, commonly called corticosteroids, include the glucocorticoids, such as cortisol, and the mineralocorticoids, such as aldosterone. Glucocorticoids influence carbohydrate storage, exert anti-inflammatory effects, suppress corticotropin secretion, and increase protein catabolism. Mineralocorticoids help regulate electrolyte balance, mainly by promoting sodium retention and potassium loss. The adrenal cortex also produces sex hormones. The adrenal medulla hormones are epinephrine and norepinephrine (see Chap. 17).

**Thyroid hormones** include triiodothyronine ( $T_3$  or liothyronine) and tetraiodothyronine ( $T_4$  or thyroxine). These hormones regulate the metabolic rate of the body and greatly influence growth and development.

**Parathyroid hormone**, also called parathormone or PTH, regulates calcium and phosphate metabolism.

**Pancreatic hormones** are insulin and glucagon, which regulate the metabolism of glucose, lipids, and proteins.

**Ovarian hormones** (female sex hormones) are estrogens and progesterone. Estrogens promote growth of specific body cells and development of most female secondary sexual characteristics. Progesterone helps prepare the uterus for pregnancy and the mammary glands for lactation.

**Testicular hormone** (male sex hormone) is testosterone, which regulates development of masculine characteristics.

**Placental hormones** are chorionic gonadotropin, estrogen, progesterone, and human placental lactogen, all of which are concerned with reproductive functions.

grate and regulate body functions. In general, the nervous system regulates rapid muscular and sensory activities by secreting substances that act as neurotransmitters, circulating hormones, and local hormones (e.g., norepinephrine, epinephrine). The endocrine system regulates slow metabolic activities by secreting hormones that control cellular metabolism, transport of substances across cell membranes, and other functions (e.g., reproduction, growth and development, secretion).

The main connecting link between the nervous system and the endocrine system is the hypothalamus, which responds to nervous system stimulation by producing hormones. Secretion of almost all hormones from the pituitary gland is controlled by the hypothalamus. Special nerve fibers originating in the hypothalamus and ending in the posterior pituitary gland control secretions of the posterior pituitary. The hypothalamus secretes hormones, called releasing and inhibitory factors, that regulate functions of the anterior pituitary. The anterior pituitary, in turn, secretes hormones that act on target tissues, usually to stimulate production of other hormones. For example, hypothalamic corticotropin-releasing hormone stimulates the anterior pituitary to produce corticotropin, and corticotropin, in turn, stimulates the adrenal cortex to produce cortisol. This complex interrelationship is often referred to as the *hypothalamic–pituitary–adrenocortical (HPA) axis*. It functions by a *negative feedback system*, in which hormone secretion is stimulated when hormones are needed and inhibited when they are not needed. The hypothalamic–pituitary–thyroid axis also functions by a negative feedback mechanism.

## General Characteristics of Hormones

Hormones are extremely important in regulating body activities. Their normal secretion and function help to maintain the internal environment and determine response and adaptation to the external environment. Hormones participate in complex interactions with other hormones and nonhormone chemical substances in the body to influence every aspect of life. Although hormones are usually studied individually, virtually all endocrine functions are complex processes that are influenced by more than one hormone.

Although hormones circulating in the bloodstream reach essentially all body cells, some (e.g., growth hormone, thyroid hormone) affect almost all cells, whereas others affect specific “target” tissues (e.g., corticotropin stimulates the adrenal cortex). In addition, one hormone can affect different tissues (e.g., ovarian estrogen can act on ovarian follicles to promote their maturation, on the endometrial lining of the uterus to stimulate its growth and cyclic changes, on breast tissue to stimulate growth of milk ducts, and on the hypothalamic–pituitary system to regulate its own secretion), or several hormones can affect a single tissue or function (e.g., catecholamines, glucagon, secretin, and prolactin regulate lipolysis [release of fatty acids from adipose tissue]).

Several hormones are secreted in cyclic patterns. For example, ACTH, cortisol, and growth hormone are secreted in 24-hour (circadian) cycles, whereas estrogen and progesterin secretion are related to the 28-day menstrual cycle.

## Hormone Pharmacokinetics

Protein-derived hormones (amines, amino acids, peptides, and polypeptides) are synthesized, stored, and released into the bloodstream in response to a stimulus. The steroid hormones, which are synthesized in the adrenal cortex and gonads from cholesterol, are released as they are synthesized. Most hormones are constantly present in the blood; plasma concentrations vary according to body needs, the rate of synthesis and release, and the rate of metabolism and excretion.

Protein-derived hormones usually circulate in an unbound, active form. Steroid and thyroid hormones are transported by specific carrier proteins synthesized in the liver. (Some drugs may compete with a hormone for binding sites on the carrier protein. If this occurs, hormone effects are enhanced because more unbound, active molecules are available to act on body cells.)

Hormones must be continuously inactivated to prevent their accumulation and excessive effects. Several mechanisms operate to eliminate hormones from the body. The water-soluble, protein-derived hormones have a short duration of action and are inactivated by enzymes mainly in the liver and kidneys. The lipid-soluble steroid and thyroid hormones have a longer duration of action because they are bound to plasma proteins. After they are released by the plasma proteins, these hormones are conjugated in the liver to inactive forms and then excreted in bile or urine. A third, less common mechanism is inactivation by enzymes at receptor sites on target cells.

## Hormone Action at the Cellular Level

Hormones modify rather than initiate cellular reactions and functions. After hormone molecules reach a responsive cell, they bind with receptors in the cell membrane (e.g., catecholamines and protein hormones) or inside the cell (e.g., steroid and thyroid hormones). The number of hormone receptors and the affinity of the receptors for the hormone are the major determinants of target-cell response to hormone action.

The main target organs for a given hormone contain large numbers of receptors. However, the number of receptors may be altered by various conditions. For example, receptors may be increased (called *up-regulation*) when there are low levels of hormone. This allows the cell to obtain more of the needed hormone than it can obtain with fewer receptors. Receptors may be decreased (called *down-regulation*) when there are excessive amounts of hormone. This mechanism protects the cell by making it less responsive to excessive hormone levels. Receptor up-regulation and down-regulation occur with chronic exposure to abnormal levels of hormones. In addition, receptor proteins may be decreased by inadequate formation or antibodies that destroy them. Thus, receptors are constantly

being synthesized and degraded, so the number of receptors may change within hours. Receptor affinity for binding with hormone molecules probably changes as well.

After binding occurs, the resulting hormone–receptor complex initiates intracellular biochemical reactions, depending on the particular hormone and the type of cell. Many hormones act as a “first messenger” to the cell, and the hormone–receptor complex activates a “second messenger.” The second messenger then activates intracellular structures to produce characteristic cellular functions and products. Steroid hormones from the adrenal cortex, ovaries, and testes stimulate target cells to synthesize various proteins (e.g., enzymes, transport and structural proteins) needed for normal cellular function.

## Second-Messenger System

Three major *second-messenger systems*, cyclic adenosine monophosphate (cAMP), calcium–calmodulin, and phospholipid products, are described in this section.

Cyclic AMP is the second messenger for many hormones, including corticotropin, catecholamines, glucagon, thyroid-stimulating hormone, follicle-stimulating hormone, luteinizing hormone, parathyroid hormone, secretin, and antidiuretic hormone. It is formed by the action of the enzyme adenylyl cyclase on adenosine triphosphate, a component of all cells and the main source of energy for cellular metabolism. After it is formed, cAMP activates a series of enzyme reactions that alter cell function. The amount of intracellular cAMP is increased by hormones that activate adenylyl cyclase (e.g., the pituitary hormones, calcitonin, glucagon, parathyroid hormone) and is decreased by hormones that inactivate adenylyl cyclase (e.g., angiotensin, somatostatin). Cyclic AMP is inactivated by phosphodiesterase enzymes.

Calcium is the second messenger for angiotensin II, a strong vasoconstrictor that participates in control of arterial blood pressure, and for gonadotropin-releasing hormone. The postulated sequence of events is that hormone binding to receptors increases intracellular calcium. The calcium binds with an intracellular regulatory protein called calmodulin. The calcium–calmodulin complex activates protein kinases, which then regulate contractile structures of the cell, cell membrane permeability, and intracellular enzyme activity. Specific effects include contraction of smooth muscle, changes in the secretions produced by secreting cells, and changes in ciliary action in the lungs.

Phospholipid products are mainly involved with local hormones. *Phospholipids* are major components of the cell membrane portion of all body cells. Some local hormones activate cell membrane receptors and transform them into phospholipase C, an enzyme that causes some of the phospholipids in cell membranes to split into smaller molecules (e.g., inositol triphosphate and diacylglycerol). These products then act as second messengers to intracellular structures. Inositol triphosphate mobilizes intracellular calcium ions and the calcium ions then fulfill their functions as second messengers, as described previously. Diacylglycerol activates protein kinase C,

an enzyme important in cell reproduction. Also, the lipid component of diacylglycerol is arachidonic acid, the precursor for prostaglandins, leukotrienes, and other local hormones with extensive effects.

### Steroid Stimulation of Protein Synthesis

Steroid hormones are lipid soluble and therefore cross cell membranes easily. Inside the cell cytoplasm, the hormone molecules bind with specific receptor proteins. The hormone-receptor complex then enters the nucleus of the cell, where it activates nucleic acids (DNA and RNA) and the genetic code to synthesize new proteins.

### Hormonal Disorders

Abnormal secretion and function of hormones, even minor alterations, can impair physical and mental health. Malfunction of an endocrine organ is usually associated with hyposecretion, hypersecretion, or inappropriate secretion of its hormones. Any malfunction can produce serious disease or death.

#### Glandular Hypofunction

Hypofunction may be associated with a variety of circumstances, including the following:

1. A congenital defect may result in the absence of an endocrine gland, the presence of an abnormally developed gland, or the absence of an enzyme required for glandular synthesis of its specific hormone.
2. The endocrine gland may be damaged or destroyed by impaired blood flow, infection or inflammation, autoimmune disorders, or neoplasms.
3. The endocrine gland may atrophy and become less able to produce its hormone because of aging, drug therapy, disease, or unknown reasons.
4. The endocrine gland may produce adequate hormone, but the hormone may not be able to function normally because of receptor defects (not enough receptors or the receptors present are unable to bind with the hormone).

5. Even if there is adequate hormone and adequate binding to receptors, intracellular metabolic processes (e.g., enzyme function, protein synthesis, energy production) may not respond appropriately.

#### Glandular Hyperfunction

Hyperfunction is usually characterized by excessive hormone production. Excessive amounts of hormone may occur from excessive stimulation and enlargement of the endocrine gland, from a hormone-producing tumor of the gland, or from a hormone-producing tumor of nonendocrine tissues (e.g., some primary lung tumors produce antidiuretic hormone and ACTH).

### Use of Hormonal Drugs

Hormonal drugs are powerful drugs that produce widespread therapeutic and adverse effects. Hormones given for therapeutic purposes may be natural hormones from human or animal sources or synthetic. Many of the most important hormones have been synthesized, and synthetic preparations may have more potent and prolonged effects than naturally occurring hormones. Administration of one hormone may alter effects of other hormones through complex hormone interactions.

Hormones are given for physiologic or pharmacologic effects and are more often given for disorders resulting from endocrine gland hypofunction than for those related to hyperfunction. Physiologic use involves giving small doses as a replacement or substitute for the amount secreted by a normally functioning endocrine gland. Such use is indicated only when a gland cannot secrete an adequate amount of hormone. Examples of physiologic use include insulin administration in diabetes mellitus and adrenal corticosteroid administration in Addison's disease. Pharmacologic use involves relatively large doses for effects greater than physiologic effects. For example, adrenal corticosteroids are widely used for anti-inflammatory effects in endocrine and nonendocrine disorders.

## Key Concepts

- The endocrine system is comprised of the hypothalamus of the brain, pituitary gland, thyroid gland, parathyroid glands, pancreas, adrenal glands, ovaries, and testes.
- Endocrine tissues function through hormones, which act as chemical messengers to transmit information between body cells and organs.
- Water-soluble, protein-derived hormones have a short duration of action and are inactivated by enzymes mainly in the liver and kidneys.
- Lipid-soluble steroid and thyroid hormones have a longer duration of action because they are bound to plasma proteins.
- Secretion of almost all hormones from the pituitary gland is controlled by the hypothalamus.
- The endocrine and nervous systems are closely connected, anatomically and physiologically, and work in harmony to integrate and regulate body functions.
- ACTH, cortisol, and growth hormone are secreted in 24-hour (circadian) cycles, whereas estrogen and progesterin secretion are related to the 28-day menstrual cycle.

- Many hormones act as a “first messenger” to the cell, and the hormone–receptor complex activates a “second messenger,” which activates intracellular structures to produce characteristic cellular functions and products.
- Receptors are capable of increasing (up-regulation) or decreasing (down-regulation) with chronic exposure to abnormal levels of hormones.

## Review and Application Exercises

---

### Short Answer Exercises

1. How do hormones function in maintaining homeostasis?
2. What is the connection between the nervous system and the endocrine system?
3. What is meant by a negative feedback system?
4. Because classic hormones are secreted into blood and circulated to essentially all body cells, why do they not affect all body cells?
5. What are the functions and characteristics of the pituitary gland?

- Inhibiting hormone
- Oxytocin
- Releasing hormone
- Somatotropin
- Thyroid-stimulating hormone (TSH)
- Thyrotropin

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Identify clinical uses of selected hormones.
2. Differentiate characteristics and functions of anterior and posterior pituitary hormones.
3. Recognize the limitations of hypothalamic and pituitary hormones as therapeutic agents.
4. Identify major nursing considerations in the care of patients receiving specific hypothalamic and pituitary hormones.

## Applying Your Knowledge

Jose Rojas is a 24-year-old man who has suffered a head injury while riding his motorcycle without a helmet. He has been admitted for observation, with multiple abrasions and a blow to the head. Mr. Rojas begins to produce massive amounts of clear, pale-yellow urine. The physician diagnoses him with diabetes insipidus and orders desmopressin 0.2 mL in two divided doses intranasally.

## Introduction

The hypothalamus of the brain and the pituitary gland interact to control most metabolic functions of the body and to maintain homeostasis (Fig. 22-1). They are anatomically connected by the funnel-shaped hypophyseal stalk. The hypothalamus controls secretions of the pituitary gland. The pituitary gland, in turn, regulates secretions or functions of other body tissues, called target tissues. The pituitary gland is actually two glands, each with different structures and functions. The anterior pituitary is composed of different types of glandular cells that synthesize and secrete different hormones. The posterior pituitary is anatomically an extension of the hypothalamus and is composed mainly of nerve fibers. Although it does not manufacture any hormones itself, it stores and releases hormones synthesized in the hypothalamus.

## Types of Hormones

### Hypothalamic Hormones

Hormones are chemical messenger with specific regulatory effect on the cells that control various bodily functions. The hypothalamus produces a *releasing hormone* to accelerate the secretion of a given hormone or an *inhibiting hormone* that decreases hormone secretion that corresponds to each of the major hormones of the anterior pituitary gland.

**Figure 22-1** ■ Hypothalamic and pituitary hormones and their target organs. The hypothalamus produces hormones that act on the anterior pituitary or are stored in the posterior pituitary. The anterior pituitary produces hormones that act on various body tissues and stimulate production of other hormones.  $T_3$ , triiodothyronine;  $T_4$ , thyroxine; TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone.

**Corticotropin-releasing hormone** or **factor** (CRH or CRF) causes release of *corticotropin* (also called *adrenocorticotrophic hormone* [ACTH]) in response to stress and threatening stimuli. CRH is secreted most often during sleep, and its secretion is influenced by several neurotransmitters. Acetylcholine and serotonin stimulate secretion, and gamma-aminobutyric acid (GABA) and norepinephrine inhibit secretion. The ability of CRH to stimulate corticotropin secretion is increased by vasopressin and decreased or prevented by somatostatin and elevated levels of glucocorticoids. CRH can be used in the diagnosis of Cushing's disease, a disorder characterized by excess cortisol.

**Growth hormone-releasing hormone** (GHRH) causes release of *growth hormone* (GH) in response to low blood levels of GH. Secretion of hypothalamic GHRH is stimulated by dopamine, norepinephrine, epinephrine, GABA, acetylcholine, and serotonin. The stimulatory effect of GHRH on secretion of GH is blocked by somatostatin. GHRH may

be used to test pituitary function and to stimulate growth in children with GHRH deficiency.

**Growth hormone release-inhibiting hormone** (somatostatin) inhibits release of GH and is distributed throughout the brain and spinal cord, where it functions as a neurotransmitter. It is also found in the intestines and the pancreas, where it regulates secretion of insulin and glucagon. Somatostatin secretion is increased by several neurotransmitters, including acetylcholine, dopamine, epinephrine, GABA, and norepinephrine.

Somatostatin also inhibits other functions, including secretion of corticotropin, *thyroid-stimulating hormone* (TSH or *thyrotropin*), prolactin, pancreatic secretions (e.g., insulin, glucagon), and gastrointestinal (GI) secretions (gastrin, cholecystokinin, secretin, vasoactive intestinal peptide) as well as GI motility, bile flow, and mesenteric blood flow. Hypothalamic somatostatin blocks the action of GHRH and decreases thyrotropin-releasing hormone (TRH)-induced release of

TSH. GH stimulates secretion of somatostatin, and the effects of somatostatin on TSH may contribute to TSH deficiency in children being treated with GH. A long-acting somatostatin analog, octreotide (Sandostatin), may be used to treat acromegaly, carcinoid tumors, and vasoactive intestinal peptide tumors (VIPomas).

**Thyrotropin-releasing hormone (TRH)** causes release of TSH in response to stress, such as exposure to cold. TRH may be used in diagnostic tests of pituitary function and hyperthyroidism.

**Gonadotropin-releasing hormone (GnRH)** causes release of follicle-stimulating hormone (FSH) and luteinizing hormone (LH). Several synthetic equivalents of GnRH are used clinically.

**Prolactin-releasing factor** is active during lactation after childbirth. **Prolactin-inhibitory factor (PIF)** is active at times other than during lactation.

## Anterior Pituitary Hormones

The anterior pituitary gland produces seven hormones. Two of these, GH and prolactin, act directly on their target tissues; the other five act indirectly by stimulating target tissues to produce other hormones.

**Corticotropin**, also called ACTH, stimulates the adrenal cortex to produce corticosteroids. Secretion is controlled by the hypothalamus and by plasma levels of cortisol, the major corticosteroid. A negative feedback mechanism inhibits the release of cortisol when plasma levels are adequate for body needs. Corticotropin is less predictable and less convenient than glucocorticoids and therefore has no apparent advantages.

**GH**, also called *somatotropin*, stimulates growth of body tissues. It regulates cell division and protein synthesis required for normal growth and promotes an increase in cell size and number, including growth of muscle cells and lengthening of bone. These effects occur mainly via altered metabolism of carbohydrate, protein, and fat by direct and indirect effects. GH is often considered an insulin antagonist because it suppresses the abilities of insulin to stimulate uptake of glucose in peripheral tissues and enhance glucose synthesis in the liver. Paradoxically, administration of GH produces hyperinsulinemia by stimulating insulin secretion. In addition, GH stimulates protein anabolism in many tissues. The hormone also enhances fat utilization by stimulating triglyceride breakdown and oxidation in fat-storing cells.

Levels of GH rise rapidly during adolescence, peak in the 20s, and then start to decline. Deficient GH in children produces *dwarfism*, a condition marked by severely decreased linear growth and, frequently, severely delayed mental, emotional, dental, and sexual growth as well. If untreated, excessive GH in preadolescents produces gigantism, resulting in heights of eight or nine feet.

In adults, deficient GH (less than expected for age) can cause increased fat, reduced skeletal and heart muscle mass, reduced strength, reduced ability to exercise, and worsened cholesterol levels (i.e., increased low-density lipoprotein cho-

lesterol and decreased high-density lipoprotein cholesterol), which increase risk factors for cardiovascular disease. Excessive GH in adults produces *acromegaly*, a chronic disease characterized by an abnormal pattern of bone and connective-tissue growth associated with an increased incidence of diabetes mellitus and hypertension.

**Thyrotropin** (also called TSH) regulates secretion of thyroid hormones. Thyrotropin secretion is controlled by a negative feedback mechanism in proportion to metabolic needs. Thus, increased thyroid hormones in body fluids inhibit secretion of thyrotropin by the anterior pituitary and of TRH by the hypothalamus.

**FSH**, one of the gonadotropins, stimulates functions of sex glands. FSH is produced by the anterior pituitary gland of both sexes, beginning at puberty. It acts on the ovaries in a cyclical fashion during the reproductive years, stimulating growth of ovarian follicles. These follicles then produce estrogen, which prepares the endometrium for implantation of a fertilized ovum. FSH acts on the testes to stimulate the production and growth of sperm (spermatogenesis), but it does not stimulate secretion of male sex hormones.

**LH** (also called interstitial cell-stimulating hormone) is another gonadotropin that stimulates hormone production by the gonads of both sexes. In women, LH is important in the maturation and rupture of the ovarian follicle (ovulation). After ovulation, LH acts on the cells of the collapsed follicular sac to produce the corpus luteum, which then produces progesterone during the last half of the menstrual cycle. When blood progesterone levels rise, a negative feedback effect is exerted on hypothalamic and anterior pituitary secretion of gonadotropins. Decreased pituitary secretion of LH causes the corpus luteum to die and stop producing progesterone. Lack of progesterone causes slough and discharge of the endometrial lining as menstrual flow. (Of course, if the ovum has been fertilized and attached to the endometrium, menstruation does not occur.) In men, LH stimulates the Leydig's cells in the spaces between the seminiferous tubules to secrete androgens, mainly testosterone.

**Prolactin** plays a part in milk production by nursing mothers. It is not usually secreted in nonpregnant women because of the hypothalamic hormone PIF. During late pregnancy and lactation, various stimuli, including suckling, inhibit the production of PIF, and thus prolactin is synthesized and released.

**Melanocyte-stimulating hormone (MSH)** plays a role in skin pigmentation and has recently been found to play important roles in feeding and energy metabolism as well as in inflammation. Recently, MSH, particularly gamma-MSH, has been linked to cardiovascular regulation and sodium metabolism.

## Posterior Pituitary Hormones

The posterior pituitary gland stores and releases two hormones that are synthesized by nerve cells in the hypothalamus.

**Antidiuretic hormone (ADH)**, also called vasopressin, functions to regulate water balance. When ADH is secreted, it makes renal tubules more permeable to water. This allows water in renal tubules to be reabsorbed into the plasma and

so conserves body water. In the absence of ADH, little water is reabsorbed, and large amounts are lost in the urine.

ADH is secreted when body fluids become concentrated (high amounts of electrolytes in proportion to the amount of water) and when blood volume is low. In the first instance, ADH causes reabsorption of water, dilution of extracellular fluids, and restoration of normal osmotic pressure. In the second instance, ADH raises blood volume and arterial blood pressure toward homeostatic levels.

**Oxytocin** functions in childbirth and lactation. It initiates uterine contractions at the end of gestation to induce childbirth, and it causes milk to move from breast glands to nipples so the infant can obtain the milk by suckling.

## Individual Drugs

Although hypothalamic hormones and pituitary hormones have few therapeutic uses, they have important functions when used in certain circumstances, and drug formulations of most hormones have been synthesized. Selected drugs are described below. Indications for use, routes, and dosage ranges are listed in Table 22-1.

### Hypothalamic Hormones

**Goserelin** (Zoladex), **histrelin** (Vantas), **leuprolide** (Lupron), **nafarelin** (Synarel), and **triptorelin** (Trelstar) are equivalent

to GnRH. After initial stimulation of LH and FSH secretion, chronic administration of therapeutic doses inhibits gonadotropin secretion. This action results in decreased production of testosterone and estrogen, which is reversible when administration is stopped. In males, testosterone is reduced to castrate levels. In premenopausal females, estrogens are reduced to postmenopausal levels. These effects occur within 2 to 4 weeks after drug therapy is begun. In children with central precocious puberty, gonadotropins (testosterone in males; estrogen in females) are reduced to prepubertal levels.

These GnRH equivalents cannot be given orally, because they would be destroyed by enzymes in the GI tract. Most are given by injection and are available in depot preparations that can be given once monthly or less often. Adverse effects are basically those of testosterone or estrogen deficiency. When given for prostate cancer, the drugs may cause increased bone pain and increased difficulty in urinating during the first few weeks of treatment. The drugs may also cause or aggravate depression.

**Octreotide** (Sandostatin) has pharmacologic actions similar to those of somatostatin. Indications for use include acromegaly, in which the drug reduces blood levels of GH and insulin-like growth factor-1 (IGF-1); carcinoid tumors, in which it inhibits diarrhea and flushing; and vasoactive intestinal peptide tumors, in which it relieves diarrhea (by decreasing GI secretions and motility). It is also used to treat diarrhea in acquired immunodeficiency syndrome (AIDS) and other

Table 22-1

Drugs at a Glance: Hypothalamic and Pituitary Drugs

Generic/Trade name	Indications for use	ROUTES AND DOSAGE RANGES	
		Adults	Children
<b>Hypothalamic Hormones</b>			
<b>Goserelin</b> (Zoladex)	Endometriosis Metastatic breast cancer Prostate cancer	Sub-Q implant into upper abdominal wall, 3.6 mg every 28 days or 10.8 mg every 3 mo	
<b>Histrelin</b> (Vantas; Supprelin LA)	Palliative treatment of advanced prostate cancer (Vantas) CPR (Supprelin LA) in children	1 implant Sub-Q q 12 mo	Supprelin LA, Implant Sub-Q q 12 mo
<b>Leuprolide</b> (Lupron)	Advanced prostatic cancer CPP in children Endometriosis Uterine fibroid tumors	Endometriosis, uterine fibroids, IM depot injection, 3.75 mg every mo or 11.25 mg every 3 mo for 6 mo Prostate cancer, Sub-Q 1 mg daily; IM depot 7.5 mg every mo, 22.5 mg every 3 mo, or 30 mg every 4 mo; implant (Viadur) one (72 mg) every 12 mo	CPP, Sub-Q 50 mcg/kg/d; IM Depot-Ped, weight 25 kg or less, 7.5 mg; more than 25 to 37.5 kg, 11.25 mg; more than 37.5 kg, 15 mg every mo

<b>ROUTES AND DOSAGE RANGES</b>			
<b>Generic/Trade name</b>	<b>Indications for use</b>	<b>Adults</b>	<b>Children</b>
<b>Nafarelin</b> (Synarel)	Endometriosis CPP in children	1 spray (200 mcg) in one nostril in the morning and 1 spray in the other nostril in the evening (400 mcg/d), starting between the 2nd and 4th days of the menstrual cycle	2 sprays (400 mcg) in each nostril morning and evening (1600 mcg/d), until resumption of puberty is desired
<b>Octreotide</b> (Sandostatin; LAR Depot [long-acting])	Acromegaly Carcinoid tumors Vasoactive intestinal peptide tumors Diarrhea	Acromegaly, Sub-Q 50–100 mcg 3 times daily; long-acting: 100–200 mcg 3 times daily, may be adjusted up to 500 mcg 3 times daily  Carcinoid tumors, Sub-Q 100–600 mcg daily (average 300 mcg) in 2–4 divided doses  Intestinal tumors, Sub-Q 200–300 mcg daily in 2–4 divided doses  Diarrhea, IV, Sub-Q 50 mcg 2 or 3 times daily initially, then adjusted according to response	Dosage not established but 1–10 mcg/kg reportedly well tolerated in young clients
<b>Triptorelin</b> (Trelstar)	Advanced prostatic cancer	3.75 mg depot injection IM	
<b>Anterior Pituitary Hormones</b>			
<b>Corticotropin</b> (Acthrel; HP Acthar Gel)	Stimulate synthesis of hormones by the adrenal cortex  Diagnostic test of adrenal function  Treatment of acute exacerbation of multiple sclerosis	Diagnostic use, IM Sub-Q up to 80 units as a single injection. HP Acthar Gel, IM or Sub-Q 40–80 units q24–72  IM 80–120 units daily for 2–3 wk	
<b>Cosyntropin</b> (Cortrosyn)	Diagnostic test in suspected adrenal insufficiency	IM, IV 0.25 mg (equivalent to 25 units ACTH)	older than 2 y: same as adult dose under 2 y: IM, IV 0.125 mg
<b>Growth hormone: Somatrem</b> <b>Somatropin</b> (Genotropin, Humatrope, Norditropin, Nutropin, Serostim)	Promote growth in children whose growth is impaired by a deficiency of endogenous growth hormone		<b>Somatrem</b> , IM up to 0.1 mg/kg 3 times per wk <b>Somatropin</b> , IM up to 0.06 mg/kg 3 times per wk
<b>HCG</b> (Chorex, Choron, Pregnyl)	Cryptorchidism Induce ovulation in the treatment of infertility	Cryptorchidism and male hypogonadism, IM 500–4000 units 2–3 times per wk for several wk  To induce ovulation, IM 5000–10,000 units in 1 dose, 1 d after treatment with menotropins	<b>Preadolescent boys:</b> Cryptorchidism and hypogonadism, IM 500–4000 units 2–3 times per wk for several wk
<b>Choriogonadotropin alpha</b> (Ovidrel)	Induce ovulation in the treatment of infertility	250 mcg Sub-Q in 1 dose, 1 d after treatment with menotropins	
<b>Follitropin alfa</b> (Gonal-F, Gonal-F RFF pen)	Stimulate ovulation	Sub-Q 75 IU of FSH to maximum daily dose of 300 IU  Prefilled pen: 300–900 IU IV of FSH as individualized dosage	

(continued on page 350)

Table 22-1

**Drugs at a Glance: Hypothalamic and Pituitary Drugs** (continued)

Generic/Trade name	Indications for use	ROUTES AND DOSAGE RANGES	
		Adults	Children
<b>Follitropin beta</b> (Follistim)	Stimulate ovulation	Sub-Q 75 IU of FSH to maximum daily dose of 300 IU	
<b>Menotropins</b> (Pergonal)	Combined with HCG to induce ovulation in treatment of infertility caused by lack of pituitary gonadotropins	IM 1 ampule (75 units FSH and 75 units LH) daily for 9–12 d, followed by HCG to induce ovulation	
<b>Pegvisomant</b> (Somavert)	Acromegaly unresponsive to other management strategies	Load: 40 mg Sub-Q Maintenance: 10 mg Sub-Q; titrate by 5 mg increments q4–6 wk according to IGF-1 levels to maximum of 30 mg/d	
<b>Thyrotropin alfa</b> (Thyrogen)	Diagnostic test of thyroid function	IM 0.9 mg every 24 h for 2 doses or every 72 h for 3 doses	<i>under 16 y</i> : Dosage not established
<b>Urofollitropin</b> (Bravelle)	Stimulate ovulation	Sub-Q 150 IU of FSH daily for the first 5 d to maximum daily dose of 450 IU	
<b>Posterior Pituitary Hormones</b>			
<b>Desmopressin</b> (DDAVP, Stimate)	Neurogenic diabetes insipidus Hemostasis (parenteral only) in spontaneous, trauma-induced, and perioperative bleeding	Diabetes insipidus, intranasally 0.1–0.4 mL/d, usually in 2 divided doses Hemophilia A, von Willebrand's disease, IV 0.3 mcg/kg in 50 mL sterile saline, infused over 15–30 min	<i>3 mo–2 y</i> : Diabetes insipidus, intranasally 0.05–0.3 mL/d in 1–2 doses <i>Weight more than 10 kg</i> : Hemophilia A, von Willebrand's disease, same as adult dosage <i>Weight 10 kg or less</i> : Hemophilia A, von Willebrand's disease, IV 0.3 mcg/kg in 10 mL of sterile saline
<b>Vasopressin</b> (Pitressin)	Diabetes insipidus	IM, Sub-Q, intranasally on cotton pledgets, 0.25–0.5 mL (5–10 units) 2–3 times daily	IM, Sub-Q, intranasally on cotton pledgets, 0.125–0.5 mL (2.5–10 units) 3–4 times daily
<b>Oxytocin</b> (Pitocin)	Induce labor Control postpartum bleeding	Induction of labor, IV 1-mL ampule (10 units) in 1000 mL of 5% dextrose injection (10 units/1000 mL = 10 milliunits/mL), infused at 0.2–2 milliunits/min initially, then regulated according to frequency and strength of uterine contractions Prevention or treatment of postpartum bleeding, IV 10–40 units in 1000 mL of 5% dextrose injection, infused at 125 mL/h (40 milliunits/min) or 0.6–1.8 units (0.06–0.18 mL) diluted in 3–5 mL sodium chloride injection and injected slowly; IM 0.3–1 mL (3–10 units)	

ACTH, adrenocorticotropic hormone; CPP, central precocious puberty; FSH, follicle-stimulating hormone; HCG, human chorionic gonadotropin; IGF-1, insulin-like growth factor-1; LH, luteinizing hormone.

conditions. The drug is most often given subcutaneously and may be self-administered. The long-acting formulation (Sandostatin LAR Depot) must be given intramuscularly in a gluteal muscle. Dosage should be reduced for older adults.

## Anterior Pituitary Hormones

**Corticotropin** (ACTH, Acthar Gel), which is obtained from animal pituitary glands, is mainly of historical interest. For therapeutic purposes, it has been replaced by adrenal corticosteroids. It may be used occasionally as a diagnostic test to differentiate primary adrenal insufficiency (Addison's disease, which is associated with atrophy of the adrenal gland) from secondary adrenal insufficiency caused by inadequate pituitary secretion of corticotropin. However, **cosyntropin** (Cortrosyn), a synthetic formulation, is more commonly used to test for suspected adrenal insufficiency.

**Growth hormone** is synthesized from bacteria by recombinant DNA technology. **Somatropin** (e.g., Humatrope) is therapeutically equivalent to endogenous GH produced by the pituitary gland. The main clinical use of GH is for children whose growth is impaired by a deficiency of endogenous hormone. The drugs are ineffective when impaired growth results from other causes or after puberty, when epiphyses of the long bones have closed. GH is also used to treat short stature in children that is associated with chronic renal failure or Turner's syndrome (a genetic disorder that occurs in girls). In adults, the drugs may be used to treat deficiency states (e.g., those caused by disease, surgery, or radiation of the pituitary gland) or the tissue wasting associated with AIDS. In general, dosage should be individualized according to response. Excessive administration can cause gigantism.

**Human chorionic gonadotropin** (HCG; e.g., Chorex) produces physiologic effects similar to those of naturally occurring LH. In males, it is used to evaluate the ability of Leydig's cells to produce testosterone, to treat hypogonadism due to pituitary deficiency, and to treat cryptorchidism (undescended testicle) in preadolescent boys. In women, recombinant HCG **choriogonadotropin alpha** (Ovidrel) is used in combination with menopins to induce ovulation in the treatment of infertility. Excessive doses or prolonged administration can lead to sexual precocity, edema, and breast enlargement caused by oversecretion of testosterone and estrogen.

**Menotropins** (Pergonal), a gonadotropin preparation obtained from the urine of postmenopausal women, contains both FSH and LH. It is usually combined with HCG to induce ovulation in the treatment of infertility caused by lack of pituitary gonadotropins.

**Pegvisomant** (Somavert) is a GH receptor antagonist used in the treatment of acromegaly in adults who are unable to tolerate or are resistant to other management strategies. The drug selectively binds to GH receptors, blocking the binding of endogenous GH. In general, dosage should be individualized according to response. Dosage reduction of hypoglycemic agents may be required because the drug may increase glucose

tolerance. Increased dosages of pegvisomant may be necessary when administered with narcotics. The drug should be used with caution in the elderly and in people with renal or hepatic disease.

**Thyrotropin alfa** (Thyrogen) is a synthetic formulation of TSH used as a diagnostic adjunct for serum thyroglobulin (Tg) testing in individuals with well-differentiated thyroid cancer. The testing can be performed with or without radioiodine imaging. Because there is a risk of missing the diagnosis of thyroid cancer or predicting the extent of the disease, thyroid hormone withdrawal Tg testing radioactive imaging is the standard test for evaluating the presence, extent, and location of thyroid cancer. Thyrotropin alfa must be used cautiously in patients with coronary artery disease and with a large amount of residual thyroid tissue as the drug produces a temporary rise of thyroid hormone concentration in the blood.

**Urofollitropin** (Bravelle), **follitropin alfa** (Gonal-F), and **follitropin beta** (Follistim) are drug preparations of FSH. These drugs are used to stimulate ovarian function in the treatment of infertility and are used sequentially with HCG. Urofollitropin is extracted from the urine of postmenopausal women and acts directly on the ovaries to stimulate follicular ovulation. The development of follitropin alfa and follitropin beta as recombinant products advances the treatment of infertility, appears to be well tolerated, and has similar efficacy. A new liquid formulation of follitropin alfa (Gonal-F RFF Pen) is available in a prefilled and ready-to-use multidose FSH injection.

## Posterior Pituitary Hormones

**Desmopressin** (DDAVP, Stimate) and vasopressin (Pitressin) are synthetic equivalents of ADH. A major clinical use is the treatment of neurogenic diabetes insipidus, a disorder characterized by a deficiency of ADH and the excretion of large amounts of dilute urine. Diabetes insipidus may be idiopathic, hereditary, or acquired as a result of trauma, surgery, tumor, infection, or other conditions that impair the function of the hypothalamus or posterior pituitary.

Parenteral desmopressin is also used as a hemostatic in patients with hemophilia A or mild to moderate von Willebrand's disease (type 1). The drug is effective in controlling spontaneous or trauma-induced bleeding and intraoperative and postoperative bleeding when given 30 minutes before the procedure. Vasopressin is also used in the treatment of bleeding esophageal varices because of its vasoconstrictive effects. Desmopressin may be inhaled intranasally; vasopressin must be injected.

**Oxytocin** (Pitocin) is a synthetic drug that exerts the same physiologic effects as the posterior pituitary hormone. Thus, it promotes uterine contractility and is used clinically to induce labor and in the postpartum period to control bleeding. Oxytocin must be used only when clearly indicated and when the recipient can be supervised by well-trained personnel, as in a hospital.

## Applying Your Knowledge 22-1

### How Can You Avoid This Medication Error?

The nurse prepares Mr. Rojas' medication and administers 0.2 mL of desmopressin intranasally.

## Nursing Process

### Assessment

Assess for disorders for which hypothalamic and pituitary hormones are given.

- For children with impaired growth, assess height and weight (actual and compared with growth charts) and diagnostic radiographic reports of bone age.
- For patients with diabetes insipidus, assess baseline blood pressure, weight, ratio of fluid intake to urine output, urine specific gravity, and laboratory reports of serum electrolytes.
- For patients with diarrhea, assess the number and consistency of stools per day as well as hydration status.
- For patients with infertility, assess drug-specific adverse effects (dizziness, nausea, headache and abdominal cramps, hot flashes/flushes, ovarian enlargement, blurring of vision and other visual symptoms).

### Nursing Diagnoses

- Deficient Knowledge: Drug administration and effects
- Altered Growth and Development
- Anxiety related to multiple injections
- Risk for Injury: Adverse drug effects
- Ineffective Coping related to frustration with difficulty with conception

### Planning/Goals

The patient will

- Experience relief of symptoms without serious adverse effects
- Take or receive the drug accurately
- Comply with procedures for monitoring and follow-up
- Cope effectively and acknowledge feelings of grief, disappointment, and failure

### Interventions

- For children receiving GH, help the family set reasonable goals for increased height and weight and comply with accurate drug administration and follow-up procedures (e.g., periodic radiographs to determine bone growth and progress toward epiphyseal closure; recording

height and weight at least weekly). Patient Guidelines for Growth Hormone are given in the accompanying display.

- For patients with diabetes insipidus, help them develop a daily routine to monitor their response to drug therapy (e.g., weigh themselves; monitor fluid intake and urine output for approximately equal amounts; check urine specific gravity [should be at least 1.015] and replace fluids accordingly).
- For patients with infertility, reinforce teaching about potential risks and benefits of drug therapy and about proper self-administration techniques of preparation, injection, and disposal of medication and supplies. Educate about evaluating basal body temperature patterns and continuing medical supervision as long as the drugs are being taken, and alert the couple about the risk of multiple births. Refer to local support groups, and acknowledge feelings of grief, disappointment, and failure. Patient Guidelines for Fertility Drugs are given in the accompanying display.

### Evaluation

- Interview and observe for compliance with instructions for taking the drug(s).
- Observe for relief of symptoms for which pituitary hormones were prescribed.
- Observe for effective coping with the underlying condition and the effects of treatment.

## Applying Your Knowledge 22-2

What nursing measures should be implemented to appropriately monitor Mr. Rojas?

## Principles of Therapy

Hypothalamic hormones and pituitary hormones have few therapeutic uses. Most hypothalamic hormones are used to diagnose pituitary insufficiency. Pituitary hormones are not used extensively because most conditions in which they are indicated are uncommon, other effective agents are available for some uses, and deficiencies of target-gland hormones (e.g., corticosteroids, thyroid hormones, male or female sex hormones) are usually more effectively treated with those hormones than with anterior pituitary hormones that stimulate their secretion. However, the hormones perform important functions when used in particular circumstances, and drug formulations of most hormones have been synthesized for these purposes.

Because the hormones are proteins, they must be given by injection or nasal inhalation. If taken orally, the hormones would be destroyed by the proteolytic enzymes in the GI tract.

## Hypothalamic Hormones

Hypothalamic hormones are rarely used in most clinical practice settings. The drugs should be prescribed by health care providers who are knowledgeable about endocrinology and should be administered according to the manufacturers' literature.

### Applying Your Knowledge 22-3

The nurse returns to Mr. Rojas' room to assess the patient. Mr. Rojas has an elevated blood pressure of 190/100. His sodium level is low, at 117 mEq/L, and his urine osmolality is below normal. How do you respond?

## Pituitary Hormones

Most drug therapy with pituitary hormones is given to replace or supplement naturally occurring hormones in situations involving inadequate function of the pituitary gland (hypopituitarism). Conditions resulting from excessive amounts of pituitary hormones (hyperpituitarism) are more often treated with surgery or radiation. Diagnosis of suspected pituitary disorders should be thorough to promote more effective treatment, including drug therapy. Dosage of all pituitary hormones must be individualized, because the responsiveness of affected tissues varies.

## Toxicity: Abuse of Growth Hormone

Inappropriate use of GH is an increasing concern. Young athletes may use the drug for bodybuilding and to enhance athletic performance. If so, they are likely to use relatively high doses. In addition, the highest levels of physiologic hormone are secreted during adolescence. The combination of high pharmacologic and high physiologic amounts increases risks of health problems from excessive hormone. Also, there is little

evidence that hormone use increases muscle mass or strength beyond that achieved with exercise alone.

Middle-aged and older adults may use GH to combat the effects of aging, such as decreased energy, weaker muscles and joints, and wrinkled skin. One source of the product is apparently "anti-aging" clinics. Although it is not illegal for health care providers to prescribe GH for these populations, such use is unproven in safety and effectiveness. Endocrinologists emphasize that optimal adult levels of GH are unknown, and use of GH to slow aging is unproven and potentially dangerous because the long-term effects are unknown.

Possible adverse effects associated with GH, especially with high doses or chronic use, include acromegaly, diabetes, hypertension, and increased risk of serious cardiovascular disease (e.g., heart failure). There is also concern about a possible link between GH, which stimulates tumor growth, and cancer. GH stimulates the release of IGF-1 (also called somatomedin), a substance that circulates in the blood and stimulates cell division. Most tumor cells have receptors that recognize IGF-1, bind it, and allow it to enter the cell, where it could trigger uncontrolled cell division. This concern may be greater for middle-aged and older adults, because malignancies are more common in these groups than in adolescents and young adults.

### Applying Your Knowledge 22-4

#### Legal/Ethical Dilemma

During his stay, Mr. Rojas' family comes to visit him often. You meet his mother and his two younger brothers. After one of their visits, Mr. Rojas confides that Juan, age 13, is taking GH because he is in the 35th height percentile for his age. His other brother, Miguel, age 15, plays basketball and wants to be taller. Miguel has convinced his brother Juan to share his drug with him. What action should you take and why?

## Patient Teaching Guidelines

## Growth Hormone

### General Considerations

- Growth hormone (GH) is taken to normalize growth and development in children with a GH deficiency, not for people merely desiring an increase in stature. The drugs are contraindicated in children after epiphyseal closure occurs.
- GH is taken until a satisfactory height has been achieved, epiphyseal closure occurs, or until no further stimulation of growth occurs.
- Periodic tests of growth curve, bone age, serum glucose levels, thyroid function, and somatomedin levels are necessary, as well as fundoscopic eye examinations.
- Children who have GH deficiency may develop slipped capital femoral epiphysis more frequently, and those with scoliosis may see a progression of the condition.

### Self-Administration

- Take GH only if prescribed and as prescribed.
- Continue with medical supervision as long as GH is being taken.
- Ask a health care provider if you are uncertain about how to administer GH.
- Report severe hip or knee pain or the development of a limp to the prescriber immediately, because this may indicate slipped capital femoral epiphysis. In addition, report any signs of severe headache or acute visual changes, because they may indicate the complication of increased intracranial pressure.

## Patient Teaching Guidelines Fertility Drugs

### General Considerations

- Fertility drugs stimulate ovulation and fertility. Pregnancy typically may occur within 4–6 weeks of therapy.
- These drugs are contraindicated in pregnant women. If pregnancy is suspected, the drugs should be discontinued, and the physician who prescribed them should be notified.
- These drugs should not be used by women who are breast-feeding or by children.
- In many cases, couples who are infertile experience feelings of grief, disappointment, and failure. Often they can benefit from participation in local support groups.

### Self-Administration

- Take fertility drugs only if prescribed and as prescribed.
- Continue with medical supervision as long as the drugs are being taken.
- Ask the health care provider if you are uncertain about how the drug is administered; proper use of infusion devices; and how to monitor basal body temperature patterns.
- Monitor ovulation and discontinue the drug, if instructed, when ovulation is suspected.
- Recognize that the risk of multiple births is increased with the use of these drugs.
- Report adverse effects, such as dizziness, nausea, headache and abdominal cramps, hot flashes/flushes, and blurring of vision and other visual symptoms.
- For maximum desired response, have intercourse daily beginning the day before human chorionic gonadotropin therapy until ovulation occurs.

## Nursing Actions Hypothalamic and Pituitary Hormones

### NURSING ACTIONS

#### 1. Administer accurately

- a. Read the manufacturer's instructions and drug labels carefully before drug preparation and administration.

#### 2. Observe for therapeutic effects

- a. With goserelin and related drugs, observe for ovulation or decreased symptoms of endometriosis and absence of menstruation.
- b. With corticotropin, therapeutic effects stem largely from increased secretion of adrenal cortex hormones, especially the glucocorticoids, and include anti-inflammatory effects (see Chap. 23).
- c. With chorionic gonadotropin, menotropins, follitropin alpha, and follitropin beta given in cases of female infertility, ovulation and conception are therapeutic effects.
- d. With chorionic gonadotropin given in cryptorchidism, the therapeutic effect is descent of the testicles from the abdomen to the scrotum.
- e. With growth hormone, observe for increased skeletal growth and development.
- f. With antidiuretics (desmopressin and vasopressin), observe for decreased urine output, increased urine specific gravity, decreased signs of dehydration, decreased thirst.
- g. With oxytocin given to induce labor, observe for the beginning or the intensifying of uterine contractions.
- h. With oxytocin given to control postpartum bleeding, observe for a firm uterine fundus and decreased vaginal bleeding.
- i. With octreotide given for diarrhea, observe for decreased number and fluidity of stools.

#### 3. Observe for adverse effects

- a. With goserelin, observe for headache, nausea, lightheadedness, and local edema, pain, and pruritus after subcutaneous injections.

### RATIONALE/EXPLANATION

These hormone preparations are given infrequently and often require special techniques of administration.

Therapeutic effects vary widely, depending on the particular pituitary hormone given and the reason for use.

Therapeutic effects depend on the reason for use. Note that different formulations are used to stimulate ovulation and treat endometriosis.

Corticotropin is usually not recommended for the numerous nonendocrine inflammatory disorders that respond to glucocorticoids. Administration of glucocorticoids is more convenient and effective than administration of corticotropin.

Indicated by appropriate increases in height and weight

These effects indicate control of diabetes insipidus.

Octreotide is often used to control diarrhea associated with a number of conditions.

Systemic reactions occur infrequently.

**NURSING ACTIONS**

- b. With corticotropin, observe for sodium and fluid retention, edema, hypokalemia, hyperglycemia, osteoporosis, increased susceptibility to infection, myopathy, behavioral changes.
- c. With human chorionic gonadotropin given to preadolescent boys, observe for sexual precocity, breast enlargement, and edema.
- d. With growth hormone, observe for mild edema, headache, localized muscle pain, weakness, and hyperglycemia.
- e. With menotropins, observe for symptoms of ovarian hyperstimulation, such as abdominal discomfort, weight gain, ascites, pleural effusion, oliguria, and hypotension.
  
- f. With desmopressin, observe for headache, nasal congestion, nausea, and increased blood pressure. A more serious adverse reaction is water retention and hyponatremia.
- g. With pegvisomant, observe for pain, injection site reaction, nausea, flu syndrome, and diarrhea.
- h. With vasopressin, observe for water intoxication; chest pain, myocardial infarction, increased blood pressure; abdominal cramps, nausea, and diarrhea.
- i. With oxytocin, observe for excessive stimulation or contractility of the uterus, uterine rupture, and cervical and perineal lacerations.
- j. With octreotide, observe for dysrhythmias, bradycardia, diarrhea, headache, hyperglycemia, injection-site pain, and symptoms of gallstones.
- k. With triptorelin, observe for hot flushes, skeletal pain, impotence, headache, and hypertension.

**4. Observe for drug interactions**

- a. Drugs that *increase* effects of vasopressin:
  - (1) General anesthetics, chlorpropamide (Diabinese)
- b. Drug that *decreases* effects of vasopressin:
  - (1) Lithium
- c. Drugs that *increase* effects of oxytocin:
  - (1) Estrogens
  
  - (2) Vasoconstrictors or vasopressors (e.g., ephedrine, epinephrine, norepinephrine)

**RATIONALE/EXPLANATION**

These adverse reactions are in general the same as those produced by adrenal cortex hormones. Severity of adverse reactions tends to increase with dosage and duration of corticotropin administration.

Sexual precocity results from stimulation of excessive testosterone secretion at an early age.

Adverse effects are not common. Another adverse effect may be development of antibodies to the drug, but this does not prevent its growth-stimulating effects.

Adverse effects can be minimized by frequent pelvic examinations to check for ovarian enlargement and by laboratory measurement of estrogen levels. Multiple gestation (mostly twins) is a possibility and is related to ovarian overstimulation.

Adverse reactions usually occur only with high dosages and tend to be relatively mild. Water intoxication (headache, nausea, vomiting, confusion, lethargy, coma, convulsions) may occur with any antidiuretic therapy if excessive fluids are ingested.

Adverse effects are usually mild or occur infrequently.

With high doses, vasopressin constricts blood vessels, especially coronary arteries, and stimulates smooth muscle of the gastrointestinal tract. Special caution is necessary in clients with heart disease, asthma, or epilepsy.

Severe adverse reactions are most likely to occur when oxytocin is given to induce labor and delivery.

These are more common effects, especially in those receiving octreotide for acromegaly.

Adverse reactions due to decreased levels of LH and FSH

Potentiate vasopressin

Inhibits the renal tubular reabsorption of water normally stimulated by vasopressin

With adequate estrogen levels, oxytocin increases uterine contractility. When estrogen levels are low, the effect of oxytocin is reduced.

Severe, persistent hypertension with rupture of cerebral blood vessels may occur because of additive vasoconstrictor effects. This is a potentially lethal interaction and should be avoided.

**Key Concepts**

- The hypothalamus and the pituitary gland interact to control most metabolic functions of the body and to maintain homeostasis.
- The anterior pituitary gland produces seven hormones: 6H, ACTH, TSH, FSH, LH, MSH, and prolactin.
- The posterior pituitary gland stores and releases two hormones that are synthesized by nerve cells in the hypothalamus: ADH and oxytocin.
- Antidiuretic hormone (ADH), also called vasopressin, functions to regulate water balance.

## Review and Application Exercises

### Short Answer Exercises

1. What hormones are secreted by the hypothalamus and pituitary, and what are their functions?
2. What are the functions and clinical uses of ADH and GH?
3. What are adverse effects of the hypothalamic and pituitary hormones used in clinical practice?

### NCLEX-Style Questions

4. Because growth hormone (GH) is an insulin antagonist, administration of GH to a person with type 1 diabetes mellitus may result in which of the following?
  - a. hyperglycemia
  - b. an increase in insulin production
  - c. a decreased need for insulin
  - d. no significant effect
5. The father of an 11-year-old boy is concerned because his son is shorter than his friends. He asks the nurse whether the boy should be taking GH so that he can be competitive when playing basketball in middle school. Both of the boy's parents are of short stature. Which of the following is the best response on the part of the nurse?
  - a. "The treatment is very expensive so we need to check and see if your insurance will cover it."
  - b. "Don't worry; many basketball players who are short in stature are successful."
  - c. "Short stature is not the only requirement for treatment with GH. Let's spend some time discussing the assessment that is being done to determine your son's need for GH."
  - d. "GH will not increase your child's stature, because you and your wife are also very short."
6. Your patient has an IV order for cosyntropin (Cortrosyn) and asks why he is to be given this medication. You explain that it is not a treatment but is commonly used to test for which of the following conditions?
  - a. hypothalamic dysfunction
  - b. thyroid cancer
  - c. pituitary dysfunction
  - d. adrenal insufficiency
7. A patient taking high doses of vasopressin has a blood pressure of 188/96 mm Hg and complains of abdominal cramps, nausea, and diarrhea. The nurse contacts the prescribing provider and recognizes that these GI symptoms result from which of the following conditions?
  - a. smooth-muscle stimulation of the GI tract
  - b. neurologic toxicity
  - c. gastroparesis
  - d. drug interaction with a nutrient

# Corticosteroids

## KEY TERMS

- Addison's disease
- Addisonian crisis
- Adrenocortical insufficiency
- Aldosterone
- Corticosteroids
- Cortisol
- Cushing's disease
- Glucocorticoids
- Immunosuppression
- Mineralocorticoids
- Negative feedback mechanism
- Steroids

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Review physiologic effects of endogenous corticosteroids.
2. Discuss clinical indications for use of exogenous corticosteroids.
3. Differentiate between physiologic and pharmacologic doses of corticosteroids.
4. Differentiate between short-term and long-term corticosteroid therapy.
5. Recognize at least 10 adverse effects of long-term corticosteroid therapy.
6. Explain the pathophysiologic basis of adverse drug effects.
7. Examine the potential benefits for administering corticosteroids topically when possible rather than systemically.
8. Analyze the use other drugs and interventions to decrease the need for corticosteroids.
9. Discuss the use of corticosteroids in selected populations and conditions.
10. Apply the nursing process with a patient receiving long-term systemic corticosteroid therapy, including teaching needs.

## Applying Your Knowledge

Sue Hubble is a 70-year-old African-American woman. She is 5 feet 9 inches tall and weighs 275 pounds. She has type 2 diabetes mellitus and, as a result of lifelong smoking, has been diagnosed with chronic obstructive pulmonary disease (COPD). In her home, she uses oxygen. In addition to her respiratory drugs and her drugs for diabetes, she has been taking prednisone 20 mg PO daily for the past month. You are Ms. Hubble's home care nurse.

## Introduction

Corticosteroids, also called *glucocorticoids* or *steroids*, are hormones produced by the adrenal cortex, part of the adrenal glands. These hormones affect almost all body organs and are extremely important in maintaining homeostasis when secreted in normal amounts. Disease results from inadequate or excessive secretion. Exogenous corticosteroids are used as drugs in a variety of disorders. Their use must be closely monitored, because they have profound therapeutic and adverse effects. To understand the effects of corticosteroids used as drugs (exogenous corticosteroids), it is necessary to understand the physiologic effects and other characteristics of the endogenous hormones.

## Secretion of Endogenous Corticosteroids

Corticosteroid secretion is controlled by the hypothalamus, the anterior pituitary, and adrenal cortex (the hypothalamic–pituitary–adrenal, or HPA, axis). Various stimuli (e.g., low plasma levels of corticosteroids, pain, anxiety, trauma, illness, anesthesia) activate the system. These stimuli cause the hypothalamus of the brain to secrete corticotropin-releasing hormone or factor (CRH or CRF), which stimulates the anterior pituitary gland to secrete corticotropin, and corticotropin then stimulates the adrenal cortex to secrete corticosteroids.

The rate of corticosteroid secretion is usually maintained within relatively narrow limits but changes according to need. When plasma corticosteroid levels rise to an adequate level, secretion of corticosteroids slows or stops. The mechanism by which the hypothalamus and anterior pituitary “learn” that no more corticosteroids are needed is called a *negative feedback mechanism*.

This negative feedback mechanism is normally very important, but it does not work during stress responses. The stress response activates the sympathetic nervous system (SNS) to produce more epinephrine and norepinephrine and the adrenal cortex to produce as much as 10 times the normal amount of cortisol. The synergistic interaction of these hormones increases the person’s ability to respond to stress. However, the increased SNS activity continues to stimulate cortisol production (the main glucocorticoids secreted as part of the body’s response to stress) and overrules the negative feedback mechanism. Excessive and prolonged corticosteroid secretion damages body tissues.

Corticosteroids are secreted directly into the bloodstream. *Cortisol* is approximately 90% bound to plasma proteins, and this high degree of protein binding slows cortisol movement out of the plasma, so that it has a relatively long plasma half-life of 60 to 90 minutes. The remaining 10% is unbound and biologically active. In contrast, aldosterone is only 60% bound to plasma proteins and has a short half-life of 20 minutes. In general, protein binding functions as a storage area from which the hormones are released as needed. This promotes more consistent blood levels and more uniform distribution to the tissues.

## Types of Endogenous Corticosteroids

The adrenal cortex produces approximately 30 steroid hormones, which are divided into glucocorticoids, mineralocorticoids, and adrenal sex hormones. Chemically, all corticosteroids are derived from cholesterol and have similar chemical structures. Despite their similarities, however, slight differences cause them to have different functions.

### Glucocorticoids

The term *corticosteroids* actually refers to all secretions of the adrenal cortex, but it is most often used to designate the glucocorticoids, which are important in metabolic, inflammatory, and immune processes. Glucocorticoids include cortisol, corticosterone, and cortisone. Cortisol accounts for at least 95% of glucocorticoid activity; corticosterone and cortisone accounts for a small amount of activity. Glucocorticoids are secreted cyclically, with the largest amount being produced in the early morning and the smallest amount during the evening hours (in people with a normal day–night schedule). At the cellular level, glucocorticoids account for most of the characteristics and physiologic effects of the corticosteroids (Box 23-1).

### Box 23-1

## Effects of Glucocorticoids on Body Processes and Systems

### Carbohydrate Metabolism

- ↑ Formation of glucose (gluconeogenesis) by breaking down protein into amino acids. The amino acids are then transported to the liver, where they are acted on by enzymes that convert them to glucose. The glucose is then returned to the circulation for use by body tissues or storage in the liver as glycogen.
- ↓ Cellular use of glucose, especially in muscle cells. This is attributed to a ↓ effect of insulin on the proteins that normally transport glucose into cells and by ↓ numbers and functional capacity of insulin receptors.
- Both the ↑ production and ↓ use of glucose promote higher levels of glucose in the blood (hyperglycemia) and may lead to diabetes mellitus. These actions also increase the amount of glucose stored as glycogen in the liver, skeletal muscles, and other tissues.

### Protein Metabolism

- ↑ Breakdown of protein into amino acids (catabolic effect); ↑ rate of amino acid transport to the liver and conversion to glucose

- ↓ Rate of new protein formation from dietary and other amino acids (antianabolic effect)
- The combination of ↑ breakdown of cell protein and ↓ protein synthesis leads to protein depletion in virtually all body cells except those of the liver. Thus, glycogen stores in the body are ↑ and protein stores are ↓.

### Lipid Metabolism

- ↑ Breakdown of adipose tissue into fatty acids; the fatty acids are transported in the plasma and used as a source of energy by body cells.
- ↑ Oxidation of fatty acids within body cells

### Inflammatory and Immune Responses

- ↓ Inflammatory response. Inflammation is the normal bodily response to tissue damage and involves three stages. First, a large amount of plasma-like fluid leaks out of capillaries into the damaged area and becomes clotted. Second, leukocytes migrate into the area. Third, tissue healing occurs, largely by growth of fibrous scar tissue. Normal or physiologic amounts of glucocorticoids probably do not

significantly affect inflammation and healing, but large amounts of glucocorticoids inhibit all three stages of the inflammatory process.

More specifically, corticosteroids stabilize lysosomal membranes (and thereby prevent the release of inflammatory proteolytic enzymes); ↓capillary permeability (and thereby ↓leakage of fluid and proteins into the damaged tissue); ↓the accumulation of neutrophils and macrophages at sites of inflammation (and thereby impair phagocytosis of pathogenic microorganisms and waste products of cellular metabolism); and ↓production of inflammatory chemicals, such as interleukin-1, prostaglandins, and leukotrienes, by injured cells.

- ↓Immune response. The immune system normally protects the body from foreign invaders, and several immune responses overlap inflammatory responses, including phagocytosis. In addition, the immune response stimulates the production of antibodies and activated lymphocytes to destroy the foreign substance. Glucocorticoids impair protein synthesis, including the production of antibodies; ↓the numbers of circulating lymphocytes, eosinophils, and macrophages; and ↓amounts of lymphoid tissue. These effects help to account for the immunosuppressive and antiallergic actions of the glucocorticoids.

#### Cardiovascular System

- Help to regulate arterial blood pressure by modifying vascular smooth muscle tone, by modifying myocardial contractility, and by stimulating renal mineralocorticoid and glucocorticoid receptors
- ↑The response of vascular smooth muscle to the pressor effects of catecholamines and other vasoconstrictive agents

↑, increase/increased; ↓, decrease/decreased.

#### Nervous System

- Physiologic amounts help to *maintain normal nerve excitability*; pharmacologic amounts ↓nerve excitability, slow activity in the cerebral cortex, and alter brain wave patterns.
- ↓Secretion of corticotropin-releasing hormone by the hypothalamus and of corticotropin by the anterior pituitary gland. This results in suppression of further glucocorticoid secretion by the adrenal cortex (negative feedback system).

#### Musculoskeletal System

- Maintain muscle strength when present in physiologic amounts but cause muscle atrophy (from protein breakdown) when present in excessive amounts
- ↓Bone formation and growth and ↑bone breakdown. Glucocorticoids also ↓intestinal absorption and ↑renal excretion of calcium. These effects contribute to bone demineralization (osteoporosis) in adults and to ↓linear growth in children.

#### Respiratory System

- Maintain open airways. Glucocorticoids do not have direct bronchodilating effects, but help to maintain and restore responsiveness to the bronchodilating effects of endogenous catecholamines, such as epinephrine.
- Stabilize mast cells and other cells to inhibit the release of bronchoconstrictive and inflammatory substances, such as histamine.

#### Gastrointestinal System

- ↓Viscosity of gastric mucus. This effect may ↓protective properties of the mucus and contribute to the development of peptic ulcer disease.

## Mineralocorticoids

Mineralocorticoids are a class of steroids that play a vital role in the maintenance of fluid and electrolyte balance through their influence on salt and water metabolism. *Aldosterone* is

the main mineralocorticoid and is responsible for approximately 90% of mineralocorticoid activity. Characteristics and physiologic effects of mineralocorticoids are summarized in Box 23-2.

### Box 23-2

### Effects of Mineralocorticoids on Body Processes and Systems

- The overall physiologic effects are to conserve sodium and water and eliminate potassium. Aldosterone increases sodium reabsorption from kidney tubules, and water is reabsorbed along with the sodium. When sodium is conserved, another cation must be excreted to maintain electrical neutrality of body fluids; thus, potassium is excreted. This is the only potent mechanism for controlling the concentration of potassium ions in extracellular fluids.
- Secretion of aldosterone is controlled by several factors, most of which are related to kidney function. In general, secretion is increased when the potassium level of extracellular fluid is high, the sodium level of extracellular fluid is low, the renin-angiotensin system of the kidneys is activated, or the anterior pituitary gland secretes corticotropin.
- Inadequate secretion of aldosterone causes hyperkalemia, hyponatremia, and extracellular fluid volume deficit (dehydration). Hypotension and shock may result from decreased cardiac output. Absence of mineralocorticoids causes death.
- Excessive secretion of aldosterone produces hypokalemia, hypernatremia, and extracellular fluid volume excess (water intoxication). Edema and hypertension may result.

## Adrenal Sex Hormones

The adrenal cortex secretes male (androgens) and female (estrogens and progesterone) sex hormones. Compared with the effect of hormones produced by the testes and ovaries, the adrenal sex hormones have an insignificant effect on normal body function. Adrenal androgens, secreted continuously in small quantities by both sexes, are responsible for most of the physiologic effects exerted by the adrenal sex hormones. They increase protein synthesis (anabolism), which increases the mass and strength of muscle and bone tissue; they affect development of male secondary sex characteristics; and they increase hair growth and libido in women. Excessive secretion of adrenal androgens in women causes masculinizing effects (e.g., hirsutism, acne, breast atrophy, deepening of the voice, amenorrhea). Female sex hormones are secreted in small amounts and normally exert few physiologic effects. Excessive secretion may produce feminizing effects in men (e.g., breast enlargement, decreased hair growth, voice changes).

## Disorders of the Adrenal Cortex

Disorders of the adrenal cortex involve increased or decreased production of corticosteroids, especially cortisol as the primary glucocorticoid and aldosterone as the primary mineralocorticoid. These disorders include the following:

- **Primary adrenocortical insufficiency** (*Addison's disease*) is associated with destruction of the adrenal cortex by disorders such as tuberculosis, cancer, or hemorrhage; with atrophy of the adrenal cortex caused by autoimmune disease or prolonged administration of exogenous corticosteroids; and with surgical excision of the adrenal glands. In primary adrenocortical insufficiency, there is inadequate production of both cortisol and aldosterone.
- **Secondary adrenocortical insufficiency**, produced by inadequate secretion of corticotropin, is most often caused by prolonged administration of corticosteroids. This condition is largely a glucocorticoid deficiency; mineralocorticoid secretion is not significantly impaired.
- **Congenital adrenogenital syndromes and adrenal hyperplasia** result from deficiencies in one or more enzymes required for cortisol production. Low plasma levels of cortisol lead to excessive corticotropin secretion, which then leads to excessive adrenal secretion of androgens and hyperplasia (abnormal increase in number of cells).
- **Androgen-producing tumors** of the adrenal cortex, which are usually benign, produce masculinizing effects.
- **Adrenocortical hyperfunction** (*Cushing's disease*) may result from excessive corticotropin or a primary adrenal tumor. Adrenal tumors may be benign or malignant. Benign tumors often produce one corticosteroid normally secreted by the adrenal cortex, but malignant tumors often secrete several corticosteroids.
- **Hyperaldosteronism** is a rare disorder caused by adenoma (a benign tissue from glandular tissue) or hyperplasia of the

adrenal cortex cells that produce aldosterone. It is characterized by hypokalemia, hypernatremia, hypertension, thirst, and polyuria.

## General Characteristics of Exogenous Corticosteroids

### Mechanisms of Action

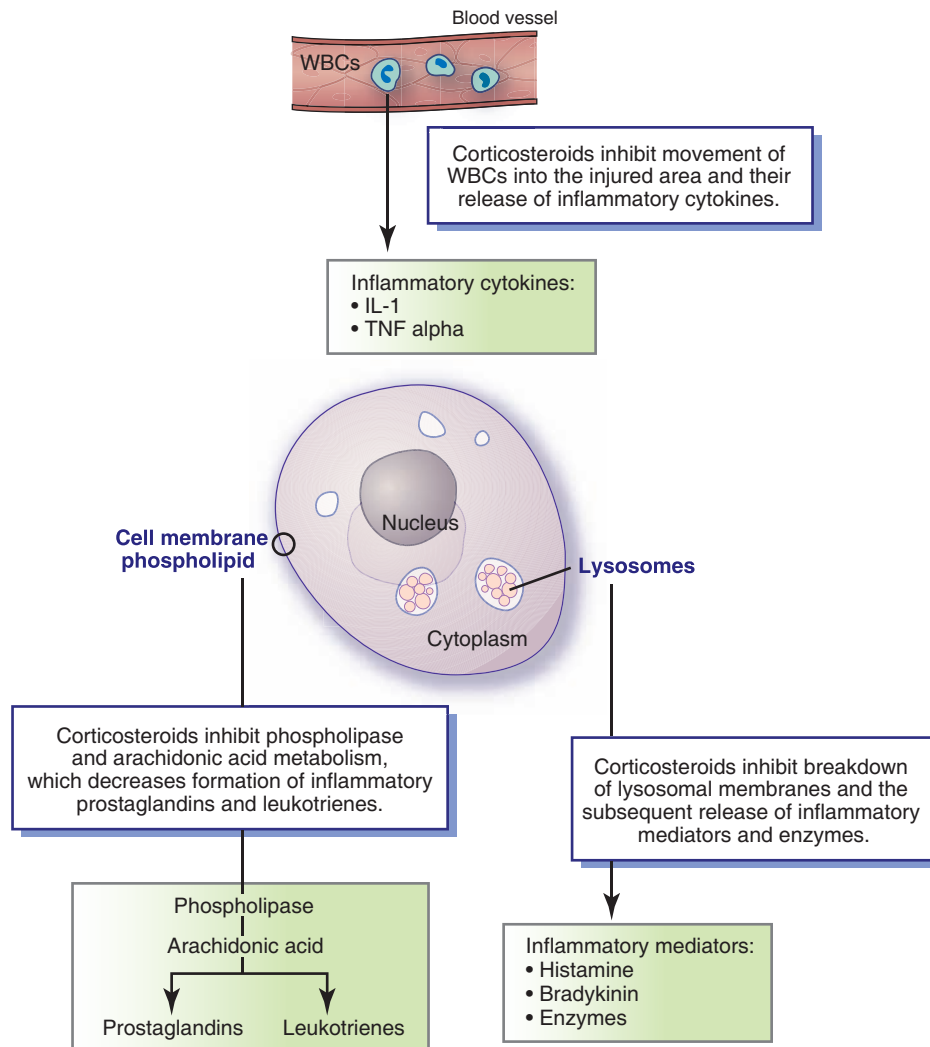

Like endogenous glucocorticoids, exogenous drug molecules act at the cellular level by binding to glucocorticoid receptors in target tissues. The drugs are lipid soluble and easily diffuse through the cell membranes of target cells. Inside the cell, they bind with receptors in intracellular cytoplasm. The drug-receptor complex then moves to the cell nucleus, where it interacts with DNA to stimulate or suppress gene transcription.

Glucocorticoids increase or decrease transcription of many genes to alter the synthesis of proteins that regulate their many physiologic effects (e.g., enzymes, transport proteins, structural proteins). Metabolic effects do not occur for at least 45 to 60 minutes because of the time required for protein synthesis. Several hours or days may be needed for full production of proteins.

Because the genes vary in different types of body cells, glucocorticoid effects also vary, depending on the specific cells being targeted. For example, supraphysiologic concentrations of glucocorticoids induce the synthesis of lipolytic and proteolytic enzymes and other specific proteins in various tissues. Overall, corticosteroids have multiple mechanisms of action and effects (Fig. 23-1), including the following:

- **Inhibiting arachidonic acid metabolism.** Normally, when a body cell is injured or activated by various stimuli, the enzyme phospholipase A<sub>2</sub> causes the phospholipids in cell membranes to release arachidonic acid. Free arachidonic acid is then metabolized to produce proinflammatory prostaglandins (see Chap. 7) and leukotrienes. At sites of tissue injury or inflammation, corticosteroids induce the synthesis of proteins that suppress the activation of phospholipase A<sub>2</sub>. This action, in turn, decreases the release of arachidonic acid and the formation of prostaglandins and leukotrienes.
- **Strengthening or stabilizing biologic membranes.** Two biologic membranes are especially important in inflammatory processes. Stabilization of cell membranes inhibits the release of arachidonic acid and production of prostaglandins and leukotrienes, as described above. Stabilization of lysosomal membranes inhibits release of bradykinin, histamine, enzymes, and perhaps other substances from lysosomes. (Lysosomes are intracellular structures that contain inflammatory chemical mediators and enzymes that destroy cellular debris and phagocytized pathogens.) This reduces capillary permeability and thus prevents leakage of fluid into the injured area and development of edema. It also reduces the chemicals that normally cause vasodilation and tissue irritation.

**Figure 23-1** ■ Inflammatory processes and anti-inflammatory actions of corticosteroids. Cellular responses to injury include the following. Phospholipid in the cell membrane is acted on by phospholipase to release arachidonic acid. Metabolism of arachidonic acid produces the inflammatory mediators prostaglandins and leukotrienes. Lysosomal membrane breaks down and releases inflammatory chemicals (e.g., histamine, bradykinin, intracellular digestive enzymes). White blood cells (WBCs) are drawn to the area and release inflammatory cytokines (e.g., interleukin-1 [IL-1], tumor necrosis factor [TNF] alpha). Overall, corticosteroid drugs act to inhibit the release, formation, or activation of various inflammatory mediators.

- **Inhibiting the production of interleukin-1, tumor necrosis factor, and other cytokines.** This action also contributes to the anti-inflammatory and immunosuppressant effects of glucocorticoids.
- **Impairing phagocytosis.** The drugs inhibit the ability of phagocytic cells to leave the bloodstream and move into the injured or inflamed tissue.
- **Impairing lymphocytes.** The drugs inhibit the ability of these immune cells to increase in number and perform their functions.
- **Inhibiting tissue repair.** The drugs inhibit the growth of new capillaries, fibroblasts, and collagen needed for tissue repair.

## Indications for Use

Corticosteroids are extensively used to treat many different disorders. Except for replacement therapy in deficiency states, the use of corticosteroids is largely empiric. Because the drugs affect virtually every aspect of inflammatory and immune responses, they are used in the treatment of a broad spectrum of diseases with an inflammatory or immunologic component.

Corticosteroid preparations applied topically in ophthalmic and dermatologic disorders are discussed in Chapters 63 and 64, respectively. The corticosteroids discussed in this chapter are used to treat potentially serious or disabling disorders. These disorders include the following:

- **Allergic** or hypersensitivity disorders, such as allergic reactions to drugs, serum and blood transfusions, and dermatoses with an allergic component
- **Collagen** disorders, such as systemic lupus erythematosus, scleroderma, and periarteritis nodosa. Collagen is the basic structural protein of connective tissue, tendons, cartilage, and bone, and it is therefore present in almost all body tissues and organ systems. The collagen disorders are characterized by inflammation of various body tissues. Signs and symptoms depend on which body tissues or organs are affected and the severity of the inflammatory process.
- **Dermatologic** disorders that may be treated with systemic corticosteroids include acute contact dermatitis, erythema multiforme, herpes zoster (prophylaxis of postherpetic neuralgia), lichen planus, pemphigus, skin rashes caused by drugs, and toxic epidermal necrolysis.
- **Endocrine** disorders, such as adrenocortical insufficiency and congenital adrenal hyperplasia. Corticosteroids are given to replace or substitute for the natural hormones (both glucocorticoids and mineralocorticoids) in cases of insufficiency and to suppress corticotropin when excess secretion causes adrenal hyperplasia. These conditions are rare and account for a small percentage of corticosteroid usage.
- **Gastrointestinal** disorders, such as ulcerative colitis and regional enteritis (Crohn's disease)
- **Hematologic** disorders, such as idiopathic thrombocytopenic purpura or acquired hemolytic anemia
- **Hepatic** disorders characterized by edema, such as cirrhosis and ascites
- **Neoplastic disease**, such as acute and chronic leukemias, Hodgkin's disease, other lymphomas, and multiple myeloma. The effectiveness of corticosteroids in these conditions probably stems from their ability to suppress lymphocytes and other lymphoid tissue.
- **Neurologic** conditions, such as cerebral edema, brain tumor, acute spinal cord injury, and myasthenia gravis
- **Ophthalmic** disorders, such as optic neuritis, sympathetic ophthalmia, and chorioretinitis
- **Organ or tissue transplants and grafts** (e.g., kidney, heart, bone marrow). Corticosteroids suppress cellular and humoral immune responses (see Chap. 41) and help prevent rejection of transplanted tissue. Drug therapy is usually continued as long as the transplanted tissue is in place.
- **Renal** disorders characterized by edema, such as the nephrotic syndrome
- **Respiratory** disorders, such as asthma, status asthmaticus, chronic obstructive pulmonary disease (COPD), and inflammatory disorders of nasal mucosa (rhinitis). In asthma, corticosteroids increase the number of beta-adrenergic receptors and increase or restore responsiveness of beta receptors to beta-adrenergic bronchodilating drugs. In asthma, COPD, and rhinitis, the drugs decrease mucus secretion and inflammation.
- **Rheumatic** disorders, such as ankylosing spondylitis, acute and chronic bursitis, acute gouty arthritis, rheumatoid arthritis, and osteoarthritis
- **Shock.** Corticosteroids are clearly indicated only for shock resulting from *adrenocortical insufficiency* (adrenal or *Addisonian crisis*), which may mimic hypovolemic or septic shock. The use of corticosteroids in septic shock has been highly controversial, and randomized studies and meta-analyses have indicated that corticosteroids are not beneficial in treating septic shock. However, more recent small studies indicate possible clinical usefulness in septic shock, because this form of shock may be associated with relative adrenal insufficiency. In anaphylactic shock resulting from an allergic reaction, corticosteroids may increase or restore cardiovascular responsiveness to adrenergic drugs.

Indications for use, routes, and dosage ranges are given in Table 23-1.

Table 23-1

### Drugs at a Glance: Corticosteroids\*

Generic/Trade Name	ROUTES AND DOSAGE RANGES	
	Adults	Children
<b>Glucocorticoids</b>		
<b>Beclamethasone</b> oral inhalation (QVAR)	1–2 inhalations (40–80 mcg) 2 times daily (maximum daily dose 320 mcg)	
Nasal inhalation (Beconase AQ)	1–2 inhalations (42–84 mcg in each nostril) 2 times daily; as maintenance, 1 inhalation each nostril	older than 6 y: 1–2 inhalations (42–84 mcg) each nostril daily
<b>Betamethasone</b> (Celestone)	PO 0.6–7.2 mg daily initially, gradually reduced to lowest effective dose	
Betamethasone acetate and sodium phosphate (Celestone Soluspan)	IM 0.5–9 mg daily	Intra-articular injection 0.25–2 mL

## ROUTES AND DOSAGE RANGES

Generic/Trade Name	Adults	Children
<b>Budesonide</b> oral inhalation (Pulmicort Turbuhaler, Pulmicort Respules)	Turbuhaler, 200–400 mcg twice daily	Turbuhaler, <i>older than 6 y</i> : 200 mcg twice daily Respules, 12 <i>mo</i> –8 <i>y</i> : 0.5 mg daily in 1 single or 2 divided doses
Nasal inhalation (Rhinocort)	256 mcg daily initially (2 sprays each nostril morning and evening or 4 sprays each nostril every morning). When symptoms are controlled, reduce dosage to lowest effective maintenance dose.	<i>older than 6 y</i> : Same as adults
Oral capsule (Entocort EC)	Crohn's disease, PO 9 mg once daily in the morning, for up to 8 wk	
<b>Cortisone</b>	PO 25–300 mg daily, individualized for condition and response	
<b>Dexamethasone</b> (Decadron)	PO 0.75–9 mg daily in 2–4 doses; higher ranges for serious diseases	
<b>Dexamethasone</b> acetate	IM 8–16 mg (1–2 mL) in single dose, repeated every 1–3 wk if necessary	
<b>Dexamethasone</b> sodium phosphate	IM, IV 0.5–9 mg, depending on severity of disease	
<b>Flunisolide</b> oral inhalation (AeroBid)	2 inhalations (500 mcg) twice daily	6–15 <i>y</i> : Same as adults
Nasal inhalation (Nasarel)	2 sprays in each nostril twice daily; maximal daily dose 8 sprays in each nostril	6–14 <i>y</i> : 1 spray in each nostril 3 times daily or 2 sprays in each nostril 2 times daily; maximal daily dose 4 sprays in each nostril
<b>Fluticasone</b> (Flovent) oral inhalation	2 inhalations (88 mcg) 2 times daily (maximum daily dose 440 mcg inhaled 2 times daily)	<i>under 12 y</i> : not recommended
(Flonase) nasal inhalation	200 mcg daily initially (2 sprays each nostril once daily or 1 spray each nostril twice daily). After a few days, reduce dosage to 100 mcg daily (1 spray each nostril once daily) for maintenance therapy.	12 <i>y and older</i> : 100 mcg daily (1 spray per nostril once daily)
<b>Hydrocortisone</b> (Cortef)	PO 20–240 mg daily, depending on condition and response	
<b>Hydrocortisone</b> sodium phosphate	IV, IM, Sub-Q 15–240 mg daily in 2 divided doses	
<b>Hydrocortisone</b> sodium succinate	IV, IM 100–400 mg initially, repeated at 2, 4, or 6 hour intervals if necessary	
<b>Hydrocortisone</b> retention enema (Cortenema)	Rectally, one enema (100 mg) nightly for 21 d or until optimal response	
<b>Hydrocortisone</b> acetate intrarectal foam (Cortifoam)	1 applicatorful 1–2 times daily for 2–3 wk, then once every 2–3 d if needed	
<b>Methylprednisolone</b> (Medrol)	PO 4–48 mg daily initially, gradually reduced to lowest effective level	
<b>Methylprednisolone</b> sodium succinate (Solu-Medrol)	IV, IM 10–40 mg initially, adjusted to condition and response	Infants and children: IV, IM not less than 0.5 mg/kg/24 hours
<b>Methylprednisolone</b> acetate (Depo-Medrol)	IM 40–120 mg once daily	

(continued on page 364)

Table 23-1

## Drugs at a Glance: Corticosteroids\* (continued)

Generic/Trade Name	ROUTES AND DOSAGE RANGES	
	Adults	Children
<b>Mometasone</b> (Nasonex)	2 sprays (50 mcg/spray) in each nostril once daily (200 mcg/d)	older than 12 y: Same as adults 3–11 y: 1 spray (50 mcg) in each nostril once daily (100 mcg/d)
<b>Prednisolone</b>	PO 5–60 mg daily initially, adjusted for maintenance	
<b>Prednisolone</b> acetate	IM 4–60 mg daily initially, adjusted for maintenance	
<b>Prednisone</b>	PO 5–60 mg daily initially, reduced for maintenance	PO: 0.25 - 2mg /kg/dose every 6 h for 48 h, then 1–2 mg/kg/24 h, (maximum 60 mg/24 h)
<b>Triamcinolone</b>	PO 4–48 mg daily initially, reduced for maintenance	
<b>Triamcinolone</b> acetonide (Kenalog-40)	IM 2.5–60 mg daily, depending on the disease. Reduce dosage and start oral therapy when feasible.	
Oral inhalation (Azmacort)	2 inhalations (200 mcg) 3–4 times daily or 4 inhalations (400 mcg) 2 times daily	6–12 y: 1–2 inhalations (100–200 mcg) 3–4 times daily or 2–4 inhalations (200–400 mcg) 2 times daily. Maximum daily dose, 12 inhalations (1200 mcg)
Nasal inhalation (Nasacort)	2 sprays (110 mcg) in each nostril once daily (total dose 220 mcg/d). May increase to maximal daily dose of 440 mcg if indicated	6 y or older: 2 sprays (110 mcg) in each nostril once daily (220 mcg/d) initially; reduce to 1 spray per nostril once daily (110 mcg/d)
<b>Triamcinolone</b> diacetate (Aristocort Forte)	IM 20–80 mg initially	
<b>Mineralocorticoid</b> <b>Fludrocortisone</b> (Florinef)	Chronic adrenocortical insufficiency, PO 0.1 mg daily Salt-losing adrenogenital syndromes, PO 0.1–0.2 mg daily	PO 0.05–0.1 mg daily

\*Ophthalmic and dermatologic preparations are discussed in Chapters 63 and 64, respectively.

## Contraindications to Use

Corticosteroids are contraindicated in systemic fungal infections and in people who are hypersensitive to drug formulations. They should be used with caution in patients at risk for infections (they may decrease resistance), patients with infections (they may mask signs and symptoms so that infections become more severe before they are recognized and treated), diabetes mellitus (they cause or increase hyperglycemia), peptic ulcer disease, inflammatory bowel disorders, hypertension, congestive heart failure, and renal insufficiency.

## Applying Your Knowledge 23-1

You arrive at Ms. Hubble's home and begin your assessment of the patient. You notice the appearance of white patches on Ms. Hubble's mouth. What action do you take?

All adrenal corticosteroids are available as drug preparations, as are many synthetic derivatives developed by altering the basic steroid molecule in efforts to increase therapeutic effects while minimizing adverse effects. When corticosteroids are administered from sources outside the body, they are given mainly for replacement or therapeutic purposes. Replacement involves small doses to correct a deficiency state and restore normal function (physiologic effects). Therapeutic purposes require relatively large doses to exert pharmacologic effects. Drug effects involve extension of the physiologic effects of endogenous corticosteroids and new effects that do not occur with small, physiologic doses. The most frequently desired pharmacologic effects are anti-inflammatory, immunosuppressive, antiallergic, and antistress. These are glucocorticoid effects. Mineralocorticoid and androgenic effects are usually considered adverse reactions.

- The drugs are palliative; they control many symptoms but do not cure underlying disease processes. In chronic disorders,

they may enable patients to continue the usual activities of daily living and delay disability. However, the disease may continue to progress, and long-term use of systemic corticosteroids inevitably produces serious adverse effects.

- Drug effects vary, so a specific effect may be considered therapeutic in one patient but adverse in another. For example, an increased blood sugar level is therapeutic for the patient with adrenocortical insufficiency or an isletcell adenoma of the pancreas but is an adverse reaction for most patients, especially those with diabetes mellitus. In addition, some patients respond more favorably or experience adverse reactions more readily than others taking equivalent doses. This is partly caused by individual differences in the rate at which corticosteroids are metabolized.
- Administration of exogenous corticosteroids suppresses the HPA axis. This decreases secretion of corticotropin, which, in turn, causes atrophy of the adrenal cortex and decreased production of endogenous adrenal corticosteroids.
- **P Hydrocortisone**, the exogenous equivalent of endogenous cortisol, is the prototype of corticosteroid drugs. When a new corticosteroid is developed, it is compared with hydrocortisone to determine its potency in producing anti-inflammatory and antiallergic responses, increasing deposition of liver glycogen, and suppressing secretion of corticotropin. Daily administration of physiologic doses (15–20 mg of hydrocortisone or its equivalent) or administration of pharmacologic doses (more than 15–20 mg of hydrocortisone or its equivalent) for approximately 2 weeks suppresses the HPA axis. HPA recovery usually occurs within a few weeks or months after corticosteroids are discontinued but may take 9 to 12 months. During that time, supplemental corticosteroids are usually needed during stressful situations (e.g., fever, illness, surgical procedures) to improve the patient's ability to respond to stress and prevent acute adrenocortical insufficiency.
- Anti-inflammatory activity of glucocorticoids is approximately equal when the drugs are given in equivalent doses (hydrocortisone 20 mg, prednisone and prednisolone 5 mg, methylprednisolone and triamcinolone 4 mg, dexamethasone 0.75 mg, and betamethasone 0.6 mg). Mineralocorticoid activity is high in cortisone (which is rarely used); intermediate in hydrocortisone, prednisolone, and prednisone; and low in newer agents.
- Duration of action also varies and is only known for oral drugs. Betamethasone and dexamethasone last 48 hours; methylprednisolone, prednisolone, prednisone, and triamcinolone last 18 to 36 hours; and hydrocortisone lasts 18 hours.
- Corticosteroids are metabolized in the liver (mainly by cytochrome P450 3A4 enzymes) and conjugated to inactive metabolites. About 25% of the metabolites are excreted in the bile, then in the feces. The other 75% enter the circulation and are excreted by the kidneys. Metabolism is slowed by hepatic disease, and excretion is slowed by renal

disease. In these conditions, corticosteroids may accumulate and cause signs and symptoms of hypercorticism.

## Applying Your Knowledge 23-2

Ms. Hubble asks you why she has to take the prednisone because it has not made her COPD go away. How should you respond?

.....

## Nursing Process

### Assessment

#### Initiation of Corticosteroid Therapy

- For a patient expected to receive short-term corticosteroid therapy, the major focus of assessment is the extent and severity of symptoms. Such data can then be used to evaluate the effectiveness of drug therapy.
- For a patient expected to receive long-term, systemic corticosteroid therapy, a thorough assessment is needed. This may include diagnostic tests for diabetes mellitus, tuberculosis, and peptic ulcer disease, because these conditions may develop from or be exacerbated by administration of corticosteroid drugs. If one of these conditions is present, corticosteroid therapy must be altered and other drugs given concomitantly.
- If acute infection is found on initial assessment, it should be treated with appropriate antibiotics either before corticosteroid drugs are started or concomitantly with corticosteroid therapy. This is necessary because corticosteroids may mask symptoms of infection and impair healing. Thus, even minor infections can become serious if left untreated during corticosteroid therapy. If infection occurs during long-term corticosteroid therapy, appropriate antibiotic therapy (as determined by culture of the causative microorganism and antibiotic sensitivity studies) is again indicated. Also, increased doses of corticosteroids are usually indicated to cope with the added stress of the infection.

#### Previous or Current Corticosteroid Therapy

Initial assessment of every patient should include information about previous or current treatment with systemic corticosteroids. This can usually be determined by questioning the client or reviewing medical records.

- If the nurse determines that the patient has taken corticosteroids in the past, additional information is needed about the specific drug and dosage taken, the purpose and length of therapy, and when therapy was stopped. Such information is necessary for planning nursing care. If the patient had an acute illness and received an oral or

*Nursing Process continues on page 366*

injected corticosteroid for approximately 1 week or received corticosteroids by local injection or application to skin lesions, no special nursing care is likely to be required. However, if the patient took systemic corticosteroids for 2 weeks or longer during the past year, nursing observations must be especially vigilant. Such a patient may be at higher risk for acute adrenocortical insufficiency during stressful situations. If the patient has surgery, corticosteroid therapy is restarted either before or on the day of surgery and continued, in decreasing dosage, for a few days after surgery. In addition to anesthesia and surgery, potentially significant sources of stress include hospitalization, various diagnostic tests, concurrent infection or other illnesses, and family problems.

If the patient is currently taking a systemic corticosteroid drug, again the nurse must identify the drug, the dosage and schedule of administration, the purpose for which the drug is being taken, and the length of time involved. After this basic information is obtained, the nurse can further assess patient status and plan nursing care. Some specific factors include the following:

- If the patient undergoes anesthesia and surgery, expect that higher doses of corticosteroids will be given for several days. This may be done by changing the drug, the route of administration, and the dosage. Specific regimens vary according to type of anesthesia, surgical procedure, patient condition, prescriber preference, and other variables. A patient having major abdominal surgery may be given 300 to 400 mg of hydrocortisone (or the equivalent dosage of other drugs) on the day of surgery and then be tapered back to maintenance dosage within a few days.
- Note that additional corticosteroids may be given in other situations as well. One extra dose may be adequate for a short-term stress situation, such as an angiogram or other invasive diagnostic test.
- Using all available data, assess the likelihood of the patient having acute adrenal insufficiency.
- Assess for signs and symptoms of adrenocortical excess and adverse drug effects.
- Assess for signs and symptoms of the disease for which long-term corticosteroid therapy is being given.

### Nursing Diagnoses

- Disturbed Body Image related to cushingoid changes in appearance
- Imbalanced Nutrition: Less Than Body Requirements related to protein and potassium losses
- Imbalanced Nutrition: More Than Body Requirements related to sodium and water retention and hyperglycemia
- Excess Fluid Volume related to sodium and water retention
- Risk for Injury related to adverse drug effects of impaired wound healing, increased susceptibility to infection, weakening of skin and muscles, osteoporosis, gastrointestinal

ulceration, diabetes mellitus, hypertension, and acute adrenocortical insufficiency

- Ineffective Coping related to chronic illness; long-term drug therapy and drug-induced mood changes, irritability and insomnia
- Deficient Knowledge related to disease process and corticosteroid drug therapy

### Planning/Goals

#### The patient will

- Take the drug correctly
- Practice measures to decrease the need for corticosteroids and minimize adverse effects
- Be monitored regularly for adverse drug effects
- Keep appointments for follow-up care
- Be assisted to cope with body image changes
- Verbalize or demonstrate essential drug information

### Interventions

For patients on long-term, systemic corticosteroid therapy, use supplementary drugs as ordered and nondrug measures to decrease dosage and adverse effects of corticosteroid drugs. Specific measures include the following:

- Help patients set reasonable goals of drug therapy. For example, partial relief of symptoms may be better than complete relief if the latter requires larger doses or longer periods of treatment with systemic drugs.
- In patients with bronchial asthma and COPD, other treatment measures should be continued during corticosteroid therapy. With asthma, the corticosteroid needs to be given on a regular schedule; inhaled bronchodilators can usually be taken as needed.
- In patients with rheumatoid arthritis, rest, physical therapy, and salicylates or other nonsteroid anti-inflammatory drugs are continued. Systemic corticosteroid therapy is reserved for severe, acute exacerbations when possible.
- Help patients identify stressors and find ways to modify or avoid stressful situations when possible. For example, most patients probably do not think of extreme heat or cold or minor infections as significant stressors. However, they can be for people taking corticosteroids. This assessment of potential stressors must be individualized because a situation viewed as stressful by one patient may not be stressful to another.
- Encourage activity, if not contraindicated, to slow demineralization of bone (osteoporosis). This is especially important in postmenopausal women who are not taking replacement estrogens, because they are very susceptible to osteoporosis. Walking is preferred if the patient is able. Range-of-motion exercises are indicated in immobilized or bedridden people. Also, bedridden patients taking corticosteroids should have their positions changed frequently

because these drugs thin the skin and increase the risk of pressure ulcers. This risk is further increased if edema also is present.

- Dietary changes may be beneficial in some patients. Salt restriction may help prevent hypernatremia, fluid retention, and edema. Foods high in potassium may help prevent hypokalemia. A diet high in protein, calcium, and vitamin D may help prevent osteoporosis. Increased intake of vitamin C may help decrease bleeding in the skin and soft tissues.
- Avoid exposing the patient to potential sources of infection by washing hands frequently; using aseptic technique when changing dressings; keeping health care personnel and visitors with colds or other infections away from the patient; and following other appropriate measures. Reverse or protective isolation is sometimes indicated, commonly for those patients who have had organ transplantation and are receiving corticosteroids to help prevent rejection of the transplanted organ.
- Handle tissues very gently during any procedures (e.g., bathing, assisting out of bed, venipunctures). Because long-term corticosteroid therapy weakens the skin and bones, there are risks of skin damage and fractures with even minor trauma.

Patient Guidelines for Long-Term Corticosteroid Therapy are presented in the accompanying display.

## Evaluation

- Interview and observe for relief of symptoms for which corticosteroids were prescribed.
- Interview and observe for accurate drug administration.
- Interview and observe for use of nondrug measures indicated for the condition being treated.
- Interview and observe for adverse drug effects on a regular basis.
- Interview regarding drug knowledge and effects to be reported to health care providers.

## Applying Your Knowledge 23-3

You test Ms. Hubble's blood glucose level, and it is 345 mg/dL. Why is this patient hyperglycemic, and what action should you take?

## Principles of Therapy

### Goal of Therapy

The goal of corticosteroid therapy is usually to reduce symptoms to a tolerable level. Total suppression of symptoms may require excessively large doses and produce excessive adverse

effects. Because systemic corticosteroids can cause serious adverse reactions, indications for their clinical use should be as clear-cut as possible.

## Drug Selection

Choice of corticosteroid drug is influenced by many factors, including the purpose for use, characteristics of specific drugs, desired route of administration, characteristics of individual patients, and expected adverse effects. Some guidelines for rational drug choice include the following:

- Hydrocortisone and cortisone are usually the drugs of choice in adrenocortical insufficiency, which requires replacement of both glucocorticoids and mineralocorticoids whether caused by Addison's disease, adrenalectomy, or inadequate corticotropin. These drugs have greater mineralocorticoid activity compared with other corticosteroids. If additional mineralocorticoid activity is required, fludrocortisone can be given.
- Prednisone is often the glucocorticoid of choice in nonendocrine disorders in which anti-inflammatory, antiallergic, antistress, and immunosuppressive effects are desired. A corticosteroid drug with primarily glucocorticoid activity is necessary.
- Beclomethasone (QVAR, Beconase AQ), budesonide (Pulmicort, Rhinocort), flunisolide (AeroBid), fluticasone (Flonase, Flovent), mometasone (Nasonex), and triamcinolone (Azmacort, Nasacort) are corticosteroids formulated to be given by oral or nasal inhalation in respiratory disorders. Their use replaces, prevents, delays, or decreases use of systemic drugs and thereby decreases risks of serious adverse effects. However, high doses or frequent use may suppress adrenocortical function.
- Dexamethasone (parenterally or orally) is considered the corticosteroid of choice for cerebral edema associated with brain tumors, craniotomy, or head injury, because dexamethasone is thought to penetrate the blood–brain barrier more readily and achieve higher concentrations in cerebrospinal fluids and tissues. It also has minimal sodium- and water-retaining properties. With brain tumors, the drug is more effective in metastatic lesions and glioblastomas than astrocytomas and meningiomas.
- Hydrocortisone, dexamethasone, and methylprednisolone are among those drugs that may be given parenterally and are useful in acute, life-threatening situations that require such administration, usually intravenously (IV). This requirement limits the choice of drugs, because not all corticosteroids are available in injectable preparations.

## Drug Dosage

Many factors have an effect on drug dosage, such as the specific drug to be given, the desired route of administration, the reason for use, expected adverse effects, and patient characteristics. In general, the smallest effective dose should be given for the shortest effective time. The dosage must be individualized

## Patient Teaching Guidelines

## Long-Term Corticosteroid Therapy

### General Considerations

- In most instances, corticosteroids are used to relieve symptoms; they do not cure the underlying disease process. However, they can improve comfort and quality of life.
- When taking an oral corticosteroid (e.g., prednisone) for longer than 2 weeks, it is extremely important to take the drug as directed. Missing a dose or two, stopping the drug, changing the amount or time of administration, taking extra drug (except as specifically directed during stress situations), or any other alterations may result in complications. Some complications are relatively minor; several are serious, even life threatening. When these drugs are being discontinued, the dosage is gradually reduced over several weeks. They must not be stopped abruptly.
- Wear a special medical alert bracelet or tag or carry an identification card stating the drug being taken; the dosage; the prescriber's name, address, and telephone number; and instructions for emergency treatment. If an accident or emergency situation occurs, health care providers must know about corticosteroid drug therapy to give additional amounts during the stress of the emergency.
- Report to all health care providers consulted that corticosteroid drugs are being taken or have been taken within the past year. Current or previous corticosteroid therapy can influence treatment measures, and such knowledge increases the ability to provide appropriate treatment.
- Maintain regular medical supervision. This is extremely important so that the prescriber can detect adverse reactions, evaluate disease status, and evaluate drug response and indications for dosage change, as well as other responsibilities that can be carried out only with personal contact between the prescriber and the patient. Periodic blood tests, x-ray studies, and other tests may be performed during long-term corticosteroid therapy.
- Take no other drugs, prescription or nonprescription, without notifying the prescriber who is supervising corticosteroid therapy. Corticosteroid drugs influence reactions to other drugs, and some other drugs interact with corticosteroids either to increase or decrease their effects. Thus, taking other drugs can decrease the expected therapeutic benefits or increase the incidence or severity of adverse effects.
- Avoid exposure to infection when possible. Avoid crowds and people known to have an infection. Also, wash hands frequently and thoroughly. These drugs increase the likelihood of infection, so preventive measures are necessary. Also, if infection does occur, healing is likely to be slow.
- Practice safety measures to avoid accidents (e.g., falls and possible fractures due to osteoporosis, cuts or other injuries because of delayed wound healing, soft tissue trauma because of increased tendency to bruise easily).
- Weigh frequently when starting corticosteroid therapy and at least weekly during long-term maintenance. An initial weight gain is likely to occur and is usually attributed to increased appetite. Later weight gains may be caused by fluid retention.
- Ask the prescriber about the amount and kind of activity or exercise needed. As a general rule, being as active as possible helps to prevent or delay osteoporosis, a common adverse effect. However, increased activity may not be desirable for everyone. A patient with rheumatoid arthritis, for example, may become too active when drug therapy relieves joint pain and increases mobility.
- Follow instructions for other measures used in treatment of the particular condition (e.g., other drugs and physical therapy for rheumatoid arthritis). Such measures may allow smaller doses of corticosteroids and decrease adverse effects.
- Because the corticosteroid impairs the ability to respond to stress, dosage may need to be temporarily increased with illness, surgery, or other stressful situations. Clarify with the prescriber predictable sources of stress and the amount of drug to be taken if the stress cannot be avoided.
- In addition to stressful situations, report sore throat, fever, or other signs of infection; weight gain of 5 pounds or more in a week; or swelling in the ankles or elsewhere. These symptoms may indicate adverse drug effects and changes in corticosteroid therapy may be indicated.
- Muscle weakness and fatigue or disease symptoms may occur when drug dosage is reduced, withdrawn, or omitted (e.g., the nondrug day of alternate-day therapy). Although these symptoms may cause some discomfort, they should be tolerated if possible rather than increasing the corticosteroid dose. If severe, of course, dosage or time of administration may have to be changed.
- Dietary changes may be helpful in reducing some adverse effects of corticosteroid therapy. Decreasing salt intake (e.g., by not adding table salt to foods and avoiding obviously salty foods, such as many snack foods and prepared sandwich meats) may help decrease swelling. Eating high-potassium foods, such as citrus fruits and juices or bananas, may help prevent potassium loss. An adequate intake of calcium, protein, and vitamin D (meat and dairy products are good sources) may help to prevent or delay osteoporosis. Vitamin C (e.g., from citrus fruits) may help to prevent excessive bruising.
- Do not object when your prescriber reduces your dose of oral corticosteroid, with the goal of stopping the drug entirely or continuing with a smaller dose. Long-term therapy should be used only when necessary because of the potential for serious adverse effects, and the lowest effective dose should be given.
- With local applications of corticosteroids, there is usually little systemic absorption and few adverse effects, compared with oral or injected drugs. When effective in relieving symptoms, it is better to use a local than a systemic corticosteroid. In some instances, combined systemic and local application allows administration of a lesser dose of the systemic drug.
  - Commonly used local applications are applied topically for skin disorders; by oral inhalation for asthma; and by nasal inhalation for allergic rhinitis. Although long-term use is usually well tolerated, systemic toxicity can occur if excess corticosteroid is inhaled or if occlusive dressings are used over skin lesions. Thus, a corticosteroid for local application must be applied correctly and not overused.
- Corticosteroids are not the same as the steroids often abused by athletes and body builders. Those are anabolic steroids derived from testosterone, the male sex hormone.

### Self- or Caregiver Administration

- Take an oral corticosteroid with a meal or snack to decrease gastrointestinal upset.
- If taking the medication once a day or every other day, take before 9 A.M. if taking multiple doses, take at evenly spaced intervals throughout the day.
- Report to the prescriber if unable to take a dose orally because of vomiting or some other problem. In some circumstances, the dose may need to be given by injection.
- If taking an oral corticosteroid in tapering doses, be sure to follow instructions exactly to avoid adverse effects.
- When applying a corticosteroid to skin lesions, do not apply more often than ordered and do not cover with an occlusive dressing unless specifically instructed to do so.
- With an intranasal corticosteroid, use on a regular basis (usually once or twice daily) for the best anti-inflammatory effects.
- With an oral-inhalation corticosteroid, use on a regular schedule for anti-inflammatory effects. The drugs are not effective in relieving acute asthma attacks or shortness of breath and should not be used “as needed” for that purpose. Use metered-dose inhalers as follows (unless instructed otherwise by a health care provider):
  1. Shake canister thoroughly.
  2. Place canister between lips (both open and pursed lips have been recommended) or outside lips.
  3. Exhale completely.
  4. Activate canister while taking a slow, deep breath.
  5. Hold breath for 10 seconds or as long as possible.
  6. Wait at least 1 minute before taking additional inhalations.
  7. Rinse mouth after inhalations to decrease the incidence of oral thrush (a fungal infection).
  8. Rinse mouthpiece at least once per day.

according to the severity of the disorder being treated, whether the disease is acute or chronic, and the patient's response to drug therapy. (Dosage for children is calculated according to severity of disease rather than weight.) If life-threatening disease is present, high doses are usually given until acute symptoms subside. Then the dose is gradually reduced until a maintenance dose is determined or the drug is discontinued. If life-threatening disease is not present, relatively high doses may still be given initially and then lowered. Doses should be gradually reduced (tapered) over several days. With long-term corticosteroid therapy, periodic attempts to reduce dosage are desirable to decrease adverse effects. One way is to reduce the dose gradually until symptoms worsen, indicating the minimally effective dose.

Physiologic doses (approximately 15–20 mg of hydrocortisone or its equivalent daily) are given to replace or substitute for endogenous adrenocortical hormone. Pharmacologic doses (supraphysiologic amounts) are usually required for anti-inflammatory, antiallergic, antistress, and immunosuppressive effects.

Compared with hydrocortisone, newer corticosteroids are more potent on a weight basis but are equipotent in anti-inflammatory effects when given in equivalent doses. Statements of equivalency with hydrocortisone are helpful in evaluating new drugs, comparing different drugs, and changing drugs or dosages. However, dosage equivalents apply only to drugs given orally or IV.

## Drug Administration

### Routes of Administration

Corticosteroids can be given by several different routes, based on the clinical problem, to produce local or systemic effects. If feasible, these drugs should be given locally rather than systemically to prevent or decrease systemic toxicity. In recent years there have been several formulations developed for oral inhalation in the treatment of asthma and for nasal inhalation in the treatment of allergic rhinitis. When these drugs must be given

systemically, the oral route is preferred. Parenteral administration is indicated only for patients who are seriously ill or unable to take oral medications.

For intramuscular or IV injections, sodium phosphate or sodium succinate salts are used because they are most soluble in water. For intra-articular or intralesional injections, acetate salts are used because they have low solubility in water and provide prolonged local action.

### Frequency of Administration

Scheduling of drug administration is more important with corticosteroids than with most other drug classes. Most adverse effects occur with long-term administration of high doses. A major adverse reaction is suppression of the HPA axis and subsequent loss of adrenocortical function. Certain schedules are often recommended to prevent or minimize HPA suppression.

Corticosteroids can be given in relatively large, divided doses for approximately 48 to 72 hours in acute situations until the condition has been brought under control. After acute symptoms subside or 48 to 72 hours have passed, the dosage is tapered so that a slightly smaller dose is given each day until the drug can be discontinued completely (total period of use: approximately 1 week). Such a regimen may be useful in allergic reactions, contact dermatitis, exacerbations of chronic conditions (e.g., bronchial asthma), and stressful situations such as surgery.

Daily administration is required in cases of chronic adrenocortical insufficiency. The entire daily dose can be taken each morning, between 6 and 9 A.M. This schedule simulates normal endogenous corticosteroid secretion.

Alternate-day therapy (ADT), in which a double dose is taken every other morning, is usually preferred for other chronic conditions. This schedule allows rest periods so that adverse effects are decreased while anti-inflammatory effects continue. ADT seems to be as effective as more frequent administration in most patients with bronchial asthma, ulcerative colitis, and other conditions for which long-term corticosteroid therapy is prescribed. ADT is used only for

maintenance therapy (i.e., clinical signs and symptoms are controlled initially with more frequent drug administration). ADT can be started after symptoms have subsided and stabilized.

Intermediate-acting glucocorticoids (e.g., prednisone, prednisolone, methylprednisolone) are the drugs of choice for ADT. Long-acting drugs (e.g., betamethasone, dexamethasone) are not recommended because of their prolonged suppression of adrenocortical function.

ADT has other advantages. It probably decreases susceptibility to infection and does not retard growth in children, as do other schedules.

ADT is not usually indicated in patients who have previously received corticosteroids on a long-term basis. First, these patients already have maximal HPA suppression, so a major advantage of ADT is lost. Second, if these patients begin ADT, recurrence of symptoms and considerable discomfort may occur on days when drugs are omitted. Patients with severe disease and very painful or disabling symptoms also may experience severe discomfort with ADT.

### Stress Dosage Corticosteroid Therapy

Long-term use of pharmacologic doses (e.g., more than 5 mg of prednisone daily) produces adverse reactions. For this reason, long-term corticosteroid therapy should be reserved for life-threatening conditions or severe, disabling symptoms that do not respond to treatment with more benign drugs or other measures. For people receiving chronic corticosteroid therapy, dosage must be increased during periods of stress or illness. Some common sources of stress for most people include surgery and anesthesia, infections, anxiety, and extremes of temperature. Note that events that are stressful for one patient may not be stressful for another. Some guidelines for corticosteroid dosage during stress include the following:

- During minor or relatively mild illness (e.g., viral upper respiratory infection, any febrile illness, strenuous exercise, gastroenteritis with vomiting and diarrhea, minor surgery), doubling the daily maintenance dose is usually adequate. After the stress period is over, dosage may be reduced abruptly to the usual maintenance dose.
- During major stress or severe illness, even larger doses are necessary. For example, a patient undergoing abdominal surgery may require 300 to 400 mg of hydrocortisone on the day of surgery. This dose can gradually be reduced to usual maintenance doses within approximately 5 days if postoperative recovery is uncomplicated. As a general rule, it is better to administer excessive doses temporarily than to risk inadequate doses and adrenal insufficiency. The patient also may require sodium chloride and fluid replacement, antibiotic therapy if infection is present, and supportive measures if shock occurs.
- During acute stress situations of short duration, such as traumatic injury or invasive diagnostic tests (e.g., angiography), a single dose of approximately 100 mg of hydrocortisone

immediately after the injury or before the diagnostic test is usually sufficient.

- Many chronic diseases that require long-term corticosteroid therapy are characterized by exacerbations and remissions. Dosage of corticosteroids usually must be increased during acute flare-ups of disease symptoms but can then be decreased gradually to maintenance levels.

## Treatment of Specific Disorders

### Allergic Rhinitis

Allergic rhinitis (also called seasonal rhinitis, hay fever, and perennial rhinitis) is a common problem for which corticosteroids are given by nasal spray, once or twice daily. Therapeutic effects usually occur within a few days with regular use. Systemic adverse effects are minimal with recommended doses but may occur with higher doses, including adrenocortical insufficiency from HPA suppression.

### Arthritis

Corticosteroids are the most effective drugs for rapid relief of the pain, edema, and restricted mobility associated with acute episodes of joint inflammation. They are usually given on a short-term basis. When inflammation is limited to three or fewer joints, the preferred route of drug administration is by injection directly into the joint. Intra-articular injections relieve symptoms in approximately 2 to 8 weeks, and several formulations are available for this route. However, corticosteroids do not prevent disease progression and joint destruction. As a general rule, a joint should not be injected more often than three times yearly because of risks of infection and damage to intra-articular structures from the injections and from overuse when pain is relieved.

### Asthma

Corticosteroids are commonly used in the treatment of asthma because of their anti-inflammatory effects. In addition, corticosteroids increase the effects of adrenergic bronchodilators to prevent or treat bronchoconstriction and bronchospasm. The drugs work by increasing the number and responsiveness of beta-adrenergic receptors and preventing the tolerance usually associated with chronic administration of these bronchodilators. Research studies indicate that responsiveness to beta-adrenergic bronchodilators increases within 2 hours and that numbers of beta receptors increase within 4 hours. A meta-analysis of randomized controlled trials was completed to determine the efficacy of corticosteroids on the outcome in patients with acute exacerbations of COPD. Findings are outlined in Evidence-Based Practice Box 23-1.

In acute asthma or status asthmaticus unrelieved by inhaled beta-adrenergic bronchodilators, high doses of systemic corticosteroids are given orally or IV along with bronchodilators for approximately 5 to 10 days. Although these high doses suppress the HPA axis, the suppression lasts for only 1 to 3 days, and other serious adverse effects are avoided. Thus, systemic corticosteroids are used for short-term therapy, as

## Evidence-Based Practice

### 23-1 Efficacy of Corticosteroids on the Outcome in Patients With Acute Exacerbations of COPD

The Cochrane Airways Group reviewed nine randomized controlled trials (N = 921 individuals) comparing either parenterally or orally corticosteroids with appropriate placebo groups to determine the efficacy of corticosteroids on the outcome in patients with acute exacerbations of COPD. Meta-analysis demonstrated that treatment with oral or parenteral corticosteroids significantly helped individuals with an exacerbation of COPD, especially in the first 3 days, and reduced the need for additional medical treatment. A significant increased risk of an adverse drug reaction was observed (Wood-Baker, Gibson, Hannay, Walters, & Walters, 2007).

needed, and not for long-term treatment. People who regularly use inhaled corticosteroids also require high doses of systemic drugs during acute attacks because aerosols are not effective. As soon as acute symptoms subside, the dose should be tapered; the lowest effective maintenance dose should be used, or the drug should be discontinued. In chronic asthma, inhaled corticosteroids are the drugs of first choice. This recommendation evolved from increased knowledge about the importance of inflammation in the pathophysiology of asthma and the development of aerosol corticosteroids that are effective with minimal adverse effects. Inhaled drugs may be given alone or with systemic drugs. In general, inhaled corticosteroids can replace oral drugs when daily dosage of the oral drug has been tapered to 10 to 15 milligrams of prednisone or the equivalent. When a patient is being switched from an oral to an inhaled corticosteroid, the inhaled drug should be started during tapering of the oral drug, approximately 1 or 2 weeks before discontinuing or reaching the lowest anticipated dose of the oral drug. When a patient requires a systemic corticosteroid, co-administration of an aerosol allows smaller doses of the systemic corticosteroid. Although the inhaled drugs can cause suppression of the HPA axis and adrenocortical function, especially at higher doses, they are much less likely to do so than systemic drugs. However, a **BLACK BOX WARNING** has been issued by the Food and Drug Administration (FDA) for individuals who are transferred from systemically active corticosteroids to flunisolide inhaler because deaths have occurred from adrenal insufficiency.

### Cancer

Corticosteroids are commonly used in the treatment of lymphomas, lymphocytic leukemias, and multiple myeloma. In these disorders, corticosteroids inhibit cell reproduction and are cytotoxic to lymphocytes. In addition to their anticancer effects in hematologic malignancies, corticosteroids are beneficial in treatment of several signs and symptoms that often accompany cancer, although the mechanisms of action are unknown and drug/dosage regimens vary widely. Cortico-

steroids are used to treat anorexia, nausea and vomiting, cerebral edema and inflammation associated with brain metastases or radiation of the head, spinal cord compression, pain and edema related to pressure on nerves or bone metastases, graft-versus-host disease after bone marrow transplantation, and other disorders that occur in patients with cancer. Patients tend to feel better when taking corticosteroids, although the basic disease process may be unchanged.

### Primary Central Nervous System Lymphomas

Formerly considered rare tumors of older adults, central nervous system lymphomas are being diagnosed more frequently in younger patients. They are usually associated with chronic *immunosuppression* caused by immunosuppressant drugs or acquired immunodeficiency syndrome (AIDS). Many of these lymphomas are very sensitive to corticosteroids, and therapy is indicated when the diagnosis is established.

### Other Central Nervous System Tumors

Corticosteroid therapy may be useful in both supportive and definitive treatment of brain and spinal cord tumors, and neurologic signs and symptoms often improve dramatically within 24 to 48 hours. Corticosteroids help relieve symptoms by controlling edema around the tumor, at operative sites, and at sites receiving radiation therapy. Some patients no longer require corticosteroids after surgical or radiation therapy, whereas others require continued therapy to manage neurologic symptoms. Adverse effects of long-term corticosteroid therapy may include mental changes ranging from mild agitation to psychosis and steroid myopathy (muscle weakness and atrophy) that may be confused with tumor progression. Mental symptoms usually improve if drug dosage is reduced and resolve if the drug is discontinued; steroid myopathy may persist for weeks or months.

### Chemotherapy-Induced Emesis

Corticosteroids have strong antiemetic effects; the mechanism is unknown. One effective regimen is a combination of an oral or IV dose of dexamethasone (10–20 mg) and a serotonin antagonist or metoclopramide given immediately before the chemotherapeutic drug. This regimen is the treatment of choice for chemotherapy with cisplatin, which is a strongly emetic drug.

### Chronic Obstructive Pulmonary Disease

Corticosteroids are more helpful in acute exacerbations than in stable COPD. However, oral corticosteroids may improve pulmonary function and symptoms in some patients. For example, for a patient with inadequate relief from a bronchodilator, a trial of a corticosteroid (e.g., prednisone 20–40 mg each morning for 5–7 days) may be justified. Treatment should be continued only if there is significant improvement. As in other conditions, the lowest effective dose is needed to minimize adverse drug effects.

Inhaled corticosteroids can also be tried. They produce minimal adverse effects, but their effectiveness in COPD has not been clearly demonstrated.

### Inflammatory Bowel Disease

Crohn's disease and ulcerative colitis often require periodic corticosteroid therapy.

In moderate Crohn's disease, oral prednisone, 40 milligrams daily, is usually given until symptoms subside. With severe disease, patients often require hospitalization, IV fluids for hydration, and parenteral corticosteroids until symptoms subside. An oral form of budesonide (Entocort EC) may be used for Crohn's disease. The capsule dissolves in the small intestine and acts locally before being absorbed into the bloodstream and transported to the liver for metabolism. It has fewer adverse effects than systemic corticosteroids but is also less effective and more expensive.

In ulcerative colitis, corticosteroids are usually used when aminosalicylates (e.g., mesalamine) are not effective or when symptoms are more severe. Initially, hydrocortisone enemas may be effective. If not effective, oral prednisone (20–60 mg daily) may be given until symptoms subside. In severe disease, oral prednisone may be required initially. After remission of symptoms is achieved, the dose can be tapered by 2.5 to 5 milligrams per day each week to a dose of 20 milligrams. Then, tapering may be slowed to 2.5 to 5 milligrams per day every other week. As in Crohn's disease, patients with severe ulcerative colitis often require hospitalization and parenteral corticosteroids. One regimen uses IV hydrocortisone 300 milligrams per day or the equivalent dose of another drug. When the patient's condition improves, oral prednisone can replace the IV corticosteroid.

### Spinal Cord Injury

High-dose corticosteroid therapy to treat spinal cord injury is a common practice in clinical settings, although controversy exists regarding its use. Data suggest that methylprednisolone may be effective in acute spinal cord injury when given in high doses within 8 hours of the injury. Methylprednisolone improves neurologic recovery, although it does not improve mortality, and its use is unlikely to result in normal neurologic function. In addition, severe adverse outcomes, including wound and systemic infections, gastrointestinal hemorrhage, and pneumonia, have been reported.

### Prevention of Acute Adrenocortical Insufficiency

Suppression of the HPA axis may occur with corticosteroid therapy and may lead to life-threatening inability to increase cortisol secretion when needed to cope with stress. It is most likely to occur with abrupt withdrawal of systemic corticosteroid drugs. The risk of HPA suppression is high with systemic drugs given for more than a few days, although patients vary in degree and duration of suppression with comparable doses, and the minimum dose and duration of therapy that cause suppression are unknown.

When corticosteroids are given for replacement therapy, adrenal insufficiency is lifelong, and drug administration must be continued. When the drugs are given for purposes other than replacement and then discontinued, the HPA axis

usually recovers within several weeks to months, but recovery may take a year. Several strategies have been developed to minimize HPA suppression and risks of acute adrenal insufficiency, including

- Administering a systemic corticosteroid during high-stress situations (e.g., moderate or severe illness, trauma, surgery) to patients who have received pharmacologic doses for 2 weeks within the previous year or who receive long-term systemic therapy (i.e., are steroid dependent)
- Giving short courses of systemic therapy for acute disorders, such as asthma attacks, then decreasing the dose or stopping the drug within a few days
- Gradually tapering the dose of any systemic corticosteroid. Although specific guidelines for tapering dosage have not been developed, higher doses and longer durations of administration in general require slower tapering, possibly over several weeks. The goal of tapering may be to stop the drug or to decrease the dosage to the lowest effective amount.
- Using local rather than systemic therapy when possible, alone or in combination with low doses of systemic drugs. Numerous preparations are available for local application, including aerosols for oral or nasal inhalation; formulations for topical application to the skin, eyes, and ears; and drugs for intra-articular injections.
- Using ADT, which involves titrating the daily dose to the lowest effective maintenance level, then giving a double dose every other day

## Use in Special Populations

### Use in Children

Corticosteroids are used for the same conditions in children as in adults; a common indication is for treatment of asthma. With severe asthma, continual corticosteroid therapy may be required. For children with asthma, evidence indicates that with inhaled corticosteroids, starting with a moderate dose of inhaled corticosteroid is comparable with starting with a high dose and titrating down. A concern with children is growth retardation, which can occur short term with small doses and administration by inhalation. Many children have a growth spurt when the corticosteroid is discontinued. Adult stature does not appear to be affected by inhaled corticosteroid therapy during childhood.

Parents and prescribers can monitor drug effects by recording height and weight weekly. ADT is less likely to impair normal growth and development than daily administration. In addition, for both systemic and inhaled corticosteroids, each child's dose should be titrated to the lowest effective amount.

### Use in Older Adults

Corticosteroids are used for the same conditions in older adults as in younger ones. Older adults are especially likely to have conditions that are aggravated by the drugs (e.g., congestive heart failure, hypertension, diabetes mellitus, arthritis, osteoporosis, increased susceptibility to infection, concomitant drug

therapy that increases risks of gastrointestinal ulceration and bleeding). Consequently, risk–benefit ratios of systemic corticosteroid therapy should be carefully considered, especially for long-term therapy.

When used, lower doses are usually indicated because of decreased muscle mass, plasma volume, hepatic metabolism, and renal excretion in older adults. In addition, therapeutic and adverse responses should be monitored regularly by a health care provider (e.g., blood pressure, serum electrolytes, and blood glucose levels at least every 6 months). As in other populations, adverse effects are less likely to occur with oral or nasal inhalations than with oral drugs.

### Use in Patients With Renal Impairment

Systemic corticosteroids should be used with caution because of slowed excretion, with possible accumulation and signs and symptoms of hypercorticism. In renal transplantation, corticosteroids are extensively used, along with other immunosuppressive drugs, to prevent or treat rejection reactions. In these patients, as in others, adverse effects of systemic corticosteroids may include infections, hypertension, glucose intolerance, obesity, cosmetic changes, bone loss, growth retardation in children, cataracts, pancreatitis, peptic ulcerations, and psychiatric disturbances. Doses should be minimized, and eventually the drugs can be withdrawn in some patients.

### Use in Patients With Hepatic Impairment

Metabolism of corticosteroids is slowed by severe hepatic disease, and corticosteroids may accumulate and cause signs and symptoms of hypercorticism. In addition, patients with liver disease should be given prednisolone rather than prednisone. Liver metabolism of prednisone is required to convert it to its active form, prednisolone.

### Use in Patients With Critical Illness

Corticosteroids have been extensively used in the treatment of serious illness, with much empiric usage.

#### Adrenal Insufficiency

Adrenal insufficiency is the most clear-cut indication for use of a corticosteroid, and even a slight impairment of the adrenal response during severe illness can be lethal if corticosteroid therapy is not instituted. For example, hypotension is a common symptom in critically ill patients, and hypotension caused by adrenal insufficiency may mimic either hypovolemic or septic shock. If adrenal insufficiency is the cause of the hypotension, administration of corticosteroids can eliminate the need for vasopressor drugs to maintain adequate tissue perfusion.

However, adrenal insufficiency may not be recognized because hypotension and other symptoms also occur with many illnesses. The normal response to critical illness (e.g., pain, hypovolemia) is an increased and prolonged secretion of cortisol. If this does not occur, or if too little cortisol is produced, a state of adrenal insufficiency exists. One way to evaluate a patient for adrenal insufficiency is a test in which a

baseline serum cortisol level is measured, after which corticotropin is given IV to stimulate cortisol production, and the serum cortisol level is measured again in approximately 30 to 60 minutes. Test results are hard to interpret in seriously ill patients, though, because serum cortisol concentrations that would be normal in normal subjects may be low in this population. In addition, a lower-than-expected rise in serum cortisol levels may indicate a normal HPA axis that is already maximally stimulated or interference with the ability of the adrenal cortex to synthesize cortisol. Thus, a critically ill patient may have a limited ability to increase cortisol production in response to stress.

In any patient suspected of having adrenal insufficiency, a single IV dose of corticosteroid seems justified. If the patient does have adrenal insufficiency, the corticosteroid may prevent immediate death and allow time for other diagnostic and therapeutic measures. If the patient does not have adrenal insufficiency, the single dose is not harmful.

#### Acute Respiratory Failure in Chronic Obstructive Pulmonary Disease

Some studies support the use of IV methylprednisolone. Thus, if other medications do not produce adequate bronchodilation, it seems reasonable to try an IV corticosteroid during the first 72 hours of the illness. However, corticosteroid therapy increases the risks of pulmonary infection.

#### Adult Respiratory Distress Syndrome

Although corticosteroids have been widely used, several well-controlled studies demonstrate that the drugs are not beneficial in early treatment or in prevention of adult respiratory distress syndrome (ARDS). Thus, corticosteroids should be used in these patients only if there are other specific indications.

#### Sepsis

Sepsis may be complicated by impaired corticosteroid production. There is sufficient evidence to support that giving a long course of low dose of corticosteroids in patients with septic shock could improved survival without causing harm. However, overall corticosteroids did not impact on mortality

#### Acquired Immunodeficiency Syndrome

Adrenal insufficiency is being increasingly recognized in patients with AIDS, who should be assessed and treated for it, if indicated. In addition, corticosteroids improve survival and decrease risks of respiratory failure with pneumocystosis, a common cause of death in patients with AIDS. The recommended regimen is prednisone 40 milligrams twice daily for 5 days, then 40 milligrams once daily for 5 days, then 20 milligrams daily until completion of treatment for pneumocystosis. The effect of corticosteroids on risks of other opportunistic infections or neoplasms is unknown.

#### Use in Home Care

Corticosteroids are extensively used in the home setting, by all age groups, for a wide variety of disorders, and by most routes of administration. Because of potentially serious adverse

effects, especially with oral drugs, it is extremely important that these drugs be used as prescribed. A major responsibility of home care nurses is to teach, demonstrate, supervise, monitor, or do whatever is needed to facilitate correct use. In addition, home care nurses must teach patients and caregivers interventions to minimize adverse effects of these drugs.

### Applying Your Knowledge 23-4

Long-term therapy with corticosteroids involves multiple teaching opportunities for the nurse. What should you include as priorities when providing a teaching plan for Ms. Hubble?

.....

## Nursing Actions Corticosteroids

### NURSING ACTIONS

#### 1. Administer accurately

- a. Read the drug label carefully to be certain of having the correct preparation for the intended route of administration.
- b. With oral corticosteroids:
  - (1) Give single daily doses or alternate day doses between 6 and 9 A.M.
  - (2) Give multiple doses at evenly spaced intervals.
  - (3) If dosage is being tapered, follow the exact schedule.
  - (4) Give with meals or snacks.
  - (5) With oral budesonide (Entocort EC), ask the patient to swallow the drug whole, without biting or chewing.
  - (6) Do not give these drugs with an antacid containing aluminum or magnesium (e.g., Maalox, Mylanta).
- c. For IV or IM administration:
  - (1) Shake the medication vial well before withdrawing medication.
  - (2) Give a direct IV injection over at least 1 minute.
- d. For oral or nasal inhalation of a corticosteroid, check the instruction leaflet that accompanies the inhaler.

#### 2. Observe for therapeutic effects

- a. With adrenocortical insufficiency, observe for absence or decrease of weakness, weight loss, anorexia, nausea, vomiting, hyperpigmentation, hypotension, hypoglycemia, hyponatremia, and hyperkalemia.
- b. With rheumatoid arthritis, observe for decreased pain and edema in joints, greater capacity for movement, and increased ability to perform usual activities of daily living.
- c. With asthma and chronic obstructive pulmonary disease, observe for decrease in respiratory distress and increased tolerance of activity.
- d. With skin lesions, observe for decreasing inflammation.
- e. When the drug is given to suppress the immune response to organ transplants, therapeutic effect is the absence of signs and symptoms indicating rejection of the transplanted tissue.

### RATIONALE/EXPLANATION

Many corticosteroid drugs are available in several different preparations. For example, hydrocortisone is available in formulations for intravenous (IV) or intramuscular (IM) administration, for intraarticular injection, and for topical application in creams and ointments of several different strengths. These preparations cannot be used interchangeably without causing potentially serious adverse reactions and decreasing therapeutic effects. Some drugs are available for only one use. For example, several preparations are for topical use only; beclomethasone is prepared only for oral and nasal inhalation.

Early-morning administration causes less suppression of hypothalamic-pituitary-adrenal (HPA) function.

To avoid adverse effects

To decrease gastrointestinal (GI) upset

This drug is formulated to dissolve in the intestine and have local anti-inflammatory effects. Biting or chewing allows it to dissolve in the stomach.

The antacids decrease absorption of corticosteroids, with possible reduction of therapeutic effects.

Most of the injectable formulations are suspensions, which need to be mixed well for accurate dosage.

To increase safety of administration

These drugs are given by metered-dose inhalers or nasal sprays, and correct usage of the devices is essential to drug administration and therapeutic effects.

The primary objective of corticosteroid therapy is to relieve signs and symptoms, because the drugs are not curative.

Therefore, therapeutic effects depend largely on the reason for use.

These signs and symptoms of impaired metabolism do not occur with adequate replacement of corticosteroids.

**NURSING ACTIONS****3. Observe for adverse effects**

- a. Adrenocortical insufficiency—fainting, weakness, anorexia, nausea, vomiting, hypotension, shock, and if untreated, death
- b. Adrenocortical excess (hypercorticism or Cushing's disease)
  - (1) "Moon face," "buffalo hump" contour of shoulders, obese trunk, thin extremities
  - (2) Diabetes mellitus—glycosuria, hyperglycemia, polyuria, polydipsia, polyphagia, impaired healing, and other signs and symptoms
  - (3) Central nervous system effects—euphoria, psychological dependence, nervousness, insomnia, depression, personality and behavioral changes, aggravation of pre-existing psychiatric disorders
  - (4) Musculoskeletal effects—osteoporosis, pathologic fractures, muscle weakness and atrophy, decreased linear growth in children
  - (5) Cardiovascular, fluid, and electrolyte effects—fluid retention, edema, hypertension, congestive heart failure, hypernatremia, hypokalemia, metabolic alkalosis
  - (6) Gastrointestinal effects—nausea, vomiting, possible peptic ulcer disease, increased appetite, obesity
  - (7) Increased susceptibility to infection and delayed wound healing
  - (8) Menstrual irregularities, acne, excessive facial hair
  - (9) Ocular effects—increased intraocular pressure, glaucoma, cataracts
  - (10) Integumentary effects—skin becomes reddened, thinner, has stretch marks, and is easily injured

**4. Observe for drug interactions**

- a. Drugs that *increase* effects of corticosteroids:
  - (1) Estrogens, oral contraceptives, ketoconazole, macrolide antibiotics (e.g., erythromycin)
  - (2) Diuretics (e.g., furosemide, thiazides)
- b. Drugs that *decrease* effects of corticosteroids:
  - (1) Antacids, cholestyramine
  - (2) Carbamazepine, phenytoin, rifampin

**RATIONALE/EXPLANATION**

These are uncommon with replacement therapy but common with long-term administration of the pharmacologic doses used for many disease processes. Adverse reactions may affect every body tissue and organ.

This reaction is likely to occur in patients receiving daily corticosteroid drugs who encounter stressful situations. It is caused by drug-induced suppression of the HPA axis, which makes the patient unable to respond to stress by increasing adrenocortical hormone secretion.

Most adverse effects result from excessive corticosteroids.

This appearance is caused by abnormal fat deposits in cheeks, shoulders, breasts, abdomen, and buttocks. These changes are more cosmetic than physiologically significant. However, the alterations in self-image can lead to psychological problems. These changes cannot be prevented, but they may be partially reversed if corticosteroid therapy is discontinued or reduced in dosage.

Corticosteroid drugs can cause hyperglycemia and diabetes mellitus or aggravate pre-existing diabetes mellitus by their effects on carbohydrate metabolism.

Some patients enjoy the drug-induced euphoria so much that they resist attempts to withdraw the drug or decrease its dosage.

Deminerlization of bone produces thin, weak bones that fracture easily. Fractures of vertebrae, long bones, and ribs are relatively common, especially in postmenopausal women and immobilized patients. Myopathy results from abnormal protein metabolism. Decreased growth in children results from impaired bone formation and protein metabolism.

These effects result largely from mineralocorticoid activity, which causes retention of sodium and water. They are more likely to occur with older corticosteroids, such as hydrocortisone and prednisone.

Caused by suppression of normal inflammatory and immune processes and impaired protein metabolism

Caused by excessive sex hormones, primarily androgens

These drugs apparently inhibit the enzymes that normally metabolize corticosteroids in the liver.

Increase hypokalemia

Decrease absorption

These drugs induce microsomal enzymes in the liver and increase the rate at which corticosteroids are metabolized or deactivated.

## Key Concepts

- The most frequently desired pharmacologic effects of exogenous corticosteroids are anti-inflammatory, immunosuppressive, antiallergic, and antistress.
- Mineralocorticoid and androgenic effects of exogenous corticosteroids are usually considered adverse reactions.
- Daily administration of corticosteroids and mineralocorticoids is required in cases of chronic adrenocortical insufficiency (Addison's disease).
- Adrenocortical hyperfunction (Cushing's disease) may result from excessive corticotropin or a primary adrenal tumor.
- Strategies to minimize HPA suppression and risks of acute adrenal insufficiency, include (1) administering a systemic corticosteroid during high-stress situations to those who receive long-term systemic therapy (i.e., are steroid dependent); (2) giving short courses of systemic therapy for acute disorders; (3) gradually tapering the dose of any systemic corticosteroid; (4) using local rather than systemic therapy when possible, alone or in combination with low doses of systemic drugs; and (5) using ADT.
- Adverse effects of systemic corticosteroids may include infections, hypertension, glucose intolerance, obesity, cosmetic changes, bone loss, growth retardation in children, cataracts, pancreatitis, peptic ulcerations, and psychiatric disturbances.
- A **BLACK BOX WARNING** has been issued by the FDA for individuals who are transferred from systemically active corticosteroids to flunisolide inhaler; deaths have been reported from adrenal insufficiency.

## Review and Application Exercises

### Short Answer Exercises

1. What are the main characteristics and functions of cortisol?
2. What is the difference between glucocorticoid and mineralocorticoid components of corticosteroids?
3. How do glucocorticoids affect body metabolism?
4. What is meant by the HPA axis?
5. What are the mechanisms by which exogenous corticosteroids may cause adrenocortical insufficiency and excess?
6. What adverse effects are associated with chronic use of systemic corticosteroids?
7. What are the main differences between administering corticosteroids in adrenal insufficiency versus in other disorders?
8. When a corticosteroid is given by inhalation to patients with asthma, what is the expected effect?

### NCLEX-Style Questions

9. Your patient is being discontinued from long-term systemic corticosteroid therapy. You know that it is important to taper the dose in long-term systemic corticosteroid therapy rather than stopping the drug abruptly, because tapering results in which of the following?
  - a. less suppression of hypothalamic–pituitary–adrenal function
  - b. increased patient compliance with drug therapy
  - c. greater tolerance of adverse effects
  - d. significantly increased anti-inflammatory effect
10. A nurse is instructing a patient regarding the correct way to follow the order, “prednisone 10 mg PO once daily.” The nurse should tell the patient to take
  - a. the entire dose once a day at bedtime
  - b. the entire dose once a day on arising
  - c. half of the dose in the morning and half at bedtime
  - d. one third of the dose in the morning and two thirds in the afternoon
11. A patient who has been on long-term corticosteroid therapy begins to gain weight and complains that her rings no longer fit on her hands. She asks the nurse why she is gaining weight. The nurse tells the patient that the most likely cause of later weight gain when undergoing corticosteroid therapy is
  - a. increased appetite
  - b. hyperglycemia
  - c. muscle hypertrophy
  - d. fluid retention
12. A patient taking an inhaled steroid should be instructed to rinse her mouth after administration of the drug to avoid development of which of the following conditions?
  - a. anorexia
  - b. nausea and vomiting
  - c. thrush
  - d. gingival hyperplasia
13. Patients taking oral or IV glucocorticoids have an increased risk for which of the following conditions?
  - a. allergic reaction
  - b. hypotension
  - c. hypoglycemia
  - d. infection

# Thyroid and Antithyroid Drugs

## KEY TERMS

- Cretinism
- Euthyroid
- Goiter
- Graves' disease
- Hyperthyroidism
- Hypothyroidism
- Myxedema
- Thyroid storm
- Thyroiditis
- Thyroxine

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Recognize physiologic effects of thyroid hormone.
2. Assess subclinical, symptomatic, and severe effects of inadequate or excessive thyroid hormone.
3. Describe characteristics, uses, and effects of thyroid drugs.
4. Identify characteristics, uses, and effects of antithyroid drugs.
5. Evaluate the influence of thyroid and antithyroid drugs on the metabolism of other drugs.
6. Teach patients effective self-care activities related to the use of thyroid and antithyroid drugs.
7. Apply the nursing process with patients receiving thyroid and antithyroid drugs.

## Applying Your Knowledge

Brenda Zalewski is a 45-year-old woman who had a goiter as a child and a thyroidectomy at age 12. She has been taking a synthetic thyroid preparation since that time. Ms. Zalewski takes a maintenance dose of Synthroid 0.1 mg PO daily. She is 5 feet 8 inches tall and weighs 215 pounds.

## Introduction

Normal serum levels of thyroid hormones and a physiologic state of normal thyroid function (*euthyroid*) require a functioning thyroid gland and feedback mechanism. The thyroid gland produces three hormones: *thyroxine*, *triiodothyronine*, and *calcitonin*. Thyroxine (also called  $T_4$ ) contains four atoms of iodine, and triiodothyronine (also called  $T_3$ ) contains three atoms of iodine.  $T_3$  is more potent than  $T_4$  and has a more rapid onset but a shorter duration of action. Despite these minor differences, the two hormones produce the same physiologic effects and have the same actions and uses. Calcitonin functions in calcium metabolism and is discussed in Chapter 25.

Production of  $T_3$  and  $T_4$  depends on the presence of iodine and tyrosine in the thyroid gland. In a series of chemical reactions, iodine atoms become attached to tyrosine, an amino acid derived from dietary protein, to form the thyroid hormones  $T_3$  and  $T_4$ . After they are formed, the hormones are stored within the chemically inactive thyroglobulin molecule. Tyrosine forms the basic structure of thyroglobulin.

Thyroid hormones are released into the circulation when the thyroid gland is stimulated by thyroid-stimulating hormone (thyrotropin or TSH) from the anterior pituitary gland (Fig. 24-1). The hormones become largely bound to plasma proteins with only the small unbound remaining

**Figure 24-1** ■ Thyroid-releasing hormone (TRH) from the hypothalamus stimulates the anterior pituitary to release thyroid-stimulating hormone (TSH). It also inhibits the hypothalamus from releasing TRH. TSH stimulates the thyroid gland to release T<sub>3</sub> and T<sub>4</sub>. It also inhibits the hypothalamus from releasing TRH and the anterior pituitary from releasing more TSH. The release of T<sub>3</sub> and T<sub>4</sub> from the thyroid gland inhibits TRH release from the hypothalamus, TSH release from the pituitary, and further T<sub>3</sub> and T<sub>4</sub> release from the thyroid gland. Falling T<sub>3</sub> and T<sub>4</sub> levels stimulate the hypothalamus to release TRH, and the process repeatedly continues to maintain effective hormone levels. ACTH, adrenocorticotropic hormone; CRH, corticotropin-releasing hormone; FSH, follicle-stimulating hormone; GH, growth hormone; GHRH, growth hormone-releasing hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone; PIF, prolactin-inhibiting factor; PRL, prolactin; PRF, prolactin-releasing factor; SRIF, somatotropin release-inhibiting factor.

biologically active. The bound thyroid hormones are released to tissue cells very slowly. In tissue cells, the hormones combine with intracellular proteins so they are again stored. They are released slowly within the cell and used over a period of

days or weeks. When they are used by the cells, the thyroid hormones release iodine atoms. Most of the iodine is reabsorbed and used to produce new thyroid hormones; the remainder is excreted in the urine.

Thyroid hormones control the rate of cellular metabolism and thereby influence the functioning of virtually every cell in the body. The heart, skeletal muscle, liver, and kidneys are especially responsive to the stimulating effects of thyroid hormones. The brain, spleen, and gonads are less responsive. Thyroid hormones are required for normal growth and development and are considered especially critical for brain and skeletal development and maturation.

Thyroid hormones also influence linear growth; brain function, including intelligence and memory; neural development; dentition; and bone development. These hormones are thought to act mainly by controlling intracellular protein synthesis. Some specific physiologic effects include

- Increased rate of cellular metabolism and oxygen consumption with a resultant increase in heat production
- Increased heart rate, force of contraction, and cardiac output (increased cardiac workload)
- Increased carbohydrate metabolism
- Increased fat metabolism, including increased lipolytic effects of other hormones and metabolism of cholesterol to bile acids
- Inhibition of pituitary secretion of TSH

Two types of thyroid disorders requiring drug therapy are hypothyroidism and hyperthyroidism. These disorders produce opposing effects on body tissues, depending on the levels of circulating thyroid hormone. Specific effects and clinical manifestations are listed in Table 24-1.

## Hyperthyroidism

Primary *hypothyroidism* occurs when disease or destruction of thyroid gland tissue causes inadequate production of thyroid hormones. Common causes of primary hypothyroidism include chronic (Hashimoto's) *thyroiditis*, an autoimmune disorder characterized by inflammation of the thyroid gland, and treatment of hyperthyroidism with antithyroid drugs, radiation therapy, or surgery. Other causes include previous radiation to the thyroid area of the neck and treatment with amiodarone, lithium, or iodine preparations. Secondary hypothyroidism occurs when there is decreased TSH from the anterior pituitary gland or decreased thyrotropin-releasing hormone (TRH) secreted from the hypothalamus.

Congenital hypothyroidism (*cretinism*) occurs when a child is born with a poorly functioning or absent thyroid gland. Cretinism is uncommon in the United States but may occur with a lack of iodine in the mother's diet. Symptoms are rarely present at birth but develop gradually during infancy and early childhood, and they include poor growth and development, lethargy and inactivity, feeding problems, slow pulse, subnormal temperature, and constipation. If cretinism is untreated

until the child is several months old, permanent mental retardation is likely to result.

Adult hypothyroidism (*myxedema*) may be subclinical or clinical and occurs much more often in women than in men. Subclinical hypothyroidism, the most common thyroid disorder, involves a mildly elevated serum TSH and normal serum thyroxine levels. It is usually asymptomatic. If the thyroid gland cannot secrete enough hormone despite excessive release of TSH, hypothyroidism occurs, and a *goiter* (visible enlargement of the thyroid gland) may occur from the overstimulation. Clinical hypothyroidism produces variable signs and symptoms, depending on the amount of circulating thyroid hormone. Initially, manifestations (see Table 24-1) are mild

and vague. They usually increase in incidence and severity over time as the thyroid gland gradually atrophies and functioning glandular tissue is replaced by nonfunctioning fibrous connective tissue.

Myxedema coma is severe, life-threatening hypothyroidism characterized by coma, hypothermia, cardiovascular collapse, hypoventilation, and severe metabolic disorders such as hyponatremia, hypoglycemia, and lactic acidosis. Predisposing factors include exposure to cold, infection, trauma, respiratory disease, and administration of central nervous system depressants (e.g., anesthetics, analgesics, sedatives). A person with severe hypothyroidism cannot metabolize and excrete the drugs.

Table 24-1

Thyroid Disorders and Their Effects on Body Systems

HYPOTHYROIDISM	HYPERTHYROIDISM
<b>Cardiovascular Effects</b>	
Increased capillary fragility	Tachycardia
Decreased cardiac output	Increased cardiac output
Decreased blood pressure	Increased blood volume
Decreased heart rate	Increased systolic blood pressure
Cardiac enlargement	Decreased diastolic blood pressure
Congestive heart failure	Cardiac dysrhythmias
Anemia	Congestive heart failure
More rapid development of atherosclerosis and its complications (e.g., coronary artery and peripheral vascular disease)	
<b>Central Nervous System Effects</b>	
Apathy and lethargy	Nervousness
Emotional dullness	Emotional instability
Slow speech, perhaps slurring and hoarseness as well	Restlessness
Hypoactive reflexes	Anxiety
Forgetfulness and mental sluggishness	Insomnia
Excessive drowsiness and sleeping	Hyperactive reflexes
<b>Metabolic Effects</b>	
Intolerance of cold	Intolerance of heat
Subnormal temperature	Low-grade fever
Increased serum cholesterol	Weight loss despite increased appetite
Weight gain	
<b>Gastrointestinal Effects</b>	
Decreased appetite	Increased appetite
Constipation	Abdominal cramps
	Diarrhea
	Nausea and vomiting
<b>Muscular Effects</b>	
Weakness	Weakness
Fatigue	Fatigue

HYPOTHYROIDISM	HYPERTHYROIDISM
Vague aches and pains	Muscle atrophy Tremors
<b>Integumentary Effects</b>	
Dry, coarse, and thickened skin Puffy appearance of face and eyelids	Moist, warm, flushed skin due to vasodilation and increased sweating
Dry and thinned hair Thick and hard nails	Hair and nails soft
<b>Reproductive Effects</b>	
Prolonged menstrual periods Infertility or sterility Decreased libido	Amenorrhea or oligomenorrhea
<b>Miscellaneous Effects</b>	
Increased susceptibility to infection	Dyspnea
Increased sensitivity to narcotics, barbiturates, and anesthetics due to slowed metabolism of these drugs	Polyuria Hoarse, rapid speech Increased susceptibility to infection Excessive perspiration Localized edema around the eyeballs, which produces characteristic eye changes, including exophthalmos

## Hyperthyroidism

*Hyperthyroidism* is characterized by excessive secretion of thyroid hormone and usually involves an enlarged thyroid gland that has an increased number of cells and an increased rate of secretion. It may be associated with *Graves' disease*, nodular goiter, thyroiditis, overtreatment with thyroid drugs, functioning thyroid carcinoma, and pituitary adenoma that secretes excessive amounts of TSH. The hyperplastic thyroid gland may secrete 5 to 15 times the normal amount of thyroid hormone. As a result, body metabolism is greatly increased. Specific physiologic effects and clinical manifestations of hyperthyroidism are listed in Table 24-1. These effects vary, depending on the amount of circulating thyroid hormone, and they usually increase in incidence and severity with time if hyperthyroidism is not treated.

Subclinical hyperthyroidism is defined as a reduced TSH (less than 0.1 microunit/L) and normal  $T_3$  and  $T_4$  levels. The most common cause is excess thyroid hormone therapy. Subclinical hyperthyroidism is a risk factor for osteoporosis in postmenopausal women who do not take estrogen replacement therapy, because it leads to reduced bone mineral density. It also greatly increases the risk of atrial fibrillation in patients older than 60 years of age.

*Thyroid storm* or thyrotoxic crisis is a rare but severe complication characterized by extreme symptoms of hyperthyroidism, such as severe tachycardia, fever, dehydration, heart failure, and coma. It is most likely to occur in patients with hyperthyroidism that has been inadequately treated, especially when stressful situations occur (e.g., trauma, infection, surgery, emotional upset).

It should be noted that iodine is present in foods (especially seafood and kelp) and in radiographic contrast dyes. Reports of iodine-induced hyperthyroidism have been reported after ingestion of dietary sources of iodine.

## General Characteristics of Thyroid and Antithyroid Drugs

### Mechanism of Action

Thyroid drugs such as the synthetic drug levothyroxine provide an exogenous source of thyroid hormone. Antithyroid drugs act by decreasing production or release of thyroid hormones. The thioamide drugs inhibit synthesis of thyroid hormone. Iodine preparations inhibit the release of thyroid hormones and cause them to be stored within the thyroid gland. Radioactive iodine emits rays that destroy the thyroid gland tissue.

### Indications for Use

Thyroid drugs are indicated for primary or secondary hypothyroidism, cretinism, and myxedema. Antithyroid drugs may be necessary for hyperthyroidism associated with *Graves' disease*, nodular goiter, thyroiditis, overtreatment with thyroid drugs, functioning thyroid carcinoma, and pituitary adenoma that secretes excessive amounts of TSH. Antithyroid drugs may also be indicated for thyroid storm. The Food and Drug Administration (FDA) has issued a **BLACK BOX WARNING** regarding the use of thyroid hormones for the treatment of obesity or for weight loss, either alone or with other therapeutic agents.

Additional administration of thyroid preparations in euthyroid individuals may produce serious or life-threatening manifestations of toxicity; this effect is increased when given in conjunction with sympathomimetic amines, often used for their anorectic effects in weight loss management.

### Contraindications to Use

Iodine preparations and thioamide antithyroid drugs are contraindicated in pregnancy, because they can lead to goiter and hypothyroidism in the fetus or newborn. Radioactive iodine is

contraindicated during lactation as well. Because radioactive iodine may cause cancer and chromosome damage in children, it should be used only for hyperthyroidism that cannot be controlled by other drugs or surgery.

### Individual Drugs

Thyroid and antithyroid drugs are described in the following section. Dosages are listed in Table 24-2.

Table 24-2

### Drugs at a Glance: Drugs for Hypothyroidism and Hyperthyroidism

Generic/Trade name	ROUTES AND DOSAGE RANGES	
	Adults	Children
<b>Drugs for Hypothyroidism</b>		
<b>P Levothyroxine</b> (Synthroid, Levothroid)	PO 0.05 mg/d initially, increased by 0.025 mg every 2–3 wk until desired response obtained; usual maintenance dose, 0.1–0.2 mg/d (100–200 mcg/d)  Myxedema coma, IV 0.4 mg in a single dose; then 0.1–0.2 mg daily  Thyroid-stimulating hormone (TSH) suppression in thyroid cancer, nodules, and euthyroid goiters, PO 2.6 mcg/kg/d for 7–10 d  <i>Older adults, patients with cardiac disorders, and patients with hypothyroidism of long duration:</i> PO 0.0125–0.025 mg/d for 6 wk, then dose is doubled every 6–8 wk until the desired response is obtained  Myxedema coma, same as adult dosage	Congenital hypothyroidism, PO as follows: <i>older than 12 y:</i> >150 mcg/d (or 2–3 mcg/kg/d) <i>6–12 y:</i> 100–150 mcg/d (or 4–5 mcg/kg/d) <i>1–5 y:</i> 75–100 mcg/d (or 5–6 mcg/kg/d) <i>6–12 mo:</i> 50–75 mcg/d (or 6–8 mcg/kg/d) <i>Birth–6 mo:</i> 25–50 mcg/d (or 8–10 mcg/kg/d)
<b>Drugs for Hyperthyroidism</b>		
<b>P Propylthiouracil</b>	PO 300–400 mg/d in divided doses q8h, until the patient is euthyroid; then 100–150 mg/d in 3 divided doses, for maintenance	<i>older than 10 y:</i> PO 150–300 mg/d in divided doses q8h; usual maintenance dose, 100–300 mg/d in 2 divided doses, q12h <i>6–10 y:</i> 50–150 mg/d in divided doses q8h
<b>Methimazole</b> (Tapazole)	PO 15–60 mg/d initially, in divided doses q8h until the patient is euthyroid; maintenance, 5–15 mg/d in 2 or 3 doses	PO 0.4 mg/kg/d initially, in divided doses q8h; maintenance dose, one half initial dose
<b>Strong iodine solution</b> (Lugol's solution)	PO 2–6 drops 3 times per day for 10 d before thyroidectomy	PO 2–6 drops 3 times per day for 10 d before thyroidectomy
<b>Saturated solution of potassium iodide</b> (SSKI)	PO 5 drops 3 times per day for 10 d before thyroidectomy	PO 5 drops 3 times per day for 10 d before thyroidectomy
<b>Sodium iodide</b> <sup>131</sup> I (Iodotope)	PO, IV, dosage as calculated by a radiologist trained in nuclear medicine	PO, IV, dosage as calculated by a radiologist trained in nuclear medicine
<b>Propranolol</b> (Inderal)	PO 40–160 mg/d in divided doses	

## Thyroid Drugs (Used in Hypothyroidism)

**P** **Levothyroxine** (Synthroid, Levothroid), a synthetic preparation of  $T_4$ , is the drug of choice for long-term treatment of hypothyroidism and serves as the prototype. This potent form of  $T_4$  contains a uniform amount of hormone and can be given parenterally. Absorption with oral administration varies from 48% to 79% of the dose administered. Taking the medication on an empty stomach increases absorption; malabsorption syndromes cause excessive fecal loss. Most (99%) of the circulating levothyroxine is bound to serum proteins, including thyroid-binding globulin as well as thyroid-binding prealbumin and albumin. Levothyroxine has a long half-life of about 6 to 7 days in euthyroidism (normal thyroid function) but is prolonged to 9 to 10 days in hypothyroidism and shortened to 3 to 4 days in hyperthyroidism.

### Applying Your Knowledge 24-1

While Ms. Zalewski is in the hospital, you are administering her daily medications. Hospital routine is to administer all once-daily medications at 9:00 A.M. When reviewing the medication administration sheets, you note Ms. Zalewski is to receive Synthroid at 9:00 A.M. Breakfast trays are usually served to patients between 8:00 and 8:30 A.M. What action should you take with regard to administration of the Synthroid?

## Antithyroid Drugs (Used in Hyperthyroidism)

**P** **Propylthiouracil** (PTU) is the prototype of the thioamide antithyroid drugs. It can be used alone to treat hyperthyroidism, as part of the preoperative preparation for thyroidectomy, before or after radioactive iodine therapy, and in the treatment of thyroid storm. PTU acts by inhibiting production of thyroid hormones and peripheral conversion of  $T_4$  to the more active  $T_3$ . It does not interfere with release of thyroid hormones previously produced and stored. Thus, therapeutic effects do not occur for several days or weeks until the stored hormones have been used.

PTU is well absorbed with oral administration, and peak plasma levels occur within 30 minutes. Plasma half-life is 1 to 2 hours. However, duration of action depends on the half-life within the thyroid gland rather than plasma half-life. Because this time is relatively short, PTU must be given every 8 hours. The drug is metabolized in the liver and excreted in urine.

**Methimazole** (Tapazole) is similar to PTU in actions, uses, and adverse reactions. It is also well absorbed with oral administration and rapidly reaches peak plasma levels.

**Strong iodine solution** (Lugol's solution) and **saturated solution of potassium iodide** (SSKI) are iodine preparations sometimes used in short-term treatment of hyperthyroidism.

These drugs inhibit release of thyroid hormones, causing them to accumulate in the thyroid gland. Lugol's solution is usually used to treat thyrotoxic crisis and to decrease the size and vascularity of the thyroid gland before thyroidectomy. SSKI is more often used as an expectorant but may be given as preparation for thyroidectomy. Iodine preparations should not be followed by propylthiouracil, methimazole, or radioactive iodine because the latter drugs cause release of stored thyroid hormone and may precipitate acute hyperthyroidism.

**Sodium iodide**  $^{131}\text{I}$  (Iodotope) is a radioactive isotope of iodine. The thyroid gland cannot differentiate between regular iodide and radioactive iodide, so it picks up the radioactive iodide from the circulating blood. As a result, small amounts of radioactive iodide can be used as a diagnostic test of thyroid function, and larger doses are used therapeutically to treat hyperthyroidism. Therapeutic doses act by emitting beta and gamma rays, which destroy thyroid tissue and thereby decrease production of thyroid hormones. It is also used to treat thyroid cancer.

**Propranolol** (Inderal) is an antiadrenergic, not an antithyroid, drug. It does not affect thyroid function, hormone secretion, or hormone metabolism. It is most often used to treat cardiovascular conditions, such as dysrhythmias, angina pectoris, and hypertension. When given to patients with hyperthyroidism, propranolol blocks beta-adrenergic receptors in various organs and thereby controls symptoms of hyperthyroidism resulting from excessive stimulation of the sympathetic nervous system. These symptoms include tachycardia, palpitations, excessive sweating, tremors, and nervousness. Propranolol is useful for controlling symptoms during the delayed response to thioamide drugs and radioactive iodine, before thyroidectomy, and in treating thyrotoxic crisis. When the patient becomes euthyroid and hyperthyroid symptoms are controlled by definitive treatment measures, propranolol should be tapered and discontinued.

## Nursing Process

### Assessment

- Assess for signs and symptoms of thyroid disorders (see Table 24-1). During the course of treatment with thyroid or antithyroid drugs, the patient's blood level of thyroid hormone may range from low to normal to high. At either end of the continuum, signs and symptoms may be dramatic and obvious. As blood levels change toward normal as a result of treatment, signs and symptoms become less obvious. If presenting signs and symptoms are treated too aggressively, they may change toward the opposite end of the continuum and indicate adverse drug effects. Thus, *each patients receiving a drug that alters thyroid function must be assessed for indicators of hypothyroidism, euthyroidism, and hyperthyroidism.*

*Nursing Process continues on page 384*

- Check laboratory reports for serum TSH (normal = 0.5 to 4.2  $\mu\text{U}/\text{mL}$ ) when available. An elevated serum TSH is the first indication of primary hypothyroidism and commonly occurs in middle-aged women, even in the absence of other signs and symptoms. Serum TSH is used to monitor response to drugs that alter thyroid function.

## Nursing Diagnoses

- Decreased Cardiac Output related to disease- or drug-induced thyroid disorders
- Imbalanced Nutrition: Less Than Body Requirements with hyperthyroidism
- Imbalanced Nutrition: More Than Body Requirements with hypothyroidism
- Ineffective Thermoregulation related to changes in metabolism rate and body heat production
- Deficient Knowledge: Disease process and drug therapy

## Planning/Goals

### The patient will

- Achieve normal blood levels of thyroid hormone
- Receive or take drugs accurately
- Experience relief of symptoms of hypothyroidism or hyperthyroidism
- Be assisted to cope with symptoms until therapy becomes effective
- Avoid preventable adverse drug effects
- Maintain the therapeutic and avoid the adverse effects of drug therapy

## Interventions

Use nondrug measures to control symptoms, increase effectiveness of drug therapy, and decrease adverse reactions. Some areas for intervention include the following:

- **Environmental temperature.** Regulate for the patient's comfort, when possible. Patients with *hypothyroidism* are very intolerant of cold, due to their slow metabolism rate. Chilling and shivering should be prevented because of added strain on the heart. Please provide blankets and warm clothes as needed. Patients with *hyperthyroidism* are very intolerant of heat and perspire excessively, due to their rapid metabolism rate. Provide cooling baths and lightweight clothing as needed.
- **Diet.** Despite a poor appetite, *hypothyroid* patients are often overweight because of a slow metabolism rate. Thus, a low-calorie, weight-reduction diet may be indicated. In addition, an increased intake of high-fiber foods is usually needed to prevent constipation as a result of decreased gastrointestinal secretions and motility. Despite a good appetite, *hyperthyroid* patients are often underweight because of a rapid metabolism rate. They often need extra calories and nutrients to prevent tissue breakdown.

These can be provided by extra meals and snacks. The patient may wish to avoid highly seasoned and high-fiber foods because they may increase diarrhea.

- **Fluids.** With *hypothyroidism*, patients need an adequate intake of low-calorie fluids to prevent constipation. With *hyperthyroidism*, patients need large amounts of fluids (3000–4000 mL/day) unless contraindicated by cardiac or renal disease. The fluids are needed to eliminate heat and waste products produced by the hypermetabolic state. Much of the patient's fluid loss is visible as excessive perspiration and urine output.
- **Activity.** With *hypothyroidism*, encourage activity to maintain cardiovascular, respiratory, gastrointestinal, and musculoskeletal function. With *hyperthyroidism*, encourage rest and quiet, nonstrenuous activity. Because patients differ in what they find restful, this must be determined with each patient. A quiet room, reading, and soft music may be helpful. Mild sedatives are often given. The patient is caught in the dilemma of needing rest because of the high metabolic rate but being unable to rest because of nervousness and excitement.
- **Skin care.** *Hypothyroid* patients are likely to have edema and dry skin. When edema is present, inspect pressure points, turn often, and avoid trauma when possible. Edema increases risks of skin breakdown and decubitus ulcer formation. Also, increased capillary fragility increases the likelihood of bruising from seemingly minor trauma. When skin is dry, use soap sparingly and lotions and other lubricants freely.
- **Eye care.** *Hyperthyroid* patients may have exophthalmos. In mild cases, use measures to protect the eye. For example, dark glasses, local lubricants, and patching of the eyes at night may be needed. Diuretic drugs and elevating the head of the bed may help reduce periorbital edema and eyeball protrusion. If the eyelids cannot close, they are sometimes taped shut to avoid corneal abrasion. In severe exophthalmos, the preceding measures are taken and large doses of corticosteroids are usually given.

Patient Guidelines for Levothyroxine and for Propylthiouracil or Methimazole are presented in the accompanying displays.

## Evaluation

- Interview and observe for compliance with instructions for taking medications.
- Observe for relief of symptoms.
- Check laboratory reports for normal blood levels of TSH or thyroid hormones.
- Interview and observe for adverse drug effects.
- Check appointment records for compliance with follow-up procedures.

### Applying Your Knowledge 24-2

You are preparing a teaching plan for Ms. Zalewski. Considering her height and weight, what should you include for this patient?

## Principles of Therapy

### Goals of Therapy

The goal of treatment with thyroid drugs is to restore the individual to a euthyroid state with normal metabolism. In hypothyroidism, the goal of thyroid replacement therapy is to administer a dosage in sufficient amounts to compensate for the thyroid deficit, so as to resolve symptoms and restore serum TSH and thyroid hormone to normal. In hyperthyroidism, the goals are to reduce thyroid hormone production to relieve symptoms, return serum TSH and thyroid hormone levels to normal, and avoid complete destruction of the thyroid gland.

### Applying Your Knowledge 24-3

You are performing the assessment of Ms. Zalewski and observe tachycardia, increased systolic blood pressure, nervousness, insomnia, hunger, and fatigue. What laboratory test should be assessed and what action should you take?

## Thyroid Drugs

### Drug Selection

Regardless of the cause of hypothyroidism and the age at which it occurs, the specific treatment is replacement of thyroid hormone from an exogenous source. Synthetic levothyroxine is the drug of choice for thyroid hormone replacement because of uniform potency, once-daily dosing, and low cost. In patients with subclinical hypothyroidism, levothyroxine should be given if the serum TSH level is higher than 10 microunits per liter. There is some difference of opinion about treatment for TSH values between 5 and 10 microunits per liter. Arguments for treatment of subclinical hypothyroidism are the high rate of progression to symptomatic hypothyroidism, improvement of cholesterol metabolism (e.g., low-density lipoprotein, or “bad” cholesterol, is reduced with treatment), and improvement in left ventricular function.

In patients with symptomatic hypothyroidism, levothyroxine therapy is definitely indicated. In addition to improvement of metabolism, treatment may also improve cardiac function, energy level, mood, muscle function, and fertility. In myxedema coma, levothyroxine is given intravenously, along with interventions to relieve precipitating factors and to support vital functions until the thyroid hormone becomes effective, often within 24 hours.

### Drug Dosage

Dosage is influenced by the choice of drug, the patient’s age and general condition, severity and duration of hypothyroidism, and clinical response to drug therapy. The dosage must be individualized to approximate the amount of thyroid

## Patient Teaching Guidelines

### Levothyroxine

#### General Considerations

- Thyroid hormone is required for normal body functioning and for life. When a person’s thyroid gland is unable to produce enough thyroid hormone, levothyroxine is used as a synthetic substitute. Thus, levothyroxine therapy for hypothyroidism is lifelong; stopping it may lead to life-threatening illness.
- Periodic tests of thyroid function are needed.
- Dosage adjustments are made according to clinical response and results of thyroid function tests.
- Do not switch from one brand name to another; effects may be different.
- Levothyroxine stimulates the central nervous system and the heart; excessive stimulation may occur if it is taken with other stimulating drugs. Thus, you should consult a health care provider before taking over-the-counter drugs that stimulate the heart or cause nervousness

(e.g., asthma remedies, cold remedies, decongestants). In addition, you should probably limit your intake of caffeine-containing beverages to 2 to 3 servings daily.

#### Self-Administration

- Take every morning, on an empty stomach, for best absorption. Also, do not take the drug with an antacid (e.g., Tums, Maalox), an iron preparation, or sucralfate (Carafate). These drugs decrease absorption of levothyroxine. If it is necessary to take one of these drugs, take levothyroxine 2 hours before or 4 to 6 hours after the other drug.
- Take at about the same time each day for more consistent blood levels and more normal body metabolism.
- Report chest pain, heart palpitations, nervousness, or insomnia. These adverse effects result from excessive stimulation and may indicate that drug dosage or intake of other stimulants needs to be reduced.

## Patient Teaching Guidelines

## Propylthiouracil or Methimazole

### General Considerations

- These drugs are sometimes called *antithyroid drugs* because they are given to decrease the production of thyroid hormone by an overactive thyroid gland.
- These drugs must be taken for 1 year or longer to decrease thyroid hormone levels to normal.
- Periodic tests of thyroid function and drug dosage adjustments are needed.
- Ask the prescribing physician if it is necessary to avoid or restrict amounts of seafood or iodized salt. These sources of iodide may need to be reduced or omitted during antithyroid drug therapy.

### Self-Administration

- Take at regular intervals around the clock, usually every 8 hours.
- Report fever, sore throat, unusual bleeding or bruising, headache, skin rash, yellowing of the skin, or vomiting. If these adverse effects occur, drug dosage may need to be reduced or the drug may need to be discontinued.
- Consult a health care provider before taking over-the-counter drugs. Some drugs contain iodide, which can increase the likelihood of goiter and the risk of adverse effects from excessive doses of iodide (e.g., some cough syrups, asthma medications, and multivitamins may contain iodide).

hormone needed to make up the deficit in endogenous hormone production. As a general rule, initial dosage is relatively small. Dosage is gradually increased at approximately 2-week intervals until symptoms are relieved and a normal serum TSH level (0.5–4.2 microunits/L) is reestablished. Maintenance dosage for long-term therapy is based on the patient's clinical status and periodic measurement of serum TSH.

### Duration of Therapy

Thyroid replacement therapy in the patient with hypothyroidism is lifelong. Medical supervision is needed frequently during early treatment and at least annually after the patient's condition has stabilized and maintenance dosage has been determined.

### Hypothyroidism and the Metabolism of Other Drugs

Changes in the rate of body metabolism affect the metabolism of many drugs. Most drugs given to patients with hypothyroidism have a prolonged effect, because drug metabolism in the liver is delayed and the glomerular filtration rate of the kidneys is decreased. Drug absorption from the intestine or a parenteral injection site also may be slowed. As a result, dosage of many other drugs should be reduced, including digoxin and insulin. In addition, people with hypothyroidism are especially likely to experience respiratory depression and myxedema coma with opioid analgesics and other sedating drugs. These drugs should be avoided when possible. However, when necessary, they are given very cautiously and in dosages of approximately one third to one half the usual dose. Even then, patients must be observed very closely for respiratory depression.

After thyroid replacement therapy is started and stabilized, the patient becomes euthyroid (having normal thyroid gland function), has a normal rate of metabolism, and can tolerate usual doses of most drugs if other influencing factors are not present. On the other hand, excessive doses of

thyroid drugs may produce hyperthyroidism and a greatly increased rate of metabolism. In this situation, larger doses of most other drugs are necessary to produce the same effects. However, rather than increasing dosage of other drugs, dosage of thyroid drugs should be reduced so the patient is euthyroid again.

### Adrenal Insufficiency

When hypothyroidism and adrenal insufficiency coexist, the adrenal insufficiency should be treated with a corticosteroid drug before starting thyroid replacement. Thyroid hormones increase tissue metabolism and tissue demands for adrenocortical hormones. If adrenal insufficiency is not treated first, administration of thyroid hormone may cause acute adrenocortical insufficiency, a life-threatening condition.

### Antithyroid Drugs

Treatment of hyperthyroidism depends on the cause. If the cause is an adenoma or multinodular goiter surgery or radioactive iodine therapy is recommended, especially in older patients. If the cause is excessive doses of levothyroxine (for hypothyroidism), the dose of levothyroxine should be reduced. If the cause is Graves' disease, antithyroid drugs, radioactive iodine, surgery, or a combination of these methods may be warranted. All these methods reduce the amount of thyroid hormones circulating in the bloodstream.

### Drug Selection

The antithyroid drugs include the thioamide derivatives (propylthiouracil and methimazole) and iodine preparations (Lugol's solution and SSKI). The thioamide drugs are inexpensive and relatively safe, and they do not damage the thyroid gland. These drugs may be used as the primary treatment (for which they may be given 6 months to 2 years) or to decrease blood levels of thyroid hormone before radioactive iodine therapy or surgery.

Radioactive iodine is a frequently used treatment. It is safe, effective, inexpensive, and convenient. One disadvantage is hypothyroidism, which usually develops within a few months and requires lifelong thyroid hormone replacement therapy. Another disadvantage is the delay in therapeutic benefits. Results may not be apparent for 3 months or longer, during which time severe hyperthyroidism must be brought under control with one of the thioamide antithyroid drugs.

Other iodine preparations are not used in long-term treatment of hyperthyroidism. They are indicated when a rapid clinical response is needed, as in thyroid storm and acute hyperthyroidism, or to prepare a hyperthyroid person for thyroidectomy. A thioamide drug is given to produce a euthyroid state, and an iodine preparation is given to reduce the size and vascularity of the thyroid gland to reduce the risk of excessive bleeding. Maximal effects are reached in approximately 10 to 15 days of continuous therapy, and this is probably the primary advantage. Disadvantages of this combination of drugs include the following:

- They may produce goiter, hyperthyroidism, or both.
- They cannot be used alone. Therapeutic benefits are temporary, and symptoms of hyperthyroidism may reappear and even be intensified if other treatment methods are not also used.
- Radioactive iodine cannot be used effectively for a prolonged period in a patient who has received iodine preparations. Even if the iodine preparation is discontinued, the thyroid gland is saturated with iodine and does not attract enough radioactive iodine for treatment to be effective. Also, if radioactive iodine is given later, acute hyperthyroidism is likely to result because the radioactive iodine causes the stored hormones to be released into the circulation.
- Although giving a thioamide drug followed by an iodine preparation is standard preparation for thyroidectomy, the opposite sequence of administration is unsafe. If the iodine preparation is given first and followed by PTU or methimazole, the patient is likely to experience acute hyperthyroidism because the thioamide causes release of the stored thyroid hormones.

### Drug Dosage

Dosage of the thioamide antithyroid drugs is relatively large until a euthyroid state is reached, usually in 6 to 8 weeks. A maintenance dose, in the smallest amount that prevents recurrent symptoms of hyperthyroidism, is then given for 1 year or longer. Dosage should be decreased if the thyroid gland enlarges or signs and symptoms of hypothyroidism occur.

Radioactive iodide is usually given in a single dose to middle-aged and elderly people on an outpatient basis. For most patients, no special radiation precautions are necessary. If a very large dose is given, the patient may be isolated for 8 days, which is the half-life of radioactive iodide.

### Duration of Therapy

No clear-cut guidelines exist regarding duration of antithyroid drug therapy because exacerbations and remissions occur. It is usually continued until the patient is euthyroid for 6 to 12 months. Diagnostic tests to evaluate thyroid function or a trial withdrawal then may be implemented to determine whether the patient is likely to remain euthyroid without further drug therapy. If a drug is to be discontinued, this is usually done gradually over weeks or months.

The therapeutic effects of radioactive iodide are delayed for several weeks or as long as 6 months. During this time, symptoms may be controlled with thioamide drugs or propranolol.

### Hyperthyroidism and the Metabolism of Other Drugs

Treatment of hyperthyroidism changes the rate of body metabolism, including the rate of metabolism of many drugs. In the hyperthyroid state, drug metabolism may be very rapid, and higher doses of most drugs may be necessary to achieve therapeutic results. When the patient becomes euthyroid, the rate of drug metabolism is decreased. Consequently, doses of all medications should be evaluated and probably reduced to avoid severe adverse effects.

## Use in Special Populations

### Use in Children

For hypothyroidism, replacement therapy is required because thyroid hormone is essential for normal growth and development. As in adults, levothyroxine is the drug of choice in children and dosage needs may change with growth. For congenital hypothyroidism (cretinism), drug therapy should be started within 6 weeks of birth and continued for life. Initially, the recommended dose is 10 to 15 micrograms per kilogram of body weight per day. Delay in replacement therapy may result in permanent retardation despite resolution of the symptoms that resulted from thyroid deficit. Then, maintenance doses for long-term therapy vary with the child's age and weight, usually decreasing over time to a typical adult dose at 11 to 20 years of age. Infants requiring thyroid hormone replacement need relatively large doses. After thyroid drugs are started, the maintenance dosage is determined by periodic radioimmunoassay of serum thyroxine levels and by periodic radiographs to follow bone development.

To monitor drug effects on growth in children, height and weight should be recorded and compared with growth charts at regular intervals. Children should be monitored closely for adverse drug effects, which are similar to those seen in adults.

For hyperthyroidism, PTU or methimazole is used. Potential risks for adverse effects are similar to those in adults. Radioactive iodine may cause cancer and chromosome damage in children; therefore, this agent should be used only for hyperthyroidism that cannot be controlled by other antithyroid drugs or surgery.

## Nursing Actions Thyroid and Antithyroid Drugs

### NURSING ACTIONS

#### 1. Administer accurately

##### a. With thyroid drugs:

- (1) Administer in a single daily dose, on an empty stomach (e.g., before breakfast).
- (2) Check the pulse rate before giving the drug. If the rate is over 100 per minute or if any changes in cardiac rhythm are noted, consult the physician before giving the dose.
- (3) To give levothyroxine to an infant or young child, the tablet may be crushed and a small amount of formula or water added. After it is mixed, administer it soon, by spoon or dropper. Do not store the liquid very long. The crushed tablet may also be sprinkled on a small amount of food (e.g., cereal, applesauce).
- (4) Do not switch among various brands or generic forms of the drug.

##### b. With antithyroid and iodine drugs:

- (1) Administer q8h.
- (2) Dilute iodine solutions in a full glass of fruit juice or milk, if possible, and have the patient drink the medication through a straw.

#### 2. Observe for therapeutic effects

##### a. With thyroid drugs, observe for:

- (1) Increased energy and activity level, less lethargy and fatigue
- (2) Increased alertness and interest in surroundings
- (3) Increased appetite
- (4) Increased pulse rate and temperature
- (5) Decreased constipation
- (6) Reversal of coarseness and other changes in skin and hair
- (7) With cretinism, increased growth rate (record height periodically)
- (8) With myxedema, diuresis, weight loss, and decreased edema
- (9) Decreased serum cholesterol and possibly decreased creatine phosphokinase, lactate dehydrogenase, and aspartate aminotransferase levels

##### b. With antithyroid and iodine drugs, observe for:

- (1) Slower pulse rate
- (2) Slower speech
- (3) More normal activity level (slowing of hyperactivity)
- (4) Decreased nervousness
- (5) Decreased tremors
- (6) Improved ability to sleep and rest
- (7) Weight gain

### RATIONALE/EXPLANATION

Fasting increases drug absorption; early administration allows peak activity during daytime hours and is less likely to interfere with sleep.

Tachycardia or other cardiac dysrhythmias may indicate adverse cardiac effects. Dosage may need to be reduced or the drug stopped temporarily.

Accurate and consistent administration is vital to promoting normal growth and development.

Differences in bioavailability have been identified among products. Changes in preparations may alter dosage and therefore symptom control.

All these drugs have rather short half-lives and must be given frequently and regularly to maintain therapeutic blood levels. In addition, if iodine preparations are not given every 8 hours, symptoms of hyperthyroidism may recur.

Dilution of the drug reduces gastric irritation and masks the unpleasant taste. Using a straw prevents staining the teeth.

Therapeutic effects result from a return to normal metabolic activities and relief of the symptoms of hypothyroidism. Therapeutic effects may be evident as early as 2 or 3 days after drug therapy is started or delayed up to approximately 2 weeks. All signs and symptoms of myxedema should disappear in approximately 3 to 12 weeks.

These serum levels are often elevated with myxedema and may return to normal when thyroid replacement therapy is begun.

With propylthiouracil and methimazole, some therapeutic effects are apparent in 1 or 2 weeks, but euthyroidism may not occur for 6 or 8 weeks.

With iodine solutions, therapeutic effects may be apparent within 24 hours. Maximal effects occur in approximately 10 to 15 days. However, therapeutic effects may not be sustained. Symptoms may reappear if the drug is given longer than a few weeks, and they may be more severe than initially.

## NURSING ACTIONS

## 3. Observe for adverse effects

- a. With thyroid drugs, observe for tachycardia and other cardiac dysrhythmias, angina pectoris, myocardial infarction, congestive heart failure, nervousness, hyperactivity, insomnia, diarrhea, abdominal cramps, nausea and vomiting, weight loss, fever, intolerance to heat.
- b. With propylthiouracil and methimazole, observe for:
  - (1) Hypothyroidism—bradycardia, congestive heart failure, anemia, coronary artery and peripheral vascular disease, slow speech and movements, emotional and mental dullness, excessive sleeping, weight gain, constipation, skin changes, and others
  - (2) Blood disorders—leukopenia, agranulocytosis, hypoprothrombinemia
  - (3) Integumentary system—skin rash, pruritus, alopecia
  - (4) Central nervous system (CNS)—headache, dizziness, loss of sense of taste, drowsiness, paresthesias
  - (5) Gastrointestinal system—nausea, vomiting, abdominal discomfort, gastric irritation, cholestatic hepatitis
  - (6) Other—lymphadenopathy, edema, joint pain, drug fever
- c. With iodine preparations, observe for:
  - (1) Iodism—metallic taste, burning in mouth, soreness of gums, excessive salivation, gastric or respiratory irritation, rhinitis, headache, redness of conjunctiva, edema of eyelids
  - (2) Hypersensitivity—acneiform skin rash, pruritus, fever, jaundice, angioedema, serum sickness
  - (3) Goiter with hypothyroidism

## 4. Observe for drug interactions

- a. Drugs that increase effects of thyroid hormones:
  - (1) Activating antidepressants (e.g., bupropion, venlafaxine), adrenergic antiasthmatic drugs (e.g., albuterol, epinephrine), nasal decongestants
- b. Drugs that decrease effects of thyroid hormones:
  - (1) Antacids, cholestyramine, iron, sucralfate
  - (2) Antihypertensives
  - (3) Estrogens, including oral contraceptives containing estrogens
  - (4) Propranolol (Inderal)
  - (5) Phenytoin, rifampin
- c. Drug that increases effects of antithyroid drugs:
  - (1) Lithium

## RATIONALE/EXPLANATION

Most adverse reactions stem from excessive doses, and signs and symptoms produced are the same as those occurring with hyperthyroidism. Excessive thyroid hormones make the heart work very hard and fast in attempting to meet tissue demands for oxygenated blood and nutrients. Symptoms of myocardial ischemia occur when the myocardium does not get an adequate supply of oxygenated blood. Symptoms of congestive heart failure occur when the increased cardiac workload is prolonged. Cardiovascular problems are more likely to occur in patients who are elderly or who already have heart disease.

Leukopenia may be difficult to evaluate because it may occur with hyperthyroidism and with antithyroid drugs. Agranulocytosis occurs rarely but is the most severe adverse reaction; the earliest symptoms are likely to be sore throat and fever. If these occur, report them to the physician immediately.

Adverse effects are uncommon with short-term use.

Allergic reactions rarely occur.

Uncommon but may occur in adults and newborns whose mothers have taken iodides for long periods

These drugs may cause CNS and cardiovascular stimulation when taken alone. When combined with thyroid hormones, excessive cardiovascular stimulation may occur and cause myocardial ischemia, cardiac dysrhythmias, hypertension, and other adverse cardiovascular effects. Excessive CNS stimulation may produce anxiety, nervousness, hyperactivity, and insomnia.

Decrease absorption of levothyroxine; give levothyroxine 2 hours before or 4 to 6 hours after one of these drugs.

Decrease cardiac-stimulating effects

Estrogens increase thyroxine-binding globulin, thereby increasing the amount of bound, inactive levothyroxine in patients with hypothyroidism. This decreased effect does not occur in patients with adequate thyroid-hormone secretion because the increased binding is offset by increased  $T_4$  production. Women taking oral contraceptives may need larger doses of thyroid hormone replacement than would otherwise be needed.

This drug decreases cardiac effects of thyroid hormones. It is used in hyperthyroidism to reduce tachycardia and other symptoms of excessive cardiovascular stimulation.

Induce enzymes that metabolize (inactivate) levothyroxine more rapidly

Acts synergistically to produce hypothyroidism

### Use in Older Adults

Signs and symptoms of thyroid disorders may mimic those of other disorders that often occur in older adults (e.g., congestive heart failure). Therefore, a thorough physical examination and diagnostic tests of thyroid function are necessary before starting any type of treatment.

For hypothyroidism, levothyroxine is given. Thyroid hormone replacement increases the workload of the heart and may cause serious adverse effects in older adults, especially those with cardiovascular disease. Cardiac effects also may be increased in patients receiving bronchodilators or other cardiac stimulants. Patients who are older or who have cardiovascular disease require cautious treatment because of a high risk of adverse effects on the cardiovascular system. Thus, these patients are given smaller initial dosages and smaller increments at longer intervals than younger adults. For example, the drugs should be given in small initial dosages (e.g., 25 mcg/day) and increased by 25 micrograms pre day at monthly intervals until a euthyroid state is attained and a maintenance dose established. Periodic measurements of serum TSH levels are indicated to monitor drug therapy, and doses can be adjusted when indicated.

Blood pressure and pulse should be monitored regularly. As a general rule, the drug should not be given if the resting heart rate is more than 100 beats per minute.

For hyperthyroidism, PTU or methimazole may be used, but radioactive iodine is often preferred because it is associated with fewer adverse effects than other antithyroid drugs or surgery. Patients should be monitored closely for hypothyroidism, which usually develops within a year after receiving treatment for hyperthyroidism.

### Use in Patients With Renal Impairment

Some thyroid and antithyroid drugs are excreted by the kidneys, and dosage adjustment may be required in the presence of renal impairment. PTU is an example of such medication.

Most drugs given to patients with hypothyroidism have a prolonged effect, because the glomerular filtration rate of the kidneys is decreased.

### Use in Patients With Hepatic Impairment

The liver plays an important role in thyroid hormone metabolism, and euthyroidism is important for normal hepatic function and bilirubin metabolism. Drugs used to treat hypothyroidism and hyperthyroidism are commonly metabolized in the liver. Therefore, in the presence of hepatic impairment, drugs may accumulate and cause adverse effects. Drug metabolism in the liver is delayed in patients with hypothyroidism, so most drugs given to these patients have a prolonged effect. Conversely, individuals who are hyperthyroid metabolize drugs more slowly than in the euthyroid state.

### Use in Patients With Critical Illness

Individuals in thyroid storm or thyrotoxic crisis are commonly managed in the critical care unit. Increased rate of cellular metabolism and oxygen consumption occur with a resultant increase in heat production. The hypermetabolic state increases the metabolism of medications, so increased or more frequent dosing may be necessary.

### Use in Home Care

The home care nurse may be involved in a wide range of activities, including assessing the patient's response to therapy, teaching about the disease process, managing symptoms, and preventing and managing adverse drug effects.

## Applying Your Knowledge 24-4

### How Can You Avoid This Medication Error?

Ms. Zalewski complains about acid indigestion. You notice that alumina and magnesia gel (Maalox) has been ordered for her and give a dose with her morning medication.

.....

## Key Concepts

- Propylthiouracil (PTU) is the prototype of the thioamide antithyroid drugs and is used alone to treat hyperthyroidism, as part of the preoperative preparation for thyroidectomy, before or after radioactive iodine therapy, and in the treatment of thyroid storm.
- Patients should be monitored closely for hypothyroidism while taking antithyroid drugs, which may typically develop within a year after receiving treatment for hyperthyroidism.
- Levothyroxine (Synthroid, Levothroid), a synthetic prepa-

ration of  $T_4$ , is the drug of choice for long-term treatment of hypothyroidism and serves as the prototype.

- Thyroid replacement therapy in the patient with hypothyroidism is lifelong; no clear-cut guidelines exist regarding duration of antithyroid drug therapy because exacerbations and remissions. Replacement therapy usually continues until the patient is euthyroid for 6 to 12 months.
- For congenital hypothyroidism (cretinism), drug therapy should be started within 6 weeks of birth and continued for life or mental retardation may result.

- Individuals with hypothyroidism are especially likely to experience respiratory depression and myxedema coma with opioid analgesics and other sedating drugs.
- The FDA has issued a **BLACK BOX WARNING** regarding the use of thyroid hormones for the treatment of obesity

or for weight loss, either alone or with other therapeutic agents. Significant and serious complications may develop in euthyroid individuals taking thyroid hormones.

## Review and Application Exercises

### Short Answer Exercises

1. Where is TSH produced, and what is its function?
2. What is the role of thyroid hormones in maintaining body functions?
3. What signs and symptoms are associated with hypothyroidism?
4. In primary hypothyroidism, are blood levels of TSH increased or decreased?
5. What are adverse effects of drug therapy for hypothyroidism?
6. What signs and symptoms are associated with hyperthyroidism?
7. Which drugs reduce blood levels of thyroid hormone in hyperthyroidism, and how do they act?
8. What are adverse effects of drug therapy for hyperthyroidism?
9. When propranolol is used in the treatment of hyperthyroidism, what are its expected effects?
10. What is the effect of thyroid disorders on metabolism of other drugs?

### NCLEX-Style Questions

11. A male patient asks a nurse when he should take his daily dose of levothyroxine. The nurse recommends that the patient take the drug
  - a. before breakfast on an empty stomach
  - b. with meals in divided doses
  - c. at bedtime with a snack
  - d. whenever it is convenient

12. Which of the following agents is the drug of first choice for treatment of hypothyroidism?
  - a. propranolol (Inderal)
  - b. levothyroxine (Synthroid, Levothroid)
  - c. methimazole
  - d. propylthiouracil (PTU)
13. Which of the following patients with Graves' disease would be the most appropriate candidate for sodium iodide  $^{131}\text{I}$  therapy?
  - a. an 8-year-old boy
  - b. a 28-year-old breast-feeding mother
  - c. a 35-year-old pregnant woman
  - d. a 40-year-old man
14. The nurse who is taking care of a patient with hyperthyroidism and receives an order to administer propranolol knows that it is ordered to relieve which of the following symptoms?
  - a. heat intolerance
  - b. exophthalmos
  - c. dry skin
  - d. tachycardia
15. Which of the following orders should a nurse question in a patient with hypothyroidism?
  - a. psyllium seed (Metamucil)
  - b. levothyroxine (Synthroid)
  - c. morphine sulfate
  - d. albuterol (Ventolin inhaler)

# Hormones That Regulate Calcium and Bone Metabolism

## KEY TERMS

- Bisphosphonates
- Calcitonin
- Hypercalcemia
- Hypocalcemia
- Hyperparathyroidism
- Hypoparathyroidism
- Osteoporosis
- Paget's disease
- Parathyroid hormone (PTH)
- Tetany
- Vitamin D (Calciferol)

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Examine the roles of parathyroid hormone, calcitonin, and vitamin D in regulating calcium metabolism.
2. Manage individuals at risk for hypocalcemia.
3. Discuss prevention and treatment of hypocalcemia and osteoporosis.
4. Manage individuals at risk for hypercalcemia.
5. Outline appropriate management strategies of hypercalcemia as a medical emergency.
6. Evaluate the use of calcium and vitamin D supplements, calcitonin, and bisphosphonate drugs in the treatment of osteoporosis.

## Applying Your Knowledge

Carolyn Taylor is a 68-year-old retired teacher. She has chronic venous insufficiency and osteoporosis. Ms. Taylor has suffered two fractures from falls in recent years. She has been menopausal for 16 years and has not been on estrogen replacement therapy due to her vascular disease. Her physician prescribes alendronate in the once-weekly dose.

## Introduction

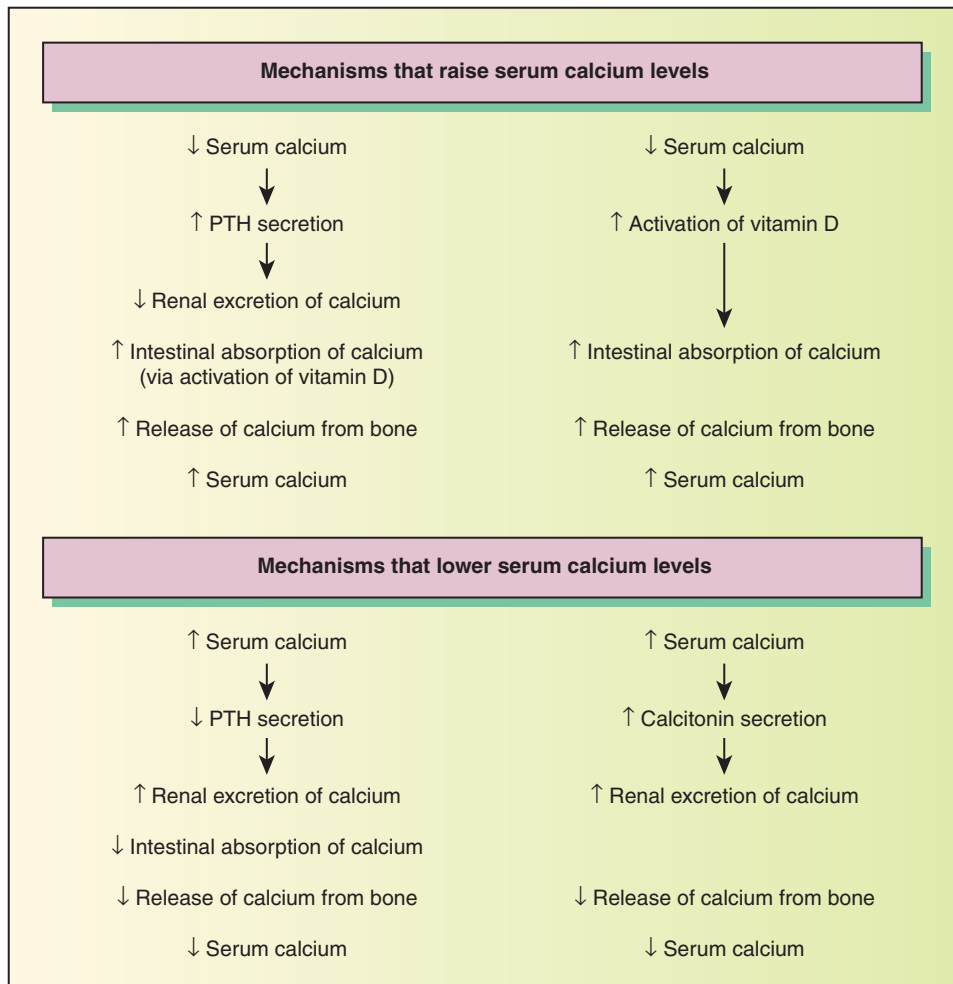

Three hormones regulate calcium and bone metabolism, *parathyroid hormone (PTH)*, calcitonin, and vitamin D, which act to maintain normal serum levels of calcium. When serum calcium levels are decreased, hormonal mechanisms are activated to raise them; when they are elevated, mechanisms act to lower them (Fig. 25-1). Overall, the hormones alter absorption of dietary calcium from the gastrointestinal tract, movement of calcium from bone to serum, and excretion of calcium through the kidneys.

Disorders of calcium and bone metabolism include hypocalcemia, hypercalcemia, osteoporosis, Paget's disease, and bone breakdown associated with breast cancer and multiple myeloma. Drugs used to treat these disorders mainly alter serum calcium levels or strengthen bone. This chapter describes the characteristics of the hormones, calcium, phosphorus, and some associated disorders.

## Hormones Involved in Calcium Metabolism

### Parathyroid Hormone

PTH secretion is stimulated by low serum calcium levels and inhibited by normal or high levels (a negative feedback system). Because phosphate is closely related to calcium in body functions, PTH also regulates phosphate metabolism. In general, when serum calcium levels increase, serum

**Figure 25-1** ■ Hormonal regulation of serum calcium levels. When serum calcium levels are low (hypocalcemia), there is increased secretion of parathyroid hormone (PTH) and increased activation of vitamin D. These mechanisms lead to decreased loss of calcium in the urine, increased absorption of calcium from the intestine, and increased resorption of calcium from the bone. These mechanisms work together to raise serum calcium levels to normal.

When serum calcium levels are high (hypercalcemia), there is decreased secretion of PTH and increased secretion of calcitonin. These mechanisms lead to increased loss of calcium from the intestine and decreased resorption of calcium from bone. These mechanisms lower serum calcium levels to normal.

phosphate levels decrease, and vice versa. Thus, an inverse relationship exists between calcium and phosphate.

When the serum calcium level falls below the normal range, PTH raises the level by acting on bone, intestines, and kidneys. In bone, breakdown is increased, so that calcium moves from bone into the serum. In the intestines, there is increased absorption of calcium ingested in food (PTH activates vitamin D, which increases intestinal absorption). In the kidneys, there is increased reabsorption of calcium in the renal tubules and less urinary excretion. The opposite effects occur with phosphate (e.g., PTH decreases serum phosphate and increases urinary phosphate excretion).

Disorders of parathyroid function are related to insufficient production of PTH (hypoparathyroidism) or excessive production of PTH (hyperparathyroidism). *Hypoparathyroidism* is most often caused by removal of or damage to the parathyroid glands during neck surgery. *Hyperparathyroidism* is most often caused by a tumor or hyperplasia of a parathyroid gland. It also may result from ectopic secretion of PTH by malignant tumors (e.g., carcinomas of the lung, pancreas, kidney, ovary, prostate gland, or bladder). Clinical manifestations and treatment of hypoparathyroidism are the same as those of hypocalcemia. Clinical manifestations and treatment of hyperparathyroidism are the same as those of hypercalcemia.

### Calcitonin

*Calcitonin* is a hormone from the thyroid gland whose secretion is controlled by the concentration of ionized calcium in the blood flowing through the thyroid gland. When the serum level of ionized calcium is increased, secretion of calcitonin is increased. The function of calcitonin is to lower serum calcium in the presence of hypercalcemia, which it does by decreasing movement of calcium from bone to serum and increasing urinary excretion of calcium. The action of calcitonin is rapid but of short duration. Thus, this hormone has little effect on long-term calcium metabolism.

### Vitamin D (Calciferol)

*Vitamin D (Calciferol)* is a fat-soluble vitamin that includes both ergocalciferol (obtained from foods) and cholecalciferol (formed by exposure of skin to sunlight). It functions as a hormone and plays an important role in calcium and bone metabolism. The main action of vitamin D is to raise serum calcium levels by increasing intestinal absorption of calcium and mobilizing calcium from bone. It also promotes bone formation by providing adequate serum concentrations of minerals. Vitamin D is not physiologically active in the body. It must be converted to an intermediate metabolite in the liver, then to an active metabolite (1,25-dihydroxyvitamin D or calcitriol) in

the kidneys. PTH and adequate hepatic and renal function are required to produce the active metabolite.

Deficiency of vitamin D causes inadequate absorption of calcium and phosphorus. This, in turn, leads to low levels of serum calcium and stimulation of PTH secretion. In children, this sequence of events produces inadequate mineralization of bone (rickets), a rare condition in the United States. In adults, vitamin D deficiency causes osteomalacia, a condition characterized by decreased bone density and strength.

## Calcium and Phosphorus

Calcium and phosphorus are discussed together because they are closely related physiologically. These mineral nutrients are found in many of the same foods, from which they are absorbed together. They are regulated by PTH and excreted through the kidneys. They are both required in cellular structure and function and, as calcium phosphate, in formation and maintenance of bones and teeth. Their characteristics and functions are summarized in Box 25-1.

### Box 25-1

### Characteristics and Functions of Calcium and Phosphorus

#### Calcium

Calcium is the most abundant cation in the body. Approximately 99% is located in the bones and teeth; the rest is in the extracellular fluid and soft tissues. Approximately half of serum calcium is bound, mostly to serum proteins, and is physiologically inactive. The other half is ionized and physiologically active. Ionized calcium can leave the vascular compartment and enter cells, where it participates in intracellular functions. An adequate amount of free (ionized) calcium is required for normal function of all body cells.

Calcium is obtained from the diet, but only 30% to 50% is absorbed from the small intestine; the rest is lost in feces. Absorption is increased in the presence of vitamin D, lactose, moderate amounts of fat, and high protein intake; increased acidity of gastric secretions; and a physiologic need. Absorption is inhibited by vitamin D deficiency; a high-fat diet; the presence of oxalic acid (from beet greens, chard), which combines with calcium to form insoluble calcium oxalate in the intestine; alkalinity of intestinal secretions, which leads to formation of insoluble calcium phosphate; diarrhea or other conditions of rapid intestinal motility, which do not allow sufficient time for absorption; and immobilization.

Calcium is lost from the body in feces, urine, and sweat. Even when there is deficient intake, approximately 150 mg are lost daily through the intestines (in mucosal and biliary secretions and sloughed intestinal cells). In lactating women, relatively large amounts are lost in breast milk.

#### Functions

- Calcium participates in many metabolic processes, including the regulation of:
  - Cell membrane permeability and function
  - Nerve-cell excitability and transmission of impulses (e.g., it is required for release of neurotransmitters at synapses)
  - Contraction of cardiac, skeletal, and smooth muscle
  - Conduction of electrical impulses in the heart
  - Blood coagulation and platelet adhesion processes
  - Hormone secretion
  - Enzyme activity
  - Catecholamine release from the adrenal medulla
  - Release of chemical mediators (e.g., histamine from mast cells)

- Calcium is required for building and maintaining bones and teeth. Bone calcium is composed mainly of calcium phosphate and calcium carbonate. In addition to these bound forms, a small amount of calcium is available for exchange with serum. This acts as a reserve supply of calcium. Calcium is constantly shifting between bone and serum as bone is formed and broken down. When serum calcium levels become low, calcium moves into serum.

#### Requirements and Sources

The calcium requirement of normal adults is approximately 1000 mg daily. Increased daily amounts are needed by growing children (1200 mg), pregnant or lactating women (1200 mg), and postmenopausal women who do not take replacement estrogens (1500 mg to prevent osteoporosis).

The best sources of calcium are milk and milk products. Three 8-oz glasses of milk daily contain approximately the amount needed by healthy adults. Calcium in milk is readily used by the body because milk also contains lactose and vitamin D, both of which are involved in calcium absorption. Other sources of calcium include vegetables (e.g., broccoli, spinach, kale, mustard greens) and seafood (e.g., clams, oysters).

#### Phosphorus

Phosphorus is one of the most important elements in normal body function. Most phosphorus is combined with calcium in bones and teeth as calcium phosphate (approximately 80%). The remainder is distributed in every body cell and in extracellular fluid. It is combined with carbohydrates, lipids, proteins, and various other compounds.

Phosphorus is obtained from the diet, and approximately 70% of dietary phosphorus is absorbed from the gastrointestinal (GI) tract. The most efficient absorption occurs when calcium and phosphorus are ingested in approximately equal amounts. Because this equal ratio is present in milk, milk is probably the best source of phosphorus. In general, factors that increase or decrease calcium absorption act the same way on phosphorus absorption. Vitamin D enhances, but is not essential for, phosphorus absorption. Large amounts of calcium or aluminum in the GI tract may combine with phosphate to form insoluble compounds and thereby decrease absorption of phosphorus.

**Box 25-1****Characteristics and Functions of Calcium and Phosphorus (continued)**

Phosphorus is lost from the body primarily in urine. In people with acute or chronic renal failure, phosphorus intake is restricted because excretion is impaired.

**Functions**

Phosphorus, most of which is located intracellularly as the phosphate ion, performs many metabolic functions:

- It is an essential component of deoxyribonucleic acid, ribonucleic acid, and other nucleic acids in body cells. Thus, it is required for cell reproduction and body growth.
- It combines with fatty acids to form phospholipids, which are components of all cell membranes in the body. This reaction also prevents buildup of excessive amounts of free fatty acids.
- It forms a phosphate buffer system, which helps to maintain acid–base balance. When excess hydrogen ions are present in kidney tubules, phosphate combines with them and allows their excretion in urine. At the same time,

bicarbonate is retained by the kidneys and contributes to alkalinity of body fluids. Although there are other buffering systems in the body, failure of the phosphate system leads to metabolic acidosis (retained hydrogen ions or acid and lost bicarbonate ions or base).

- It is necessary for cellular use of glucose and production of energy.
- It is necessary for proper function of several B vitamins (i.e., the vitamins function as coenzymes in various chemical reactions only when combined with phosphate).

**Requirements and Sources**

Daily requirements for phosphorus are approximately 800 mg for normal adults and 1200 mg for growing children and pregnant or lactating women. Phosphorus is widely available in foods. Good sources are milk and other dairy products, meat, poultry, fish, eggs, and nuts. There is little risk of phosphorus deficiency with an adequate intake of calcium and protein.

## Calcium Disorders and Bone Metabolism

The calcium disorders are *hypocalcemia* and *hypercalcemia*, either of which can be life threatening. The bone disorders

discussed in this chapter are those characterized by increased resorption of calcium and loss of bone mass. These disorders weaken bone and lead to fractures, pain, and disability. Selected calcium and bone disorders are described in Box 25-2.

**Box 25-2****Calcium and Bone Disorders****Hypocalcemia**

Hypocalcemia is an abnormally low blood calcium level (i.e., <8.5 mg/dL). It may be caused by inadequate intake of calcium and vitamin D, numerous disorders (e.g., diarrhea or malabsorption syndromes that cause inadequate absorption of calcium and vitamin D, hypoparathyroidism, renal failure, severe hypomagnesemia, hypermagnesemia, acute pancreatitis, rhabdomyolysis, tumor lysis syndrome, vitamin D deficiency), and several drugs (e.g., cisplatin, cytosine arabinoside, foscarnet, ketoconazole, pentamidine, agents used to treat hypercalcemia). Calcium deficits caused by inadequate dietary intake affect bone tissue rather than serum calcium levels. Hypocalcemia associated with renal failure is caused by two mechanisms. First, inability to excrete phosphate in urine leads to accumulation of phosphate in the blood (hyperphosphatemia). Because phosphate levels are inversely related to calcium levels, hyperphosphatemia induces hypocalcemia. Second, when kidney function is impaired, vitamin D conversion to its active metabolite is impaired. This results in decreased intestinal absorption of calcium.

Clinical manifestations are characterized by increased neuromuscular irritability, which may progress to tetany. Tetany is characterized by numbness and tingling of the lips, fingers, and toes; twitching of facial muscles; spasms of skeletal muscle;

carpopedal spasm; laryngospasm; and convulsions. In young children, hypocalcemia may be manifested by convulsions rather than tetany and erroneously diagnosed as epilepsy. This may be a serious error because anticonvulsant drugs used for epilepsy may further decrease serum calcium levels. Severe hypocalcemia may cause lethargy or confusion.

**Hypercalcemia**

Hypercalcemia is an abnormally high blood calcium level (i.e., >10.5 mg/dL). It may be caused by hyperparathyroidism, hyperthyroidism, malignant neoplasms, vitamin D or vitamin A intoxication, aluminum intoxication, prolonged immobilization, adrenocortical insufficiency, and ingestion of thiazide diuretics, estrogens, and lithium. Cancer is a common cause, especially carcinomas (of the breast, lung, head and neck, or kidney) and multiple myeloma. Cancer stimulates bone breakdown, which increases serum calcium levels. Increased urine output leads to fluid volume deficit. This leads, in turn, to increased reabsorption of calcium in renal tubules and decreased renal excretion of calcium. Decreased renal excretion potentiates hypercalcemia. Patients at risk for hypercalcemia should be monitored for early signs and symptoms so treatment can be started before severe hypercalcemia develops.

Clinical manifestations are caused by the decreased ability of nerves to respond to stimuli and the decreased ability of muscles to contract and relax. Hypercalcemia has a depressant effect on nerve and muscle function. Gastrointestinal problems with hypercalcemia include anorexia, nausea, vomiting, constipation, and abdominal pain. Central nervous system problems include apathy, depression, poor memory, headache, and drowsiness. Severe hypercalcemia may produce lethargy, syncope, disorientation, hallucinations, coma, and death. Other signs and symptoms include weakness and decreased tone in skeletal and smooth muscle, dysphagia, polyuria, polyphagia, and cardiac dysrhythmias. In addition, calcium may be deposited in various tissues, such as the conjunctiva, cornea, and kidneys. Calcium deposits in the kidneys (renal calculi) may lead to irreversible damage and impairment of function.

### Osteoporosis

Osteoporosis is characterized by decreased bone density (osteopenia) and weak, fragile bones that often lead to fractures, pain, and disability. Although any bones may be affected, common fracture sites are the vertebrae of the lower dorsal and lumbar spines, wrists, and hips. Risk factors include female sex, advanced age, small stature, lean body mass, white or Asian race, positive family history, low calcium intake, menopause, sedentary lifestyle, nulliparity, smoking, excessive

ingestion of alcohol or caffeine, high protein intake, high phosphate intake, hyperthyroidism, and chronic use of certain medications (e.g., corticosteroids, phenytoin). Postmenopausal women who do not take estrogen replacement therapy are at high risk because of estrogen deficiency, age-related bone loss, and a low peak bone mass. Osteoporosis occurs in men but less often than in women. Both men and women who take high doses of corticosteroids are at high risk because the drugs demineralize bone. In addition, renal transplant recipients can acquire osteoporosis from corticosteroid therapy, decreased renal function, increased parathyroid hormone secretion, and cyclosporine immunosuppressant therapy.

Osteopenia or early osteoporosis may be present and undetected unless radiography or a bone density measurement is done. If detected, treatment is needed to slow bone loss. If undetected or untreated, clinical manifestations of osteoporosis include shortened stature (a measurable loss of height), back pain, spinal deformity, or a fracture. Fractures often occur with common bending or lifting movements or falling.

### Paget's Disease

Paget's disease is an inflammatory skeletal disease that affects older people. Its etiology is unknown. It is characterized by a high rate of bone turnover and results in bone deformity and pain. It is treated with non-narcotic analgesics and drugs that decrease bone resorption (e.g., bisphosphonates, calcitonin).

Bone is mineralized connective tissue that functions as structural support and a reservoir for calcium, phosphorus, magnesium, sodium, and carbonate. The role of bone in maintaining serum calcium levels takes precedence over its structural function (i.e., bone may be weakened or destroyed as calcium leaves bone and enters serum). Bone tissue is constantly being formed and broken down in a process called remodeling. During childhood, adolescence, and early adulthood, formation usually exceeds breakdown (resorption) as the person attains adult height and peak bone mass. After approximately 35 years of age, resorption is greater than formation. *Osteoporosis* results when bone strength (bone density and bone quality) is impaired, leading to increased porosity and vulnerability to fracture. Hormonal deficiencies, some diseases, and some medications (e.g., glucocorticoids) can also increase resorption, resulting in loss of bone mass and osteoporosis.

## Individual Drugs

### Calcium and Vitamin D Preparations

Calcium and vitamin D supplements are used to treat hypocalcemia and to prevent and treat osteoporosis. These drugs are described in the following sections, and names and dosages of individual drug preparations are listed in Table 25-1.

#### Calcium Preparations

An intravenous (IV) calcium salt (usually **calcium gluconate**) is given for acute, symptomatic hypocalcemia. An oral prepara-

tion (e.g., **calcium carbonate** or **citrate**) is given for asymptomatic, less severe, or chronic hypocalcemia. These preparations differ mainly in the amounts of calcium they contain and the routes by which they are given.

Even when serum calcium levels are normal, people who do not get enough calcium in their diets may need calcium supplements. Most diets in people of all ages, especially in young women and older adults, are thought to be deficient in calcium. Calcium supplements are also used in the prevention and treatment of osteoporosis.

#### Vitamin D Preparations

Vitamin D is used in chronic hypocalcemia if calcium supplements alone cannot maintain serum calcium levels within a normal range. It is also used to prevent deficiency states and treat hypoparathyroidism and osteoporosis. Although authorities agree that dietary intake is better than supplements, some suggest a vitamin D supplement for people who ingest less than the recommended amount. Supplementation recommendations include 400 international units daily for those 6 months to 24 years of age, 200 international units for those 25 to 50 years of age, 400 international units daily for those 51 to 70 years of age, and 600 international units for those 70 years of age and older. Supplementation of 800 international units daily is recommended for individuals at risk for vitamin D deficiency due to lack of sunlight exposure. If used, vitamin D supplements should be taken cautiously and not overused; excessive amounts can cause serious problems, including hypercalcemia.

Table 25-1

## Drugs at a Glance: Calcium and Vitamin D Preparations

Generic/Trade Name	ROUTES AND DOSAGE RANGES	
	Adults	Children
<b>Oral Calcium Products</b>		
<b>Calcium acetate</b> (25% calcium) (PhosLo)	PO 2–4 tablets with each meal	Dosage not established
<b>Calcium carbonate precipitated</b> (40% calcium) (Os-Cal, Tums)	PO 1–1.5 g 3 times daily with meals (maximal dose, 8 g daily)	
<b>Calcium citrate</b> (21% calcium) (Citracal)	PO 1–2 tablets (200 mg calcium per tablet) 2–4 times daily	
<b>Calcium gluconate</b> (9% calcium)	PO 1–2 g 3 or 4 times daily	PO 500 mg/kg/d in divided doses
<b>Parenteral Calcium Products</b>		
<b>Calcium chloride</b> (10 mL of 10% solution contains 273 mg [13.6 mEq] of calcium)	IV 500 mg–1 g (5–10 mL of 10% solution) every 1–3 d, depending on clinical response or serum calcium measurements	2.7–5 mg/kg/dose every 4–6 h depending on clinical response or serum calcium measurements
<b>Calcium gluconate</b> (10 mL of 10% solution contains 93 mg [4.65 mEq] of calcium)	IV 5–20 mL of 10% solution	IV 500 mg/kg/d in divided doses
<b>Vitamin D Preparations</b>		
<b>Calcitriol</b> (Rocaltrol, Calcijex)	Dialysis patients, hypoparathyroidism, PO 0.25 mcg daily initially, then adjusted according to serum calcium levels (usual daily maintenance dose, 0.5–1 mcg)	Hypoparathyroidism, ≥6 y: PO 0.5–2 mcg daily 1–5 y: PO 0.25–0.75 mcg daily
<b>Cholecalciferol</b> (Delta-D)	PO 400–1000 IU daily	
<b>Ergocalciferol</b> (Calciferol, Drisdol)	Hypoparathyroidism, PO 50,000–200,000 units daily initially (average daily main- tenance dose, 25,000–100,000 units)	
<b>Paricalcitol</b> (Zemplar)	Dialysis patients, 0.04–0.1 mcg/kg every other d initially; increased by 2–4 mcg at 2- to 4-week intervals, if necessary. Reduce dosage or stop therapy if hyper- calcemia occurs.	

## Drugs Used in Hypercalcemia and Selected Bone Disorders

Drugs used for hypercalcemia include bisphosphonates, calcitonin, corticosteroids, 0.9% sodium chloride IV infusion, and others. Drugs used for osteoporosis inhibit bone breakdown and demineralization and include *bisphosphonates*, calcitonin, estrogens, and antiestrogens. These drugs are described in the following sections, and most indications for use and dosages are listed in Table 25-2.

### Bisphosphonates

**Alendronate** (Fosamax), **ibandronate** (Boniva), **pamidronate** (Aredia), **risedronate** (Actonel), and **zoledronate** (Zometa) are drugs that bind to bone and inhibit calcium resorption from bone. **Alendronate** (Fosamax PLUS D) is compounded to pro-

vide 2800 international units of vitamin D in a once-weekly dose. Although indications for use vary among the drugs, they are used mainly in the treatment of hypercalcemia and osteoporosis.

Bisphosphonates are poorly absorbed from the intestinal tract and must be taken on an empty stomach, with water at least 30 minutes before any other fluid, food, or medication. The drugs are not metabolized. The drug bound to bone is slowly released into the bloodstream. Most of the drug that is not bound to bone is excreted in the urine.

**Calcitonin-salmon** (Calcimar, Miacalcin) is used in the treatment of hypercalcemia, Paget's disease, and osteoporosis. In hypercalcemia, calcitonin lowers serum calcium levels by inhibiting bone resorption. Calcitonin is most likely to be effective in hypercalcemia caused by hyperparathyroidism,

Table 25-2

## Drugs at a Glance: Drugs Used in Hypercalcemia and Selected Bone Disorders

GENERIC/TRADE NAME	INDICATIONS FOR USE	ROUTES AND DOSAGE RANGES
<b>Bisphosphonates</b>		
<b>Alendronate</b> (Fosamax)	Osteoporosis: Prevention and treatment in postmenopausal women  Treatment in men and women with glucocorticoid-induced osteoporosis Paget's disease	Osteoporosis: <i>Postmenopausal women</i> : Prevention, PO 5 mg once daily or 35 mg once weekly; treatment, PO 10 mg once daily or 70 mg once weekly. <i>Men</i> : 10 mg once daily Glucocorticoid-induced, 5 mg once daily Paget's disease, PO 40 mg daily for 6 mo; repeated if necessary
<b>Ibandronate</b> (Boniva)	Treatment and prevention of osteoporosis in postmenopausal women	PO 2.5 mg once daily or 150 mg every month
<b>Pamidronate</b> (Aredia)	Hypercalcemia of malignancy  Osteolytic lesions of breast cancer metastases or multiple myeloma  Paget's disease	Hypercalcemia, if IV 60 mg give over 4 h; if 90 mg give over 24 h  Osteolytic bone lesions; Breast cancer, IV 90 mg over 2 h every 3–4 wk; multiple myeloma, IV 90 mg over 4 h once monthly Paget's disease, IV 30 mg over 4 h, daily for 3 doses
<b>Risedronate</b> (Actonel)	Osteoporosis, postmenopausal and glucocorticoid-induced, prevention and treatment Paget's disease	Prevention and treatment of osteoporosis, PO 5 mg once daily or 35 mg once weekly  Paget's disease, PO 30 mg once daily for 2 mo
<b>Zoledronate</b> (Zometa)	Hypercalcemia of malignancy	IV 4 mg over 15 min or longer
<b>Selective Estrogen Receptor Modulator</b>		
<b>Raloxifene</b> (Evista)	Osteoporosis: Prevention and treatment in postmenopausal women	PO 60 mg once daily
<b>Calcitonin</b>		
<b>Calcitonin-salmon</b> (Calcimar, Miacalcin)	Hypercalcemia  Paget's disease Postmenopausal osteoporosis	Hypercalcemia, Sub-Q, IM 4 IU/kg q12h; can be increased after 1 or 2 d to 8 IU/kg q12h; maximum dose, 8 IU/kg q6h Paget's disease, Sub-Q, IM 50–100 IU/d Postmenopausal osteoporosis, Sub-Q, IM 100 IU/d; nasal spray (Miacalcin) 200 IU/d
<b>Parathyroid Hormone</b>		
<b>Teriparatide</b> (Forteo)	Osteoporosis	Sub-Q 20 mcg daily
<b>Miscellaneous Agents</b>		
<b>Furosemide</b> (Lasix)	Hypercalcemia	<i>Adults</i> : IV 80–100 mg q2h until a diuretic response is obtained or other treatment measures are initiated <i>Children</i> : IV 20–40 mg q4h until a diuretic response is obtained or other treatment measures are initiated
<b>Phosphate salts</b> (Neutra-Phos)	Hypercalcemia	PO 1–2 tablets 3 or 4 times daily, or contents of 1 capsule mixed with 75 mL of water 4 times daily
<b>Prednisone or hydrocortisone</b>	Hypercalcemia	Prednisone PO 20–50 mg twice daily (or equivalent dose of another glucocorticoid) for 5–10 d, then tapered to the minimum dose required to prevent hypercalcemia Hydrocortisone IM, IV 100–500 mg/d 4–6 L/d
<b>0.9% Sodium chloride injection</b>	Acute hypercalcemia	

prolonged immobilization, or certain malignant neoplasms. In acute hypercalcemia, calcitonin may be used along with other measures to lower serum calcium levels rapidly. A single injection of calcitonin decreases serum calcium levels in approximately 2 hours, and its effects last approximately 6 to 8 hours.

In *Paget's disease*, calcitonin slows the rate of bone turnover, improves bone lesions on radiologic examination, and relieves bone pain. In osteoporosis, calcitonin prevents further bone loss in the presence of adequate calcium and vitamin D. In addition, calcitonin helps control pain in patients with osteoporosis or metastatic bone disease. Both subcutaneous injections and intranasal administration relieve pain within 1 to 12 weeks. The drug is given daily initially, then two to three times a week. The mechanism by which pain is reduced is unknown.

### Estrogens and Antiestrogens

Estrogens are discussed here in relation to osteoporosis; see Chapter 27 for other uses and dosages. Estrogen replacement therapy (ERT) is beneficial for preventing postmenopausal osteoporosis. ERT is most beneficial immediately after menopause, when a period of accelerated bone loss occurs. Mechanisms by which ERT protects against bone loss and fractures are thought to include decreased bone breakdown, increased calcium absorption from the intestine, and increased calcitriol (active form of vitamin D that promotes absorption and use of calcium in bone building) concentration. Progestins have been used with estrogens in women with an intact uterus because of the increased risk of endometrial cancer with estrogen therapy alone. However, estrogen and estrogen-progestin combinations are no longer recommended because adverse effects are thought to outweigh benefits.

In postmenopausal osteoporosis, other drugs may be used instead of estrogen. Raloxifene (Evista) and tamoxifen (Nolvadex) act like estrogen in some body tissues and prevent the action of estrogen in other body tissues. Raloxifene is classified as a selective estrogen receptor modulator and is approved for prevention of postmenopausal osteoporosis. It has estrogenic effects in bone tissue, thereby decreasing bone breakdown and increasing bone mass density. It has antiestrogen effects in uterine and breast tissue. Tamoxifen, which is classified as an antiestrogen, is used to prevent and treat breast cancer. It also has estrogenic effects and can be used to prevent osteoporosis and cardiovascular disease, although it is not approved for these uses. Tamoxifen may help prevent osteoporosis in patients with breast cancer.

### Parathyroid Hormone

**Teriparatide** (Forteo) is a recombinant DNA version of PTH. It is approved for the treatment of osteoporosis in women. Other drugs for osteoporosis slow bone loss, whereas teriparatide increases bone formation by increasing the number of bone-building cells (osteoblasts). Teriparatide also increases serum levels of calcium and calcitriol. In clinical trials, the drug increased vertebral bone mineral density and decreased vertebral fractures. It is recommended for use in patients with severe osteoporosis or those who have not responded ade-

quately to other treatments, partly because osteosarcoma developed in some animals given high doses for long periods. No osteosarcoma developed in humans during clinical trials, but the longest of these trials was 2 years.

Teriparatide is rapidly and well absorbed after subcutaneous injection. Bioavailability is 95%, and peak serum levels occur in 30 minutes. The drug is metabolized and excreted through the liver, kidneys, and bone. It is not expected to accumulate in bone or other tissues, to interact significantly with other drugs, or to require dosage adjustment with renal or hepatic impairment. Adverse effects include nausea, headache, back pain, dizziness, syncope, and leg cramps.

### Corticosteroids

Glucocorticoids (see Chap. 23) are used in the treatment of hypercalcemia due to malignancies or vitamin D intoxication. These drugs lower serum calcium levels by inhibiting cytokine release, by direct cytolytic effects on some tumor cells, by inhibiting calcium absorption from the intestine, and by increasing calcium excretion in the urine. Hydrocortisone or prednisone is often used. The serum calcium level decreases in approximately 5 to 10 days, and after it stabilizes, the dosage should be gradually reduced to the minimum needed to control symptoms of hypercalcemia. High dosage or prolonged administration leads to serious adverse effects.

### Other Drugs for Hypercalcemia

**Furosemide** (Lasix) is a loop diuretic (see Chap. 53) that increases calcium excretion in urine by preventing its reabsorption in renal tubules. It can be given via IV route for rapid effects in acute hypercalcemia, but authorities do not agree about its use. Some recommend furosemide after extracellular fluid volume has been restored and saline diuresis occurs with IV infusion of several liters of 0.9% sodium chloride. Others recommend furosemide only if evidence of fluid overload is found or if heart failure occurs. Thiazide diuretics are contraindicated in patients with hypercalcemia because they decrease urinary excretion of calcium.

**Phosphate salts** (Neutra-Phos) inhibit intestinal absorption of calcium and increase deposition of calcium in bone. (Neutra-Phos is an oral combination of sodium phosphate and potassium phosphate.) Oral salts are effective in the treatment of hypercalcemia due to any cause. A potential adverse effect of phosphates is calcification of soft tissues due to deposition of calcium phosphate, which can lead to severe impairment of function in the kidneys and other organs. Phosphates should be given only when hypercalcemia is accompanied by hypophosphatemia (serum phosphorus < 3 mg/dL) and renal function is normal to minimize the risk of soft tissue calcification. Serum calcium, phosphorus, and creatinine levels should be monitored frequently, and the dose should be reduced if serum phosphorus exceeds 4.5 milligrams per deciliter or the product of serum calcium and phosphorus exceeds 60 milligrams per deciliter.

**Sodium chloride (0.9%) injection** (normal saline) is an IV solution that contains water, sodium, and chloride. It is included here because it is the treatment of choice for hyper-

calcemia and is usually effective. The sodium contained in the solution inhibits the reabsorption of calcium in renal tubules and thereby increases urinary excretion of calcium. The solution relieves the dehydration caused by vomiting and polyuria, and it dilutes the calcium concentration of serum and urine. Several liters are given daily. Patients should be monitored closely for signs of fluid overload, and serum calcium, magnesium, and potassium levels should be measured every 6 to 12 hours. Large amounts of magnesium and potassium are lost in the urine, and adequate replacement is essential.

### Applying Your Knowledge 25-1

You are giving instructions to Ms. Taylor on the proper administration method for taking her alendronate. In addition to instructing Ms. Taylor to take this medication with water, what important instruction must you include for this patient?

### Applying Your Knowledge 25-2

Patients like Ms. Taylor, who has osteoporosis, should take preventive measures in addition to taking their prescribed medication. One important measure is to increase the intake of foods that contain high levels of calcium. What dietary recommendations would you make to Ms. Taylor?

## Nursing Process

### Assessment

- Assess for risk factors and manifestations of hypocalcemia and calcium deficiency:
  - Assess dietary intake of dairy products, other calcium-containing foods, and vitamin D.
  - Check serum calcium reports for abnormal values. The normal total serum calcium level is approximately 8.5 to 10.5 mg/dL (SI units 2.2–2.6 mmol/L). Approximately half of the total serum calcium (e.g., 4–5 mg/dL) should be free ionized calcium, the physiologically active form. To interpret serum calcium levels accurately, serum albumin levels and acid–base status must be considered. Low serum albumin decreases the total serum level of calcium by decreasing the amount of calcium that is bound to protein; however, the ionized concentration is unaffected by serum albumin levels. Metabolic and respiratory alkalosis increase binding of calcium to serum proteins, thereby maintaining normal total serum calcium but decreasing the ionized values. Conversely, metabolic and respiratory acidosis decrease binding and therefore increase the concentration of ionized calcium.

- Check for *Chvostek's sign*: Tap the facial nerve just below the temple, in front of the ear. If facial muscles twitch, hyperirritability of the nerve is present, and tetany may occur.
- Check for *Trousseau's sign*: Constrict blood circulation in an arm (usually with a blood-pressure cuff) for 3 to 5 minutes. This produces ischemia and increased irritability of peripheral nerves, which causes spasms of the lower arm and hand muscles (carpedal spasm) if tetany is present.
- Assess for conditions in which hypercalcemia is likely to occur (e.g., cancer, prolonged immobilization, vitamin D overdose).
- Observe for signs and symptoms of hypercalcemia in clients at risk. Electrocardiographic changes indicative of hypercalcemia include a shortened Q–T interval and an inverted T wave.
- Assess for risk factors and manifestations of osteoporosis, especially in postmenopausal women and men and women on chronic corticosteroid therapy.
  - If risk factors are identified, ask if preventive measures are being used (e.g., increasing calcium intake, exercise, medications).
  - If the patient is known to have osteoporosis, ask about duration and severity of symptoms, age at onset, location, whether fractures have occurred, what treatments have been performed, and response to treatments.
- If Paget's disease is suspected, assess for an elevated serum alkaline phosphatase level and abnormal bone scan reports.

### Nursing Diagnoses

- Deficient Knowledge: Recommended daily amounts and dietary sources of calcium and vitamin D
- Deficient Knowledge: Disease process and drug therapy for osteoporosis
- Risk for Injury: Tetany, sedation, seizures from hypocalcemia
- Risk for Injury: Hypercalcemia related to overuse of supplements; hypocalcemia from aggressive treatment of hypercalcemia

### Planning/Goals

#### The patient will

- Achieve and maintain normal serum levels of calcium
- Increase dietary intake of calcium-containing foods to prevent or treat osteoporosis
- Use calcium or vitamin D supplements in recommended amounts
- Comply with instructions for safe drug use
- Be monitored closely for therapeutic and adverse effects of drugs used to treat hypercalcemia

*Nursing Process continues on page 402*

- Comply with procedures for follow-up treatment of hypocalcemia, hypercalcemia, or osteoporosis
- Avoid preventable adverse effects of treatment for acute hypocalcemia or hypercalcemia

## Interventions

Assist all patients in meeting the recommended daily requirements of calcium and vitamin D. With an adequate protein and calcium intake, enough phosphorus also is obtained.

- The best dietary source is milk and other dairy products, including yogurt.
- Unless contraindicated by the patient's condition, recommend that adults drink at least two 8-oz glasses of milk daily. This furnishes approximately half the daily calcium requirement; the remainder will probably be obtained from other foods.
- Children need approximately four glasses of milk or an equivalent amount of calcium in milk and other foods to support normal growth and development.
- Pregnant and lactating women also need approximately four glasses of milk or the equivalent to meet increased needs. Vitamin and mineral supplements are often prescribed during these periods.
- Postmenopausal women who take estrogens need at least 1000 mg of calcium daily. Those who do not take estrogens need at least 1500 mg. Dosage adjusted to dietary calcium intake.
- For patients who avoid or minimize their intake of dairy products because of the calories, identify low-calorie sources, such as skim milk and low-fat yogurt.
- Milk that has been fortified with vitamin D is the best food source. Exposure of skin to sunlight is also needed to supply adequate amounts of vitamin D.
- For people who are unable or unwilling to ingest sufficient calcium, a supplement may be needed to prevent osteoporosis.

Assist patients with hypercalcemia to decrease formation of renal calculi by forcing fluids to approximately 3000 to 4000 milliliters per day and preventing urinary tract infections.

Patient Guidelines for Drugs for Osteoporosis are presented in the accompanying display.

## Evaluation

- Check laboratory reports of serum calcium levels for normal values.
- Interview and observe for relief of symptoms of hypocalcemia, hypercalcemia, or osteoporosis.
- Interview and observe intake of calcium-containing foods.
- Question about normal calcium requirements and how to meet them.
- Interview and observe for accurate drug usage and compliance with follow-up procedures.
- Interview and observe for therapeutic and adverse drug effects.

## Principles of Therapy

### Goal of Therapy

The goal of therapy is to restore normal calcium balance in the body. Drugs used for hypocalcemia help correct calcium deficit, reduce the risk of *tetany* (prolonged and painful spasms of the voluntary muscles), and slow development of osteoporosis. Drugs used for hypercalcemia support treatment of the underlying condition and control serum calcium levels.

### Drugs Used for Hypocalcemia

#### Drug Dosage and Administration

Calcium preparations and perhaps vitamin D are used to treat hypocalcemia. IV administration of calcium, usually 10 to 20 milliliters of 10% calcium gluconate (1–2 g of calcium), is necessary to treat acute, severe hypocalcemia, which is a medical emergency. Doses may be repeated, a continuous infusion may be given, or oral supplements may be used to avoid symptoms of hypocalcemia and maintain normal serum calcium levels (as measured every 4–6 hours). Once the hypocalcemia is stabilized, treatment is aimed at management of the underlying cause or prevention of recurrence. If hypocalcemia is caused by diarrhea or malabsorption, treatment of the underlying condition decreases loss of calcium from the body and increases absorption. Serum magnesium levels should also be measured, and, if hypomagnesemia is present, it must be treated before treatment of hypocalcemia can be effective.

Oral calcium supplements are preferred for less acute situations or for long-term treatment of chronic hypocalcemia. Vitamin D is given also if a calcium preparation alone cannot maintain serum calcium levels within a normal range. When vitamin D is given to treat hypocalcemia, dosage is determined by frequent measurement of serum calcium levels. Usually, higher doses are given initially, and lower doses are given for maintenance therapy. Calcium salts and vitamin D are combined in many over-the-counter preparations promoted as dietary supplements (Table 25-3). These preparations contain variable amounts of calcium and vitamin D. In general, intake of calcium should not exceed 2500 milligrams daily, from all sources, and intake of vitamin D should not exceed 400 international units daily. These mixtures are not indicated for maintenance therapy in chronic hypocalcemia.

Calcium supplements can decrease bone loss and fractures, especially in women. Calcium carbonate contains the most elemental calcium by weight (40%). It is inexpensive and available in a nonprescription form as the antacid Tums. Calcium citrate is reportedly better absorbed than calcium carbonate.

#### Effects of Calcium Preparations on Other Drugs

Calcium preparations and digoxin have similar effects on the myocardium. Therefore, if calcium is given to a patient taking digoxin, the risks of digitalis toxicity and cardiac dysrhythmias are increased. This combination must be used very cautiously. Oral calcium preparations decrease effects of oral tetracycline drugs by combining with the antibiotic and preventing its

## Patient Teaching Guidelines

## Drugs for Osteoporosis

### General Considerations

- Osteoporosis involves weak bones that fracture easily and may cause pain and disability.
- Important factors in prevention and treatment include an adequate intake of calcium and vitamin D (from the diet, from supplements, or from a combination of both sources), regular weight-bearing exercise, and drugs that can slow bone loss.
- It is better to obtain calcium and vitamin D from foods such as milk and other dairy products. Approximately 1000 to 1500 milligrams of calcium and a minimum of 400 IU of vitamin D are recommended daily.
- If unable to get sufficient dietary calcium and vitamin D, consider supplements of these nutrients. Consult a health care provider about the types and amounts. For example, a daily multivitamin and mineral supplement may contain adequate amounts when added to dietary intake. If taking other supplements, avoid those containing bone meal because they may contain lead and other contaminants that are toxic to the human body. Do not take more than the recommended amounts of supplements; overuse can cause serious, life-threatening problems.
- The main drugs approved for prevention and treatment of osteoporosis are the bisphosphonates (e.g., Fosamax, Actonel). These drugs help prevent the loss of calcium from bone, thereby strengthening bone and reducing the risks of fractures.
- For people at high risk for development of osteoporosis (e.g., postmenopausal women, men and women who take an oral or inhaled corticosteroid such as prednisone or

fluticasone [Flonase]), or those being treated for osteoporosis, a baseline measurement of bone mineral density and periodic follow-up measurements are needed. This is a noninvasive test that does not involve any injections or device insertions.

### Self-Administration

- If taking a calcium supplement, calcium carbonate 500 milligrams twice daily is often recommended. This can be obtained with the inexpensive over-the-counter antacid Tums, which contains 200 milligrams of calcium per tablet.
- Do not take a calcium supplement with an iron preparation, tetracycline, ciprofloxacin, or phenytoin. Instead, take the drugs at least 2 hours apart to avoid calcium interference with absorption of the other drugs.
- If taking both a calcium supplement and a bisphosphonate, take the calcium at least 2 hours after the bisphosphonate. Calcium, antacids, and other drugs interfere with absorption of bisphosphonate.
- Take bisphosphonates with 6 to 8 ounces of water at least 30 minutes before any food, other fluid, or other medication. Beverages other than water and foods decrease absorption and effectiveness.
- Take a bisphosphonate in an upright position and do not lie down for at least 30 minutes. This helps prevent esophageal irritation and stomach upset.
- If taking a bisphosphonate, report new or worsening dysphagia, retrosternal pain, or heartburn to your health care provider. This may be an indication of esophageal irritation due to the bisphosphonate.

absorption. They should not be given at the same time or within 2 to 3 hours of each other.

## Drugs Used for Hypercalcemia

Treatment of hypercalcemia depends largely on the cause and severity. When the cause is a tumor of parathyroid tissue, sur-

gical excision is commonly used. When the cause is a malignant tumor, treatment of the tumor with surgery, radiation, or chemotherapy may reduce production of PTH. When the cause is excessive intake of vitamin D, the vitamin D preparation should be stopped immediately. Serum calcium levels should be measured periodically to monitor effects of therapy.

Table 25-3

### Selected Calcium/Vitamin D Combination Products

GENERIC/ TRADE NAME	CALCIUM (MG)*/ TABLET OR CAPSULE	VITAMIN D (IU)†/ TABLET
Caltrate 600 + D and Caltrate Plus	600	200
Citracal caplets + D	315	200
Dical-D tablets	117	133
Dical-D wafers	233	200
Os-Cal 250 + D	250	125
Os-Cal 500 + D	500	125
Posture-D	600	125

\*mg of elemental calcium; †IU, international units.

### Drug Dosage and Administration

Acute hypercalcemia (e.g., severe symptoms or a serum calcium level > 12 mg/dL) is a medical emergency, and rehydration is a priority. An IV saline infusion (0.9% or 0.45% NaCl) of 4000 milligrams a day (or more if kidney function is adequate) is effective. After rehydration, furosemide may be given IV to increase renal excretion of calcium and prevent fluid overload. Because sodium, potassium, and water are also lost in the urine, these must be replaced in the IV fluids.

In mild hypercalcemia, further drug therapy is usually not necessary; most patients respond to the aforementioned treatment. In moderate to severe hypercalcemia, pamidronate or zoledronate may be the drug of choice. When pamidronate is given in a single IV infusion containing 60 or 90 milligrams, serum calcium levels decrease within 2 days, reach their lowest levels in approximately 7 days, and remain lower for 2 weeks or longer. Treatment can be repeated if hypercalcemia recurs. Zoledronate can be given over 15 minutes, and effects may last longer than those of pamidronate. Adverse effects of the two

drugs are similar. Phosphates should not be used, unless hypophosphatemia is present. They are also contraindicated in patients with persistent urinary tract infections and an alkaline urine, because kidney stones composed of calcium phosphate are likely to form in such cases.

In chronic hypercalcemia, treatment of the underlying disease process and measures to control serum calcium levels (e.g., a high fluid intake and mobilization to help retain calcium in bone) are necessary. Oral phosphate administration may help if other measures are ineffective.

For patients receiving a calcium channel blocker (see Chap. 50), the drugs may be less effective in the presence of hypercalcemia. For calcium channel blocker overdose, replacement may require an hourly infusion after a bolus dose.

## Drugs Used for Osteoporosis

To avoid or slow bone loss, preventive measures should be implemented in people of all ages, including a consistently adequate dietary intake of calcium to promote normal bone development and maintenance. In children, adolescents, and young adults, an adequate calcium intake promotes bone growth and peak bone mass. A well-stocked “reservoir” means that in later years, when bone loss exceeds formation, more bone can be lost before osteoporosis develops. Measures to prevent osteoporosis include the following:

- Adequate calcium intake, which may slow the development of osteoporosis and fractures in postmenopausal women and men older than 40 years of age. Although dietary intake is much preferred, a supplement may be needed to ensure a daily intake of 1000 to 1500 milligrams, especially in adolescent girls, frail older adults, and those receiving corticosteroids.
- Use of alendronate (Fosamax) and risedronate (Actonel), which are approved by the Food and Drug Administration for prevention of osteoporosis. (With alendronate, recommended dosage is smaller for prevention than for treatment.) Raloxifene (Evista) is approved for prevention and treatment of postmenopausal osteoporosis in women.
- Adequate intake of vitamin D. However, supplementation is probably not indicated unless a deficiency can be demonstrated. Serum calcitriol can be measured in patients at risk for vitamin D deficiency, including older adults and those on chronic corticosteroid therapy.
- Lifestyle changes, including regular exercise and smoking cessation. Numerous studies indicate that vigorous, weight-bearing exercise helps promote and maintain strong bone, and inactivity promotes bone weakening and loss. Smoking decreases the amount of active estrogen in the body and thus accelerates bone loss.

Preventive measures are necessary for patients on chronic corticosteroid therapy (e.g., prednisone 7.5 mg daily; equivalent amounts of other systemic drugs; high doses of inhaled drugs). For both men and women, most of the preceding guide-

lines apply (e.g., calcium supplements, regular exercise, a bisphosphonate drug). In addition, low doses and nonsystemic routes help prevent osteoporosis and other adverse effects. For men, corticosteroids decrease testosterone levels by approximately one half, and replacement therapy may be needed.

Preventive measures are also necessary for patients taking **phenytoin** (Dilantin) and phenobarbital, because these drugs may contribute to osteoporosis through their effects on calcium metabolism. These anticonvulsant medications increase hepatic metabolism of vitamin D, which leads to a decrease in calcium absorption in the intestine. Supplemental calcium and vitamin D as well as specific drugs for osteoporosis should be considered if bone density is low.

When bone loss is evident (from diagnostic tests of bone density or occurrence of fractures), several interventions may help slow further skeletal bone loss or prevent fractures. Most drugs used to treat osteoporosis decrease the rate of bone breakdown and thus slow the rate of bone loss. Alendronate (Fosamax) 10 milligrams daily or 70 milligrams weekly and risedronate (Actonel) 5 milligrams daily can increase bone mineral density, reduce risks of vertebral fractures, and slow progression of vertebral deformities and loss of height. One of these drugs is often used in combination with estrogen and calcium and vitamin D supplements. The drug teriparatide (Forteo) actually increases bone formation.

Patients diagnosed with osteoporosis require adequate calcium and vitamin D (at least the recommended dietary allowance), whether obtained from the diet or from supplements. Calcium 600 milligrams and vitamin D 200 international units once or twice daily are often recommended for postmenopausal women with osteoporosis, and pharmacologic doses of vitamin D are sometimes used to treat patients with serious osteoporosis. If such doses are used, caution should be exercised, because excessive amounts of vitamin D can cause hypercalcemia and hypercalciuria.

In addition, regular exercise and smoking cessation may be necessary. Treatment of men is similar to that of women, except that testosterone replacement may be required. In corticosteroid-induced osteoporosis, multiple treatment measures may be necessary, including increased dietary and supplemental calcium and possibly vitamin D supplementation, hormone replacement, corticosteroid dosage reduction, exercise, and a bisphosphonate or calcitonin to slow skeletal bone loss.

## Use in Special Populations

### Use in Children

Hypocalcemia is uncommon in children. However, inadequate calcium in the diet is thought to be common, especially in girls. Both inadequate calcium and exercise in children are risk factors for eventual osteoporosis. If hypocalcemia or dietary calcium deficiency develops, principles of using calcium or vitamin D supplements are the same as those in adults. Children should be monitored closely for signs and symptoms of adverse effects, including hypercalcemia. Hypercalcemia is

probably most likely to occur in children with a malignant tumor. Guidelines for treating hypercalcemia in children are essentially the same as those for adults, with drug dosages adjusted. Safety, effectiveness, and dosage of pamidronate and zoledronate have not been established.

### Use in Older Adults

Hypocalcemia is uncommon, because calcium moves from bone to blood to maintain normal serum levels. However, calcium deficiency commonly occurs because of long-term dietary deficiencies of calcium and vitamin D, impaired absorption of calcium from the intestine, lack of exposure to sunlight, and impaired liver or kidney metabolism of vitamin D to its active form. These and other factors lead to demineralization and weakening of bone (osteoporosis) and an increased risk of fractures. Postmenopausal women are at high risk for osteoporosis. Although osteoporosis also develops in older men, it occurs less often, at a later age, and to a lesser extent than in older women. Both men and women who take corticosteroids are at risk for osteoporosis. The risk is higher with systemic corticosteroids but may also occur with oral or inhaled drugs, especially at higher doses. In general, all older adults must continue their dietary intake of dairy products and other calcium-containing foods. Older adults with osteoporosis or risk factors for osteoporosis may need calcium supplements and a bisphosphonate or calcitonin to prevent or treat the disorder.

Hypercalcemia usually requires large amounts of IV 0.9% sodium chloride (e.g., 150–200 mL/hour). Older adults often have chronic cardiovascular disorders that may be aggravated by this treatment, and they should be monitored closely for signs of fluid overload, congestive heart failure, pulmonary edema, and hypertension.

### Use in Patients With Renal Impairment

Patients with renal impairment or failure often have disturbances in calcium and bone metabolism. If hypercalcemia develops in patients with severely impaired renal function, hemodialysis or peritoneal dialysis with calcium-free solution is effective and safe. Calcium acetate may be used to prevent or treat hyperphosphatemia. The calcium reduces blood levels of phosphate by reducing its absorption from foods. That is, calcium binds with dietary phosphate to produce calcium phosphate, which is insoluble and excreted in feces. If vitamin D therapy is needed to treat osteomalacia associated with renal impairment, calcitriol (e.g., Rocaltrol) is preferred (see

Table 25-1). Calcitriol is the active form of vitamin D and thus requires no metabolism.

None of the bisphosphonate drugs is recommended for use in severe renal impairment (e.g., serum creatinine > 5 mg/dL or creatinine clearance < 30 mL/minute). With alendronate, dosage does not need to be reduced in mild to moderate impairment (e.g., creatinine clearance 35–60 mL/minute). Pamidronate and zoledronate are nephrotoxic, and renal function should be closely monitored during their use.

Teriparatide (Forteo), a form of PTH, apparently does not require dosage adjustment in renal impairment.

### Use in Patients With Hepatic Impairment

The bisphosphonates are not metabolized in the liver and are unlikely to affect liver function. Teriparatide (Forteo), a form of PTH, apparently does not require dosage adjustment in hepatic impairment.

### Use in Home Care

Home care nurses have an excellent opportunity to promote health and prevent illness related to calcium and bone disorders. Nurses who assist in the care of any seriously ill patient should also be able to recognize and obtain immediate treatment for hypocalcemia or hypercalcemia. For example, hypercalcemia may occur in patients with cancer, especially cancers involving bone.

All members of a household should be assessed in relation to calcium and vitamin D intake because an adequate amount of these nutrients is needed throughout life. Intake of both calcium and vitamin D is often inadequate in children and adolescent girls, who may risk developing osteoporosis. It may be necessary to teach about dietary and supplemental sources of these nutrients as well as adverse effects of excessive amounts. Patients who are taking medications to prevent or treat osteoporosis may also require teaching or other assistance.

## Applying Your Knowledge 25-3

### How Can You Avoid This Medication Error?

Ms. Taylor knows she cannot drink her morning coffee or eat her breakfast for 30 minutes after taking her alendronate. You tell her to get up and take her medication, then go back to bed for half an hour.

.....

## Nursing Actions Drugs Used in Calcium and Bone Disorders

### NURSING ACTIONS

### RATIONALE/EXPLANATION

#### 1. Administer accurately

##### a. With calcium preparations:

- (1) Give oral preparations with or after meals.
- (2) Give intravenous (IV) preparations slowly (0.5–2 mL/min), check pulse and blood pressure closely, and monitor the electrocardiogram (ECG) if possible.
- (3) Do not mix IV preparations with any other drug in the same syringe.

To increase absorption

These solutions may cause dysrhythmias and hypotension if injected rapidly. They are also irritating to tissues.

Calcium reacts with some other drugs and forms a precipitate.

##### b. With bisphosphonates:

- (1) Give alendronate, ibandronate, and risedronate with 6–8 ounces of plain water, at least 30 minutes before the first food, beverage, or medication of the day.
- (2) Give etidronate on an empty stomach, as a single dose or in divided doses. Avoid giving within 2 hours of ingesting dairy products, antacids, or vitamin or mineral preparations.
- (3) Give IV pamidronate and zoledronate according to the manufacturers' instructions.

To promote absorption and decrease esophageal and gastric irritation

If gastrointestinal (GI) symptoms occur with the single dose, divided doses may relieve them. Substances containing calcium or other minerals decrease absorption of etidronate.

These drugs require reconstitution, diluting with IV fluids, and specific time intervals of administration.

To decrease nausea and discomfort from flushing

##### c. Give calcitonin at bedtime.

##### d. With phosphate salts, mix powder forms with water for oral administration. See package inserts for specific instructions.

#### 2. Observe for therapeutic effects

##### a. With calcium preparations, observe for:

- (1) Relief of symptoms of neuromuscular irritability and tetany, such as decreased muscle spasms and decreased paresthesias
- (2) Serum calcium levels within the normal range (8.5–10.5 mg/dL)
- (3) Absence of Chvostek's and Trousseau's signs

##### b. With alendronate or risedronate for osteoporosis, observe for improved bone mass density and absence of fractures.

Early osteopenia and osteoporosis are asymptomatic. Measurement of bone mass density is the only way to quantify bone loss.

##### c. With calcitonin, corticosteroids, pamidronate, or zoledronate for hypercalcemia, observe for:

- (1) Decreased serum calcium level

Calcitonin lowers serum calcium levels in about 2 hours after injection and effects last 6–8 hours. Corticosteroids require 10–14 days to lower serum calcium. Bisphosphonates lower serum calcium levels within 2 days, but may require a week or more to produce normal serum calcium levels.

- (2) Decreased signs and symptoms of hypercalcemia

#### 3. Observe for adverse effects

##### a. With calcium preparations, observe for hypercalcemia:

- (1) GI effects—*anorexia, nausea, vomiting, abdominal pain, constipation*
- (2) Central nervous system effects—*apathy, poor memory, depression, drowsiness, disorientation*
- (3) Other effects—*weakness and decreased tone in skeletal and smooth muscles, dysphagia, polyuria, polydipsia, cardiac dysrhythmias*
- (4) Serum calcium >10.5 mg/dL
- (5) ECG changes indicating hypercalcemia (a prolonged Q-T interval and an inverted T wave)

##### b. With vitamin D preparations, observe for hypervitaminosis D and hypercalcemia (see above).

This is most likely to occur with chronic ingestion of high doses daily. In children, accidental ingestion may lead to acute toxicity.

## NURSING ACTIONS

- c. With alendronate, ibandronate, and risedronate, observe for:
- (1) GI effects—abdominal distention, acid regurgitation, dysphagia, esophagitis, flatulence
  - (2) Other effects—headache, musculoskeletal pain, decreased serum calcium and phosphate
- d. With calcitonin, observe for nausea, vomiting, tissue irritation at administration sites, and allergic reactions.
- e. With drug therapy for hypercalcemia, observe for hypocalcemia.
- f. With pamidronate and zoledronate, observe for:
- (1) GI effects—*anorexia, nausea, vomiting, constipation*
  - (2) Cardiovascular effects—*fluid overload, hypertension*
  - (3) Electrolyte imbalances—*hypokalemia, hypomagnesemia, hypophosphatemia*
  - (4) Musculoskeletal effects—*muscle and joint pain*
  - (5) Miscellaneous effects—*fever, tissue irritation at IV insertion site, pain, anemia*
- g. With etidronate, observe for *anorexia, nausea, diarrhea, bone pain, fever, fluid overload, and increased serum creatinine.*
- h. With phosphates, observe for *nausea, vomiting, and diarrhea.*

## 4. Observe for drug interactions

- a. Drugs that *increase* effects of calcium:
- (1) Vitamin D
  - (2) Thiazide diuretics
- b. Drugs that *decrease* effects of calcium:
- (1) Corticosteroids (prednisone, others), calcitonin, and phosphates
- c. Drugs that *increase* effects of vitamin D:
- (1) Thiazide diuretics
- d. Drugs that *decrease* effects of vitamin D:
- (1) Phenytoin
  - (2) Cholestyramine resin (Questran)
  - (3) Mineral oil
- e. Drugs that *decrease* effects of oral bisphosphonates:
- (1) Antacids and calcium supplements
- f. Drug that *decreases* the effects of tiludronate:
- (1) Aspirin
- g. Drugs that alter effects of calcitonin:
- (1) Testosterone and other androgens *increase* effects.
  - (2) Parathyroid hormone *decreases* effects.
- h. Drugs that *decrease* effects of phosphate salts:
- (1) Antacids containing aluminum and magnesium

## RATIONALE/EXPLANATION

Adverse effects are usually minor with the doses taken for prevention or treatment of osteoporosis, if the drugs are taken as directed. More severe effects may occur with the higher doses taken for Paget's disease.

Adverse effects are usually mild and transient. Nasal administration produces greater patient compliance than injections, with few adverse effects.

Hypocalcemia may occur with vigorous treatment of hypercalcemia. This can be minimized by monitoring serum calcium levels frequently and adjusting drug dosages and other treatments.

Adverse effects are more frequent and more severe at higher doses. The drug is nephrotoxic and should not be used in patients with renal failure.

Increases intestinal absorption of calcium from both dietary and supplemental drug sources  
Reduce calcium losses in urine

These drugs lower serum calcium levels by various mechanisms. They are used in the treatment of hypercalcemia.

Thiazide diuretics administered to hypoparathyroid patients may cause hypercalcemia (potentiate vitamin D effects). Accelerates metabolism of vitamin D in the liver and may cause vitamin D deficiency, hypocalcemia, and rickets or osteomalacia. Increased intake of vitamin D may be needed. May decrease intestinal absorption of vitamin D preparations. Mineral oil is a fat and therefore combines with fat-soluble vitamins, such as vitamin D, and prevents their absorption from the gastrointestinal tract.

These drugs interfere with absorption of bisphosphonates and should be taken at least 2 hours after a bisphosphonate.

Aspirin decreases the bioavailability of tiludronate by up to 50% when taken within 2 hours of tiludronate.

Androgens and calcitonin have additive effects on calcium retention and inhibition of bone resorption (movement of calcium from bone to serum). Parathyroid hormone antagonizes or opposes calcitonin.

Aluminum and magnesium may combine with phosphate and thereby prevent its absorption and therapeutic effect.

## Key Concepts

- Hypoparathyroidism is most often caused by removal of or damage to the parathyroid glands during neck surgery.
- Hyperparathyroidism is most often caused by a tumor or hyperplasia of a parathyroid gland.
- Deficiency of vitamin D causes inadequate absorption of calcium and phosphorus.
- In general, intake of calcium should not exceed 2500 mg daily, from all sources, and intake of vitamin D should not exceed 400 international units daily.
- Calcium deficiency commonly occurs in the elderly because of long-term dietary deficiencies of calcium and vitamin D, impaired absorption of calcium from the intestine, lack of exposure to sunlight, and impaired liver or kidney metabolism of vitamin D to its active form.
- Postmenopausal women are at high risk for osteoporosis.
- Both men and women who take corticosteroids are at risk for osteoporosis.
- For men, corticosteroids decrease testosterone levels by approximately one half, and replacement therapy may be needed.

## Review and Application Exercises

### Short Answer Exercises

1. What are the major physiologic functions of calcium?
2. What is the normal serum level of calcium?
3. What are some nursing interventions to prevent hypocalcemia?
4. What signs and symptoms may indicate hypocalcemia?
5. How is hypocalcemia treated?
6. What signs and symptoms may indicate hypercalcemia?
7. How is hypercalcemia treated?
8. Why is it important to have an adequate intake of calcium and vitamin D throughout life?
9. What are the main elements of prevention and treatment of osteoporosis?

### NCLEX-Style Questions

10. To decrease nausea and discomfort from flushing with calcitonin, the nurse should instruct the patient to take the drug in which of the following ways?
  - a. with a warm beverage
  - b. with a glass of orange juice
  - c. with breakfast
  - d. at bedtime
11. Rapid administration of IV calcium may result in which of the following conditions?
  - a. cardiac dysrhythmias
  - b. nephrotoxicity
  - c. ototoxicity
  - d. pathologic fractures
12. Which of the following drugs is used to treat osteoporosis and can actually increase bone formation?
  - a. teriparatide (Forteo)
  - b. phosphate salts (Neutra-Phos)
  - c. furosemide (Lasix)
  - d. calcitriol (Rocaltrol)
13. If oral calcium preparations are given at the same time or within 2 to 3 hours of administration of antibiotics, they prevent absorption of which of the following antibiotics?
  - a. penicillin
  - b. cephalosporin
  - c. tetracycline
  - d. erythromycin
14. Alendronate is used in postmenopausal women for the prevention and treatment of osteoporosis. It acts to decrease plasma calcium levels by
  - a. inhibiting calcium resorption from bone
  - b. binding calcium in the blood
  - c. promoting renal excretion of calcium
  - d. limiting intestinal absorption of calcium

## LEARNING OBJECTIVES

After studying this chapter, you will be able to:

1. Describe major effects of endogenous insulin on body tissues.
2. Discuss characteristics and uses of the various types of insulins and insulin analogs.
3. Discuss the relationships among diet, exercise, and drug therapy in controlling diabetes.
4. Differentiate types of oral agents used to manage diabetes mellitus in terms of mechanisms of action, indications for use, adverse effects, and nursing process implications.
5. Discuss the indications, characteristics, and benefits of amylin analogs, incretin mimetics, and dipeptidyl peptidase-4 (DPP-4) inhibitors.
6. Explain the benefits of maintaining glycemic control in preventing complications of diabetes mellitus.
7. State reasons for combinations of insulin and oral agents or different types of oral agents.
8. Assist patients or caregivers in learning how to manage diabetes care, including administration of medication agents used to manage diabetes mellitus.
9. Collaborate with nurse diabetes educators, dietitians, pharmacists, and others in teaching self-care activities to patients with diabetes.
10. Assess and monitor patients' conditions in relation to diabetes mellitus and their compliance with prescribed management strategies.
11. Discuss dietary and herbal supplements that affect blood sugar and diabetes control.
12. Review the National Cholesterol Education Program (NCEP) Adult Treatment Panel III (ATP III) guidelines for lipid management in high risk and/or diabetic states.

## Applying Your Knowledge

Carwein Coulter is a 55 year-old African American with type 2 diabetes. He has been a diagnosed diabetic for at least 10 years and is overweight. Mr. Coulter's current daily medications include Novolin 70/30 insulin, glimepiride, and metformin. He has a sliding scale of insulin lispro for elevated blood glucose results.

.....

## Introduction

Insulin and oral hypoglycemic agents are two of the several types of medications used to lower blood glucose in diabetes mellitus. New drug therapies include amylin analogs, incretin mimetics, and dipeptidyl peptidase-4 (DPP-4) inhibitors. To assist readers in understanding the clinical use of these drugs, characteristics of endogenous insulin, diabetes mellitus, and the medications are described.

## Endogenous Insulin

Insulin is a protein hormone secreted by beta cells in the pancreas. The average adult pancreas secretes 40 to 60 units of insulin daily. This includes a basal amount of 1 to 2 units per hour and additional amounts (4–6 units/hour) after meals or when the blood glucose level exceeds 100 milligrams per deciliter. In a fasting state, serum insulin levels are low and stored glucose and amino acids are used for energy needs of tissues that require glucose. After a meal, serum insulin levels increase and peak in a few minutes, then decrease to baseline levels in 2 to 3 hours.

Amylin, a pancreatic hormone secreted with insulin, delays gastric emptying, increases satiety, and suppresses glucagon secretion, thus complementing the effects of insulin on the blood sugar. A synthetic form of amylin, pramlintide (Symlin), has been developed to assist with glucose control in both type 1 and type 2 diabetic patients.

Insulin is secreted into the portal circulation and transported to the liver, where about half is used or degraded. The other half reaches the systemic circulation, where it circulates mainly in an unbound form and is transported to body cells.

At the cellular level (Fig. 26-1), insulin binds with and activates receptors on the cell membranes of about 80% of body cells. Liver, muscle, and fat cells have many insulin receptors and are primary tissues for insulin action. After insulin–receptor binding occurs, cell membranes become highly permeable to glucose and allow rapid entry of glucose into the cells. The cell membranes also become more permeable to amino acids, fatty acids, and electrolytes such as potassium, magnesium, and phos-

phate ions. Cellular metabolism is altered by the movement of these substances into the cells, by activation of some enzymes and inactivation of others, by movement of proteins between intracellular compartments, by changes in the amounts of proteins produced, and perhaps by other mechanisms. Overall, the changes in cellular metabolism stimulate anabolic effects (e.g., utilization and storage of glucose, amino acids, and fatty acids) and inhibit catabolic processes (e.g., breakdown of glycogen, fat, and protein). After binding to insulin and entering the cell, receptors may be degraded or recycled back to the cell surface.

Insulin is cleared from circulating blood in 10 to 15 minutes because of rapid binding to peripheral tissues or metabolic breakdown. The insulin that does not combine with receptors is metabolized in the liver, kidneys, plasma, and muscles. In the kidneys, insulin is filtered by the glomeruli and reabsorbed by the tubules, which also degrade it. Severe renal impairment slows the clearance of insulin from the blood.

Insulin plays a major role in metabolism of carbohydrate, fat, and protein (Box 26-1). These foodstuffs are broken down into molecules of glucose, lipids, and amino acids, respectively. The molecules enter the cells and are converted to energy for cellular activities. The energy can be used immediately or converted to storage forms for later use. When carrying out its metabolic functions, the overall effect of insulin is to lower blood glucose levels, primarily by the following mechanisms:

- In the liver, insulin acts to decrease breakdown of glycogen (glycogenolysis), form new glucose from fatty acids and amino acids (gluconeogenesis), and form ketone bodies (ketogenesis). At the same time, it acts to increase synthesis and storage of glycogen and fatty acids.
- In adipose tissue, insulin acts to decrease breakdown of fat (lipolysis) and to increase production of glycerol and fatty acids.
- In muscle tissue, insulin acts to decrease protein breakdown and amino acid output and to increase amino acid uptake, protein synthesis, and glycogen synthesis.

**Figure 26-1** ■ Normal glucose metabolism. After insulin binds with receptors on the cell membrane, glucose can move into the cell, promoting cellular metabolism and energy production.

## Box 26-1

## Effects of Insulin on Metabolism

## Carbohydrate Metabolism

- Insulin increases glucose transport into the liver, skeletal muscle, adipose tissue, the heart, and some smooth muscle organs (such as the uterus); it must be present for muscle and fat tissues to use glucose for energy.
- Insulin regulates glucose metabolism to produce energy for cellular functions. If excess glucose is present after this need is met, it is converted to glycogen and stored for future energy needs or converted to fat and stored. The excess glucose transported to liver cells is converted to fat only after glycogen stores are saturated. When insulin is absent or blood glucose levels are low, these stored forms of glucose can be reconverted. The liver is especially important in restoring blood sugar levels by breaking down glycogen or by forming new glucose.

## Fat Metabolism

- Insulin promotes transport of glucose into fat cells, where it is broken down. One of the breakdown products is alpha-glycerophosphate, which combines with fatty acids to form triglycerides. This is the mechanism by which insulin promotes fat storage.

- When insulin is lacking, fat is released into the bloodstream as free fatty acids. Blood concentrations of triglycerides, cholesterol, and phospholipids are also increased. The high blood lipid concentration probably accounts for the atherosclerosis that tends to develop early and progress more rapidly in people with diabetes mellitus. Also, when more fatty acids are released than the body can use as fuel, some fatty acids are converted into ketones. Excessive amounts of ketones produce acidosis and coma.

## Protein Metabolism

- Insulin increases the total amount of body protein by increasing transport of amino acids into cells and synthesis of protein within the cells. The basic mechanism of these effects is unknown.
- Insulin potentiates the effects of growth hormone.
- Lack of insulin causes protein breakdown into amino acids, which are released into the bloodstream and transported to the liver for energy or gluconeogenesis. The lost proteins are not replaced by synthesis of new proteins; and protein wasting causes abnormal functioning of many body organs, severe weakness, and weight loss.

## Regulation of Insulin Secretion

Insulin decreases blood sugar and regulates the amount of glucose available for cellular metabolism and energy needs, during both fasting and feeding. Insulin secretion involves coordination of various nutrients, hormones, the autonomic nervous system, and other factors.

Glucose is the major stimulus of insulin secretion; others include amino acids, fatty acids, ketone bodies (which are acidotic substances in themselves), and stimulation of beta<sub>2</sub>-adrenergic receptors or vagal nerves. Oral glucose is more effective than intravenous (IV) glucose because glucose or food in the digestive tract stimulates vagal activity and induces the release of gastrointestinal (GI) hormones called incretins. Incretin hormones stimulate the release of insulin when glucose levels are normal or elevated. In addition, incretin hormones reduce glucagon production and delay gastric emptying. Two incretin hormones have been identified: glucose-dependent insulinotropic peptide (GIP) and glucagon-like peptide-1 (GLP-1). GLP-1 also appears to improve insulin sensitivity and may increase the formation of new beta cells in the pancreas. The therapeutic uses of incretin hormones have recently been investigated, and this has led to the development of new drugs to treat diabetes mellitus.

Several hormones raise blood glucose levels and stimulate insulin secretion, including cortisol, glucagon, growth hormone, epinephrine, estrogen, and progesterone. Excessive, prolonged, endogenous secretion or administration of pharmacologic preparations of these hormones can exhaust the ability

of pancreatic beta cells to produce insulin and thereby cause or aggravate diabetes mellitus.

Factors that inhibit insulin secretion include stimulation of pancreatic alpha<sub>2</sub>-adrenergic receptors and stress conditions such as hypoxia, hypothermia, surgery, or severe burns.

## Diabetes Mellitus

*Diabetes mellitus* is a chronic systemic disease characterized by metabolic and vascular abnormalities. Metabolic problems occur early in the disease process and are related to changes in the metabolism of carbohydrate, fat, and protein. A major clinical manifestation of disordered metabolism is hyperglycemia, or fasting blood glucose levels exceeding 126 milligrams per deciliter. An individual with a fasting blood glucose level between 100 and 125 milligrams per deciliter is said to have *impaired fasting glucose (IFG)* or *prediabetes*. The recommended blood glucose level for most people diagnosed with diabetes is from approximately 80 to 120 milligrams per deciliter before a meal, 180 milligrams per deciliter or less after a meal, and between 100 and 140 milligrams per deciliter at bedtime.

Vascular problems include atherosclerosis throughout the body. Macrovascular (moderate and large vessels) clinical manifestations include hypertension, myocardial infarction, stroke, and peripheral vascular disease. Changes in small blood vessels (microvasculature) especially affect the retina and kidney, resulting in retinopathy, blindness and nephropathy.

## Classifications

The two major classifications are type 1 and type 2. Although both are characterized by hyperglycemia, they differ in onset, course, pathology, and treatment. Other types of diabetes may be induced by disease processes such as slowly progressing autoimmune disorders, certain drugs, and pregnancy.

### Type 1

Type 1 diabetes, a common chronic disorder of childhood, results from an autoimmune disorder that destroys pancreatic beta cells. A certain subtype of type 1 diabetes mellitus, latent autoimmune diabetes of the adult (LADA), has been determined to occur with an onset during adulthood. Symptoms of traditional type 1 diabetes usually develop when 10% to 20% of functioning beta cells remain but may occur at any time if acute illness or stress increases the body's demand for insulin beyond the capacity of the remaining beta cells to secrete insulin. Eventually, all the beta cells are destroyed and no insulin is produced.

Type 1 may occur at any age but usually starts between 4 and 20 years of age. The peak incidence for girls is 10 to 12 years and for boys, 12 to 14 years. Type 1 usually has a sudden onset; produces severe symptoms; is difficult to control; produces a high incidence of complications, such as diabetic ketoacidosis (DKA) and renal failure; and requires administration of exogenous insulin. About 10% of people with diabetes have type 1.

### Type 2

Type 2 is characterized by hyperglycemia and insulin resistance. The hyperglycemia results from increased production of glucose by the liver and decreased uptake of glucose in liver, muscle, and fat cells. Insulin resistance means that higher-than-usual concentrations of insulin are required. Thus, insulin is present but unable to work effectively (i.e., inhibits hepatic production of glucose and causes glucose to move from the bloodstream into liver, muscle, and fat cells). Most insulin resistance is attributed to impaired insulin action at the cellular level, possibly related to postreceptor, intracellular mechanisms.

Historically, the onset of type 2 diabetes occurred after 40 years of age. More recently, however, type 2 diabetes is increasing in prevalence among children and adolescents. Compared with type 1, it usually has a gradual onset, produces less severe symptoms initially, is easier to control, causes less DKA and renal failure but more myocardial infarctions and strokes, and does not necessarily require exogenous insulin because endogenous insulin is still produced. About 90% of people with diabetes have type 2; 20% to 30% of them require exogenous insulin at some point within their life time.

Type 2 is a heterogeneous disease, and etiology probably involves multiple factors such as a genetic predisposition and environmental factors. Obesity is a major cause. With obesity and chronic ingestion of excess calories, along with a sedentary lifestyle, more insulin is required. The increased need leads to prolonged stimulation and eventual "fatigue" of pancreatic beta cells. As a result, the cells become less responsive to elevated blood glucose levels and less able to produce enough

insulin to meet metabolic needs. Thus, insulin is secreted but is inadequate or ineffective, especially when insulin demand is increased by obesity, pregnancy, aging, or other factors.

A risk factor for the development of type 2 diabetes is the presence of the metabolic syndrome. *Metabolic syndrome* is characterized by a group of risk factors, including abdominal obesity (excessive fat tissue in and around the abdomen), hypertriglyceridemia, low HDL cholesterol, hypertension, and/or impaired fasting glucose. People with the metabolic syndrome are at increased risk of coronary heart disease and other diseases related to plaque buildup in artery walls (e.g., stroke and peripheral vascular disease) and type 2 diabetes. The metabolic syndrome has become increasingly common in the United States. It is estimated that over 50 million Americans have it.

In the United States, African Americans, Hispanics, Native Americans, Native Alaskans, and some Asian Americans and Pacific Islanders are at high risk for development of type 2 diabetes. Prevalence rates are about 13.3% in African Americans and 13.9% in Hispanic Americans and 12.8% in American Indians and Alaska Natives compared with 8.7% in Caucasians. Undiagnosed diabetes is reportedly common in Mexican Americans.

## Signs and Symptoms

Most signs and symptoms stem from a lack of effective insulin and the subsequent metabolic abnormalities. Their incidence and severity depend on the amount of effective insulin, and they may be precipitated by infection, rapid growth, pregnancy, or other factors that increase demand for insulin. Most early symptoms result from disordered carbohydrate metabolism, which causes excess glucose to accumulate in the blood (hyperglycemia). Hyperglycemia produces glucosuria, which, in turn, produces polydipsia, polyuria, dehydration, and polyphagia.

Glucosuria usually appears when the blood glucose level is approximately twice the normal value and the kidneys receive more glucose than can be reabsorbed. However, renal threshold varies, and the amount of glucose lost in the urine does not accurately reflect blood glucose. In children, glucose tends to appear in urine at much lower or even normal blood glucose levels. In older people, the kidneys may be less able to excrete excess glucose from the blood. As a result, blood glucose levels may be high with little or no glucose in the urine.

When large amounts of glucose are present, water is pulled into the renal tubule. This results in a greatly increased urine output (polyuria). The excessive loss of fluid in urine leads to increased thirst (polydipsia) and, if fluid intake is inadequate, to dehydration. Dehydration also occurs because high blood glucose levels increase osmotic pressure in the bloodstream and fluid is pulled out of the cells in the body's attempt to regain homeostasis.

Polyphagia (increased appetite) occurs because the body cannot use ingested foods. People with uncontrolled diabetes lose weight because of abnormal metabolism.

## Complications

Complications of diabetes mellitus are common and potentially disabling or life threatening. Diabetes is a leading cause

## Box 26-2

## Acute Complications of Diabetes Mellitus

**Diabetic Ketoacidosis (DKA)**

This life-threatening complication occurs with severe insulin deficiency. In the absence of insulin, glucose cannot be used by body cells for energy and fat is mobilized from adipose tissue to furnish a fuel source. The mobilized fat circulates in the bloodstream, from which it is extracted by the liver and broken down into glycerol and fatty acids. The fatty acids are further changed in the liver to ketones (e.g., acetoacetic acid, acetone), which then enter the bloodstream and are circulated to body cells for metabolic conversion to energy, carbon dioxide, and water.

The ketones are produced more rapidly than body cells can use them, and their accumulation produces acidemia (a drop in blood pH and an increase in blood hydrogen ions). The body attempts to buffer the acidic hydrogen ions by exchanging them for intracellular potassium ions. Hydrogen ions enter body cells, and potassium ions leave the cells to be excreted in the urine. Another attempt to remove excess acid involves the lungs. Deep, labored respirations, called *Kussmaul's respirations*, eliminate more carbon dioxide and prevent formation of carbonic acid. A third attempt to regain homeostasis involves the kidneys, which excrete some of the ketones, thereby producing acetone in the urine.

DKA worsens as the compensatory mechanisms fail. Clinical signs and symptoms become progressively more severe. Early ones include blurred vision, anorexia, nausea and vomit-

ing, thirst, and polyuria. Later ones include drowsiness, which progresses to stupor and coma, Kussmaul's respirations, dehydration and other signs of fluid and electrolyte imbalances, and decreased blood pressure, increased pulse, and other signs of shock.

Two major causes of DKA are omission of insulin and illnesses such as infection, trauma, myocardial infarction, or stroke.

**Hyperosmolar Hyperglycemic Nonketotic Coma (HHNC)**

HHNC is another type of diabetic coma that is potentially life threatening. It is relatively rare and carries a high mortality rate. The term *hyperosmolar* refers to an excessive amount of glucose, electrolytes, and other solutes in the blood in relation to the amount of water.

Like DKA, HHNC is characterized by hyperglycemia, which leads to osmotic diuresis and resultant thirst, polyuria, dehydration, and electrolyte losses, as well as neurologic signs ranging from drowsiness to stupor to coma. Additional clinical problems may include hypovolemic shock, thrombosis, renal problems, or stroke. In contrast with DKA, hyperosmolar coma occurs in people with previously unknown or mild diabetes, usually after an illness; occurs in hyperglycemic conditions other than diabetes (e.g., severe burns, corticosteroid drug therapy); and does not cause ketosis.

of myocardial infarction, stroke, blindness, leg amputation, and kidney failure. These complications result from hyperglycemia and other metabolic abnormalities that accompany a lack of effective insulin. The metabolic abnormalities associated with hyperglycemia can cause early, acute complications, such as DKA or hyperosmolar hyperglycemic nonketotic coma (HHNC; Box 26-2). Eventually, metabolic abnormalities lead to damage in blood vessels and other body tissues. For example, atherosclerosis develops earlier, progresses more rapidly, and becomes more severe in people with diabetes. Microvascular changes lead to nephropathy, retinopathy, and peripheral neuropathy. Other complications include musculoskeletal disorders, increased numbers and severity of infections, and complications of pregnancy.

## Hypoglycemic Drugs

### Insulin

Insulin is described in this section, and individual insulins are listed in Table 26-1.

Exogenous insulin used to replace endogenous insulin has the same effects as the pancreatic hormone. Insulin and its analogs (structurally similar chemicals) lower blood glucose levels by increasing glucose uptake by body cells, especially

skeletal muscle and fat cells, and by decreasing glucose production in the liver.

The main clinical indication for insulin is treatment of diabetes mellitus. Insulin is the only effective drug treatment for type 1 diabetes because pancreatic beta cells are unable to secrete endogenous insulin and metabolism is severely impaired. Insulin is required for patients with type 2 diabetes who cannot control their disease with diet, weight control, and oral agents. It may be needed by anyone with diabetes during times of stress, such as illness, infection, or surgery. Insulin also is used to control diabetes induced by chronic pancreatitis, surgical excision of pancreatic tissue, hormones and other drugs, and pregnancy (gestational diabetes). In nondiabetic patients, insulin is used to prevent or treat hyperglycemia induced by IV parenteral nutrition and to treat hyperkalemia. In hyperkalemia, an IV infusion of insulin and dextrose solution causes potassium to move from the blood into the cells; it does not eliminate potassium from the body. The only clear-cut contraindication to the use of insulin is hypoglycemia, because of the risk of brain damage (Box 26-3).

All insulin in the United States is human insulin. Pork and bovine insulins, which were more antigenic, are no longer manufactured in the United States. The name human insulin means that the synthetic product is identical to endogenous insulin (i.e., has the same number and sequence of amino acids).

Table 26-1

## Drugs at a Glance: Insulins

Generic/Trade Name	Characteristics	Routes and Dosage Ranges	ACTION (H)		
			Onset	Peak	Duration
<b>Short-Acting Insulin</b>					
<b>Insulin injection</b> (Humulin R, Novolin R)	<ul style="list-style-type: none"> <li>A clear liquid solution with the appearance of water</li> <li>The hypoglycemic drug of choice for diabetic patients experiencing acute or emergency situations, diabetic ketoacidosis, hyperosmolar nonketotic coma, severe infections or other illnesses, major surgery, and pregnancy</li> <li>The only insulin preparation that can be given IV</li> </ul>	<p>Sub-Q, dosage individualized according to blood glucose levels. For sliding scale, 5–20 units before meals and bedtime, depending on blood glucose levels</p> <p>IV, dosage individualized. For ketoacidosis, regular insulin may be given by direct injection, intermittent infusion, or continuous infusion. One regimen involves an initial bolus injection of 10–20 units followed by a continuous low-dose infusion of 2–10 units/h, based on hourly blood and urine glucose levels.</p>	1/2–1	2–3	5–7
<b>Intermediate-Acting Insulins</b>					
<b>Isophane insulin suspension</b> (NPH, Humulin N, Novolin N)	<ul style="list-style-type: none"> <li>Commonly used for long-term administration</li> <li>Modified by addition of protamine (a protein) and zinc</li> <li>A suspension with a cloudy appearance when correctly mixed in the drug vial</li> <li>Given only Sub-Q</li> <li>Not recommended for use in acute situations</li> <li>Hypoglycemic reactions are more likely to occur during mid to late afternoon</li> </ul>	Sub-Q, dosage individualized. Initially, 7–26 units may be given once or twice daily.	1–1½	8–12	18–24
<b>Insulin Mixtures</b>					
<b>NPH 70% Regular 30%</b> (Humulin 70/30, Novolin 70/30)	<ul style="list-style-type: none"> <li>Stable mixture</li> <li>Onset, peak, and duration of action same as individual components</li> </ul>	Sub-Q, dosage individualized			
<b>NPH 50% Regular 50%</b> (Humulin 50/50)	See Humulin 70/30, above	Sub-Q, dosage individualized			
<b>Insulin Analogs</b>					
<b>Insulin lispro</b> (Humalog)	<ul style="list-style-type: none"> <li>A synthetic insulin of recombinant DNA origin, created by reversing two amino acids</li> <li>Has a faster onset and a shorter duration of action than human regular insulin</li> <li>Intended for use with a longer-acting insulin</li> </ul>	Sub-Q, dosage individualized, 15 min before meals. May also be given in external insulin pumps	1/4	1/2–1½	6–8

(continued on page 416)

Table 26-1

## Drugs at a Glance: Insulins (continued)

Generic/Trade Name	Characteristics	Routes and Dosage Ranges	ACTION (H)		
			Onset	Peak	Duration
<b>Insulin aspart</b> (NovoLog)	Similar to lispro	Sub-Q, dosage individualized	$\frac{1}{4}$	1–3	3–5
<b>Insulin glargine</b> (Lantus)	<ul style="list-style-type: none"> <li>■ Long acting</li> <li>■ Provides basal amount of insulin</li> <li>■ Must not be diluted or mixed with any other insulin or solutions</li> </ul>	Sub-Q, dosage individualized, once daily at bedtime	1.1	None	24
<b>Insulin glulisine</b> (Apidra)	<ul style="list-style-type: none"> <li>■ Clear, colorless solution</li> <li>■ More rapid onset of action and shorter duration of action than regular human insulin</li> <li>■ Should be used in regimens that include a longer-acting insulin or basal insulin analog</li> <li>■ May be mixed with NPH insulin for injection only. Draw up Apidra first, then NPH insulin. Do NOT mix Apidra with other insulins in Sub-Q infusion pumps.</li> </ul>	Sub-Q by injection or continuous infusion pump, dosage individualized  When used as a mealtime insulin, give up to 15 min before or within 20 min of beginning the meal.	$\frac{1}{12}$ – $\frac{1}{6}$ (5–10 min)	1	4
<b>Insulin levemir</b> (Determir)	<ul style="list-style-type: none"> <li>■ Long acting</li> <li>■ Provides basal amount of insulin</li> <li>■ Must not be diluted or mixed with other insulins</li> </ul>	Sub-Q once or twice daily, dosage individualized	1	None	6–23
<b>Analog Mixture</b> <b>Insulin lispro protamine 75%</b> <b>Insulin lispro 25%</b> (Humalog Mix 75/25)	<ul style="list-style-type: none"> <li>■ Same onset, peak, and duration as individual components</li> </ul>	Sub-Q, dosage individualized			

NPH, isophane.

Insulin analogs are synthesized in the laboratory by altering the type or sequence of amino acids in insulin molecules. Insulin lispro (Humalog), insulin aspart (NovoLog), and insulin glulisine (Apidra) are short-acting products. Lispro, the first analog to be marketed, is identical to human insulin except for the reversal of two amino acids (lysine and proline). It is absorbed more rapidly and has a shorter half-life after subcutaneous (Sub-Q) injection than regular (short-acting) human insulin. As a result, it is similar to physiologic insulin secretion after a meal, more effective at decreasing postprandial hyperglycemia, and less likely to cause hypoglycemia before the next meal. Injection just before a meal produces hypoglycemic effects similar to those of an injection of conventional regular insulin given 30 minutes before a meal. Aspart has an even more rapid onset and shorter duration of action. The newest short-acting insulin analog, glulisine, has

the shortest onset time (5–10 minutes). In contrast, insulin glargine and insulin detemir are long-acting preparations used to provide a basal amount of insulin through 24 hours, similar to normal, endogenous insulin secretion.

Insulin cannot be given orally because it is a protein that is destroyed by proteolytic enzymes in the GI tract. Most insulins are given subcutaneously; regular insulin can also be administered intravenously.

Insulins differ in onset and duration of action. They are usually categorized as short, intermediate, or long acting. Short-acting insulins have a rapid onset and a short duration of action. Intermediate- and long-acting insulins (except for insulin glargine or detemir) are modified by adding protamine (a large, insoluble protein), zinc, or both to slow absorption and prolong drug action. Several mixtures of an intermediate- and a short-acting insulin are available and commonly used. U-100,

## Box 26-3

## Hypoglycemia: Characteristics and Management

Hypoglycemia may occur with insulin, meglitinides, oral sulfonylureas, amylin analogs (pramlintide [Symlin]), and incretin mimetics (exenatide [Byetta]). When hypoglycemia is suspected, the blood glucose level should be measured if possible, although signs and symptoms and the plasma glucose level at which they occur vary from person to person. Hypoglycemia is a blood glucose below 60 to 70 mg/dL and is especially dangerous at approximately 40 mg/dL or below. Central nervous system effects may lead to accidental injury or permanent brain damage; cardiovascular effects may lead to cardiac dysrhythmias or myocardial infarction. Causes of hypoglycemia include:

- Intensive insulin therapy (i.e., continuous subcutaneous [Sub-Q] infusion or three or more injections daily)
- Omitting or delaying meals
- An excessive or incorrect dose of insulin or an oral agent that causes hypoglycemia
- Altered sensitivity to insulin
- Decreased clearance of insulin or an oral agent (e.g., with renal insufficiency)
- Decreased glucose intake
- Decreased production of glucose in the liver
- Giving an insulin injection intramuscularly (IM) rather than Sub-Q
- Drug interactions that decrease blood glucose levels
- Increased physical exertion
- Ethanol ingestion

### Hormones That Raise Blood Sugar

Normally, when hypoglycemia occurs, several hormones (glucagon, epinephrine, growth hormone, and cortisol) work to restore and maintain blood glucose levels. Glucagon and epinephrine, the dominant counter-regulatory hormones, act rapidly because they are activated as soon as blood glucose levels start declining. Growth hormone and cortisol act more slowly, about 2 hours after hypoglycemia occurs.

People with diabetes who develop hypoglycemia may have impaired secretion of these hormones, especially those patients with type 1 diabetes. Decreased secretion of glucagon is often evident in patients who have had diabetes for 5 years or longer. Decreased secretion of epinephrine also occurs in people who have been treated with insulin for several years. Decreased epinephrine decreases tachycardia, a common sign of hypoglycemia, and may delay recognition and treatment.

### The Conscious Patient

Treatment of hypoglycemic reactions consists of immediate administration of a rapidly absorbed carbohydrate. For the conscious patient who is able to swallow, the carbohydrate is given orally. Foods and fluids that provide approximately 15 grams of carbohydrate include:

- Two sugar cubes or 1 to 2 teaspoons of sugar, syrup, honey, or jelly
- Two or three small pieces of candy or eight Lifesaver candies
- 4 oz of fruit juice, such as orange, apple, or grape

- 4 oz of ginger ale
- Coffee or tea with 2 teaspoons of sugar added
- Commercial glucose products (e.g., Glucose, B-D Glucose). These products must be swallowed to be effective.

Symptoms usually subside within 15 to 20 minutes. If they do not subside, the patient should take another 10 to 15 grams of oral carbohydrate. *If acarbose or miglitol has been taken with insulin or a sulfonylurea and a hypoglycemic reaction occurs, glucose (oral or intravenous [IV]) or glucagon must be given for treatment.* Sucrose (table sugar) and other oral carbohydrates do not relieve hypoglycemia because the presence of acarbose or miglitol prevents their digestion and absorption from the gastrointestinal tract.

### The Unconscious Patient

For the unconscious patient, carbohydrate cannot be given orally because of the risks of aspiration. Therefore, the treatment choices are parenteral glucose or glucagon.

If the patient is in a health care facility where medical help is readily available, IV glucose in a 25% or 50% solution is the treatment of choice. It acts rapidly to raise blood glucose levels and arouse the patient. If the patient is at home or elsewhere, glucagon may be given if available and there is someone to inject it. A family member or roommate may be taught to give glucagon Sub-Q or IM. It can also be given IV. The usual adult dose is 0.5 to 1 milligram. Glucagon is a pancreatic hormone that increases blood sugar by converting liver glycogen to glucose. It is effective only when liver glycogen is present. Some clients cannot respond to glucagon because glycogen stores are depleted by conditions such as starvation, adrenal insufficiency, or chronic hypoglycemia. The hyperglycemic effect of glucagon occurs more slowly than that of IV glucose and is of relatively brief duration. If the patient does not respond to one or two doses of glucagon within 20 minutes, IV glucose is indicated.

### Avoid Overtreatment

Caution is needed in the treatment of hypoglycemia. Although the main goal of treatment is to relieve hypoglycemia and restore the brain's supply of glucose, a secondary goal is to avoid overtreatment and excessive hyperglycemia. The patient having a hypoglycemic reaction should not use it as an excuse to eat high-caloric foods or large amounts of food. Health care personnel caring for the patient should avoid giving excessive amounts of glucose.

### Posthypoglycemia Care

Once hypoglycemia is relieved, the person should have a snack or a meal. Slowly absorbed carbohydrate and protein foods, such as milk, cheese, and bread, are needed to replace glycogen stores in the liver and to prevent secondary hypoglycemia from rapid use of the carbohydrates given earlier. In addition, the episode needs to be evaluated for precipitating factors so that these can be minimized to prevent future episodes. Repeated episodes mean that the therapeutic regimen and patient compliance must be re-evaluated and adjusted if indicated.

the main insulin concentration in the United States, contains 100 units of insulin per milliliter of solution. It can be accurately measured only in an orange-tipped syringe designed for use with U-100 insulin.

With subcutaneous injection, insulin is absorbed most rapidly from the abdomen, followed by the upper arm, thigh, and buttocks. Absorption is delayed or decreased by injection into Sub-Q tissue with lipodystrophy or other lesions, by circulatory problems such as edema or hypotension, by insulin-binding antibodies (which develop after 2 or 3 months of insulin administration), and by injecting cold (i.e., refrigerated) insulin. Absorption may also be increased when administered in an extremity before the patient engages in a sport that requires use of the specific extremity (i.e., swimming, tennis, or jogging).

Temperature extremes can cause loss of potency. Insulin retains potency up to 36 months under refrigeration and 18 to 24 months at room temperature. At high temperatures (e.g., 100°F or 37.8°C), insulin loses potency in about 2 months. If frozen, insulin clumps or precipitates, cannot be measured accurately, and should be discarded.

Regular insulin and rapid-acting insulin analogs (Lispro, Aspart, Apidra) are appropriate insulins for continuous Sub-Q insulin infusion using external insulin pumps (Fig. 26-2). An insulin pump is a device that delivers a continuous supply of insulin. The pump is often programmed to deliver small steady doses of insulin throughout the day. This steady dosage is known as a basal rate. Additional doses, called boluses, are given to cover food or high blood glucose levels. The pump holds a reservoir of insulin that is delivered through a system of plastic tubing (infusion set). Most infusion sets are started with a guide needle, then the plastic cannula (a tiny, flexible tube) is left in place, taped with a dressing, and the needle is removed. Advantages of this method of insulin delivery include improved lifestyle flexibility and better control of blood glucose levels. Disadvantages include undetected interruptions in insulin delivery, resulting in the development of

hyperglycemia and ketosis, and infection at the needle site. Hypoglycemia can also occur in pump users as with those administering insulin via Sub-Q injection. Insulin mixtures and intermediate-/long-acting insulins are not approved for use in continuous Sub-Q infusion pumps.

An inhaled insulin (Exubera) was approved by the Food and Drug Administration (FDA) in January 2006 for patients aged 18 or older with type 1 or type 2 diabetes and was used in combination with injections of intermediate- or long-acting insulin, with oral antidiabetic drugs, or alone with dietary changes. However, by October 2007, the drug manufacturer made a decision to cease production of Exubera, citing too few patients using inhaled insulin and the availability of other medications to lower blood sugar as reasons for discontinuing production. Patient concerns with Exubera included the large inhalation device (roughly the size of a flashlight), difficulty adjusting the dosage, cost, and the risk of lung disorders. Post marketing studies also identified concerns over increased risk of lung cancer, although the study results were confounded by previous use of tobacco. Currently, there are no FDA-approved inhaled insulins available; however, several drug manufacturers are working to develop new forms of insulin delivery, including mouth sprays, insulin patches, and inhalers.

### Applying Your Knowledge 26-1

The main adverse effect of insulin 70/30 is hypoglycemia. At what time during a 24-hour period should you be especially alert to assess for the effects of hypoglycemia in Mr. Coulter?

### Oral Hypoglycemic Medications

There are five types of oral antidiabetic agents, all of which may be used to treat type 2 diabetes when diet and exercise

**Figure 26-2** ■ Continuous subcutaneous (Sub-Q) insulin infusion pump. The insulin dosage is programmed into the pump's computer and the appropriate amount of insulin is injected into the adipose tissue through a needle inserted into the Sub-Q area.

**Figure 26-3** ■ Actions of oral antidiabetic drugs. The drugs lower blood sugar by decreasing absorption or production of glucose, by increasing secretion of insulin, or by increasing the effectiveness of available insulin (decreasing insulin resistance).

alone fail to control the disorder. The drugs lower blood sugar by different mechanisms (Fig. 26-3) and may be used in various combinations for additive effects. Some are also combined with insulin. These drugs are further described below and in Table 26-2.

### Sulfonylureas

The sulfonylureas are the oldest and largest group of oral agents. They lower blood glucose mainly by increasing secretion of insulin. They may also increase peripheral use of glucose, decrease production of glucose in the liver, increase the number of insulin receptors, or alter postreceptor actions to increase tissue responsiveness to insulin. Because the drugs stimulate pancreatic beta cells to produce more insulin, they are effective only when functioning pancreatic beta cells are present.

First-generation drugs (e.g., acetohexamide, chlorpropamide, tolazamide, tolbutamide) have largely been replaced by the second generation and are not discussed further. The second-generation drugs, glipizide, glyburide, and glimepiride, are similar in therapeutic and adverse effects. The main adverse effect is hypoglycemia (see Box 26-3).

The sulfonylureas are chemically related to sulfonamide antibacterial drugs, well absorbed with oral administration, more than 90% bound to plasma proteins, and metabolized in the liver to inactive metabolites, which are excreted mainly by the kidneys (except for glyburide, which is excreted about

equally in urine and bile). Therefore, this category of medications is contraindicated among patients with previous allergic sensitivities to sulfa-based medications.

A sulfonylurea may be given alone or with most other antidiabetic drugs in the treatment of type 2 diabetes, including insulin, acarbose, miglitol, metformin, pioglitazone, or rosiglitazone. Sulfonylureas are contraindicated in patients with hypersensitivity to them, with severe renal or hepatic impairment, and during pregnancy. They are unlikely to be effective during periods of stress, such as major surgery, severe illness, or infection. Insulin is usually required in these circumstances.

### Alpha-Glucosidase Inhibitors

Acarbose and miglitol inhibit alpha-glucosidase enzymes (e.g., sucrase, maltase, amylase) in the GI tract and thereby delay digestion of complex carbohydrates into glucose and other simple sugars. As a result, glucose absorption is delayed and there is a smaller increase in blood glucose levels after a meal. The drugs are metabolized in the GI tract by digestive enzymes and intestinal bacteria. Some of the metabolites are absorbed systemically and excreted in urine; plasma concentrations are increased in the presence of renal impairment. An alpha-glucosidase inhibitor may be combined with insulin or an oral agent, usually a sulfonylurea. Alpha-glucosidase inhibitors are contraindicated in patients with hypersensitivity, DKA, hepatic cirrhosis, inflammatory or malabsorptive intestinal disorders, and severe renal impairment.

Table 26-2

## Drugs at a Glance: Oral Drugs for Diabetes Mellitus

GENERIC/TRADE NAME	CHARACTERISTICS	ROUTES AND DOSAGE RANGES
<b>Sulfonylureas, Second Generation</b> <b>Glimepiride</b> (Amaryl)	Onset of action, about 1 h; peak, 2–3 h	PO, initially 1–2 mg once daily, with breakfast or first main meal. Maximum starting dose, 2 mg or less. Maintenance dose, 1–4 mg once daily. After a dose of 2 mg is reached, increase dose in increments of 2 mg or less at 1- to 2-week intervals, based on blood glucose levels. Maximum recommended dose, 8 mg once daily In combination with insulin, PO 8 mg once daily with first main meal
<b>Glipizide</b> (Glucotrol, Glucotrol XL)	Onset of action, approximately 1–1.5 h; duration, 10–16 h	PO, initially 5 mg daily in a single dose, 30 min before breakfast Maximum dose, 40 mg daily In elderly, may start with 2.5 mg daily Extended-release: Give once daily with breakfast.
<b>Glyburide</b> (DiaBeta, Micronase, Glynase Pres Tab)	Onset of action, approximately 2–4 h; duration, 24 h. Glynase is better absorbed, acts faster (onset, about 1 h; duration, 24 h), and is given in smaller doses than other forms of glyburide.	PO, initially 2.5–5 mg daily in a single dose, with breakfast Maximum dose, 20 mg daily Glynase: PO, initially 1.5–3 mg daily with breakfast. Maximum dose, 12 mg daily
<b>Alpha-Glucosidase Inhibitors</b> <b>Acarbose</b> (Precose)	Delays digestion of carbohydrate foods when acarbose and food are present in GI tract at the same time	PO, initially 25 mg, 3 times daily with first bite of main meals; increase at 4- to 8-week intervals to a maximum dose of 50 mg 3 times daily (for patients weighing under 60 kg) if necessary, depending on 1-h postprandial blood glucose levels and tolerance. Patients weighing more than 60 kg may need doses up to 100 mg 3 times daily (the maximum dose).
<b>Miglitol</b> (Glyset)	Delays digestion of carbohydrates in the GI tract	PO, initially 25 mg 3 times daily with the first bite of each main meal, gradually increased if necessary Maximum dose, 100 mg 3 times daily
<b>Biguanide</b> <b>Metformin</b> (Glucophage, Glucophage XR)	Older adults are at higher risk for development of lactic acidosis, a rare but potentially fatal reaction. Thus, smaller doses and monitoring of renal function are recommended.	PO, initially 500 mg twice daily, with morning and evening meals; increase dose in increments of 500 mg/d every 2–3 wk if necessary, up to a maximum of 3000 mg daily, based on patient tolerance and blood glucose levels. In older patients, do not increase to maximum dose. Extended-release: PO once daily with the evening meal.
<b>Glitazones</b> <b>Pioglitazone</b> (Actos)	Increases effects of insulin; may be used alone or with insulin, metformin, or a sulfonylurea	PO 15–30 mg once daily

GENERIC/TRADE NAME	CHARACTERISTICS	ROUTES AND DOSAGE RANGES
<b>Rosiglitazone</b> (Avandia)	Increases effects of insulin; may be used alone or with metformin	PO 4–8 mg once daily, in 1 dose or 2 divided doses
<b>Meglitinides</b>		
<b>Nateglinide</b> (Starlix)	■ Onset of action, within 20 min; peak, 1 h; duration, 3–4 h	PO 120 mg 3 times daily, 1–30 min before meals. Omit dose if skip a meal.
<b>Repaglinide</b> (Prandin)	■ Onset of action, within 30 min; peak, 1 h; duration, approximately 3–4 h	PO 1–2 mg 15–30 min before each meal, increased to 4 mg before meals if necessary. Maximum dose, 16 mg daily. Omit a dose if skip a meal; add a dose if add a meal.
<b>Combination Drugs*</b>		
<b>Glyburide/metformin</b> (Glucovance)	■ Available in preparations containing 1.25 mg glyburide and 250 mg metformin; 2.5 mg glyburide and 500 mg metformin; or 5 mg glyburide and 500 mg metformin	Initially, PO 1.25 mg/250 mg once or twice daily with meals. <i>Patients previously treated with glyburide or other sulfonylurea plus metformin:</i> Initially, PO 2.5 or 5 mg/500 mg twice daily with meals, not to exceed previous doses of separate drugs
<b>Metformin/glipizide</b> (Metaglip)	■ Available as tablets containing metformin 250 or 500 mg and glipizide 2.5 or 5 mg	PO 2.5/250 mg once daily, increased if necessary
<b>Rosiglitazone/metformin</b> (Avandamet)	■ Available in tablets containing 1, 2, or 4 mg rosiglitazone and 500 mg metformin and 2 or 4 mg rosiglitazone and 1000 mg metformin	PO, variable dose; maximum daily dose, 8 mg rosiglitazone and 2000 mg metformin
<b>Pioglitazone/metformin</b> (Acto Plus Met)	■ Available as tablets containing pioglitazone 15 mg plus metformin 500 or 850 mg	PO, variable dose; maximum dose for pioglitazone is 45 mg daily and maximum dose for metformin is 2550 mg daily.
<b>Pioglitazone/glimepiride</b> (Duetact)	■ Available as pioglitazone 30 mg plus glimepiride 2 mg or 4 mg.	PO, variable dose; maximum dose for pioglitazone is 45 mg daily and maximum dose for glimepiride is 8 mg daily.
<b>Rosiglitazone/glimepiride</b> (Avandaryl)	■ Available as rosiglitazone 4 mg plus 1 mg, 2 mg or 4 mg glimepiride	PO, variable dose; maximum dose for rosiglitazone is 8 mg daily, maximum dose for glimepiride is 8 mg daily.
<b>Sitagliptin/metformin</b> (Janumet)	■ Available as sitagliptin 100 mg plus metformin 1000 mg or 2000 mg	PO, variable dose; maximum dose for sitagliptin is 100 mg, maximum dose for metformin is 2000 mg.

\*See Appendix A for additional combination drugs. GI, gastrointestinal

## Biguanide

Metformin increases the use of glucose by muscle and fat cells, decreases hepatic glucose production, and decreases intestinal absorption of glucose. It is preferably called an antihyperglycemic rather than a hypoglycemic agent because it does not cause hypoglycemia, even in large doses, when used alone. Metformin is absorbed from the small intestine, circulates without binding to plasma proteins, and has a serum half-life of 1.3 to 4.5 hours. It is not metabolized in the liver and is excreted unchanged in the urine.

Metformin may be used alone or in combination with insulin or other oral agents. It is widely prescribed as the initial drug in obese patients with newly diagnosed type 2 diabetes, mainly because it does not cause weight gain as most other oral

agents do. Metformin is considered to be weight neutral and ideal for overweight individuals with type 2 diabetes, who have been known to lose weight on this medication, further improving insulin sensitivity.

Metformin is contraindicated in patients with diabetes complicated by fever, severe infections, severe trauma, major surgery, acidosis, or pregnancy (insulin is indicated in these conditions). It is also contraindicated in patients with serious hepatic or renal impairment, cardiac or respiratory insufficiency, hypoxia, or a history of lactic acidosis because these conditions may increase production of lactate and the risk of potentially fatal lactic acidosis. A **BLACK BOX WARNING** alerts nurses to the dangers of lactic acidosis with metformin therapy in these individuals.

### Thiazolidinediones (TZDs)

Thiazolidinediones include pioglitazone and rosiglitazone. They are sometimes called “glitazones” and are also referred to as insulin sensitizers. Thiazolidinediones decrease insulin resistance, a major factor in the pathophysiology of type 2 diabetes. The drugs stimulate receptors on muscle, fat, and liver cells. This stimulation increases or restores the effectiveness of circulating insulin and results in increased uptake of glucose by peripheral tissues and decreased production of glucose by the liver. Thiazolidinediones may be used as monotherapy with diet and exercise or in combination with insulin, metformin, a sulfonylurea, an amylin analog (pramlintide), or incretin mimetic (exenatide).

The drugs are contraindicated in patients with active liver disease or a serum alanine aminotransferase (ALT) level more than 2.5 times the upper limit of normal. They are also contraindicated in patients who are hypersensitive to them. The drugs should be used very cautiously, if at all, in patients at risk of developing congestive heart failure. Thiazolidinediones increase plasma volume and may cause fluid retention and heart failure. In one study, heart failure developed in 4.5% of glitazone users within 10 months and in 12.4% of users within 36 months. In people who did not take a thiazolidinedione, 2.6% developed heart failure within 10 months and 8.4% within 36 months. A **BLACK BOX WARNING** alerts health professionals to the risk of CHF in patients using pioglitazone and rosiglitazone. Furthermore, recent meta-analysis of several studies and clinical trials have raised concerns about increased risk of myocardial ischemic events including angina, myocardial infarction (heart attack), and heart-related deaths with rosigli-

tazone, prompting the FDA to issue an additional **BLACK BOX WARNING** regarding myocardial ischemia for this drug.

### Meglitinides

Nateglinide and repaglinide are nonsulfonylureas that lower blood sugar by stimulating pancreatic secretion of insulin. They can be used as monotherapy with diet and exercise or in combination with metformin. These drugs should be taken just before or up to 30 minutes before a meal. If a meal is skipped, the drug dose should be skipped; if a meal is added, a drug dose should be added.

Meglitinides are well absorbed from the GI tract; peak plasma level occurs within 1 hour. They have a plasma half-life of 1 to 1.5 hours and are highly bound (>98%) to plasma proteins. They are metabolized in the liver; metabolites are excreted in urine and feces. Repaglinide is metabolized and removed from the bloodstream within 3 to 4 hours after a dose, nateglinide within about 6 hours. This decreases the workload of pancreatic beta cells (i.e., decreases duration of beta-cell stimulation), allows serum insulin levels to return to normal before the next meal, and decreases risks of hypoglycemic episodes.

### New Types of Antidiabetic Drugs

There are several new classes of antidiabetic drugs that can be co-administered with traditional therapies to achieve better blood glucose control. Amylin analogs, incretin mimetics, and dipeptidyl peptidase-4 inhibitors are described below and in Table 26-3.

Table 26-3

Drugs at a Glance: New Antidiabetic Drugs

GENERIC/TRADE NAME	CHARACTERISTICS	ROUTES AND DOSAGE RANGES
<b>Amylin Analog</b> <b>Pramlintide</b> (Symlin)	Given with insulin at mealtimes for type 1 and type 2 diabetes	Type 1: Sub-Q 15 mcg initially, titrate in 15-mcg increments to maintenance dose of 30–60 mcg. Preprandial short-acting insulins should be reduced by 50%. Type 2: Sub-Q 60 mcg initially, may increase to 120 mcg as tolerated. Preprandial short-acting insulins should be reduced by 50%.
<b>Incretin Mimetic</b> <b>Exenatide</b> (Byetta)	Given with metformin and/or a sulfonylurea for patients with type 2 diabetes to improve glucose control	Sub-Q 5 mcg twice daily before morning and evening meal. May be increased to 10 mcg twice daily if needed. No dosage adjustment required for concurrent metformin. Reduction of sulfonylurea dosage may be needed to prevent hypoglycemia.
<b>Dipeptidyl peptidase-4 (DPP-4) Inhibitor</b> <b>Sitagliptin</b> (Januvia)	Given alone or with metformin and/or thiazolidinediones for patients with type 2 diabetes to improve glucose control	PO 100 mg daily

### Amylin Analog

Pramlintide (Symlin), a synthetic analog of amylin, is a peptide hormone secreted with insulin by the beta cells of the pancreas, important in the regulation of glucose control during the postprandial period. It is used as an adjunctive treatment with mealtime insulin for adult patients with type 1 or type 2 diabetes who have not achieved optimal glucose control with insulin therapy alone. Pramlintide slows gastric emptying, helping to regulate the postprandial rise in blood glucose. The drug also suppresses postprandial glucagon secretion, thus helping maintain better blood glucose control. Pramlintide increases the sense of satiety, possibly reducing food intake and promoting weight loss. Pramlintide and insulin therapy may be combined with metformin or sulfonylureas for patients with type 2 diabetes.

Pramlintide is given by subcutaneous injection before meals. Opened vials of pramlintide may be stored in a refrigerator or at room temperature for up to 28 days. It cannot be mixed in the same injection with mealtime insulin. Reduction in insulin dosages by 50% is required with initiation of pramlintide therapy to reduce the incidence of hypoglycemia. A **BLACK BOX WARNING** alerts nurses to the danger of severe insulin-induced hypoglycemia with pramlintide therapy, especially in type 1 diabetics. Nausea, another frequent adverse effect of pramlintide, tends to decrease with time and may be reduced with careful titration of the dosage to the therapeutic level. Pramlintide may delay the absorption of concurrently administered oral medications.

### Incretin mimetic

Before starting a patient with type 2 diabetes on insulin, the provider should consider a new option for treatment of diabetes. Exenatide (Byetta), a synthetic GLP-1 analogue, is now used when oral medications, diet, and exercise together have not assisted in reaching the target A1C goal. Exenatide is administered subcutaneously twice a day and has been approved to be administered with oral medications such as sulfonylureas, metformin, and/or thiazolidinediones. Major advantages of exenatide over insulin are increased satiety and weight loss.

Exenatide acts as a natural helper hormone by stimulating the pancreas to secrete the right amount of insulin based on the food that was just eaten. This helps to reduce the problem of high blood glucose after meals. Exenatide also halts gluconeogenesis by the liver, keeping it from making too much glucose after a meal. Exenatide slows gastric emptying, which serves to reduce the sudden rise of blood glucose after a meal, and also quickly stimulates a feeling of satiety when eating. This fosters a sense of fullness which causes the patient to eat less and potentially lose weight. Exenatide may reduce the absorption of concurrently administered oral medications.

Exenatide is available via a prefilled injection pen in two doses (5 or 10 mcg) and does not need to be adjusted based on blood glucose levels or the amount of food a patient was able to consume. The drug should be taken twice a day within 60 minutes of the morning and evening meal (at least 6 or more hours apart). Exenatide can be injected into the subcutaneous

## Evidence-Based Practice

### 26-1 Use of Alternative Medicines in Diabetes Mellitus

It is well documented in the literature that a significant number of individuals with diabetes mellitus use complementary and alternative medicine (CAM). CAM includes acupuncture, relaxation techniques, massage, chiropractic, spiritual healing, herbal medicines, and vitamin supplements. Estimates of CAM use by patients with diabetes range as high as 57% in the literature and are comparable with CAM use by nondiabetic individuals. Studies reveal that generally diabetics use the same supplements and alternative remedies as nondiabetic individuals with the exception of increased use of chromium. The literature documents that some patients use CAM to lower blood glucose as well as to treat complications of diabetes; however, the majority of individuals report using CAM for a condition unrelated to diabetes. The use of CAM by diabetics raises several concerns. One obvious concern is the implications of using CAM in replacement of traditional therapies for diabetes such as insulin and oral hypoglycemic drugs; however, one study in the literature suggested that most diabetic patients use CAM in addition to traditional therapies rather than as a replacement for traditional medications. Another study documented that diabetic patients using CAM were more likely to also use preventive care practices such as obtaining a pneumococcal vaccination and visiting their health care provider on a regular basis. A second concern is the potential of CAM to do harm. With regard to herbal and vitamin supplements, harmful effects include potential interactions with traditional drugs as well as increased risk for hepatotoxicity, nephrotoxicity, and poor glycemic control. A third concern is the cost of CAM; one study reported that diabetics using CAM spend as much on the alternative therapies as they do on prescription drugs.

Because the use of CAM is widespread and has the potential for impacting blood glucose levels of diabetic patients, nurses should take careful drug histories, including questions about use of herbal and over-the-counter supplements. Nurses should also educate diabetic patients about the potential impact of complementary therapies on blood glucose levels when this information is available.

tissue of the upper arm or leg and the abdomen areas. It should be stored at all times in the original packaging in a refrigerator at 36 to 46°F, protected from light, kept dry, and discarded once opened after 30 days.

Major side effects of exenatide are GI distress and nausea. Many patients experience nausea at first but should be encouraged to continue the medication if at all possible as nausea usually subsides and converts into a feeling of fullness. A rare but serious side effect is the development of acute pancreatitis. Patients should be taught to report unusual abdominal discomfort to their health care provider.

### Dipeptidyl peptidase-4 (DPP-4) Inhibitors

Glucagon-like peptide-1 (GLP-1) has been known for some time to have an antidiabetic action via its ability to stimulate insulin secretion. Recent advances have overcome the problems associated with short half-life and inactivation of the incretin hormone. A new medication, sitagliptin (Januvia), has been released that solves this problem. Januvia is a DPP-4 enzyme

inhibitor, which results in a longer circulating half-life of GLP-1. Januvia has been found to not only balance the release of insulin and limit the release of additional glucose from the liver, it has also been linked to increased beta cell neogenesis, inhibition of beta cell apoptosis, inhibition of glucagon secretion, delayed gastric emptying, and induction of satiety.

Sitagliptin is indicated solely for patients with type 2 diabetes mellitus in addition to exercise and proper diet. It is administered in the morning with or without food and comes in 25-, 50-, and 100-milligram doses. Common side effects of sitagliptin are upper respiratory tract infection, stuffy or runny nose, sore throat, and headache.

Sitagliptin is contraindicated in patients with type 1 diabetes mellitus, patients receiving insulin, or patients who commonly produce ketones in their urine. Sitagliptin is *only* approved to be used alone or in combination with metformin and/or thiazolidinediones. It is to be strictly avoided with medications known to cause hypoglycemia (i.e., sulfonylureas or insulin). It is also contraindicated in ESRD, and dose adjustments are to be made in earlier stages of chronic kidney diseases.

## Herbal and Dietary Supplements

Increasing numbers of people are choosing alternative medications to complement or, in some cases, to replace prescription medications. With most herbs and dietary supplements, even the commonly used ones (e.g., echinacea, St. John's wort), the effects on blood glucose levels are unknown; well-controlled, long-term studies of effects have not been done; and interactions with antidiabetic drugs are unknown. Thus, anyone with diabetes who wishes to take an herbal or dietary supplement should consult a health care provider, read product labels carefully, seek the most authoritative information available, and monitor blood glucose closely when starting the supplement. Described below are some products that reportedly affect blood sugar and that should be used cautiously, if at all, by patients with diabetes.

### Supplements That May Increase Blood Glucose Levels

**Bee pollen** may cause hyperglycemia and decrease the effects of antidiabetic medications. It should not be used by people with diabetes.

**Ginkgo biloba** extract is thought to increase blood sugar in patients with diabetes by increasing hepatic metabolism of insulin and oral hypoglycemic drugs, thereby making the drugs less effective. It is not recommended for use.

**Glucosamine**, as indicated by animal studies, may cause impaired beta-cell function and insulin secretion similar to that observed in humans with type 2 diabetes. Long-term effects in humans are unknown, but the product is considered potentially harmful to people with diabetes or prediabetes. Adverse effects on blood sugar and drug interactions with

antidiabetic medications have not been reported. However, blood sugar should be monitored carefully. With chondroitin, which is often taken with glucosamine for osteoarthritis, there is no information about effects on blood sugar, use by diabetic patients, or interactions with antidiabetic drugs.

### Supplements That May Decrease Blood Glucose Levels

**Basil**, which is commonly used in cooking, is also available as an herbal supplement. The amounts used in cooking are unlikely to affect blood sugar, but larger amounts may cause hypoglycemia or increase the hypoglycemic effects of insulin and oral antidiabetic drugs. The use of supplemental amounts should probably be avoided by people with diabetes. If used, blood glucose levels should be closely monitored.

**Bay leaf** is commonly used in cooking (it should be removed from the food before eating) and is also available as an extract made with ground leaves. It increases the effects of insulin and is sometimes recommended by nutritionists for diabetic diets. If used, blood glucose levels should be monitored closely.

**Cinnamon** has been shown to improve glucose and lipid control in patients with type 2 diabetes, reducing fasting glucose, triglyceride, low-density lipoprotein, cholesterol, and total cholesterol levels. Patients with diabetes and prediabetes may benefit from the regular inclusion of cinnamon in their daily diet to prevent and control elevated glucose and blood lipid levels. Cinnamon may be a natural and inexpensive treatment for diabetes due to its molecular similarity to insulin.

**Chromium** is a trace mineral required for normal glucose metabolism. It may increase production of insulin receptors and insulin binding to the receptors, thereby increasing insulin effectiveness, lowering blood glucose levels, and decreasing insulin requirements in people with diabetes. It also may have beneficial effects on serum cholesterol levels. However, evidence for these effects is inconsistent, with some supporting and some negating the use of chromium supplements.

Chromium deficiency, considered rare in the United States, may play a role in the development of diabetes and atherosclerosis. If so, beneficial effects of a supplement may be more evident in a deficiency state. In one study of pregnant women and older adults with marginal levels of chromium, administration of a supplement improved glucose tolerance. At present, there is insufficient evidence to recommend routine chromium supplementation in diabetic patients. In nondiabetic patients, chromium supplements do not have hypoglycemic effects.

**Echinacea** has been studied in some clinical trials, but people with diabetes were excluded. It was concluded that diabetics should not take echinacea.

**Garlic** has been reported by some sources to have no known effects on blood glucose; others report a decrease in animals and humans. Some researchers also reported increased serum insulin and improvement in liver glycogen storage after garlic administration. There is a potential for additive hypoglycemic effects with antidiabetic drugs, although no apparent interactions have been reported.

**Ginseng** has been indicated in several studies (generally small and not well designed) to lower blood glucose levels in both diabetic and nondiabetic subjects. It may be useful in preventing diabetes or complications of diabetes. However, larger and longer studies are needed before general use can be recommended for diabetic or nondiabetic patients. For nondiabetic patients who use ginseng, the herb may need to be taken with a meal to prevent unintentional hypoglycemia. For diabetic patients, ginseng should be used very cautiously (if at all), with frequent monitoring of blood glucose and signs of hypoglycemia, because of possible additive effects with antidiabetic medications. Its use should also be accompanied by proper diet, physical activity, and antidiabetic medication.

**Glucomannan**, which is promoted as a diet aid and laxative, has hypoglycemic effects and should be avoided or used very cautiously by people with diabetes. If used, blood sugar levels should be monitored closely and lower doses of antidiabetic drugs may be needed.

**Guar gum** is a type of fiber that becomes gel-like upon contact with liquids (e.g., like Metamucil). It is used as a thickening agent in foods and drugs and is an ingredient in some over-the-counter weight-loss products. It should be used cautiously, if at all, by people with diabetes because it has hypoglycemic effects and slows GI motility. Several cases of esophageal and intestinal obstruction have been reported with weight-loss products.

### Applying Your Knowledge 26-2

Mr. Coulter complains about feeling weak and confused. Your assessment reveals he is sweating and has tremors of his upper extremities. What action should you take?

### Applying Your Knowledge 26-3

Mr. Coulter does not follow a prescribed diet. Even though he tells you that he gives himself his own insulin, he does not seem to be very knowledgeable about the use of the syringe and injection sites. He has not attended diabetic education classes because the time of the class interferes with his work schedule. What nursing diagnosis would be appropriate for Mr. Coulter?

## Nursing Process

### Assessment

Assess the patient's knowledge, attitude, and condition in relation to diabetes, the prescribed treatment plan, and complications. Assessment data should include past manifestations of the disease process and the patient's response to them; present status; and potential problem areas.

- *Historic data* include age at onset of diabetes, prescribed control measures and their effectiveness, the ease or difficulty of complying with the prescribed treatment, occurrence of complications such as ketoacidosis, and whether other disease processes have interfered with diabetes control.
- *Assess the patient's current status*, in relation to the following areas:
  - **Diet.** Ask about the prescribed nutritional plan, who prepares the food, what factors help in following the diet, what factors interfere with following the diet, the current weight, and whether there has been a recent weight change. Also ask if herbal or other dietary supplements are used. If so, list each one by name and frequency of use. If a nutritionist is available, ask one to assess the patient's dietary practice and needs.
  - **Activity.** Ask the patient to describe usual activities of daily living, including those related to work, home, and recreation, and whether he or she participates in a regular exercise program. If so, ask for more information about what, how often, how long, and so forth. If not, teaching is needed because exercise is extremely important in diabetes management.
  - **Medication.** If the patient takes insulin, ask what kind; how much; who administers it; usual time of administration; sites used for injections; and if a hypoglycemic reaction to insulin has ever been experienced, how it was handled. This information helps to assess knowledge, usual practices, and teaching needs. If the patient takes an oral antidiabetic drug, ask the name, dosage, and time taken.
  - **Monitoring methods.** Testing the blood for glucose and the urine for ketones (e.g., when blood sugar is elevated, when ill and unable to eat) are the two main methods of self-monitoring glycemic control. Ask about the method used, the frequency of testing, and the pattern of results. If possible, observe the patient performing and interpreting an actual test to assess accuracy.
  - **Skin and mucous membranes.** Inspect for signs of infection and other lesions. Infections often occur in the axillary and groin areas because these areas have large numbers of microorganisms. Periodontal disease (pyorrhea) may be manifested by inflammation and bleeding of the gums. Women with diabetes are susceptible to monilial vaginitis and infections under the breasts. Check the sites of insulin injection for atrophy (dimpling or indentation), hypertrophy (nodules or lumps), and fibrosis (hardened areas). Check the lower leg for brown spots; these are caused by small hemorrhages into the skin and may indicate widespread changes in the blood vessels.

Problems are especially likely to develop in the feet from infection, trauma, pressure, vascular insufficiency,

*Nursing Process continues on page 426*

and neuropathy. Therefore, inspect the feet for calluses, ulcers, and signs of infection. When such problems develop, sensory impairment from neuropathy may delay detection and impaired circulation may delay healing. Check pedal pulses, color, and temperature in both feet to evaluate arterial blood flow. Ankle edema may indicate venous insufficiency or impaired cardiac function.

- **Eyes.** Ask about difficulties with vision and if eyes are examined regularly. Diabetic patients are prone to development of retinopathy, cataracts, and possibly glaucoma.
- **Cardiovascular system.** Patients with diabetes have a high incidence of atherosclerosis, which makes them susceptible to hypertension, angina pectoris, myocardial infarction, peripheral vascular disease, and stroke. Therefore, check blood pressure and ask about chest pain and pain in the legs with exercise (intermittent claudication).
- **Genitourinary system.** People with diabetes often have kidney and bladder problems. Assess for signs of urinary tract infection; albumin, white blood cells, or blood in urine; edema; increased urination at night; difficulty voiding; generalized itching; fatigue; and muscular weakness. Impotence may develop in men and is attributed to neuropathy.
- Assess blood sugar reports for abnormal levels. Two or more fasting blood glucose levels greater than 126 mg/dL or two random levels greater than 200 mg/dL are diagnostic of diabetes. Decreased blood sugar levels are especially dangerous at 40 mg/dL or below.
- Assess the glycosylated hemoglobin (also called *glycated hemoglobin* and  $HbA_{1c}$ ) level when available. This test indicates glucose bound to hemoglobin in red blood cells (RBCs) when RBCs are exposed to hyperglycemia. The binding is irreversible and lasts for the lifespan of RBCs (approximately 120 days). The test reflects the average blood sugar during the previous 2 to 3 months. The goal is usually less than 7% (the range for people without diabetes is approximately 4%–6%). The test should be done every 3 to 6 months.

Test results are not affected by several factors that alter blood sugar levels, such as time of day, food intake, exercise, recently administered antidiabetic drugs, emotional stress, or patient cooperation. The test is especially useful with children; those whose diabetes is poorly controlled; those who do not test blood glucose regularly; and those who change their usual habits before a scheduled appointment with a health care provider so that their blood sugar control appears better than it actually is.

## Nursing Diagnoses

- Ineffective Tissue Perfusion, peripheral, related to atherosclerosis and vascular impairment

- Disturbed Sensory Perception, visual and tactile, related to impaired vision or neuropathy
- Ineffective Coping related to chronic illness and required treatment
- Anxiety: Managing a chronic illness, finger sticks, insulin injections
- Risk for Injury: Trauma, infection, hypoglycemia, hyperglycemia
- Noncompliance related to inability or unwillingness to manage the disease process and required treatment
- Deficient Knowledge: Disease process and management; administration and effects of antidiabetic drugs; interrelationships among diet, exercise, and antidiabetic drugs; and management of hypoglycemia, “sick days,” and other complications

## Planning/Goals

### The patient will

- Learn self-care activities
- Manage drug therapy to prevent or minimize hypoglycemia and other adverse effects
- Develop a consistent pattern of diet and exercise
- Use available resources to learn about the disease process and how to manage it
- Take antidiabetic drugs accurately
- Self-monitor blood glucose and urine ketones appropriately
- Keep appointments for follow-up and monitoring procedures by a health care provider

## Interventions

Use nondrug measures to improve control of diabetes and to help prevent complications.

- Assist the patient in maintaining the prescribed diet. Specific measures vary but may include teaching the patient and family about the importance of diet; referring the patient to a dietitian; and helping the patient identify and modify factors that decrease compliance with the diet. If the patient is obese, assist in developing a program to lose weight and then maintain weight at a more nearly normal level.
- Assist the patient to develop and maintain a regular exercise program.
- Perform and interpret blood tests for glucose accurately, and assist patient and family members to do so. Self-monitoring of blood glucose levels allows the patients to see the effects of diet, exercise, and hypoglycemic medications on blood glucose levels and may promote compliance.
 

Several products are available for home glucose monitoring. All involve obtaining a drop of capillary blood from a finger or forearm with a sterile lancet. The blood is placed on a semipermeable membrane that contains a reagent. The amount of blood glucose can be read with various machines (e.g., glucometers).

- Test urine for ketones when the patient is sick, when blood glucose levels are above 200 mg/dL, and when episodes of nocturnal hypoglycemia are suspected. Also teach patients and family members to test urine when indicated.
- Promote early recognition and treatment of problems by observing for signs and symptoms of urinary tract infection, peripheral vascular disease, vision changes, ketoacidosis, hypoglycemia, and others. Teach patients and families to observe for these conditions and report their occurrence.
- Discuss the importance of regular visits to health care facilities for blood sugar measurements, weights, blood pressure measurements, and eye examinations.
- Perform and teach correct foot care. Have the patient observe the following safeguards: avoid going barefoot, to prevent trauma to the feet; wear correctly fitted shoes; wash the feet daily with warm water, dry well, inspect for any lesions or pressure areas, and apply lanolin if the skin is dry; wear cotton or wool socks because they are more absorbent than synthetic materials; cut toenails straight across and only after the feet have been soaked in warm water and washed thoroughly. Teach the patient to avoid use of hot water bottles or electric heating pads; cutting toenails if vision is impaired; use of strong antiseptics on the feet; and cutting corns or calluses. Also teach the patient to report any lesions on the feet to the physician.
- Help patients keep up with newer developments in diabetes care by providing information, sources of information, consultations with specialists, and other resources. However, do not overwhelm a newly diagnosed diabetic patient with excessive information or assume that a long-term diabetic patient does not need information.

Provide appropriate patient teaching for any drug therapy (see accompanying display).

## Evaluation

- Check blood sugar reports regularly for normal or abnormal values.
- Check glycosylated hemoglobin reports when available.
- Interview and observe for therapeutic and adverse responses to antidiabetic drugs.
- Interview and observe for compliance with prescribed treatment.
- Interview patients and family members about the frequency and length of hospitalizations for diabetes mellitus.

## Principles of Therapy

### Goals of Therapy

For most patients, the goals of treatment are to maintain blood glucose at normal or near-normal levels; promote normal metabolism of carbohydrate, fat, and protein; prevent acute and long-term complications; and prevent hypoglycemic episodes.

There is strong evidence that strict control of blood sugar delays the onset and slows progression of complications of diabetes. In addition to glycemic control, other measures can be used to help prevent complications of diabetes. Administration of angiotensin-converting enzyme (ACE) inhibitors (e.g., captopril) has protective effects on the kidneys in both type 1 and type 2 diabetes and in both normotensive and hypertensive people. Although ACE inhibitors are also used in the treatment of hypertension, their ability to delay nephropathy seems to be independent of antihypertensive effects. Additional measures to preserve renal function include effective treatment of hypertension, limited intake of dietary protein, prompt treatment of urinary tract infections, and avoidance of nephrotoxic drugs when possible.

Current research suggests a number of treatment strategies may be beneficial in reducing the cardiovascular disease risk associated with type 2 diabetes mellitus. Some clinicians are recommending the routine use of statins such as simvastatin to reduce the risk of occlusive arterial disease in all patients with diabetes regardless of cholesterol level. There is conflicting evidence regarding the effectiveness of thiazolidinediones in reducing the incidence of cardiovascular disease risk factors in patients with type 2 diabetes. Some clinical trials suggest that reducing insulin resistance through the use of thiazolidinediones has a cardioprotective benefit; however, recent safety data have shown a potentially significant increased risk of heart attack and heart-related deaths in patients taking rosiglitazone. The FDA has requested all approved oral antidiabetic drugs include labeling stating that no oral antidiabetic drug has been conclusively shown to reduce cardiovascular risk. Further studies are needed to resolve this question. Additional measures to reduce cardiovascular disease risk include reducing weight, controlling hypertension with an ACE inhibitor or angiotensin receptor blocker, use of aspirin therapy, and smoking cessation.

## Treatment Regimens

When possible, it is desirable to have an interdisciplinary diabetes care team (e.g., physician, nurse diabetes educator, dietitian, perhaps others) work with the patient to design, monitor, and revise an individualized treatment plan. This is especially important for patients with newly diagnosed diabetes to assist them in learning to manage their disease and make appropriate lifestyle changes.

The best regimen for a particular patient depends on the type of diabetes, the patient's age and general condition, and the patient's ability and willingness to comply with the prescribed therapy. In type 1 diabetes, the only effective treatment measures are insulin, diet, and exercise. In type 2, the initial treatment of choice is diet, exercise, and weight control. If this regimen is ineffective, oral agents or insulin may be added.

## Guidelines for Insulin Therapy

### Choice of Insulin

When insulin therapy is indicated, the physician may choose from several preparations that vary in composition, onset,

## Patient Teaching Guidelines Antidiabetic Drugs

### General Considerations

- Wear or carry diabetic identification (e.g., a Medic-Alert necklace or bracelet) at all times, to aid treatment if needed.
- Learn as much as you can about diabetes and its management. Few other diseases require as much adaptation in activities of daily living, and you must be well informed to control the disease, minimize complications, and achieve an optimal quality of life. Although much information is available from health care providers (physicians, nurses, nurse diabetes educators, nutritionists), an additional major resource is the

American Diabetes Association  
1660 Duke St.  
Alexandria, VA 22314  
1-800-ADA-DISC  
<http://www.diabetes.org>

- In general, a consistent schedule of diet, exercise, and medication produces the best control of blood sugar levels and the least risk of complications.
- Diet, weight control, and exercise are extremely important in managing diabetes. Maintaining normal weight and avoiding excessive caloric intake decrease the need for medication and decrease the workload of the pancreas. Exercise helps body tissues use insulin better, which means that glucose moves out of the bloodstream and into muscles and other body tissues. This promotes more normal blood glucose levels and decreases long-term complications of diabetes.
- Take any antidiabetic medication as prescribed. If unable to take a medication, notify a health care provider. To control blood sugar most effectively, medications are balanced with diet and exercise. If you take insulin, you need to know what type(s) you are taking, how to obtain more, and how to store it. Unopened vials of insulin should be refrigerated. An opened vial may be stored at room temperature for 28 days. DO NOT freeze insulin. Regular and isophane (NPH) insulins and mixtures (e.g., Humulin) are available over-the-counter; Humalog, NovoLog, Lantus, Apidra, and Demetir require a prescription. Keep several days' supply of insulin and syringes on hand to allow for weather or other conditions that might prevent replacement of insulin or other supplies when needed.

If you take Byetta, you should store it in the original package in the refrigerator and discard unused portion after 30 days. Alert your health care provider if you experience acute abdominal discomfort while taking Byetta. If you take Symlin, opened vials can be kept in the refrigerator or at room temperature for up to 28 days.

- You need to know the signs and symptoms of high blood sugar (hyperglycemia): increased blood glucose and excessive thirst, hunger, and urine output. Persistent hyperglycemia may indicate a need to change some aspect of the treatment program, such as diet or medication.
- You need to know the symptoms of low blood sugar (hypoglycemia): sweating, nervousness, hunger, weakness, tremors, and mental confusion. Hypoglycemia may indicate too much medication or exercise or too little food. Treatment is a rapidly absorbed source of sugar, which

usually reverses symptoms within 10 to 20 minutes. If you are alert and able to swallow, take 4 ounces of fruit juice, 4 to 6 ounces of a sugar-containing soft drink, a piece of fruit or  $\frac{1}{3}$  cup of raisins, two to three glucose tablets (5 grams each), a tube of glucose gel, 1 cup of skim milk, tea or coffee with 2 teaspoons of sugar, or eight Lifesaver candies. Avoid taking so much sugar that hyperglycemia occurs.

*If you take acarbose (Precose) or miglitol (Glyset) along with insulin; glimepiride (Amaryl); glipizide (Glucotrol); or glyburide (DiaBeta, Glynase, Micronase) and a hypoglycemic reaction occurs, you must take some form of glucose (or glucagon) for treatment. Sucrose (table sugar) and other oral carbohydrates do not relieve hypoglycemia because the presence of acarbose or miglitol prevents their digestion and absorption from the gastrointestinal (GI) tract.*

- You need to have a family member or another person who is able to recognize and manage hypoglycemia in case you are unable to obtain or swallow a source of glucose. If you take insulin, glucagon should be available in the home and a caregiver should know how to give it.
- The best way to prevent, delay, or decrease the severity of diabetes complications is to maintain blood sugar at a normal or near-normal level. Other measures include regular visits to health care providers, preferably a team of specialists in diabetes care; regular vision and glaucoma testing; and special foot care. In addition, if you have hypertension or elevated lipid levels, treatment can help prevent heart attacks and strokes.
- Take only drugs prescribed by a physician who knows you have diabetes. Avoid other prescriptions and over-the-counter drugs unless these are discussed with the physician treating the diabetes because adverse reactions and interactions may occur. For example, nasal decongestants (alone or in cold remedies) and asthma medications may cause tachycardia and nervousness, which may be interpreted as hypoglycemia. In addition, liquid cold remedies and cough syrups may contain sugar and raise blood glucose levels.
- If you wish to take any kind of herbal or dietary supplement, you should discuss this with the health care provider who is managing your diabetes. There has been little study of these preparations in relation to diabetes; many can increase or decrease blood sugar and alter diabetes control. If you start a supplement, you need to check your blood sugar frequently to see how it affects your blood glucose level.
- Test blood regularly for glucose. A schedule individualized to your needs is best. Testing should be done more often when medication dosages are changed or when you are ill. Current blood glucose technology allows the selection of the fingertip or other location such as the forearm to obtain the blood sample. Glucose-concentrations measured at different sites may vary. The fingertips are the most accurate site and should be the preferred test site if hypoglycemia is suspected.
- Reduce insulin dosage or eat extra food if you expect to exercise more than usual. Specific recommendations should be individualized and worked out with health care providers in relation to the type of exercise.

- Ask for written instructions about managing “sick days” and call your physician if unsure about what you need to do. Although each person needs individualized instructions, some general guidelines include the following:
  - Continue your antidiabetic medications unless instructed otherwise. Additional insulin also may be needed, especially if ketosis develops. Ketones (acetone) in the urine indicate insulin deficiency or insulin resistance.
  - Check blood glucose levels at least four times daily; test urine for ketones when the blood glucose level exceeds 250 mg/dL or with each urination. If unable to test urine, have someone else do it.
  - Rest, keep warm, do not exercise, and keep someone with you if possible.
  - If unable to eat solid food, take easily digested liquids or semiliquid foods. About 15 grams of carbohydrate every 1 to 2 hours is usually enough and can be provided by ½ cup of apple juice, applesauce, cola, cranberry juice, eggnog, Cream of Wheat cereal, custard, vanilla ice cream, regular gelatin, or frozen yogurt.
  - Drink 2 to 3 quarts of fluids daily, especially if you have a fever. Water, tea, broths, clear soups, diet soda, or carbohydrate-containing fluids are acceptable.
  - Record the amount of fluid intake as well as the number of times you urinate, vomit, or have loose stools.
  - Seek medical attention if a pre-meal blood glucose level is more than 250 mg/dL, if urine acetone is present, if you have fever above 100°F, if you have several episodes of vomiting or diarrhea, or if you have difficulty in breathing, chest pain, severe abdominal pain, or severe dehydration.

### Self-Administration

- Use correct techniques for injecting insulin:
  - Follow instructions for times of administration as nearly as possible. Different types of insulin have different onsets, peaks, and durations of action. Accurate timing (e.g., in relation to meals), can increase beneficial effects and decrease risks of hypoglycemic reactions.
  - Wash hands; wash injection site, if needed.
  - Draw up insulin in a good light, being very careful to draw up the correct dose. If you have trouble seeing the syringe markers, get a magnifier or ask someone else to draw up the insulin. Prefilled syringes or cartridges for pen devices are also available.
  - Instructions may vary about cleaning the top of the insulin vial and the injection site with an alcohol swab and about pulling back on the plunger after injection to see if any blood enters the syringe. These techniques have been commonly used, but many diabetes experts do not believe they are necessary.
  - Inject straight into the fat layer under the skin, at a 90-degree angle. If very thin, pinch up a skinfold and inject at a 45-degree angle.
  - Rotate injection sites. Your health care provider may suggest a rotation plan. Many people rotate between the abdomen and the thighs. Insulin is absorbed fastest from the abdomen. Do not inject insulin within 2 inches of the “belly button” or into any skin lesions.
- If it is necessary to mix two insulin preparations, ask for specific instructions about the technique and then follow it consistently. There is a risk of inaccurate dosage of both insulins unless measured very carefully. Commercial mixtures are also available for some combinations.
- Change insulin dosage only if instructed to do so and the circumstances are specified.
- Carry sugar, candy, or a commercial glucose preparation for immediate use if a hypoglycemic reaction occurs.
- Use correct technique for injecting amylin analogs and incretin mimetics:
  - Inject pramlintide (Symlin) subcutaneously into abdomen or thighs before meals. Do not mix in same syringe with insulin. Insulin dosages may be reduced by 50% when taking pramlintide.
  - Inject exenatide (Byetta) subcutaneously into abdomen, thigh, or upper arm within 60 minutes before morning and evening meal.
  - Rotate injection site of pramlintide and do not give in same site where insulin is administered.
- Take oral drugs as directed. Recommendations usually include the following:
  - Take glipizide or glyburide approximately 30 minutes before meals; take glimepiride with breakfast or the first main meal. Take Glucotrol XL with breakfast.
  - Take acarbose or miglitol with the first bite of each main meal. The drugs need to be in the GI tract with food because they act by decreasing absorption of sugar in the food. Starting with a small dose and increasing it gradually helps to prevent bloating, “gas pains,” and diarrhea.
  - Take metformin (Glucophage) with meals to decrease stomach upset. Take Glucophage XR with the evening meal.
  - Take repaglinide (Prandin) or nateglinide (Starlix) about 15 to 30 minutes before meals (2, 3, or 4 times daily). Doses may vary from 0.5 to 4.0 milligrams, depending on fasting blood glucose levels. Dosage changes should be at least 1 week apart. If you skip a meal, you should skip that dose of repaglinide or nateglinide; if you eat an extra meal, you should take an extra dose.
  - Take pioglitazone (Actos), rosiglitazone (Avandia), and sitagliptin (Januvia) without regard to meals.
- If you take glimepiride, glipizide, glyburide, repaglinide or nateglinide, alone or in combination with other antidiabetic drugs, be prepared to handle hypoglycemic reactions (as with insulin, above). Acarbose, miglitol, metformin, pioglitazone, and rosiglitazone do not cause hypoglycemia when taken alone. Do not skip meals and snacks. This increases the risk of hypoglycemic reactions.
- If you exercise vigorously, you may need to decrease your dose of antidiabetic drug or eat more. Ask for specific instructions related to the type and frequency of the exercise.

duration of action, and other characteristics. Some factors to be considered include the following:

- Regular insulin (insulin injection) has a rapid onset of action and can be given IV. Therefore, it is the insulin of choice during acute situations, such as DKA, severe infection or other illness, and surgical procedures.
- Isophane insulin (NPH) is often used for long-term insulin therapy. For many patients, a combination of NPH and a short-acting insulin provides more consistent control of blood glucose levels. Although several regimens are used, a common one is a mixture of regular and NPH insulins administered before the morning and evening meals. A commercial mixture is more convenient and probably more accurate than a mixture prepared by a patient or caregiver, if the proportions of insulins are appropriate for the patient.
- Insulin lispro, aspart, or glulisine may be used instead of Sub-Q regular insulin in most situations, but safe usage requires both health care providers and patients to be aware of differences. Regular insulin, insulin aspart, and insulin glulisine are also approved for use in external insulin pumps that administer a Sub-Q continuous infusion.
- Insulin glargine or insulin detemir may be used to provide a basal amount of insulin over 24 hours, with a short-acting insulin or short-acting insulin analog at meal times.

### Drug Dosage

Dosage of insulin must be individualized according to blood glucose levels. *Blood glucose meters* are devices that measure how much glucose is in the blood. A specially coated test strip containing a fresh sample of blood (obtained by pricking the skin, usually the finger or forearm, with a *lancet*) is inserted in the meter, which then measures the amount of glucose in the blood. The goal is to administer enough insulin to alleviate symptoms of hyperglycemia and to re-establish metabolic balance without causing hypoglycemia. An initial dose of 0.5 to 1 units per kilogram per day may be started and then adjusted to maintain blood glucose levels (tested before meals and at bedtime) of 90 to 130 milligrams per deciliter in adults (100–200 mg/dL in children younger than 5 years of age). However, many factors influence blood glucose response to exogenous insulin and therefore influence insulin requirements.

Factors that increase insulin requirements include weight gain, increased caloric intake, pregnancy, decreased activity, acute infections, hyperadrenocorticism (Cushing's disease), primary hyperparathyroidism, acromegaly, hypokalemia, and drugs such as corticosteroids, epinephrine, levothyroxine, and thiazide diuretics. Patients who are obese may require 2 units per kilogram per day because of resistance to insulin in peripheral tissues.

Factors that decrease insulin requirements include weight reduction; decreased caloric intake; increased physical activity; development of renal insufficiency; stopping administration of corticosteroids, epinephrine, levothyroxine, and diuretics; hypothyroidism; hypopituitarism; recovery from hyperthy-

roidism; recovery from acute infections; and the “honeymoon period” (see below), which may occur with type 1 diabetes.

People who need less than 0.5 units per kilogram per day may produce some endogenous insulin or their tissues may be more responsive to insulin because of exercise and good physical conditioning. Renal insufficiency decreases dosage requirements because less insulin is metabolized in the kidneys than with normal renal function. The “honeymoon period,” characterized by temporary recovery of beta-cell function and production of insulin, may occur after diabetes is first diagnosed. Insulin requirements may decrease rapidly, and if the dosage is not decreased, severe hypoglycemic reactions may occur.

In acute situations, dosage of regular insulin needs frequent adjustments based on measurements of blood glucose. When insulin is given IV in a continuous infusion, 20% to 30% binds to the IV fluid container and the infusion tubing.

Dosage of insulin for long-term therapy is determined by blood glucose levels at various times of the day and is adjusted when indicated (e.g., because of illness or changes in physical activity). Titrating insulin dosage may be difficult and time consuming; it requires cooperation and collaboration between patients and health care providers.

*Insulin pumps* are being increasingly used, especially by adolescents and young adults who want flexibility in diet and exercise. These devices allow continuous Sub-Q administration of regular insulin, insulin aspart, or insulin glulisine. A basal amount of insulin is injected (e.g., 1 unit/hour or a calculated fraction of the dose used previously) continuously, with bolus injections before meals. This method of insulin administration maintains more normal blood glucose levels and avoids wide fluctuations. Candidates for insulin pumps include patients with diabetes that is poorly controlled with other methods and those who are able and willing to care for the devices properly. The MiniMed Paradigm\* Real-Time System, the world's first integrated insulin pump and continuous glucose monitoring system, is now available in the United States and more than 20 other countries around the world ([www.medtronic.com/Newsroom/NewsReleaseDetails.do?itemId=1164130391890&f...](http://www.medtronic.com/Newsroom/NewsReleaseDetails.do?itemId=1164130391890&f...)). The Guardian RT System displays glucose readings every 5 minutes and sounds an alarm when glucose levels reach high or low glucose limits preset by the clinical professional. The study completed on the RT System demonstrated that patients using Medtronic RT Continuous Glucose Monitoring technology had better control of their blood glucose than patients using fingersticks only.

### Drug Administration

#### Timing of Insulin Administration

Many patients who take insulin need at least two injections daily to control hyperglycemia. A common regimen is one half to two thirds of the total daily dose in the morning before breakfast and the remaining one half or one third before the evening meal or at bedtime. With regular insulin before meals, it is very important that the medication be injected 30 to 45 minutes before meals so that the insulin is available when blood sugar increases after meals. With insulin lispro, aspart, or

glulisine before meals, it is important to inject the medication about 15 minutes before eating. Insulin glargine or detemir is most commonly given at bedtime. However, it may be administered in the morning or in split doses as needed.

### Selection of Subcutaneous Sites for Insulin Injections

Several factors affect insulin absorption from injection sites, including the site location, environmental temperature, and exercise or massage. Studies indicate that insulin is absorbed fastest from the abdomen, followed by the deltoid, thigh, and hip. Because of these differences, many clinicians recommend rotating injection sites within areas. This technique decreases rotations between areas and promotes more consistent blood glucose levels. With regard to temperature, insulin is absorbed more rapidly in warmer sites and environments. In relation to exercise, people who exercise should avoid injecting insulin into Sub-Q tissue near the muscles to be used. The increased blood flow that accompanies exercise promotes rapid absorption and may lead to hypoglycemia.

### Timing of Food Intake

Patients receiving insulin need food at the peak action time of the insulin and at bedtime. The food is usually taken as a between-meal and a bedtime snack. These snacks help prevent hypoglycemic reactions between meals and at night. When hypoglycemia occurs during sleep, recognition and treatment may be delayed. This delay may allow the reaction to become more severe.

### Use With Oral Antidiabetic Drugs

Insulin has been used successfully with all currently available types of oral agents (alpha-glucosidase inhibitors, biguanide, thiazolidinediones, meglitinides, and sulfonylureas).

### Management of Diabetic Ketoacidosis

Insulin therapy is a major component of any treatment for DKA. Patients with DKA have a deficiency in the total amount of insulin in the body and a resistance to the action of the insulin that is available, probably due to acidosis, hyperosmolality, infection, and other factors. To be effective, insulin therapy must be individualized according to frequent measurements of blood glucose. Low doses, given by continuous IV infusion, are preferred in most circumstances.

Additional measures include identification and treatment of conditions that precipitate DKA, administration of IV fluids to correct hyperosmolality and dehydration, administration of potassium supplements to restore and maintain normal serum potassium levels, and administration of sodium bicarbonate to correct metabolic acidosis. Infection is one of the most common causes of DKA. If no obvious source of infection is identified, cultures of blood, urine, and throat swabs are recommended. When infection is identified, antimicrobial drug therapy may be indicated.

IV fluids, the first step in treating DKA, usually consist of 0.9% sodium chloride, an isotonic solution. Hypotonic solutions are usually avoided because they allow intracellular fluid shifts and may cause cerebral, pulmonary, and peripheral edema.

Although serum potassium levels may be normal at first, they fall rapidly after insulin and IV fluid therapy are begun. Decreased serum potassium levels are caused by expansion of extracellular fluid volume, movement of potassium into cells, and continued loss of potassium in the urine as long as hyperglycemia persists. For these reasons, potassium supplements are usually added to IV fluids. Because both hypokalemia and hyperkalemia can cause serious cardiovascular disturbances, dosage of potassium supplements must be based on frequent measurements of serum potassium levels. Also, continuous or frequent electrocardiogram monitoring is recommended.

Severe acidosis can cause serious cardiovascular disturbances, which usually stem from peripheral vasodilation and decreased cardiac output with hypotension and shock. Acidosis usually can be corrected by giving fluids and insulin; sodium bicarbonate may be given if the pH is less than 7.2. If used, sodium bicarbonate should be given slowly and cautiously. Rapid alkalinization can cause potassium to move into body cells faster than it can be replaced IV. The result may be severe hypokalemia and cardiac dysrhythmias. Also, giving excessive amounts of sodium bicarbonate can produce alkalosis.

### Treatment of the Unconscious Patient

When a person with diabetes becomes unconscious and it is unknown whether the unconsciousness is caused by DKA or by hypoglycemia, the patient should be treated for hypoglycemia. If hypoglycemia is the cause, giving glucose may avert brain damage. If DKA is the cause, giving glucose does not harm the patient. Sudden unconsciousness in a patient who takes insulin is most likely to result from an insulin reaction producing hypoglycemia; DKA usually develops gradually over several days or weeks.

### Hyperosmolar Hyperglycemic Nonketotic Coma (HHNC)

Treatment of HHNC is similar to that of DKA in that insulin, IV fluids, and potassium supplements are major components. Regular insulin is given by continuous IV infusion, and dosage is individualized according to frequent measurements of blood glucose levels. IV fluids are given to correct the profound dehydration and hyperosmolality, and potassium is given IV to replace the large amounts lost in urine during a hyperglycemic state.

### Perioperative Insulin Therapy

Patients with diabetes who undergo major surgery have increased risks of both surgical and diabetic complications. Risks associated with surgery and anesthesia are greater if diabetes is not well controlled and complications of diabetes (e.g., hypertension, nephropathy, vascular damage) are already evident. Hyperglycemia and poor metabolic control are associated with increased susceptibility to infection, poor wound healing, and fluid and electrolyte imbalances. Risks of diabetic complications are increased because the stress of surgery increases insulin requirements and may precipitate DKA. Metabolic

responses to stress include increased secretion of catecholamines, cortisol, glucagon, and growth hormone, all of which increase blood glucose levels. In addition to hyperglycemia, protein breakdown, lipolysis, ketogenesis, and insulin resistance occur. The risk of hypoglycemia is also increased.

The goals of treatment are to avoid hypoglycemia, severe hyperglycemia, ketoacidosis, and fluid and electrolyte imbalances. Maintenance of blood glucose levels between 120 and 180 milligrams per deciliter during the perioperative period is desirable. In general, mild hyperglycemia (e.g., blood glucose levels between 150 and 250 mg/dL) is considered safer for the patient than hypoglycemia, which may go unrecognized during anesthesia and surgery. Because surgery is a stressful event that increases blood glucose levels and the body's need for insulin, insulin therapy is usually required.

The goal of insulin therapy is to avoid ketosis from inadequate insulin and hypoglycemia from excessive insulin. Specific actions depend largely on the severity of diabetes and the type of surgical procedure. Diabetes should be well controlled before any type of surgery. Minor procedures usually require little change in the usual treatment program; major operations usually require a different medication regimen.

In general, regular, short-acting insulin is used with major surgery or surgery requiring general anesthesia. IV administration of insulin is preferred because it provides more predictable absorption than Sub-Q injections. For patients who use an intermediate-acting insulin, a different regimen using regular insulin in doses approximating the usual daily requirement is needed. For patients who usually manage their diabetes with diet alone or with diet and oral medications, insulin therapy may be started. Human insulin is preferred for temporary use to minimize formation of insulin antibodies. Small doses are usually required.

For elective major surgery, patients should be scheduled early in the day to avoid prolonged fasting. In addition, most authorities recommend omitting usual doses of insulin on the day of surgery and oral antidiabetic medications for 1 or 2 days before surgery. While the patient is NPO (nothing by mouth), before and during surgery, IV insulin is usually given. Along with the insulin, patients need adequate sources of carbohydrate. This is usually supplied by IV solutions of 5% or 10% dextrose at a rate of 5 grams of glucose per hour (D<sub>5</sub>W at a rate of 100 mL/hour provides 5 g of glucose).

After surgery, IV insulin and dextrose may be continued until the patient is able to eat and drink. Several protocols exist for postoperative glucose control. Most involve continuous infusions of insulin with frequent blood glucose monitoring and subsequent titration of the insulin infusion to maintain a predetermined goal. Regular insulin can also be given Sub-Q every 4 to 6 hours, with frequent blood glucose measurements. Oral fluids and foods that contain carbohydrate should be resumed as soon as possible. When meals are fully tolerated, the preoperative insulin or oral medication regimen can be resumed. Additional regular insulin can be given for elevated blood glucose and ketone levels, if indicated.

## Guidelines for Oral Antidiabetic Drug Therapy

### Sulfonylureas

Sulfonylureas are not effective in all patients with type 2 diabetes, and many patients experience primary or secondary treatment failure. Primary failure involves a lack of initial response to the drugs. Secondary failure means that a therapeutic response occurs when the drugs are first given, but the drugs eventually become ineffective. Reasons for secondary failure may include decreased compliance with diet and exercise instructions, failure to take the drugs as prescribed, or decreased ability of the pancreatic beta cells to produce more insulin in response to the drugs.

Dosage of sulfonylureas is usually started low and increased gradually until the fasting blood glucose level is 110 milligrams per deciliter or less. The lowest dose that achieves normal fasting and postprandial blood sugar levels is recommended.

Sulfonylureas must be used cautiously in patients with impaired renal or hepatic function. They are usually not recommended for use during pregnancy because of risks of fetal hypoglycemia and death, congenital anomalies, and overt diabetes in women with gestational diabetes (because the drugs stimulate an already overstimulated pancreas).

### Alpha-Glucosidase Inhibitors

Acarbose and miglitol should be taken at the beginning of a meal so they are present in the GI tract with food and able to delay digestion of carbohydrates. Low initial doses and gradual increases decrease GI upset (e.g., bloating, diarrhea) and promote patient compliance. Patients taking acarbose or miglitol should continue their diet, exercise, and blood glucose testing routines. Alpha-glucosidase inhibitors do not alter insulin secretion or cause hypoglycemia.

### Biguanide

Renal function should be assessed before starting metformin and at least annually during long-term therapy. The drug should not be given initially if renal impairment is present; it should be stopped if renal impairment occurs during treatment. As with other antidiabetic drugs, patients taking metformin should continue their diet, exercise, and blood glucose testing regimens.

Parenteral radiographic contrast media containing iodine (e.g., Cholografin, Hypaque) may cause renal failure, and they have been associated with lactic acidosis in patients receiving metformin. Metformin should be discontinued at least 48 hours before diagnostic tests are performed with these materials and should not be resumed for at least 48 hours after the tests are done and tests indicate renal function is normal.

### Thiazolidinediones

Liver function tests (e.g., serum aminotransferase enzymes) should be checked before starting therapy and periodically thereafter. In addition, patients should be monitored closely for edema and other signs of congestive heart failure.

## Meglitinides

As with other antidiabetic drugs, patients taking one of these drugs should continue their diet, exercise, and blood glucose testing regimens. Dosage is flexible, depending on food intake, but patients should eat within a few minutes after taking a dose to avoid hypoglycemia.

## Use With Insulin

All the currently available types of oral agents (alpha-glucosidase inhibitors, biguanide, thiazolidinediones, meglitinides, and sulfonylureas) have been used successfully with insulin.

### Applying Your Knowledge 26-4

#### How Can You Avoid This Medication Error?

Mr. Coulter is scheduled for a renal arteriogram. The nurse tells him to take his antidiabetic medication as usual.

## Combination Drug Therapy for Type 2 Diabetes

Combination drug therapy is an increasing trend in type 2 diabetes that is not controlled by diet, exercise, and single-drug therapy. Useful combinations include drugs with different mechanisms of action, and several rational combinations are currently available. Most studies have involved combinations of two drugs; some three-drug combinations are also being used. All combination therapy should be monitored with periodic measurements of fasting plasma glucose and glycosylated hemoglobin levels. If adequate glycemic control is not achieved, oral drugs may need to be discontinued and insulin therapy started. Two-drug combinations include the following:

- **Insulin plus a sulfonylurea.** Advantages include lower fasting blood glucose levels, decreased glycosylated hemoglobin levels, increased secretion of endogenous insulin, smaller daily doses of insulin, and no significant change in body weight. The role of insulin analogs in combination therapy is not clear. One regimen, called BIDS, uses bedtime insulin, usually NPH, with a daytime sulfonylurea, usually glyburide.
- **Insulin plus a glitazone.** Thiazolidinediones increase the effectiveness of insulin, whether endogenous or exogenous.
- **Sulfonylurea plus acarbose or miglitol.** This combination is FDA approved for patients who do not achieve adequate glycemic control with one of the drugs alone.
- **Sulfonylurea plus metformin.** Glimepiride is FDA approved for this combination.
- **Sulfonylurea plus a glitazone.** The sulfonylurea increases insulin and the glitazone increases insulin effectiveness.
- **Metformin plus a meglitinide.** If one of the drugs alone does not produce adequate glycemic control, the other one may be added. Dosage of each drug should be titrated to the minimal dose required to achieve the desired effects.
- **Metformin plus a glitazone.** If metformin alone does not produce adequate glycemic control, a glitazone may

be added. Pioglitazone is FDA approved for this combination.

- **Metformin or glitazone plus sitagliptin.** Sitagliptin may be added as adjunctive therapy with metformin or a glitazone to achieve desired glycemic control.
- **Metformin or sulfonylurea plus exenatide.** Exenatide may be added as adjunctive therapy with metformin or a sulfonylurea to achieve desired glycemic control.
- **Mealtime insulin plus metformin, glitazone, and/or sulfonylurea plus pramlintide.** Pramlintide may be given with mealtime insulin in type 2 diabetics to achieve better postprandial glucose control.

## Use in Special Populations

### Use in Diabetic Patients Who Are Ill

Illness may affect diabetes control in several ways. First, it causes a stress response. Part of the stress response is increased secretion of glucagon, epinephrine, growth hormone, and cortisol, hormones that raise blood glucose levels (by stimulating gluconeogenesis and inhibiting insulin action) and cause ketosis (by stimulating lipolysis and ketogenesis). Second, if the illness makes a person unable or unwilling to eat, hypoglycemia can occur. Third, if the illness affects GI function (e.g., causes vomiting or diarrhea), the person may be unable to drink enough fluids to prevent dehydration and electrolyte imbalance. In addition, hyperglycemia induces an osmotic diuresis that increases dehydration and electrolyte imbalances.

As a result of these potentially serious effects, an illness that would be minor in people without diabetes may become a major illness or medical emergency in people with diabetes. Everyone involved should be vigilant about recognizing and seeking prompt treatment for any illness. In addition, patients with diabetes (or their caregivers) should be taught how to adjust their usual regimens to maintain metabolic balance and prevent severe complications. The main goal during illness is to prevent complications such as severe hyperglycemia, dehydration, and DKA.

### Use in Children

Diabetes, one of the most common chronic disorders of childhood, usually appears after 4 years of age and peaks in incidence at 10 to 12 years for girls and 12 to 14 years for boys. Approximately 75% of all newly diagnosed cases of type 1 diabetes occur in people under the age of 18. According to the Centers for Disease Control and Prevention, roughly 1 of every 400 to 600 children has type 1 diabetes. The incidence of type 2 diabetes in children and adolescents is increasing. The growing number of obese children is a major factor in this increase in type 2 diabetes among young people. Children of ethnic/minority groups such as Native Americans, Native Alaskans, African Americans, Mexican Americans, and Pacific Islanders are disproportionately affected.

### Type 1 Diabetes

Insulin is the only drug indicated for use; it is required as replacement therapy because affected children cannot produce

insulin. Effective management requires a consistent schedule of meals, snacks, blood glucose monitoring, insulin injections and dose adjustments, and exercise. Insulin injections must be given three or four times per day. Rotation of injection sites is important in infants and young children because of the relatively small areas for injection at each anatomic site and to prevent lipodystrophy. Young children usually adjust to injections and blood glucose monitoring better when the parents express less anxiety about these vital procedures.

A healthful, varied diet, rich in whole grains, fruits, and vegetables and limited in simple sugars, is recommended. According to the American Diabetes Association (2006), medical nutrition therapy should be tailored to a person's specific health issues and personal preferences to help maintain optimum health by controlling blood glucose levels, blood pressure, cholesterol, and other risk factors.

Food intake must be synchronized with insulin injections and usually involves three meals and three snacks, all at regularly scheduled times. Such a schedule is difficult to maintain in children, but it is extremely important in promoting normal growth and development. A major factor in optimal treatment is a supportive family in which at least one member is thoroughly educated about the disease and its management. Less-than-optimal treatment can lead to stunted growth, delayed puberty, and early development of complications such as retinopathy, nephropathy, or neuropathy.

Infections and other illnesses may cause wide fluctuations in blood glucose levels and interfere with metabolic control. For example, some infections cause hypoglycemia; others, especially chronic infections, may cause hyperglycemia and insulin resistance and may precipitate ketoacidosis. As a result, insulin requirements may vary widely during illness episodes and should be based on blood glucose and urine ketone levels. Hypoglycemia often develops in young children, partly because of anorexia and smaller glycogen reserves.

During illness, children are highly susceptible to dehydration, and an adequate fluid intake is very important. Many clinicians recommend sugar-containing liquids (e.g., regular sodas, clear juices, regular gelatin desserts) if blood glucose values are lower than 250 milligrams per deciliter. When blood glucose values are above 250 milligrams per deciliter, diet soda, unsweetened tea, and other fluids without sugar should be given.

Administration of insulin for infants and toddlers who weigh less than 10 kilograms or require less than 5 units of insulin per day can be difficult because small doses are hard to measure in a U-100 syringe. Use of diluted insulin allows more accurate administration. The most common dilution strength is U-10 (10 units/mL), and a diluent is available from insulin manufacturers for this purpose. Vials of diluted insulin should be clearly labeled and discarded after 1 month.

Avoiding hypoglycemia is a major goal in infants and young children because of potentially damaging effects on growth and development. For example, the brain and spinal

cord do not develop normally without an adequate supply of glucose. Animal studies indicate that prolonged hypoglycemia results in decreased brain weight, numbers of neurons, and protein content. Myelination of nerve cells is also decreased. Because complex motor and intellectual functions require an intact central nervous system, frequent, severe, or prolonged hypoglycemia can be a serious problem in infants, toddlers, and preschoolers. In addition, recognition of hypoglycemia may be delayed because signs and symptoms are vague and the children may be unable to communicate them to parents or caregivers. Because of these difficulties, most pediatric diabetologists recommend maintaining blood glucose levels between 100 and 200 milligrams per deciliter to prevent hypoglycemia. In addition, the bedtime snack and blood glucose measurement should never be skipped.

Signs and symptoms of hypoglycemia in older children are similar to those in adults (e.g., hunger, sweating, tachycardia). In young children, hypoglycemia may be manifested by changes in behavior, including severe hunger, irritability, and lethargy. In addition, mental functioning may be impaired in all age groups, even with mild hypoglycemia. Any time hypoglycemia is suspected, blood glucose should be tested.

Adolescents may resist adhering to their prescribed treatment regimens, and effective management may be especially difficult during this developmental period. Adolescents and young adults may delay, omit, or decrease dosage of insulin to fit in socially (e.g., by eating more, sleeping in, drinking alcohol) or to control their weight. Omitting or decreasing insulin dosage may lead to repeated episodes of ketoacidosis. Also, adolescent females may develop eating disorders.

A good resource is the Juvenile Diabetes Foundation (JDF), a not-for-profit health agency with support groups and other activities for families affected by diabetes: Juvenile Diabetes Foundation International, 120 Wall Street, New York, NY 10005-4001, 1-800-JDF-CURE, 1-800-223-1138, [www.jdf.org](http://www.jdf.org).

### Type 2 Diabetes

Type 2 diabetes is being increasingly identified in children. This trend is attributed mainly to obesity and inadequate exercise because most children with type 2 are seriously overweight and have poor eating habits. In addition, most are members of high-risk ethnic groups and have relatives with diabetes. These children are at high risk for development of serious complications during early adulthood, such as myocardial infarction during their fourth decade. Management involves exercise, weight loss, and a more healthful diet, and in some cases drug therapy including insulin may be indicated. Attention must also be given to treating comorbid conditions such as hypertension and hyperlipidemia.

### Use in Older Adults

It is estimated that at least 20% of people over the age of 65 have diabetes. General precautions for safe and effective use of antidiabetic drugs apply to older adults, including close monitoring of blood glucose levels; however, control of cardiovascular risk factors may play a greater role in reducing morbidity

and mortality in this population. In addition, older adults may have impaired vision, poor manual dexterity, or other problems that decrease their ability to perform needed tasks (e.g., self-administration of insulin, monitoring blood glucose levels, managing diet and exercise). They also may have other disorders and may take other drugs that complicate management of diabetes. For example, renal insufficiency may increase risks of adverse effects with antidiabetic drugs, and treatment with thiazide diuretics, corticosteroids, estrogens, and other drugs may cause hyperglycemia, thereby increasing dosage requirements for antidiabetic drugs.

With oral sulfonylureas, hypoglycemia is a concern for the older person. Drugs with a short duration of action and inactive metabolites are considered safer, especially with impaired liver or kidney function. Therapy usually should start with a low dose, which is then increased or decreased according to blood glucose levels and clinical response.
